Statistics and Data Analysis

for the Physicist

Chandra Prakash

lunar-photon.github.io

Preface

Who made these notes

These notes were made by Chandra Prakash (chandra.pp@alumni.iitg.ac.in; the latest version lives at lunar-photon.github.io) together with Claude, an AI model made by Anthropic. The goals, the vision and the way every idea is framed are Chandra's: which questions matter, which pictures make them clear, and how the whole subject hangs together for a physicist. The drafting of the text and the writing of the code were done with Claude's help, one section at a time, with Chandra reading, correcting and redirecting. It was a joint project and an ambitious one: to take a physicist who has never properly learned statistics all the way from coin tosses to Monte Carlo simulations of the microwave sky, Markov chain samplers, Fisher forecasts and the topology of random fields, and to have every step run as a Python script on the reader's own machine.

Goals and vision

What the notes are for. The reader we have in mind is a phenomenologist working in particle physics, cosmology or gravitational waves. You are at home with calculus, linear algebra, Fourier analysis, quantum mechanics and statistical mechanics. You use likelihoods, error bars and MCMC chains in your work, often through code written by someone else, and you would like to know what each tool really does and why it exists. You also want to *implement* it: to write the fifty lines of Python that do the job, see them work on data, and then trust the standard library because you know what it is doing inside.

The vision. Three convictions shape every chapter.

1. *Every idea opens with a story.* Before any definition we meet a concrete situation that makes the idea necessary, and a physical picture of what the idea will do for us. The formula comes after we know what question it answers.

2. *Probability runs in two directions.* Prediction goes forward: given a hypothesis, how often does each outcome occur? Inference goes backward: given the outcome we saw, which hypotheses could lie behind it, and how much does each deserve belief now? Bayes' theorem is the bridge. Almost every confusion in statistics is a confusion between these two directions.

3. *One pipeline organises the whole subject.* A physical model produces a field or a data set. We choose what information in it matters, compress the data into a summary S, work out how S fluctuates from one realisation of the noise to the next (its sampling distribution $p(S \mid \boldsymbol{\theta})$), and only then infer the physics (Figure P.1). The book walks along this pipeline, from probability distributions to Bayes, Monte Carlo, MCMC and the Fisher matrix, and

ends where the summaries become most interesting: topological summaries of random fields.

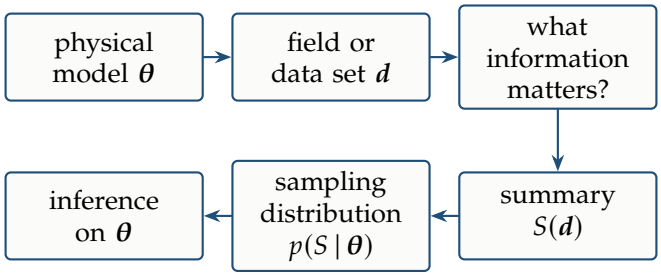

Figure P.1: The pipeline that organises the book. The top row is the physics and the observation; the bottom row is the statistics. Each chapter serves one or two of these steps, and Chapter 0 places every chapter on its step.

What you will be able to do at the end. You will be able to look at a physics measurement and say which of the two directions each part of the analysis runs in. You will be able to write down a likelihood for Poisson counts in a collider bin, for a Gaussian random field on the sphere and for a gravitational-wave detector with coloured noise, and explain why these are the same idea. You will be able to write a Monte Carlo simulation that checks an analytic result, and to recognise when the same simulation is no longer a check but the only instrument available. You will be able to code a Metropolis–Hastings sampler from scratch and diagnose it, compute a Fisher forecast and know when it can be trusted, and treat a topological summary of a field (its Betti numbers, its Euler characteristic, its persistence diagram) as one more random observable, with its own covariance and likelihood.

How the book is organised

Chapter 0 is the map: the two directions of probability, the list of questions the book answers, the pipeline, the menu of summaries, and how to run the code. Chapter T0 is the small part of Python that every script in the book uses, and how to tell whether a number a script prints can be trusted.

The first part builds the statistics. Chapter 1 and Chapter 2 build probability and the distributions a physicist meets. Chapter 3 turns data into estimates and introduces the likelihood; Chapter 4 asks whether a signal is really there and how to set a limit when it is not; Chapter 5 is Bayesian inference.

The second part collects the physics the statistics is used on, one toolkit per field, each a map of the objects and equations that the later chapters need: cosmology and weak lensing (Chapter T1), astrophysics and gravitational waves (Chapter T2), the morphology of the microwave sky (Chapter T3), and collider particle physics (Chapter T4). They can be read in order or consulted when a chapter points to them.

The third part turns the statistics into instruments. Chapter 6 is Monte Carlo and the pseudo-random numbers behind it. Chapter 7 makes the summary concrete for fields ($\xi(r)$, $P(k)$, C_ℓ) and Chapter 8 is a Monte Carlo research problem on the microwave sky. Chapter 9 and Chapter 10 turn sampling distributions into parameter constraints with MCMC and the Fisher matrix, and Chapter 11 applies all of it to galaxy surveys and the local Universe.

The last part goes beyond two-point statistics and onto real data. Chapter 12 is topological data analysis of random fields, Chapter 13 runs four complete analyses on public data (the

Planck sky, its topology, SDSS galaxies and a Higgs search), and Chapter 14 pulls the threads together: given a new problem, which idea to reach for. Every chapter opens with a roadmap and closes with a summary table.

Bayes' theorem in one picture, told with one box of each kind

The text of each chapter carries the whole argument, and it reads correctly from start to finish if every box is skipped. Boxes are a sparse sidebar: something to find again, or to skip on a first reading. Rather than describe them, we show one real box of each kind. All of them tell one story, the story that also opens Chapter 0: Bayes' theorem as information shrinking the sample space.

Story: the coin from the drawer

A drawer holds two coins that look identical. One is fair. The other is bent and lands heads 80% of the time. A friend picks one at random, tosses it ten times, and reports 8 heads. Which coin was it?

Stories give the concrete situation that makes an idea necessary. In the chapters they are ordinary prose, the first paragraph of a section.

The story contains both directions at once. If we knew which coin it was, we could predict how often it gives 8 heads. We do not know the coin; we know the 8 heads. So the question runs backward, from the outcome to the coin.

The central framing

A question about chance can face either way. Facing forward, we fix the situation and ask which outcomes it can give and how often each one turns up. Facing backward, the outcome is already in hand, and we ask which of the situations that might have been true could have given it, and how much each of them deserves to be believed now that we have seen it.
For the coin, prediction asks $\mathrm{P}(E \mid H)$: *given this coin, how likely was this outcome?* Inference asks $\mathrm{P}(H \mid E)$: *given this outcome, which way could it have happened, and how probable is each way?* The two numbers are different, and Bayes' theorem converts one into the other.

The central framing states the question a chapter answers.

To make the conversion we need one definition. We will look it up many times, so it is worth having in a box.

Working definition P.1 (conditional probability)

For events A and B with $\mathrm{P}(A) > 0$, the **conditional probability** of B given A is

$$\mathrm{P}(B \mid A) = \frac{\mathrm{P}(A \cap B)}{\mathrm{P}(A)}.$$

It is the probability of B once we know that A happened [we keep only the outcomes in which A is true] and renormalise [divide by $\mathrm{P}(A)$, so the kept outcomes again have total probability 1]. Operationally: in a long run of repetitions, throw away every run in which A failed and count the fraction of the survivors in which B happened.

Working definitions keep the precise sentence and unpack every term a forgetful reader may need, in green brackets.

Now the reasoning, in words, before any number.

The reasoning

The backward question can always be said in four plain steps before any equation is written:

1. What did we actually see?
2. Which explanations could have given it?
3. If each explanation were true, how probable would that sight have been?
4. How do those answers change the weight each explanation had before?

For the coin: (1) E = "8 heads in 10 tosses"; (2) B (bent coin) and F (fair coin), each picked with probability $\frac{1}{2}$; (3) the forward question, answered by the binomial distribution; (4) keep only the paths that end in E, and share the probability among them in proportion to how much each contributes.

Reasoning boxes state a question in words before any symbol appears.

Step 3 is ordinary prediction: if this coin were the one, how often would it give 8 heads? For n tosses of a coin with heads probability p, the probability of exactly k heads is $\binom{n}{k}p^k(1-p)^{n-k}$. The factor $p^k(1-p)^{n-k}$ is the probability of one particular sequence with k heads, and $\binom{n}{k}$ counts how many such sequences there are. With $n = 10$ and $k = 8$, the fair coin gives $\mathrm{P}(E \mid F) = \binom{10}{8}/2^{10} = 45/1024 = 0.04395$ and the bent coin gives $\mathrm{P}(E \mid B) = 45 \times 0.8^8 \times 0.2^2 = 0.302$. Step 4 is Bayes' theorem, and it has a picture.

Physical picture: information shrinks the sample space

Before the evidence, the whole sample space is relevant. Draw it as a rectangle of area one and cut it into two strips, one for each coin, each as wide as its prior, $\mathrm{P}(B) = \mathrm{P}(F) = \frac{1}{2}$. Inside each strip, mark the part in which 8 heads happens. It fills the fraction $\mathrm{P}(E \mid B) = 0.302$ of the bent-coin strip and only $\mathrm{P}(E \mid F) = 0.04395$ of the fair-coin strip, so the two pieces have areas $\mathrm{P}(E \cap B)$ and $\mathrm{P}(E \cap F)$. Together they are the event E, one box straddling the line between the strips. The evidence tells us that we are somewhere inside that box, so everything outside it is ruled out: the sample space has shrunk to the box. The posterior $\mathrm{P}(B \mid E)$ is the share of the box that the bent-coin piece fills (Figure P.2).

Intuition boxes give the physical or visual picture.

The picture turns into a calculation with no new idea in it.

Worked example P.1: the posterior for the coin

With $\mathrm{P}(B) = \mathrm{P}(F) = \frac{1}{2}$,

$$\begin{aligned}\mathrm{P}(B \mid E) &\overset{(1)}{=} \frac{\mathrm{P}(E \cap B)}{\mathrm{P}(E \cap B) + \mathrm{P}(E \cap F)} \\ &\overset{(2)}{=} \frac{\mathrm{P}(E \mid B)\,\mathrm{P}(B)}{\mathrm{P}(E \mid B)\,\mathrm{P}(B) + \mathrm{P}(E \mid F)\,\mathrm{P}(F)} \\ &\overset{(3)}{=} \frac{\mathrm{P}(E \mid B)}{\mathrm{P}(E \mid B) + \mathrm{P}(E \mid F)} = \frac{0.302}{0.302 + 0.04395} = 0.873.\end{aligned}$$

(1) Conditional probability, $\mathrm{P}(B \mid E) = \mathrm{P}(E \cap B)/\mathrm{P}(E)$, with $\mathrm{P}(E)$ split into the two disjoint ways E can happen (the two green pieces of the box).

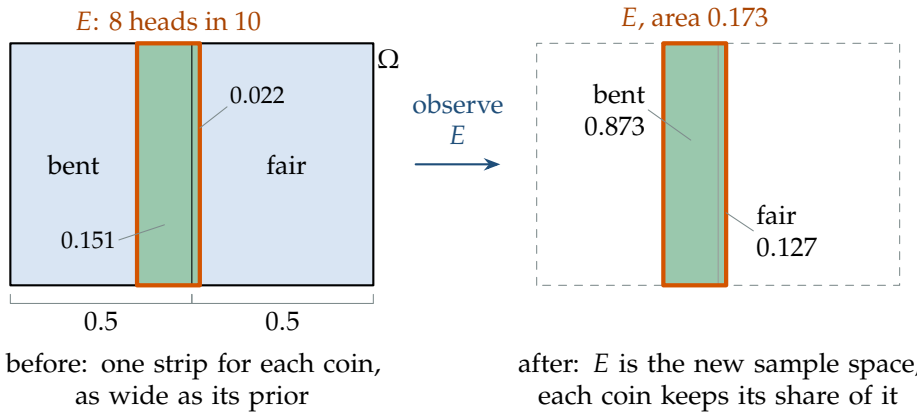

Figure P.2: Bayes' theorem as information shrinking the sample space, drawn to scale. Left: the rectangle Ω has area 1, and since the coin is either bent or fair, the two hypotheses fill it in two strips of width $\frac{1}{2}$. The event E, "8 heads in 10" (orange outline), covers the fraction 0.302 of the bent-coin strip, because that is how often the bent coin gives 8 heads, and only 0.04395 of the fair-coin strip. Each green piece therefore has area prior times likelihood. Right: hearing "8 heads" discards everything outside the orange box, and each coin keeps the share of the box that its piece fills: 0.873 for the bent coin.

(2) The product rule $\mathrm{P}(E \cap H) = \mathrm{P}(E \mid H)\,\mathrm{P}(H)$ for each piece: its share of the strip times the strip's width.
(3) The equal priors $\frac{1}{2}$ cancel between numerator and denominator.

The 8 heads moved the probability of the bent coin from 0.5 to 0.873.

Examples are solved to the last line. Every non-trivial equals sign is labelled and explained right after the chain.

One detail of the example is easy to overlook: the prior widths of the two strips cancelled only because they were equal. With unequal priors they stay in the answer.

Takeaway

In the picture, Bayes' theorem needs no extra assumption: it falls out of the picture. There is one patch, the overlap $H \cap E$, and two ways to measure it. As a share of the H strip it is $\mathrm{P}(E \mid H)$; as a share of the box E it is $\mathrm{P}(H \mid E)$. Bayes' theorem is the statement that both shares describe the same area, $\mathrm{P}(E \mid H)\,\mathrm{P}(H) = \mathrm{P}(H \mid E)\,\mathrm{P}(E)$.
For the coin, with $H = B$: a forward probability is the *share of a strip* that the evidence covers; a joint probability is an *area*; the posterior is a *ratio of areas* once the evidence has cut the sample space down to the box. Move the line between the strips and both pieces change width, so the same data give a different posterior.

Takeaways say in a sentence or two what a computation taught us.

The most common error in reading such results is to swap the two directions, and it has a famous statistical form.

Watch out: a p-value is not the probability that the null is true

Suppose we test "the coin is fair" by asking how often a fair coin gives 8 or more heads in 10 tosses. That number, $(45 + 10 + 1)/1024 \approx 0.055$, is a forward probability, $\mathrm{P}(\text{this or more extreme} \mid F)$. It is not the probability that the coin is fair, $\mathrm{P}(F \mid E)$. That we just found to be $1 - 0.873$ with equal priors, and it depends on the prior as well. Chapter 4 makes this precise.

Pitfalls flag a genuine trap.

Every step of the story is a few lines of code. The script behind the numbers above computes the forward probabilities from the binomial formula, checks them by simulating 20000 ten-toss experiments with each coin, and then runs Bayes on the observed outcome. The backward step is four lines.

Listing P.1: The backward direction: keep the paths that end at the observed k, then normalise (`code/ch00/01_coin_two_directions.py`)

```
42 # ---- backward direction: Bayes on the observed column of the tree ----
43 num_bias = pmf_bias * PRIOR_BIAS                  # path "biased, then k heads"
44 num_fair = pmf_fair * (1 - PRIOR_BIAS)            # path "fair, then k heads"
45 post_bias = num_bias / (num_bias + num_fair)      # normalise over the paths that end at k
```

Line 43 is the area of the bent-coin piece of the box in Figure P.2, line 44 the area of the fair-coin piece, and line 45 divides the first by their sum. The arrays run over every possible k at once, so the script produces the posterior for all eleven outcomes in one go. For $k = 8$ it prints 0.873; for $k = 5$ it gives 0.09696. Every number quoted in the text is written to a file by the script that computed it and read back into LaTeX. So the text and the code cannot drift apart (Chapter 0 describes the machinery).

The simulation in the same script is a small instance of an idea that runs through the book: a Monte Carlo experiment can check a formula, or it can replace one.

How this is used in real research: verification versus research

Here the simulation *verifies* a known answer. The fraction of simulated fair-coin experiments with 8 heads is 0.04105, against the exact 0.04395. The difference is about two Monte Carlo standard errors (±0.001449 each), an ordinary fluctuation that shrinks as $1/\sqrt{N}$ when more experiments N are simulated. In research the same machinery is often the only instrument. The covariance of a power-spectrum estimator on a masked, noisy microwave sky has no closed form, and thousands of simulated skies are how it is measured (Chapter 8).

These boxes separate a numerical check of known theory from the same tool used where no analytic answer exists.

When an idea has several tools, a small table says which to use when.

Taxonomy: the coin, asked four ways

question in words	object	chapter
how often does a fair coin give 8 heads?	$P(k \mid p)$	Chapter 2
what is our best guess of p?	estimator $\hat{p} = k/n$	Chapter 3
is 8 heads surprising for a fair coin?	p-value	Chapter 4
how probable is each value of p?	posterior $p(p \mid k)$	Chapter 5

Taxonomies list which tool answers which question.

The picture is not ours alone; the literature draws it in several ways.

Reading the source (Wasserman p. ix, Fig. 1)

Wasserman opens with one diagram: a data generating process and the observed data, joined by an arrow labelled "probability" going forward and one labelled "inference" coming back [Wasserman p. ix]. Kruschke describes the backward arrow as a reallocation of credibility across possibilities [Kruschke pp. 16–22]. In the chapters, such links are short citations at the point of use, with one "Reading the literature" list per chapter.

Source boxes map the notes onto the books, and flag their misprints.

The labelled-equality convention

Every calculation is written as a chain. Each non-trivial equals sign carries a small label, and the labels are explained, in order, right after the chain. For the odds form of the coin problem:

$$\frac{\mathrm{P}(B \mid E)}{\mathrm{P}(F \mid E)} \overset{(1)}{=} \frac{\mathrm{P}(E \mid B)\ \mathrm{P}(B)/\mathrm{P}(E)}{\mathrm{P}(E \mid F)\ \mathrm{P}(F)/\mathrm{P}(E)} \overset{(2)}{=} \frac{\mathrm{P}(E \mid B)}{\mathrm{P}(E \mid F)} \cdot \frac{\mathrm{P}(B)}{\mathrm{P}(F)} = 6.872 \times 1.$$

(1) Bayes' theorem for each coin.
(2) $\mathrm{P}(E)$ cancels. Posterior odds are the likelihood ratio times the prior odds.

Odds of 6.872 to 1 are a probability $6.872/(1 + 6.872) = 0.873$, as before.

The code

Every figure made from data and every simulated number comes from a short script in `code/chNN/`, runnable from the Notes directory with `python3 code/chNN/NN_name.py`. Randomness is seeded from the script's name, so rerunning a script reproduces its figures bit for bit. Each method is first implemented from scratch, so the mechanism is visible, and then checked against a standard library (`emcee`, `getdist`, `healpy`, `gudhi` and others). Chapter 0 ends with a tour of the layout and the shared helpers.

Recap: the dictionary of this preface

prediction	$\mathrm{P}(E \mid H)$, the share of the H strip covered by E
joint probability	$\mathrm{P}(E \cap H) = \mathrm{P}(E \mid H)\,\mathrm{P}(H)$, an area
evidence	$\mathrm{P}(E)$, the total surviving area
inference	$\mathrm{P}(H \mid E)$, a ratio of surviving areas
odds form	posterior odds = likelihood ratio × prior odds
the pipeline	model → data → summary → $p(S \mid \boldsymbol{\theta})$ → inference

A recap closes every part.

1 Probability: The Language of Uncertain Events 111

1.1 Sample spaces and events: probability needs a list of possibilities 112
1.2 The axioms of probability, and what they buy us 119
1.3 Equally likely outcomes: probability as counting 128
1.4 Conditional probability: shrinking the sample space 133
1.5 Probability trees and the law of total probability 141
1.6 Independence: when learning B tells us nothing about A 146
1.7 Bayes' theorem: reading the tree backwards 152
1.8 Random variables: turning outcomes into numbers 166
1.9 Mass, density and the cumulative distribution 171
1.10 Several variables at once: joint, marginal and conditional distributions 179
1.11 Functions of random variables: change of variables and Jacobians 189
1.12 Expectation and variance: the long-run average and the spread 203
1.13 Covariance and correlation: how two variables move together 214
1.14 Moments, generating functions and characteristic functions 223
Chapter summary 231

2 Probability Distributions from First Principles 234
Where this chapter is going 234
2.1 One trial: the Bernoulli distribution 235
2.2 Many successive trials: the binomial distribution 239
2.3 Histogram bins: the multinomial distribution 246
2.4 Rare events in many trials: the Poisson distribution 250
2.5 The Poisson process: constant rate, no memory 255
2.6 Waiting times: the exponential and gamma distributions 263
2.7 Discrete waiting times and extra spread: geometric and negative binomial 269
2.8 When the Poisson assumptions fail, and where the Poisson goes for large λ 275
2.9 The Gaussian, first way: the shape of a binomial with many trials 286
2.10 The Gaussian, second way: the central limit theorem 294
2.11 The Gaussian, third way: the least committal assignment 306
2.12 Many correlated Gaussians: the multivariate normal 315
2.13 Sums of squared Gaussians: the χ^2 distribution 322
2.14 When the error bar is itself estimated: Student's t and the F ratio 329
2.15 The rest of the zoo, each with the machine that makes it 335
2.16 Which distribution when 344
Chapter summary 351

3 Estimators, Error Propagation and the Likelihood 355
3.1 One number from many readings: estimators and their sampling distribution . 355
3.2 Aiming and scattering: bias, variance and mean squared error 363
3.3 Why error bars shrink like $1/\sqrt{N}$: the law of large numbers and the central limit theorem 371

3.4 Estimating the scatter itself: the sample variance and its error . . . 378
3.5 Estimating covariance and correlation matrices, and how noisy they are . . . 384
3.6 Propagating errors through a formula . . . 391
3.7 Combining measurements of different quality: the weighted mean . . . 398
3.8 The likelihood: data are the model plus noise . . . 411
3.9 Maximum likelihood: pick the value that needs the least unusual noise . . . 419
3.10 Gaussian noise: least squares and the χ^2 . . . 424
3.11 Counting experiments: the Poisson likelihood of a histogram . . . 431
3.12 The width of the likelihood is the error bar . . . 437
3.13 What makes maximum likelihood good . . . 443
3.14 Nuisance parameters and the profile likelihood . . . 448
3.15 The bootstrap: the sampling distribution from one data set . . . 453
3.16 From a model to an estimator: how to find the right one . . . 458
3.17 A worked problem: finding the estimator of the Hubble constant . . . 468
Chapter summary . . . 482

4 Hypothesis Testing: Asking the Null **486**
4.1 A bump in a histogram: new particle or luck? . . . 486
4.2 Which way is "more extreme"? Sides, and the stopping rule . . . 492
4.3 Two ways to be wrong: size, power and how much data we need . . . 497
4.4 The p-value is a random variable . . . 502
4.5 Three workhorse tests: Wald, Student's t and permutation . . . 507
4.6 The best test: the Neyman–Pearson lemma . . . 511
4.7 Likelihood-ratio tests and Wilks' theorem . . . 516
4.8 Goodness of fit: Pearson's χ^2 and Kolmogorov–Smirnov . . . 522
4.9 From p to $Z\sigma$, and why a discovery needs 5σ . . . 526
4.10 From a test to an interval: the values we cannot reject . . . 530
4.11 The Neyman construction: a belt of acceptance regions . . . 537
4.12 Coverage is a property of the procedure . . . 547
4.13 Upper limits near a physical boundary . . . 552
4.14 Many tests at once and the look-elsewhere effect . . . 559
4.15 A search as a likelihood: templates and nuisance parameters . . . 567
4.16 Discovery and exclusion: q_0, $\tilde{q}_\mu$, CL_s, Brazil band . . . 574
4.17 Confidence intervals and credible intervals . . . 582
Chapter summary . . . 588

5 Bayes' Theorem and Bayesian Inference **590**
5.1 One joint table, read in two directions . . . 590
5.2 Information shrinks the sample space . . . 596
5.3 Reallocating credibility across possibilities . . . 603
5.4 Odds and the likelihood ratio: evidence as a multiplier . . . 609

5.5 Sequential updating: yesterday's posterior is today's prior . . . 613
5.6 The denominator: the sum over all paths . . . 622
5.7 From a list of hypotheses to a continuous parameter . . . 626
5.8 Conjugate priors: posteriors on the back of an envelope . . . 632
5.9 Summarising a posterior: best values and credible intervals . . . 638
5.10 The Gaussian approximation: a peak and its curvature . . . 642
5.11 Nuisance parameters: integrating out what we do not care about . . . 647
5.12 Choosing a prior: subjective, flat and Jeffreys . . . 651
5.13 Forgetting the prior: when the data win and when they cannot . . . 657
5.14 Sampling the posterior: a histogram instead of an integral . . . 663
5.15 Which model produced the data? . . . 669
5.16 Occam's razor from the evidence . . . 674
5.17 Reading a Bayes factor . . . 681
5.18 Nested models, shortcuts and model averaging . . . 688
5.19 Why we need sampling . . . 694
Chapter summary . . . 703

II Physics Toolkits **705**

T1 Cosmology for the Data Analyst **706**
Where this chapter is going . . . 706
T1.1 Six numbers in, statistics out . . . 707
T1.2 The objects the statistics uses . . . 708
T1.3 Experiment 1: how each parameter moves the CMB spectra . . . 713
T1.4 Experiment 2: the matter power spectrum and the BAO bump . . . 716
T1.5 Weak lensing: the matter field written on galaxy shapes . . . 719
T1.6 The objects a weak-lensing analysis uses . . . 722
T1.7 Experiment 1: what cosmic shear measures, S_8 . . . 730
T1.8 Experiment 2: signal and shape noise in a Stage-III survey . . . 736
T1.9 Polarization: sticks on the sky, and two kinds of pattern . . . 741
T1.10 When power moves from E to B . . . 750
T1.11 Where B modes come from . . . 758
T1.12 Cosmic birefringence, the instrument and the Galaxy . . . 763
Chapter summary . . . 776

T2 Astrophysics for the Data Analyst **779**
Where this chapter is going . . . 779
T2.1 What a gravitational wave is . . . 780
T2.2 Why radiation starts at the quadrupole . . . 786
T2.3 How a detector turns a wave into one number . . . 792

T2.4 Why a compact binary chirps . . . 799
T2.5 The chirp in the frequency domain . . . 804
T2.6 Corrections to the phase: post-Newtonian orders and the ppE form . . . 809
T2.7 What LISA measures, and what hides the signal . . . 814
T2.8 The symbols, where they come from, and where they are used . . . 820
T2.9 Dark matter around black holes . . . 822
T2.10 Environmental forces and the power law in the phase . . . 830
T2.11 Type Ia supernovae: candles that need a correction . . . 842
T2.12 The distance ladder: why H_0 needs an anchor . . . 846
T2.13 Selection effects: what a flux limit does to a sample . . . 854
T2.14 Galaxies as biased tracers in redshift space . . . 859
T2.15 Baryon acoustic oscillations: a standard ruler . . . 866
T2.16 Photometric redshifts and their error distributions . . . 874
Chapter summary . . . 879

T3 CMB Morphology and Topology **882**
Where this chapter is going . . . 882
T3.1 The shape of a temperature map . . . 883
T3.2 What a skewed sky and a lensed sky change . . . 889
T3.3 Polarization patterns and their singularities . . . 892
T3.4 Lensing moves the pattern but keeps its topology . . . 897
T3.5 What *Planck* found . . . 900
T3.6 The topology of the cosmic web . . . 903
Chapter summary . . . 905

T4 Particle Physics for the Data Analyst **908**
Where this chapter is going . . . 908
T4.1 What a collider does, and what an event is . . . 909
T4.2 Cross section, luminosity and the expected number of events . . . 914
T4.3 Invariant mass: why a decaying particle makes a peak . . . 919
T4.4 Signal and background: where the templates come from . . . 926
T4.5 Systematic uncertainties: nuisance parameters and their calibrations . . . 932
T4.6 The Higgs boson search of 2012 . . . 937
T4.7 The open data: what is in the files . . . 942
T4.8 The symbols of a collider search . . . 946
Chapter summary . . . 948

III Simulation, Fields and Forecasts **950**

6 Monte Carlo: Drawing Samples on a Deterministic Machine **951**
6.1 Random numbers from a machine that cannot be random . . . 952

6.2 Linear congruential generators . . . 958
6.3 Random numbers fall mainly in the planes . . . 962
6.4 Modern generators: a bigger state and a better output function . . . 967
6.5 Seeds, streams and reproducible parallel simulations . . . 972
6.6 Testing a generator: randomness as a null hypothesis . . . 976
6.7 When randomness is not the point: quasi-random numbers . . . 980
6.8 Uniform numbers into any distribution: the inverse CDF . . . 985
6.9 Gaussian numbers: Box–Muller and the Cholesky factor . . . 990
6.10 Rejection sampling: throwing points under a curve . . . 995
6.11 Monte Carlo integration and the $1/\sqrt{N}$ law . . . 1000
6.12 Importance sampling, and why g needs thicker tails than f . . . 1007
6.13 A histogram of samples approximates the density . . . 1012
6.14 Unfolding: undoing the detector with a response matrix from simulation . . . 1016
6.15 Shrinking σ: variance reduction . . . 1029
6.16 Which sampler when . . . 1032
Chapter summary . . . 1034

7 Random Fields and the Angular Power Spectrum 1036
Where this chapter is going . . . 1036
7.1 A theory predicts the statistics of a field . . . 1036
7.2 Gaussian random fields: when two points tell the whole story . . . 1041
7.3 Fourier modes and the power spectrum . . . 1045
7.4 Simulating a Gaussian random field with the FFT . . . 1050
7.5 One universe: ergodicity and sample variance . . . 1055
7.6 Smoothing: beams, pixels and window functions . . . 1059
7.7 What the power spectrum throws away . . . 1065
7.8 The Fourier modes of the sphere . . . 1068
7.9 No preferred direction: why the $a_{\ell m}$ are uncorrelated . . . 1073
7.10 One sky, $2\ell+1$ numbers: the estimator $\widehat{C}_\ell$ and cosmic variance . . . 1081
7.11 Where C_ℓ and the skies come from: CAMB and HEALPix . . . 1085
7.12 Cosmic variance by Monte Carlo . . . 1093
7.13 What C_ℓ does not see . . . 1099
Chapter summary . . . 1102

8 Monte Carlo as a Research Instrument: Observing the CMB 1104
8.1 The research problem . . . 1104
8.2 What the instrument does to the sky . . . 1108
8.3 The noise bias and how to remove it . . . 1114
8.4 How much the estimate scatters . . . 1118
8.5 The Monte Carlo machine . . . 1124

8.6 What the simulations show . . . 1129

Part I

Probability and Inference

Chapter 0

The Map: Two Directions of Probability and the Pipeline from Data to Physics

Where this chapter is going

Two ideas fix the questions that every later chapter answers. The first is that probability runs in two directions. Forward, it goes from a hypothesis to the outcomes that hypothesis can produce. Backward, it goes from an outcome that has already happened to the hypotheses that could have produced it. Bayes' theorem connects the two directions. The second idea is that a physicist never feeds raw data straight into Bayes' theorem. First we decide which information in the data matters. Then we compress the data into a summary. Then we work out how that summary fluctuates from one experiment to the next. These steps form one pipeline, from a physical model to a statement about physics, and the whole book is organised along it. Very little is proved and only small things are computed; the aim is to see the questions clearly. The practical side comes last: how the Python code for every chapter is laid out and how to run it.

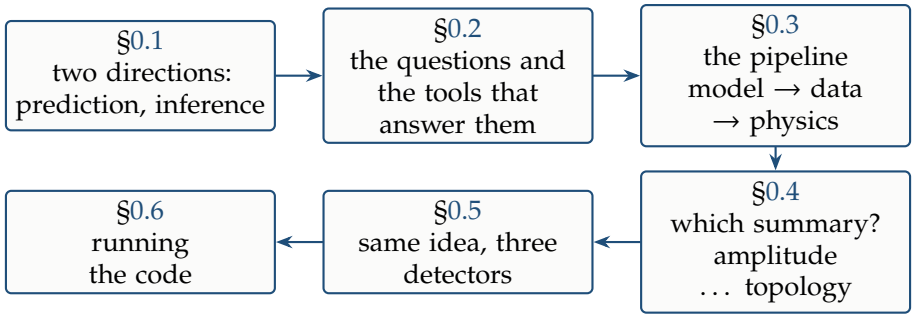

Figure 0.1: The route through the ideas. The top row sets up the logic: the two directions of probability, the list of questions they generate, and the pipeline that strings the questions together. The bottom row makes it concrete: what we choose to measure from a field, how the same logic looks in three different experiments, and how to reproduce every number in the book.

0.1 Two directions of probability

A friend runs a magic shop. In one drawer she keeps coins of two kinds, mixed together in equal numbers: honest coins, and trick coins weighted so that they land heads 80% of the time. The two kinds look identical. She takes one coin out at random and we toss it ten times. It lands heads 8 times.

Two different questions can be asked about this coin, and they must not be confused. The first could be asked *before* the tosses: "if this coin is honest, how likely is it to give 8 heads in 10

tosses?" The second is the one we actually want *after* the tosses: "we have seen 8 heads; which kind of coin is it, and how sure can we be?" Each question asks for a conditional probability, and Bayes' theorem turns an answer to the first into an answer to the second. Every later calculation in the book, from a p-value to an MCMC chain over six cosmological parameters, answers one of these two questions.

Forward and inverse problems. Physics already knows this distinction. Given a Hamiltonian and an initial state, working out where the particle goes is the *forward* problem, and it has one answer. Given the hits in a tracking detector, working out which track, momentum and vertex produced them is the *inverse* problem. Several tracks could have produced similar hits, so we must weigh them against each other. Probability in the forward direction is like integrating the equations of motion. Probability in the backward direction, called inference, is like track reconstruction: we hold the outcome and reason back to its cause.

Prediction versus inference. Probability answers two kinds of question.

Prediction	**Inference**
Start with a hypothesis H.	Start with an observed event E.
Ask what outcomes it can produce, and how often.	Ask which hypotheses might lie behind it, and how probable each is now.
Use $\mathrm{P}(E \mid H)$.	Want $\mathrm{P}(H \mid E)$.
Forward direction: $H \longrightarrow E$.	Reverse direction: $E \longrightarrow H$.

These are not two rival interpretations of probability. They are two different questions asked of the same probabilities: the probabilities of every combination of hypothesis and outcome.

In the backward direction, ask two questions in words before writing any symbol. Which hypotheses could have produced what we saw? How probable was what we saw under each of them? Chapter 5 makes this a working habit.

A **probability tree** shows both directions at once. The first set of branches chooses the hypothesis (which coin). The second set chooses the outcome (8 heads or not). Each branch carries the probability of taking it, *given that we have reached the node it leaves from*. Multiplying the numbers along a path gives the probability of the whole path.

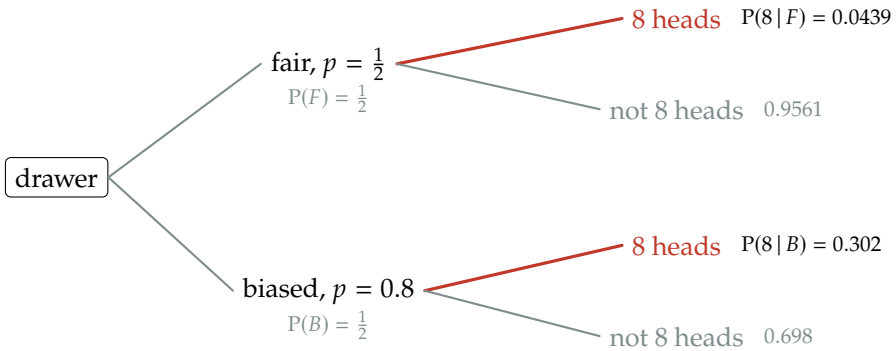

Figure 0.2: The coin as a probability tree. Read left to right, it is a prediction machine: pick a coin, then see what that coin tends to produce. Inference reads it the other way. We have observed "8 heads", so only the two red paths survive; the question is how the total probability of those two paths is split between the fair coin and the biased one.

The backward direction in four steps. Before any equation, put the question into words: (1) what did we see? (2) which hypotheses could have produced it? (3) how probable was it under each of them? (4) how must the probabilities the hypotheses had beforehand change in view of it?

The event. What we observed is "8 heads in 10 tosses".

What could have produced it? The one thing we do not know is which kind of coin came out of the drawer. So there are two candidate explanations: the coin is fair (F), or the coin is biased (B).

How probable was the event under each? This is a forward calculation, done once per candidate: if the coin is fair, how often do ten tosses give 8 heads? If it is biased, how often? These two numbers are written $\mathrm{P}(8 \mid F)$ and $\mathrm{P}(8 \mid B)$, and Example 0.1 computes them.

Only then the update. Weight each path of the tree by the prior probability of its coin, keep only the paths that end at "8 heads", and rescale so that the surviving weights add up to one.

Step 3 is where conditional probability enters. For each hypothesis it gives the probability that the event we actually saw would have had, if that hypothesis were the one nature chose. To write that in symbols we need its definition.

Working definition 0.1 (conditional probability)

For two events A and B [sets of possible outcomes, e.g. A = "the coin is biased", B = "8 heads"] with $\mathrm{P}(A) > 0$, the **conditional probability** of B given A is

$$\mathrm{P}(B \mid A) := \frac{\mathrm{P}(A \cap B)}{\mathrm{P}(A)}. \tag{0.1}$$

Operational meaning: throw away every outcome outside A, and measure the fraction of what is left that also lies in B. A becomes the new reference space [the "whole world" against which fractions are now measured]. The **prediction** question is a number $\mathrm{P}(E \mid H)$ [fraction of the H-world in which E happens]. The **inference** question is a number $\mathrm{P}(H \mid E)$ [fraction of the E-world in which H was true].

The same overlap $A \cap B$ can be divided by $\mathrm{P}(A)$ or by $\mathrm{P}(B)$. Multiply (0.1) through by its denominator; doing this with A and B in both orders gives the **product rule**

$$\mathrm{P}(A \cap B) = \mathrm{P}(B \mid A)\ \mathrm{P}(A) = \mathrm{P}(A \mid B)\ \mathrm{P}(B). \tag{0.2}$$

This one line already contains both directions. Think of probability as area. $\mathrm{P}(A \cap B)$ is the area of the overlap. The two conditional probabilities divide that *same* overlap by two *different* areas, $\mathrm{P}(A)$ or $\mathrm{P}(B)$. Figure P.2 draws this for the coin.

Now we turn the direction round, from the observed event back to the hypotheses. Let $H_1, \ldots, H_M$ be hypotheses that are **mutually exclusive and exhaustive** [exactly one of them is true]; for the coin, $M = 2$, with $H_1 = F$ and $H_2 = B$. Let E be the observed event, here "8 heads".

$$\begin{aligned} \mathrm{P}(H_j \mid E) &\overset{(1)}{=} \frac{\mathrm{P}(H_j \cap E)}{\mathrm{P}(E)} \\ &\overset{(2)}{=} \frac{\mathrm{P}(E \mid H_j)\ \mathrm{P}(H_j)}{\mathrm{P}(E)} \\ &\overset{(3)}{=} \frac{\mathrm{P}(E \mid H_j)\ \mathrm{P}(H_j)}{\sum_{i=1}^{M} \mathrm{P}(E \cap H_i)} \end{aligned}$$

$$\overset{(4)}{=} \frac{\mathrm{P}(E \mid H_j)\ \mathrm{P}(H_j)}{\sum_{i=1}^{M} \mathrm{P}(E \mid H_i)\ \mathrm{P}(H_i)}. \tag{0.3}$$

(1) Definition (0.1), with E as the reference space.
(2) Product rule (0.2), used in the other order: $\mathrm{P}(H_j \cap E) = \mathrm{P}(E \mid H_j)\,\mathrm{P}(H_j)$.
(3) The pieces $E \cap H_1, \ldots, E \cap H_M$ do not overlap (the H_i exclude each other) and together make up all of E (one H_i is always true). Probabilities of non-overlapping pieces add.
(4) Product rule again, inside each term of the sum.

This is **Bayes' theorem**. In words, $\mathrm{P}(H_j \mid E) \propto \mathrm{P}(E \mid H_j)\,\mathrm{P}(H_j)$: *take each hypothesis's prior weight, multiply it by how readily that hypothesis produces what we saw, and normalise.* The denominator, $\mathrm{P}(E) = \sum_i \mathrm{P}(E \mid H_i)\,\mathrm{P}(H_i)$, is the **law of total probability**. It is the total weight of all the paths in the tree that end at the observation. The three ingredients have names. $\mathrm{P}(H)$ is the **prior**: the probability of H before the observation. $\mathrm{P}(E \mid H)$, read as a function of the hypothesis H with E held fixed, is the **likelihood**. $\mathrm{P}(H \mid E)$ is the **posterior**: the probability of H after the observation. Chapter 5 develops all of this in full.

Example 0.1 (the forward direction: what does each coin produce?). The question is step 3 of the four: if the coin is fair, how probable are 8 heads in 10 tosses, and if it is biased, how probable? Both answers come from one formula. For a coin with heads probability p, tossed n times independently, the probability of exactly k heads is

$$\mathrm{P}(k \mid p) \overset{(1)}{=} \sum_{\text{sequences with } k \text{ heads}} p^k (1-p)^{n-k} \overset{(2)}{=} \binom{n}{k} p^k (1-p)^{n-k}.$$

(1) Independent tosses multiply, so one particular sequence with k heads and $n-k$ tails has probability $p^k(1-p)^{n-k}$, whatever the order. Different sequences are different outcomes, so their probabilities add.
(2) The number of sequences with k heads among n places is the number of ways of choosing which k places are heads, $\binom{n}{k} = \frac{n!}{k!\,(n-k)!}$.

For our two coins, the fair one with $p = \frac{1}{2}$ and the biased one with $p = 0.8$, put $n = 10$ and $k = 8$. Then $\binom{10}{8} = \frac{10 \cdot 9}{2} = 45$, so

$$\mathrm{P}(8 \mid F) \overset{(1)}{=} 45 \left(\tfrac{1}{2}\right)^{10} = \frac{45}{1024} = 0.04395,$$
$$\mathrm{P}(8 \mid B) \overset{(2)}{=} 45\,(0.8)^8 (0.2)^2 = 45 \times 0.16777 \times 0.04 = 0.3020.$$

(1) With $p = \frac{1}{2}$ every sequence has the same probability 2^{-10}.
(2) $0.8^8 = 0.16777$ and $0.2^2 = 0.04$.

The biased coin produces "8 heads" in about 30% of its ten-toss runs; the fair coin in about 4%.

Example 0.2 (the backward direction: which coin was it?). The question is step 4: having seen 8 heads, how probable is it that the coin is the biased one? We have everything Bayes' theorem (0.3) needs. The two hypotheses are F (fair) and B (biased). The drawer held equal numbers of each, so the priors are $\mathrm{P}(F) = \mathrm{P}(B) = \frac{1}{2}$. The likelihoods are the two forward numbers of Example 0.1. Then

$$\mathrm{P}(B \mid 8) \overset{(1)}{=} \frac{\mathrm{P}(8 \mid B)\,\mathrm{P}(B)}{\mathrm{P}(8 \mid B)\,\mathrm{P}(B) + \mathrm{P}(8 \mid F)\,\mathrm{P}(F)}$$
$$\overset{(2)}{=} \frac{0.3020}{0.3020 + 0.04395} = \frac{0.3020}{0.3459} = 0.873.$$

(1) Bayes' theorem (0.3): numerator is the red path through B in Figure 0.2, denominator is both red paths.
(2) The common factor $\mathrm{P}(B) = \mathrm{P}(F) = \frac{1}{2}$ cancels between numerator and denominator.

So $\mathrm{P}(B \mid 8) = 0.873$ and $\mathrm{P}(F \mid 8) = 0.127$. The coin itself did *not* change. What changed is how we share probability between the two coins it could be.

Key idea: Bayes' theorem as information shrinking the sample space

Before the evidence, the whole sample space is relevant. The evidence E tells us that we are somewhere in the region where E is true, so the sample space *shrinks* to that region. The posterior $\mathrm{P}(H \mid E)$ is the fraction of the shrunken region occupied by H:

$$\mathrm{P}(H \mid E) = \frac{\text{area of } (H \cap E)}{\text{area of } (H \cap E) + \text{area of } (\neg H \cap E)} = \frac{\mathrm{P}(E \mid H)\,\mathrm{P}(H)}{\mathrm{P}(E \mid H)\,\mathrm{P}(H) + \mathrm{P}(E \mid \neg H)\,\mathrm{P}(\neg H)}.$$

Figure P.2 draws this for the coin, with $H = B$ (the biased coin, "bent" in the figure) and $\neg H = F$ (fair; $\neg H$ means "not H"). Take a rectangle Ω, whose area 1 stands for total probability, and cut it into two strips of width $\mathrm{P}(B) = \mathrm{P}(F) = \frac{1}{2}$. The left strip is the "biased" world and the right strip is the "fair" world. In each strip, mark the part of that world in which "8 heads" happens. That part is the forward number: it fills the fraction $\mathrm{P}(8 \mid B) = 0.302$ of the biased strip and the fraction $\mathrm{P}(8 \mid F) = 0.044$ of the fair strip. So a forward probability is a *share of a strip*, and the joint probability $\mathrm{P}(8 \cap B) = \mathrm{P}(8 \mid B)\,\mathrm{P}(B)$ is an *area*, the share times the strip's width. The two marked pieces sit side by side and together make one box: the event "8 heads".

Observing 8 heads rules out everything outside the box, because those regions are worlds in which 8 heads did not happen. The box is the new sample space. The posterior $\mathrm{P}(B \mid 8)$ is the biased piece's share of the box, $0.151/(0.151 + 0.022) = 0.873$. The picture also shows why the posterior depends on the prior: making the biased strip narrower would shrink its piece, and so its share of the box.

The biased piece answers both directions. As a share of the biased strip, it is the forward probability $\mathrm{P}(8 \mid B)$. As a share of the box, it is the posterior $\mathrm{P}(B \mid 8)$. Bayes' theorem is the relation between these two ways of measuring the same piece (Section 5.2).

Example 0.3 (odds, and updating twice). With two hypotheses, Bayes' theorem is simplest as a ratio, because the normalisation drops out. Write Bayes' theorem once for B and once for F, with E the observed event ("8 heads"), and divide the first by the second. Both have the same denominator $\mathrm{P}(E)$, so it cancels:

$$\underbrace{\frac{\mathrm{P}(B \mid E)}{\mathrm{P}(F \mid E)}}_{\text{posterior odds}} \overset{(1)}{=} \underbrace{\frac{\mathrm{P}(E \mid B)}{\mathrm{P}(E \mid F)}}_{\text{likelihood ratio}} \underbrace{\frac{\mathrm{P}(B)}{\mathrm{P}(F)}}_{\text{prior odds}} \overset{(2)}{=} \frac{0.3020}{0.04395} \times 1 = 6.87.$$

(1) Ratio of two copies of (0.3); $\mathrm{P}(E)$ cancels.
(2) Numbers from Example 0.1; equal priors give prior odds 1.

Odds of 6.87 to 1 mean a probability $6.87/(1 + 6.87) = 0.873$, as before.

Now toss the same coin ten more times, and suppose we again see 8 heads. How should the odds change? Two facts answer this. First, what we believed after the first run is our starting point for the second, so the posterior odds of the first run are the prior odds of the second. Second, once the coin is fixed, the second run's tosses do not depend on the first run's, so the second run has the same likelihood ratio as the first. The second run therefore multiplies the

odds by 6.87 again:

$$\text{odds after two runs} \overset{(1)}{=} 6.87 \times 6.87 = 47.2, \qquad \mathrm{P}(B \mid \text{both runs}) \overset{(2)}{=} \frac{47.2}{48.2} = 0.979.$$

(1) Posterior odds = likelihood ratio × prior odds, with the prior odds now equal to 6.87.
(2) Odds o correspond to probability $o/(1+o)$.

Independent pieces of evidence multiply the odds, so they add in the logarithm of the odds. This is why many independent data points can overwhelm any reasonable prior.

What this bought us. The observation "8 heads" can be reached by two paths through the tree, one through each coin. The biased path is 6.87 times more likely to produce it, so the posterior odds are 6.87 times the prior odds. Inference is this *reallocation of credibility across possibilities*: the possibilities that fit the data gain credibility, and the others lose it [Kruschke pp. 16–22]. Sherlock Holmes' rule, "eliminate the impossible and whatever remains must be the truth", is the extreme case. There some likelihoods are exactly zero, and those hypotheses lose all their credibility. Kruschke's bouncy-ball example (three noisy measurements of a diameter, four candidate ball sizes) is our coin with a continuous outcome. The two directions are also the two basic problems of statistics [Wasserman p. ix]. Forward: *given a data generating process, what are the properties of the outcomes?* Backward: *given the outcomes, what can we say about the process that generated them?*

The two directions in code

The script below does both directions with numbers. Forward, it simulates 20000 ten-toss experiments with each coin and compares how often each head count k turns up with the exact binomial probabilities of Example 0.1. Backward, it computes the posterior $\mathrm{P}(B \mid k)$ for every possible outcome $k = 0, \ldots, 10$, not only for $k = 8$.

Listing 0.1: The key lines: forward simulation, exact pmf, and Bayes on each column of the tree (`code/ch00/01_coin_two_directions.py`)

```
k = np.arange(N_TOSS + 1)

def binom_pmf(k, n, p):
    """P(k heads in n tosses | p): the forward (prediction) question."""
    return np.array([comb(n, int(j)) * p**j * (1 - p) ** (n - j) for j in k])

# ---- forward direction: each coin produces a distribution of outcomes ----
pmf_fair, pmf_bias = binom_pmf(k, N_TOSS, P_FAIR), binom_pmf(k, N_TOSS, P_BIAS)
sim_fair = rng.binomial(N_TOSS, P_FAIR, size=N_EXP)      # 20000 experiments of 10 tosses
sim_bias = rng.binomial(N_TOSS, P_BIAS, size=N_EXP)
freq_fair = np.bincount(sim_fair, minlength=N_TOSS + 1) / N_EXP
freq_bias = np.bincount(sim_bias, minlength=N_TOSS + 1) / N_EXP

# ---- backward direction: Bayes on the observed column of the tree ----
num_bias = pmf_bias * PRIOR_BIAS                  # path "biased, then k heads"
num_fair = pmf_fair * (1 - PRIOR_BIAS)            # path "fair, then k heads"
post_bias = num_bias / (num_bias + num_fair)      # normalise over the paths that end at k
```

The function `binom_pmf` is Example 0.1 line for line. The generator call `rng.binomial`, with `size=N_EXP`, performs the forward experiment 20000 times and returns the list of head counts. `np.bincount` counts how often each value of k appears in that list; dividing by 20000 turns the counts into empirical frequencies. The last three lines are Bayes' theorem (0.3). `num_bias` and

`num_fair` are the weights of the two paths in the tree that end at k, and dividing by their sum is the normalisation by $\mathrm{P}(k)$.

For $k = 8$ the run gives an empirical frequency 0.04105 for the fair coin, against the exact 0.04395, and 0.3024 for the biased coin, against the exact 0.302. A theoretical probability and an empirical frequency are different objects. A fair coin has probability $\frac{1}{2}$ of heads, yet a run of 10 tosses may give 3 heads and a run of 100 may give 45. The simulation lets us watch the frequency settle onto the probability as the number of runs grows [SeeingTheory p. 5]. The simulated fraction still fluctuates. A fraction of N independent trials, each succeeding with probability q, has standard deviation $\sqrt{q(1-q)/N}$ (derived in Example 0.4). Here that is 0.001449, so both agreements are within the expected scatter. Backward, the posterior at $k = 8$ is 0.873, reproducing Example 0.2; at $k = 5$ it has fallen to 0.09696.

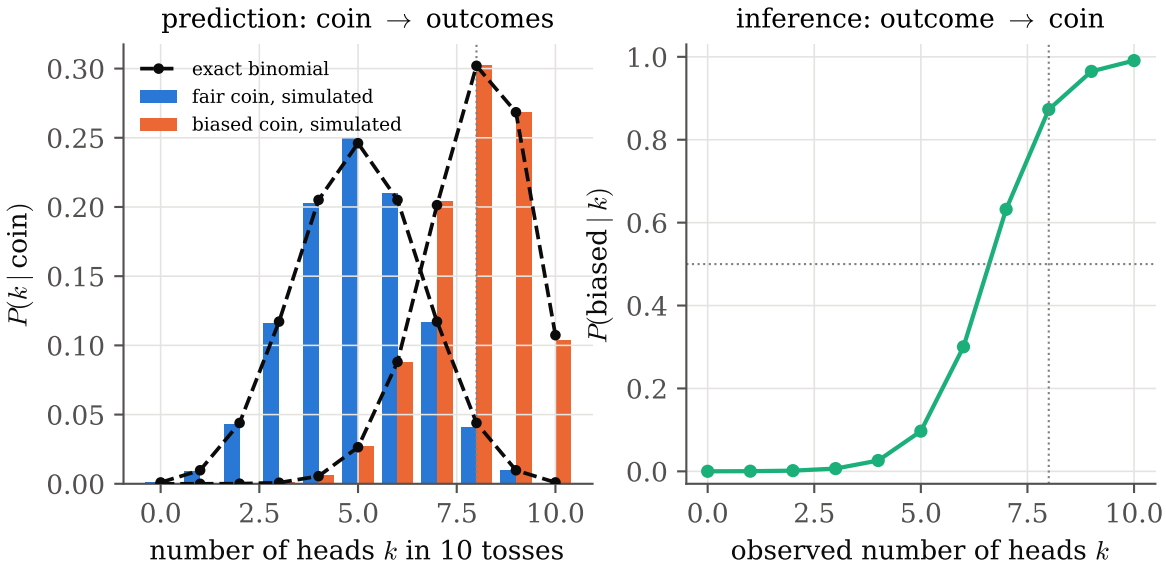

Figure 0.3: Left, prediction: each coin, tossed ten times over and over, spreads its outcomes over $k = 0, \ldots, 10$. Bars are simulated frequencies, dashed curves the exact binomial probabilities; the dotted line marks the observed $k = 8$. Right, inference: for each possible observation k, the probability that the coin was the biased one. The curve crosses the prior value $\frac{1}{2}$ between $k = 6$ and $k = 7$, where the two coins explain the data about equally well.

The forward number $\mathrm{P}(E \mid H)$ and the backward number $\mathrm{P}(H \mid E)$ can be far apart. The classic case is a medical test, and it goes through the same four steps. A disease affects 1% of people. A test detects it with probability 0.95 and gives a false positive with probability 0.10.

The event. A patient tests positive, written $+$.

What could have produced it? The one thing we do not know is whether the patient is ill. So there are two candidates: the patient has the disease (D), or does not (D^c).

How probable was the event under each? If the patient is ill, the test catches it 95% of the time: $\mathrm{P}(+ \mid D) = 0.95$. If the patient is healthy, a positive result is a false alarm, which happens 10% of the time: $\mathrm{P}(+ \mid D^c) = 0.10$.

Only then the priors, and the normalisation. Before the test, the patient was ill with probability 0.01 and healthy with probability 0.99. Bayes' theorem (0.3) gives

$$\mathrm{P}(D \mid +) = \frac{0.95 \times 0.01}{0.95 \times 0.01 + 0.10 \times 0.99} = \frac{0.0095}{0.1085} = 0.0876.$$

Watch out: $\mathrm{P}(E \mid H)$ **is not** $\mathrm{P}(H \mid E)$

The two numbers answer different questions and can be wildly different. For the positive test, the forward number $\mathrm{P}(+ \mid D) = 0.95$ is not the answer to "is the patient ill?"; the answer is $\mathrm{P}(D \mid +) = 0.0876$. Swapping the two conditionals is the "prosecutor's fallacy". Its statistical twin appears in Chapter 4: a p-value is *not* the probability that the null hypothesis is true.

The lesson is not in the arithmetic. A positive result can come by two paths: through the disease, or through a false alarm on a healthy person. Each healthy person is unlikely to take the false-alarm path, but there are 99 healthy people for every ill one. The positive result favours the disease only by the factor $\mathrm{P}(+ \mid D)/\mathrm{P}(+ \mid D^c) = 0.95/0.10 = 9.5$. A factor of 9.5 acting on a prior of 1% leaves the posterior below 10%, far from the 95% that the test's sensitivity suggests (Section 5.2 draws it to scale).

Two meanings of "prediction". In this chapter "prediction" means the forward direction, $H \to E$. Statistics and machine-learning books also use the word for guessing a *new* data point (a regression output, a class label) after learning from old data. That second kind of prediction is part of inference, because it starts from data. When Wasserman lists "prediction, classification, clustering, and estimation" as special cases of inference, he means the second sense.

0.2 The questions the book answers

One coin already raises many different questions, and each needs its own tool. Keep the coin from the magic shop of Section 0.1, but forget the drawer. Now there is a single coin whose heads probability p is unknown, and we may toss it as often as we like. *How likely is 8 heads if* $p = \frac{1}{2}$*?* is a forward calculation. *What is our best guess for* p*, and how wrong might it be?* is estimation. *Is 8 heads in 10 surprising for a fair coin?* is a test. *Which values of* p *are plausible now?* is Bayesian inference. *Could we get any of these numbers by simulation instead of algebra?* is Monte Carlo. *How many tosses would we need to pin* p *down to* ± 0.01*?* is a Fisher forecast. Each question has its own object that answers it, and each has its own chapter. If we keep the questions apart, then for any tool we can say which question it answers.

Same system, different measurements. A physicist knows this from the lab. One pendulum supports many experiments. We can measure its period, estimate g from the period, test whether the period depends on the amplitude, or forecast how precisely a longer run would pin down g. The pendulum stays the same. What changes is the question, and with it the quantity we must compute. Probability tools work the same way: the model stays fixed, and each tool computes the quantity that answers one question about it.

The questions in words. Before any formula, each kind of question can be said in one sentence.

1. *Forward:* if the hypothesis is true, how often does this outcome occur?
2. *Spread:* what values can a random quantity take, and how are they distributed?
3. *Estimation:* what value of the parameter do the data point to, and how far off is that guess likely to be?

4. *Testing:* if only chance were at work, would a result like this, or one even more extreme in the same direction, be something we would reasonably expect?
5. *Bayesian inference:* which parameter values could have produced the data, and how probable is each one?
6. *Simulation:* can we get the answer to any of these by drawing random numbers, when the algebra is too hard?
7. *Forecasting:* before the experiment is run, how well could it measure the parameter?
8. *Choosing the summary:* which property of a field (a map, a density) carries the physics, and does it survive the nuisance effects of observation?

The table below is the map of the book. Each row gives one question, the object that answers it, and the chapter where that object is built. The pictogram on the left of each row is a miniature of the central figure of that chapter, the picture to remember for the row.

Most of the rows can be tried on the coin in a few lines. Four of them need a new idea: estimation, testing, Monte Carlo and forecasting. Two definitions carry all four.

Working definition 0.2 (estimator, sampling distribution, p-value)

An **estimator** is a recipe that turns data into a guess for a parameter, $\hat{\theta} = \hat{\theta}(\boldsymbol{d})$ [a function of the data only, e.g. $\hat{p} = k/n$, the fraction of heads]. Because the data are random, so is $\hat{\theta}$. Its distribution over imagined repetitions of the whole experiment is its **sampling distribution** [the histogram of $\hat{\theta}$ if the experiment were rerun many times with the same true θ]. Its **bias** is $\mathbb{E}[\hat{\theta}] - \theta$ and its spread is $\mathrm{Var}(\hat{\theta})$.
A **null hypothesis** H_0 is a hypothesis whose sampling distribution we know ["nothing but chance", e.g. a fair coin]. Given an observed value t_{obs} of a statistic T, the **p-value** is

$$p = \mathrm{P}\left(T \geq t_{\mathrm{obs}} \,|\, H_0\right), \tag{0.4}$$

the probability, computed under H_0, of a result like the observed one *or even more in this direction* [here, larger values of T count as further out]. We can compute it only because "pure chance" is the one case whose distribution we have in hand. For a fair coin we know exactly how often each head count turns up. A small p says that, if the coin really were fair, a result this far out would be a surprise (Chapter 4).

Example 0.4 (the scatter of a fraction). The natural guess for p is the fraction of heads. The question is whether this guess is right on average, and how far it typically misses. Toss the coin n times and let $x_i = 1$ if toss i is heads and $x_i = 0$ if it is tails. The number of heads is $k = \sum_i x_i$, so the estimator is $\hat{p} = k/n = \frac{1}{n}\sum_i x_i$. Its mean and variance are

$$\mathbb{E}[\hat{p}] \overset{(1)}{=} \frac{1}{n}\sum_{i=1}^{n} \mathbb{E}[x_i] \overset{(2)}{=} \frac{1}{n}\, n\, p = p,$$

$$\mathrm{Var}(\hat{p}) \overset{(3)}{=} \frac{1}{n^2}\sum_{i=1}^{n} \mathrm{Var}(x_i) \overset{(4)}{=} \frac{1}{n^2}\, n\, \left(\mathbb{E}[x_i^2] - \mathbb{E}[x_i]^2\right) \overset{(5)}{=} \frac{p - p^2}{n} = \frac{p(1-p)}{n}.$$

(1) The expectation of a sum is the sum of expectations, and constants come out.
(2) $\mathbb{E}[x_i] = 1 \cdot p + 0 \cdot (1 - p) = p$.
(3) For *independent* tosses the variance of a sum is the sum of variances; a constant c comes out as c^2.

Taxonomy: which object answers which question

	The question, in words	The object that answers it	Ch.
	How likely is this event, if the situation is as assumed? Which paths lead to it?	$\mathrm{P}(E \mid H)$, summed over the paths of a probability tree	1
	What values can a random quantity take, and how are they spread?	a distribution: pmf or pdf, CDF, mean and variance (binomial, Poisson, Gaussian, . . .)	2
	What value of the parameter do the data point to, and how far off is that guess?	an estimator $\hat{\theta}$, its bias and variance, i.e. its sampling distribution; the likelihood $\mathcal{L}(\theta)$	3
	If H_0 (the case whose distribution we know: "it happened by chance") were true, would a result like this, or more extreme in this direction, be expected?	a test statistic and its p-value, the tail probability under H_0	4
	Which parameter values (or models) could have produced the data, and how probable is each?	the posterior $p(\boldsymbol{\theta} \mid \boldsymbol{d}) \propto \mathcal{L}(\boldsymbol{\theta})\, p(\boldsymbol{\theta})$; the evidence Z for comparing models	5
	What is the distribution of a quantity too complicated to compute by hand?	many simulated realisations; histograms and averages, with error $\propto 1/\sqrt{N}$	6
	How do we summarise a random field (a sky map), and how does the summary fluctuate?	correlation function $\xi(r)$, power spectrum $P(k)$, C_ℓ and its estimator $\widehat{C}_\ell$	7
	How do a mask, noise and a beam change the sampling distribution of the summary?	Monte Carlo as the research instrument: simulated skies through the observation pipeline	8
	How do we draw samples from a posterior in many dimensions without ever normalising it?	a Markov chain: a *biased* random walker that lingers where the posterior is high	9
	Before the experiment, how well could it measure $\boldsymbol{\theta}$?	the Fisher matrix $\mathbf{F}$; forecast errors $\sigma_i \geq \sqrt{(\mathbf{F}^{-1})_{ii}}$	10
	What do the positions and motions of galaxies say about how the Universe expands and how structure grows?	galaxy catalogues: $\xi(s)$ and $P(k)$ with weights and windows, the BAO ruler, peculiar velocities	11
	Is there information in how the structures of a field are connected, robust to nuisance effects?	excursion sets, Betti numbers, Euler characteristic, persistence: new random observables S with a $P(S \mid \theta)$	12
	Does the whole chain survive contact with real data?	complete analyses of Planck, SDSS and collider data, each reproducing a published result	13

Chapter 14 puts the rows back together: given a new problem, which row does it belong to?

(4) Definition of the variance, $\mathrm{Var}(x) = \mathbb{E}[x^2] - \mathbb{E}[x]^2$.
(5) $x_i^2 = x_i$ because x_i is 0 or 1, so $\mathbb{E}[x_i^2] = p$.

So $\hat{p}$ is **unbiased**: on average it gives the true p. Its standard deviation, the typical miss, is $\sqrt{p(1-p)/n}$. For $p = 0.8$ this is 0.126 at $n = 10$ and 0.040 at $n = 100$. The same algebra applies to *any* fraction of N independent trials that each succeed with probability q. That is why a Monte Carlo estimate of a probability q from N simulated trials has error $\sqrt{q(1-q)/N}$.

Example 0.5 (the p-value of 8 heads). *The observation.* Ten tosses gave 8 heads. *The question.* If the coin were fair, would 8 heads, or more than 8 heads, be something we would reasonably expect? *The pieces.* The null hypothesis is H_0: $p = \frac{1}{2}$. The statistic is the number of heads, $T = k$, and "more extreme" means more heads. Then

$$\mathrm{P}(K \geq 8 \mid H_0) \overset{(1)}{=} \mathrm{P}(8) + \mathrm{P}(9) + \mathrm{P}(10) \overset{(2)}{=} \frac{\binom{10}{8} + \binom{10}{9} + \binom{10}{10}}{2^{10}} = \frac{45 + 10 + 1}{1024} = \frac{56}{1024} = 0.0547.$$

(1) "This or more extreme in this direction": the outcomes $8, 9, 10$ are exclusive, so their probabilities add.
(2) Binomial probabilities with $p = \frac{1}{2}$ (Example 0.1): every sequence has probability 2^{-10}.

About 5% of fair ten-toss runs give 8 heads or more (Figure 0.4). That is mildly surprising, not damning. The p-value used only the distribution under H_0; it never mentioned the biased coin. It is *not* $\mathrm{P}(H_0 \mid \text{data})$, the probability that the coin is fair. In the drawer story of Section 0.1 (equal numbers of fair and biased coins) that number was $\mathrm{P}(F \mid 8) = 0.127$, the answer to a different question.

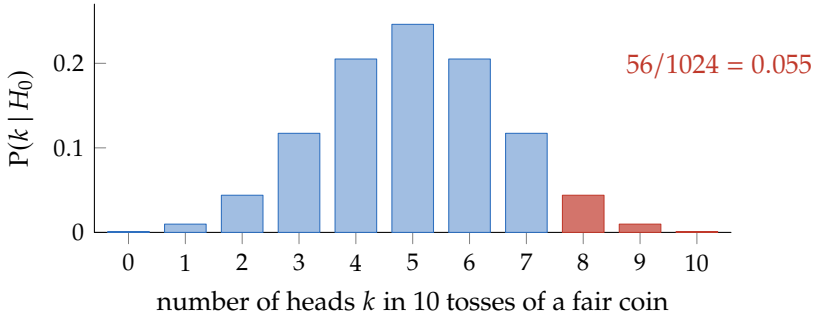

Figure 0.4: The null distribution for ten tosses of a fair coin. The red bars are the observed $k = 8$ and the outcomes more extreme in the same direction; their total height is the p-value. The blue bars never enter.

Example 0.6 (a forecast before any toss: the Fisher information). The question is asked before any toss: how precisely *could* n tosses measure p? The answer depends on how sharply the data single out one value of p. The likelihood of one particular sequence with k heads is $\mathcal{L}(p) = p^k(1-p)^{n-k}$, so its logarithm is $\ln \mathcal{L}(p) = k \ln p + (n-k)\ln(1-p)$. A log-likelihood with a sharp peak pins p down; a flat one does not. The **Fisher information** measures the sharpness. It is minus the expected curvature of $\ln \mathcal{L}$ at the true p:

$$I(p) \overset{(1)}{=} -\mathbb{E}\left[\frac{\mathrm{d}^2 \ln \mathcal{L}}{\mathrm{d}p^2}\right] \overset{(2)}{=} \mathbb{E}\left[\frac{k}{p^2} + \frac{n-k}{(1-p)^2}\right] \overset{(3)}{=} \frac{np}{p^2} + \frac{n(1-p)}{(1-p)^2} = \frac{n}{p} + \frac{n}{1-p} = \frac{n}{p(1-p)}.$$

(1) Definition (Chapter 10): a sharply curved log-likelihood pins the parameter down.
(2) $\frac{\mathrm{d}}{\mathrm{d}p} \ln \mathcal{L} = \frac{k}{p} - \frac{n-k}{1-p}$; differentiate again and change sign.

(3) $\mathbb{E}[k] = np$ and $\mathbb{E}[n-k] = n(1-p)$.

The Cramér–Rao bound (Chapters 3 and 10) says that no unbiased estimator can beat $\mathrm{Var}(\hat{\theta}) \geq 1/I$. Here $1/I = p(1-p)/n$, exactly the variance of $\hat{p}$ found in Example 0.4. So the fraction of heads is as good as any unbiased guess can be. The forecast needs no data, only an assumed p. To reach a standard deviation $\sigma_p = 0.01$ at $p \approx 0.8$ we need $n = p(1-p)/\sigma_p^2 = 0.16/10^{-4} = 1600$ tosses.

What this bought us. The same coin gave three different numbers: a spread $\sqrt{p(1-p)/n}$ (estimation), a tail probability 0.055 (testing) and a required number of tosses, 1600 (forecasting). None of them is a posterior. Each answers its own row of the table. Confusing the rows is the most common error in applied statistics.

Watch out: what a p-value and a confidence interval do *not* say

A p-value of 0.055 does not mean "the coin is fair with probability 0.055". It is $\mathrm{P}(\text{data this extreme} \mid H_0)$, a forward number. Likewise, a 95% confidence interval is a recipe that covers the true value in 95% of repetitions of the experiment; it is not an interval that contains the parameter with probability 95%. Only the posterior of Chapter 5 makes probability statements about parameters.

The questions in code

The script `02_coin_questions.py` checks two of these answers by brute force. The key lines are:

Listing 0.2: Estimation and a p-value by simulation (`code/ch00/02_coin_questions.py`)

```
# (i) sampling distribution of the estimator p_hat = k/n
n_rep = 50000
phat10 = rng.binomial(10, P_TRUE, n_rep) / 10
phat100 = rng.binomial(100, P_TRUE, n_rep) / 100

# (ii) exact p-value: P(K >= 8 | p = 1/2), "this or more extreme in this direction"
p_exact = sum(comb(N_TOSS, j) for j in range(K_OBS, N_TOSS + 1)) / 2**N_TOSS

# (iii) Monte Carlo estimate of the same number: fraction of simulated fair
#       experiments with K >= 8, for N = 10 ... 10^6 experiments
Ns = np.unique(np.logspace(1, 6, 40).astype(int))
fair = rng.binomial(N_TOSS, 0.5, Ns.max())
hits = np.cumsum(fair >= K_OBS)                  # running count of "as or more extreme"
p_mc = hits[Ns - 1] / Ns
sigma_mc = np.sqrt(p_exact * (1 - p_exact) / Ns)   # binomial error of a fraction
```

The first block reruns the whole ten-toss experiment, and the hundred-toss one, 50 000 times with the true $p = 0.8$, and keeps each $\hat{p}$. That list is a sample from the sampling distribution of $\hat{p}$. The second block is Example 0.5 in one line. The third block simulates fair experiments. In it, `np.cumsum(fair >= K_OBS)` counts, for every N at once, how many of the first N experiments were as extreme as the observed 8 heads. The last line is the error bar $\sqrt{q(1-q)/N}$ of Example 0.4.

The run confirms both calculations. The standard deviation of $\hat{p}$ is 0.1267 at $n = 10$ (theory 0.1265) and 0.03997 at $n = 100$ (theory 0.04). The mean at $n = 10$ is 0.7993, so the estimator is unbiased, as derived. The Monte Carlo p-value is 0.0566 after $N = 106$ experiments and $0.0545 \pm 2.274 \times 10^{-4}$ after 10^6, against the exact 0.05469.

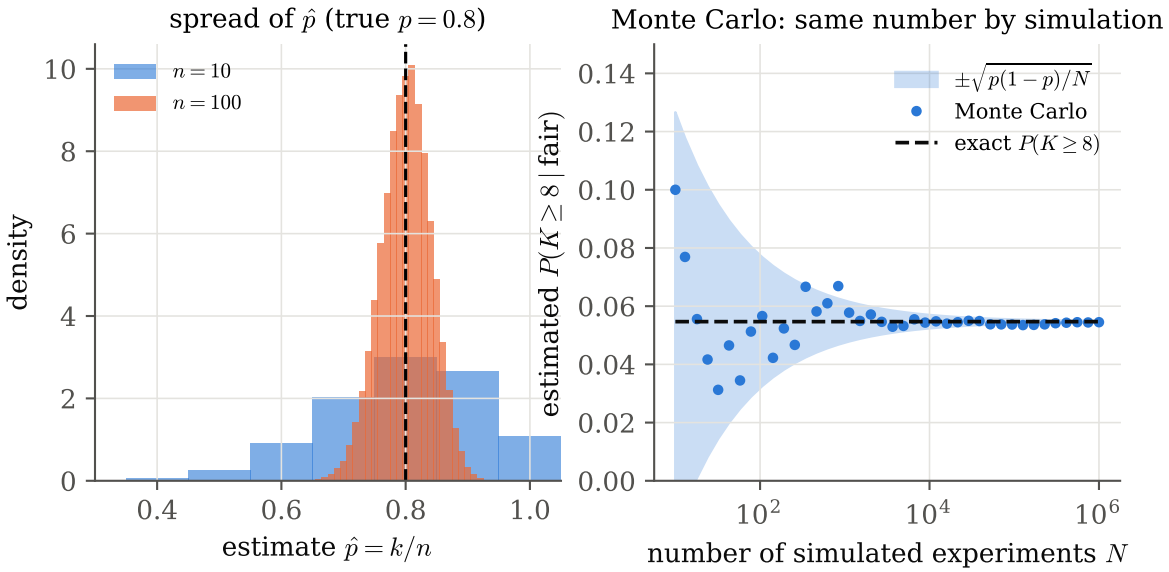

Figure 0.5: Left: the sampling distribution of $\hat{p} = k/n$ for a coin with $p = 0.8$. With 10 tosses the guesses spread over most of the interval; with 100 they crowd around the true value, ten times more tightly in variance. Right: the Monte Carlo estimate of $\mathrm{P}(K \geq 8 \mid \text{fair})$ as the number of simulated experiments grows. The points wander inside the shaded $\pm\sqrt{p(1-p)/N}$ band, which narrows onto the exact value.

How this is used in real research: verification versus research

Monte Carlo has two uses. Here it only *verifies* a number we could compute exactly, 56/1024; the first use is to check theory and code against each other. The second use is as the *research instrument*, where no exact answer exists. Suppose the "coin" were a CMB sky seen through a galactic mask, with noise and a beam. Nobody can write down the distribution of the measured power spectrum. Instead one simulates thousands of skies and makes a histogram. The code is the same: draw, compute the statistic, count. Chapter 6 builds the first use, Chapter 8 the second.

The same idea under different names. The vocabulary changes between communities, but the ideas do not. What statisticians call *estimation*, the machine-learning literature calls *learning*. The observed values (X_i, Y_i) are there the *training sample*. The inputs X_i are *covariates* in one language and *features* in the other. A few more terms recur. A *hypothesis* is a subset of the parameter space. A *confidence interval* is a recipe that covers the unknown value with a stated frequency. *Bayesian inference* means using data to update beliefs, whereas *frequentist inference* collects the methods whose long-run frequency behaviour is guaranteed [Wasserman p. xi]. Prediction in the second sense of Section 0.1, together with classification, clustering and estimation, counts as a special case of inference [Wasserman p. ix]. Only the Bayesian rows of the table above (Chapters 5 and 9) share out credibility among parameter values [Kruschke p. 15]. The estimation and testing rows instead describe how a *procedure* behaves over repeated experiments. The null hypothesis is the case whose distribution we know, because we assume the result happened by chance [Wasserman p. 149].

0.3 The pipeline: from a physical model to a statement about physics

Real data are never fed into Bayes' theorem whole; they are compressed first. A Planck temperature map at the resolution used for cosmology has about 5×10^7 pixels. The model we want to test, ΛCDM, has six parameters. Nobody writes Bayes' theorem directly for fifty million correlated pixels. Instead the map is compressed into its angular power spectrum $\widehat{C}_\ell$, about 2500 numbers, and those are compared with the theory. Each step of this is a choice. First we decide that the power spectrum is the information that matters. Then we work out how $\widehat{C}_\ell$ fluctuates from one sky to another. Only then do we infer the six parameters. Written out as one pipeline, this chain of choices has an arrow for every tool in the book. Knowing which arrow we are on is the fastest way to know what a tool is for.

Microstates and macrostates. Statistical mechanics works the same way. A gas has 10^{23} momenta, but we never infer anything from the full microstate. We compress it into a few macroscopic summaries (pressure, energy, magnetisation). Fluctuation theory then tells us how much those summaries scatter; for example, the energy of a system at temperature T with heat capacity C_V fluctuates by $\langle \Delta E^2 \rangle = k_B T^2 C_V$. A summary is chosen for two reasons: it carries the physics we care about, and its fluctuations can be calculated. Data analysis makes the same two demands of every summary statistic.

Six stages, six questions. The whole book runs along one chain, drawn in Figure 0.6:

$$\boxed{\begin{array}{l}\text{a theory with parameters } \boldsymbol{\theta} \;\rightarrow\; \text{the map or data set it produces} \\ \quad \rightarrow \text{ decide which features of the data carry the physics} \\ \quad \rightarrow \text{ compress the data into a statistic } S \;\rightarrow\; \text{work out how } S \text{ scatters, } P(S \mid \boldsymbol{\theta}) \\ \quad \rightarrow \text{ say what the observed } S \text{ tells us about } \boldsymbol{\theta}\end{array}} \tag{0.5}$$

In symbols, the last two stages are $P(S \mid \theta)$ and $P(\theta \mid S) \propto P(S \mid \theta) P(\theta)$, where θ stands for the parameters $\boldsymbol{\theta}$. The stages answer different kinds of question. The choice of summary decides what should be measured. The last two stages decide how the uncertainty in that measurement carries over to the parameters. The same chain applies whether the data vector holds pixelised CMB temperatures or measured bandpowers C_ℓ, and whatever the number M of model parameters. Each stage is a question.

1. *Physical model:* what theory, with which parameters $\boldsymbol{\theta}$, could have produced the data?
2. *Field or dataset:* what exactly did the instrument record, and how does it depend on $\boldsymbol{\theta}$ and on noise?
3. *What information matters:* which property of the data is sensitive to $\boldsymbol{\theta}$, and which is only nuisance?
4. *Summary:* which function $S[\boldsymbol{d}]$ of the data keeps that property and discards the rest?
5. *Sampling distribution:* if the experiment were repeated with the same $\boldsymbol{\theta}$, how would S scatter? That is $P(S \mid \boldsymbol{\theta})$.
6. *Infer physics:* given the one S we observed, which $\boldsymbol{\theta}$ are plausible? That is $P(\boldsymbol{\theta} \mid S) \propto P(S \mid \boldsymbol{\theta}) P(\boldsymbol{\theta})$.

Stages 1 to 5 are the forward direction of Section 0.1. Stage 6 is the backward direction.

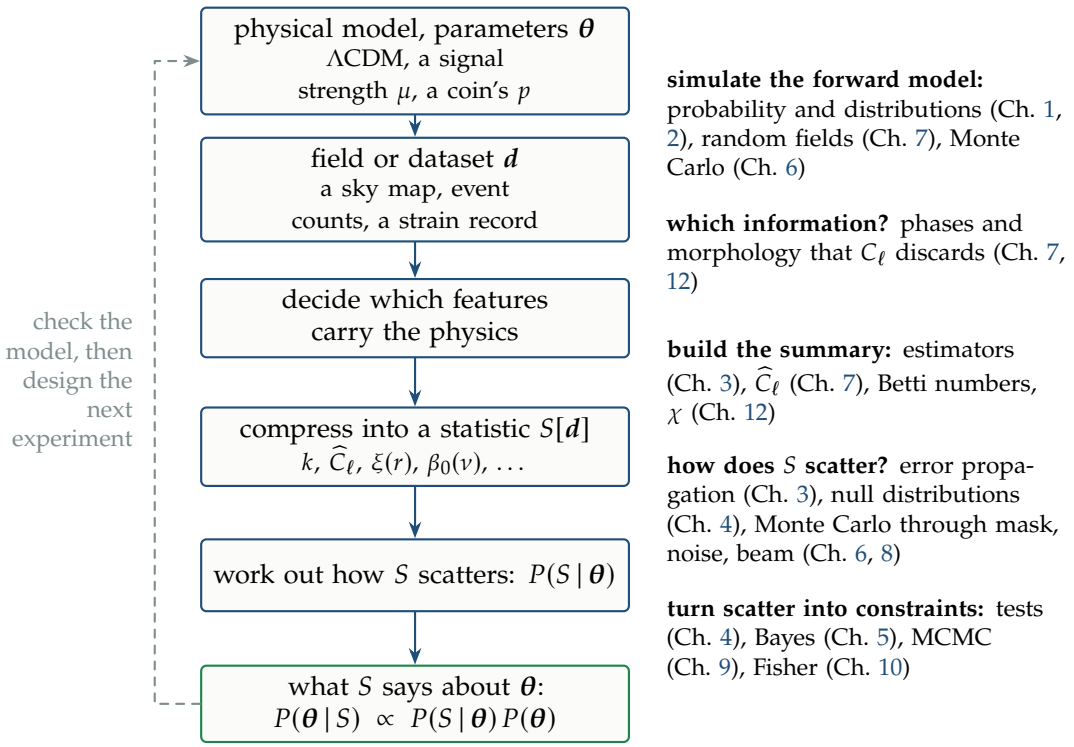

Figure 0.6: The pipeline of the whole book. Boxes are the stages; the notes on the right say which chapters serve the step from one box to the next. The top four boxes are forward modelling and a choice, the fifth is probability theory applied to that choice, and only the last box is inference. The dashed loop is the step statisticians call a posterior predictive check: simulate data from the inferred model and ask whether they look like the real data.

One step of the pipeline is not mathematics: choosing what information matters. It is a physics decision, and Section 0.4 takes it up. The next step, building the summary, does have a precise test: it tells us when compressing the data loses nothing.

Working definition 0.3 (summary statistic, sampling distribution, sufficiency)

A **summary statistic** is any function $S = S[\boldsymbol{d}]$ of the data [a number or a short vector computed from the data alone, e.g. the number of heads k]. Its **sampling distribution** $P(S \mid \boldsymbol{\theta})$ is the distribution of S over repetitions of the experiment with the parameters held fixed [the histogram of S over many simulated universes that share the same $\boldsymbol{\theta}$]. The summary is **sufficient** for $\boldsymbol{\theta}$ if the likelihood depends on the data only through S:

$$P(\boldsymbol{d} \mid \boldsymbol{\theta}) = g\big(S[\boldsymbol{d}], \boldsymbol{\theta}\big)\, h(\boldsymbol{d}) \tag{0.6}$$

[h may depend on the data but not on $\boldsymbol{\theta}$, so it cancels from every posterior and every likelihood ratio]. Then $P(\boldsymbol{\theta} \mid \boldsymbol{d}) = P(\boldsymbol{\theta} \mid S)$: nothing about $\boldsymbol{\theta}$ was thrown away.

The coin shows how the test works. The data are the whole sequence $x_1, \ldots, x_n$ of zeros and ones ($x_i = 1$ for heads, as in Example 0.4). Is the number of heads enough, or does the order of the tosses also tell us something about p? Write down the probability of the sequence:

$$\begin{aligned} P(x_1, \ldots, x_n \mid p) &\overset{(1)}{=} \prod_{i=1}^{n} p^{x_i}(1-p)^{1-x_i} \\ &\overset{(2)}{=} p^{\sum_i x_i}\,(1-p)^{n-\sum_i x_i} \overset{(3)}{=} p^{k}(1-p)^{n-k}. \end{aligned} \tag{0.7}$$

(1) The tosses are independent; one toss gives p if $x_i = 1$ and $1 - p$ if $x_i = 0$, which is what $p^{x_i}(1-p)^{1-x_i}$ says.
(2) Products of powers of the same base add their exponents.
(3) $k = \sum_i x_i$ is the number of heads.

The sequence enters only through k. So (0.7) has the form (0.6) with $S = k$, $g = p^k(1-p)^{n-k}$ and $h = 1$, and the order of the tosses carries no information about p. The sampling distribution of the summary k is the binomial of Example 0.1. The last stage puts it into Bayes' theorem.

Example 0.7 (the coin through the whole pipeline). The last stage asks: after k heads in n tosses, which values of the heads probability p are plausible, and how plausible is each? Now p can be any number in $[0, 1]$, not one of two coins. Take a flat prior, $p(p) = 1$ on $[0, 1]$, which treats every value as equally plausible beforehand. The posterior for p is then

$$p(p \mid k) \overset{(1)}{=} \frac{P(k \mid p) \cdot 1}{\int_0^1 P(k \mid p')\,\mathrm{d}p'} \overset{(2)}{=} \frac{p^k(1-p)^{n-k}}{\int_0^1 p'^k(1-p')^{n-k}\,\mathrm{d}p'} \overset{(3)}{=} \frac{(n+1)!}{k!\,(n-k)!}\,p^k(1-p)^{n-k}.$$

(1) Bayes' theorem for a continuous parameter: the sum over hypotheses in (0.3) becomes an integral.
(2) The factor $\binom{n}{k}$ does not depend on p and cancels between numerator and denominator.
(3) The Beta integral $\int_0^1 p^a(1-p)^b\,\mathrm{d}p = \frac{a!\,b!}{(a+b+1)!}$ for non-negative integers a, b (proved by b integrations by parts, each moving one power from $(1-p)$ to p).

Where is this posterior centred, and how wide is it? Its mean and variance follow from the same Beta integral:

$$\mathbb{E}[p \mid k] \overset{(1)}{=} \frac{(n+1)!}{k!\,(n-k)!}\int_0^1 p^{k+1}(1-p)^{n-k}\mathrm{d}p \overset{(2)}{=} \frac{(n+1)!}{k!\,(n-k)!}\cdot\frac{(k+1)!\,(n-k)!}{(n+2)!} = \frac{k+1}{n+2},$$
$$\mathbb{E}[p^2 \mid k] \overset{(3)}{=} \frac{(k+1)(k+2)}{(n+2)(n+3)}, \qquad \mathrm{Var}(p \mid k) \overset{(4)}{=} \frac{(k+1)(n-k+1)}{(n+2)^2(n+3)}.$$

(1) Definition of the mean: multiply the posterior by p and integrate.
(2) Beta integral with $a = k+1$, $b = n-k$; then $(k+1)!/k! = k+1$ and $(n+1)!/(n+2)! = 1/(n+2)$.
(3) Same steps with $a = k+2$.
(4) $\mathbb{E}[p^2] - \mathbb{E}[p]^2$, put over the common denominator $(n+2)^2(n+3)$: the numerator is $(k+1)\big[(k+2)(n+2) - (k+1)(n+3)\big] = (k+1)(n-k+1)$.

For large n the variance tends to $\hat{p}(1-\hat{p})/n$ with $\hat{p} = k/n$. This is the same number as the sampling variance $p(1-p)/n$ of Example 0.4, with $\hat{p}$ in place of p. Here are the six stages for the coin. Model: a coin with unknown p. Data: a toss sequence. What matters: the fraction of heads, since the order carries no information. Summary: k. Sampling distribution: binomial. Inference: the Beta-shaped posterior.

Example 0.8 (the CMB through the pipeline). The same six stages apply to a map of the sky. The data are the temperature fluctuation $\Delta T(\hat{n})$ in each direction $\hat{n}$. Expand it in spherical harmonics $Y_{\ell m}$, the sphere's analogue of Fourier modes: $\Delta T(\hat{n}) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\hat{n})$. A multipole ℓ corresponds to an angular scale of roughly $180°/\ell$, and m runs from $-\ell$ to ℓ. Statistical isotropy [no preferred direction, so the statistics are unchanged by rotations] means $\mathbb{E}[a_{\ell m} a^*_{\ell' m'}] = C_\ell\,\delta_{\ell\ell'}\delta_{mm'}$. So the theory predicts one number per ℓ, the power spectrum $C_\ell(\boldsymbol{\theta})$. The natural summary averages the squared sizes of the $2\ell+1$ measured coefficients at each ℓ.

Is it right on average?

$$\mathbb{E}\left[\widehat{C}_\ell\right] \overset{(1)}{=} \mathbb{E}\left[\frac{1}{2\ell+1}\sum_{m=-\ell}^{\ell}|a_{\ell m}|^2\right] \overset{(2)}{=} \frac{1}{2\ell+1}\sum_{m=-\ell}^{\ell}\mathbb{E}\left[a_{\ell m}a_{\ell m}^*\right] \overset{(3)}{=} \frac{1}{2\ell+1}(2\ell+1)\,C_\ell = C_\ell.$$

(1) Definition of the estimator $\widehat{C}_\ell$: the average power in the $2\ell+1$ modes of multipole ℓ.
(2) $|a|^2 = aa^*$, and the expectation of a sum is the sum of expectations.
(3) Isotropy with $\ell' = \ell$, $m' = m$; there are $2\ell+1$ values of m.

So $\widehat{C}_\ell$ is unbiased. It still scatters, because only $2\ell+1$ modes exist at each ℓ and an average of few numbers is noisy. For a Gaussian sky the scatter is $\sqrt{2/(2\ell+1)}\,C_\ell$; this is cosmic variance, derived in Chapter 7. The pipeline reads: model (ΛCDM) $\to$ map $\to$ "the physics is in the variance per scale" $\to \widehat{C}_\ell \to P(\widehat{C}_\ell \mid \boldsymbol{\theta}) \to$ posterior on six parameters. For a full-sky Gaussian map without noise, $\widehat{C}_\ell$ is sufficient, exactly as k is for the coin (Example 0.13). For a masked or noisy sky, or a non-Gaussian one, it is not, and that is where Chapters 8 and 12 begin.

What this bought us. Compression is safe exactly when the likelihood depends on the data only through the summary. For the coin this holds for k. For a Gaussian isotropic full sky it holds for $\widehat{C}_\ell$. Any other compression is a choice whose cost must be checked.

The pipeline in code

The script `03_pipeline_coin.py` checks the sufficiency claim and runs the pipeline for growing n.

Listing 0.3: Two sequences with the same k have the same likelihood (`code/ch00/03_pipeline_coin.py`)

```python
def seq_likelihood(x, p):
    """P(x_1..x_n | p) = prod p^x_i (1-p)^(1-x_i) for a 0/1 sequence x."""
    return np.prod([p**xi * (1 - p) ** (1 - xi) for xi in x], axis=0)

# (a) two different sequences, both with 8 heads in 10
seqA = np.array([1, 1, 1, 1, 1, 1, 1, 1, 0, 0])
seqB = np.array([0, 1, 1, 0, 1, 1, 1, 1, 1, 1])
LA, LB = seq_likelihood(seqA, p), seq_likelihood(seqB, p)
max_diff = np.max(np.abs(LA - LB))
```

Listing 0.4: The posterior after $n = 10, 100, 1000$ tosses (`code/ch00/03_pipeline_coin.py`)

```python
for i, n in enumerate([10, 100, 1000]):
    kk = int(tosses[:n].sum())
    logpost = kk * np.log(np.clip(p, 1e-300, None)) + (n - kk) * np.log(np.clip(1 - p,
    1e-300, None))
    post = np.exp(logpost - logpost.max())
    post /= post.sum() * dp                    # flat prior: posterior = normalised
    likelihood
    mean = np.sum(p * post) * dp
    sd = np.sqrt(np.sum((p - mean) ** 2 * post) * dp)
    a2.plot(p, post, color=SERIES[i], label=f"$n={n}$, $k={kk}$")
    out[f"PipeK{names[n]}"] = kk
    out[f"PipeSd{names[n]}"] = sd
    out[f"PipeSdTh{names[n]}"] = np.sqrt((kk / n) * (1 - kk / n) / n)
```

The first listing evaluates (0.7) toss by toss for two sequences with 8 heads each, HHHHHHHHTT and THHTHHHHHH, on a grid of 2001 values of p. The largest difference between the

two likelihood curves is 3.469×10^{-18}. That is floating-point round-off, so the curves are the same function, as sufficiency says.

The second listing computes the posterior on the grid. It works in logarithms, because a product of a thousand probabilities underflows. It subtracts the maximum before exponentiating, and then normalises numerically; that sum over the grid is Bayes' denominator. One simulated run with true $p = 0.8$ gives:

- at $n = 10$, $k = 7$, posterior standard deviation 0.1307, against the large-n formula $\sqrt{\hat{p}(1-\hat{p})/n} = 0.1449$;
- at $n = 100$, $k = 76$, 0.04238 against 0.04271;
- at $n = 1000$, $k = 819$, 0.01217 against 0.01218.

At $n = 10$ (here $k = 7$) the grid reproduces the exact value of Example 0.7,

$$\sqrt{\frac{(k+1)(n-k+1)}{(n+2)^2(n+3)}} = 0.131.$$

The large-n formula becomes accurate only as n grows.

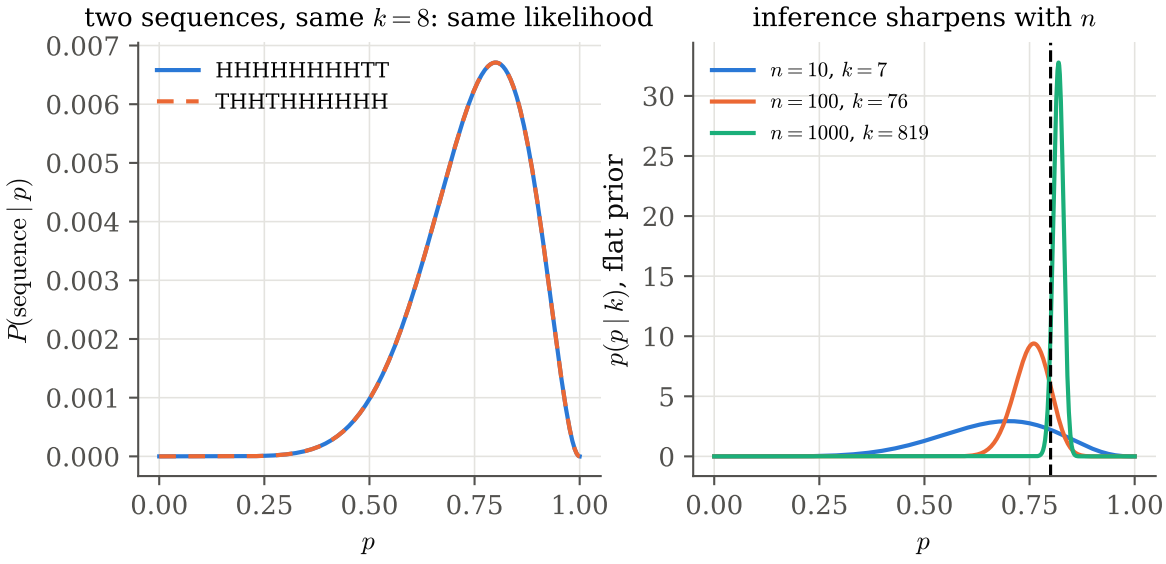

Figure 0.7: Left: the likelihoods of two different toss sequences with the same number of heads lie exactly on top of each other, so the summary k lost nothing. Right: the flat-prior posterior for p after 10, 100 and 1000 tosses of one coin with true $p = 0.8$ (dashed line). The width shrinks like $1/\sqrt{n}$.

How research uses the pipeline. In current research the hard stages are the middle ones. For the coin and the full-sky Gaussian CMB every stage has a closed form, but real problems rarely do. Which summary of a galaxy survey carries the neutrino mass: the power spectrum $P(k)$, the bispectrum, void counts, Betti numbers? What is $P(S \mid \boldsymbol{\theta})$ when S is measured on a masked, noisy, nonlinear field? Usually nobody can write it down. So one simulates the forward model many times at fixed $\boldsymbol{\theta}$ and estimates the mean and covariance of S from the simulations (Chapters 8 and 12). The inference stage then uses the standard machinery of Chapters 5, 9 and 10.

Watch out: the posterior depends on the summary

If S is not sufficient, $P(\boldsymbol{\theta} \mid S)$ is broader than $P(\boldsymbol{\theta} \mid \boldsymbol{d})$, and it can be broader in a direction that matters. That is not a bug of Bayes' theorem; it is the price of the compression chosen at stage 4. Two analyses of the same data with different summaries can legitimately give different constraints.

Kruschke's five steps. The pipeline is the physicist's version of the five steps of Bayesian data analysis [Kruschke p. 25]. They match the six stages one by one. *Identify the data relevant to the research question*: stages 2 and 3, the dataset and the choice of what information matters. *Define a descriptive model for the data*: stages 1 and 5, the model and the sampling distribution. *Specify a prior*: the factor $P(\boldsymbol{\theta})$ of stage 6. *Reallocate credibility across parameter values*: the posterior of stage 6. *Check the posterior predictions*: the dashed loop of Figure 0.6.

0.4 Which summary? From amplitude to topology

Two simulated universes are handed to us as density maps. In one, the dense matter forms a connected web of filaments. In the other, it sits in isolated clumps. By construction both maps have the same mean, the same variance and the same power spectrum $P(k)$. An analysis that compresses each map to $P(k)$ will call them identical, yet a glance tells them apart.

Whether we catch this difference or miss it is decided at the third stage of the pipeline of Section 0.3: *deciding which features carry the physics*. The power spectrum answers one question: how much variance does each scale carry? The two maps raise a different one. Is there physically meaningful information in the way the high and low regions of a field are connected, information that the summary we already use, here $P(k)$, does not bring out? A field admits several kinds of summary, and two fields can be built to agree on some kinds and differ on the others. Topological summaries are worth the trouble for a second reason too: some of them are protected against the distortions that observation introduces.

A recording with its phases scrambled. Take a recording of speech, $h(t)$, and Fourier transform it to $\tilde{h}(f)$. Keep every amplitude $|\tilde{h}(f)|$ and replace every phase by a random one. The power spectrum is untouched, and so is the loudness, yet the result is a hiss. What made it speech was in the phases: in *where* and *how* the power is arranged in time. For a field, the phases decide whether high values line up into filaments, gather into blobs or scatter as noise. Summaries beyond the power spectrum are ways of reading the phases.

The central question for a field. A theory predicts a field $\phi(\mathbf{x})$ over space. The experiment gives us one copy of it, and an imperfect one. On the way to us its values have been pushed around by perturbations, by noise, by smoothing, by whatever happened to the signal while it travelled. The question is whether something about the *shape and structure* of what we receive survives every change we count as a nuisance. If it does, we can read it off without first undoing those changes. Write such a change as a **nuisance transformation** $\phi \to \phi' = \mathcal{N}[\phi]$; examples are noise, smoothing by a beam, lensing, and a monotonic response of the detector. Three questions follow.

1. What do we want to know: how large the field is, how its values at different points are related, or how its structures are shaped and connected?
2. Which summary T answers that question?

3. Is there a summary that the nuisance cannot change, $T[\mathcal{N}[\phi]] = T[\phi]$, for a stated class of $\mathcal{N}$?

The answers to the first question form a ladder. Each rung up keeps less of the raw values and more of how they are arranged.

Taxonomy: the summaries of a field

kind	the question it answers	examples
amplitude	how large is the field typically?	$\langle\phi\rangle$, Var(ϕ), the one-point pdf $P(\phi)$
correlation	how are values a distance r apart related?	$\xi(r)$, $P(k)$, C_ℓ
higher order	is there information beyond Gaussian two-point statistics?	bispectrum B, trispectrum T, skewness
morphology	what sizes and shapes do the structures have?	areas, perimeters, curvature of excursion sets
topology	how are the structures connected, and how many holes do they have?	Betti numbers β_i, Euler characteristic χ, persistence

These are not rival theories of probability. They are different maps from the same data to different summaries $S[\phi]$. Once S is chosen it is an ordinary random observable with a sampling distribution $P(S \mid \boldsymbol{\theta})$, and Chapters 3 to 5, 9 and 10 apply to it unchanged.

A *Gaussian* random field is special: all its information is in the first two rungs. Its higher-order summaries are fixed functions of its power spectrum. Measuring them is therefore a consistency test (a search for non-Gaussianity), not new information. For any non-Gaussian field, from the late-time cosmic web to a map with foreground residuals, the upper rungs carry information that $P(k)$ does not.

Topology is a property of shapes, not of functions. So to say what topology measures, we must first turn a field into a shape.

Working definition 0.4 (excursion set, Betti numbers, Euler characteristic)

For a threshold ν, the **excursion set** of ϕ on a domain $\mathcal{M}$ is

$$X_\nu = \{\mathbf{x} \in \mathcal{M} : \ \phi(\mathbf{x}) > \nu\} \tag{0.8}$$

[the region of the map where the field exceeds ν, e.g. the sky directions hotter than ν]. In two dimensions the **Betti numbers** are $\beta_0(X_\nu)$ [the number of separate pieces] and $\beta_1(X_\nu)$ [the number of independent holes, i.e. enclosed regions that are not part of the set]. The **Euler characteristic** is $\chi = \beta_0 - \beta_1$. These numbers do not change when the set is stretched or bent without tearing or gluing (Chapter 12). A summary T is a **robust observable** under a class of nuisance transformations if $T[\mathcal{N}[\phi]] = T[\phi]$ for every $\mathcal{N}$ in the class.

Two facts make these summaries useful. First, a change of phases can leave the lower rungs untouched while moving the upper ones. Second, a distortion that changes each value by the same increasing function leaves the excursion sets themselves untouched. Each takes a few lines to prove.

Example 0.9 (phase randomisation keeps the power spectrum and the variance). The question: if we keep every Fourier amplitude of a field and scramble the phases, what stays the

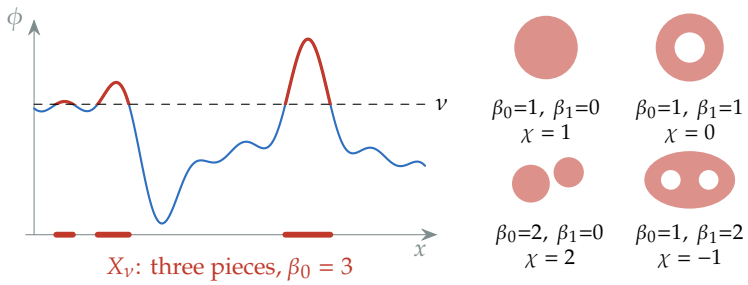

Figure 0.8: Left: a field along a line, a threshold ν, and the excursion set (the red intervals on the axis), which here has three pieces. Right: four two-dimensional sets with their numbers of pieces β_0, holes β_1 and Euler characteristic $\chi = \beta_0 - \beta_1$. Stretching any of them leaves all three numbers unchanged; cutting or gluing does not.

same? Let $\phi(\mathbf{x})$ live on an N-pixel periodic grid with zero mean, and let $\tilde{\phi}_\mathbf{k} = \sum_\mathbf{x} \phi(\mathbf{x}) e^{-2\pi i \mathbf{k}\cdot\mathbf{x}/L}$ be its discrete Fourier transform (L the side length in pixels). Build a new field ϕ' with $\tilde{\phi}'_\mathbf{k} = |\tilde{\phi}_\mathbf{k}| e^{i\alpha_\mathbf{k}}$, random phases $\alpha_\mathbf{k}$ with $\alpha_{-\mathbf{k}} = -\alpha_\mathbf{k}$ (so that ϕ' is real). Then

$$P'(k) \overset{(1)}{=} \left\langle |\tilde{\phi}'_\mathbf{k}|^2 \right\rangle_{|\mathbf{k}|=k} \overset{(2)}{=} \left\langle |\tilde{\phi}_\mathbf{k}|^2 \right\rangle_{|\mathbf{k}|=k} = P(k),$$
$$\mathrm{Var}(\phi') \overset{(3)}{=} \frac{1}{N} \sum_\mathbf{x} \phi'(\mathbf{x})^2 \overset{(4)}{=} \frac{1}{N^2} \sum_\mathbf{k} |\tilde{\phi}'_\mathbf{k}|^2 \overset{(5)}{=} \frac{1}{N^2} \sum_\mathbf{k} |\tilde{\phi}_\mathbf{k}|^2 = \mathrm{Var}(\phi).$$

(1) The measured power spectrum: average $|\tilde{\phi}_\mathbf{k}|^2$ over the wavevectors in a shell of radius k.
(2) $|re^{i\alpha}|^2 = r^2$: the phase drops out of every $|\tilde{\phi}'_\mathbf{k}|^2$ individually.
(3) Zero mean (the $\mathbf{k} = 0$ coefficient, the sum of the field, is left at zero).
(4) Parseval's theorem for the discrete Fourier transform, $\sum_\mathbf{x} |\phi(\mathbf{x})|^2 = \frac{1}{N} \sum_\mathbf{k} |\tilde{\phi}_\mathbf{k}|^2$.
(5) Same step as (2).

So every summary built from the amplitudes $|\tilde{\phi}_\mathbf{k}|$ alone is identical for ϕ and ϕ'. The skewness, the excursion sets and their Betti numbers depend on the phases, so they are free to change.

Example 0.10 (a monotonic distortion leaves the excursion sets alone). Suppose the detector does not record ϕ itself but $\phi'(\mathbf{x}) = f(\phi(\mathbf{x}))$, with f strictly increasing. Examples are a detector with a nonlinear but monotonic response, or a lognormal model $\phi' = e^\phi$. The question: which summaries of ϕ can we still read off ϕ' without knowing f? Compare the excursion sets. For every threshold ν

$$X'_{f(\nu)} \overset{(1)}{=} \{\mathbf{x} : \ f(\phi(\mathbf{x})) > f(\nu)\} \overset{(2)}{=} \{\mathbf{x} : \ \phi(\mathbf{x}) > \nu\} = X_\nu.$$

(1) Definition (0.8) applied to ϕ' at the threshold $f(\nu)$.
(2) A strictly increasing f preserves order both ways: $f(a) > f(b)$ exactly when $a > b$.

The excursion sets are the same regions of the domain $\mathcal{M}$. So the curves $\beta_0(\nu)$, $\beta_1(\nu)$, $\chi(\nu)$ are the same, except that the threshold is relabelled $\nu \to f(\nu)$. Meanwhile the variance, the skewness and $P(k)$ of ϕ' all change; for $f = \exp$ the one-point pdf goes from Gaussian to lognormal. Here topology is a robust observable in the exact sense of the working definition above, $T[\mathcal{N}[\phi]] = T[\phi]$; the power spectrum is not.

Example 0.11 (counting holes by counting cells). How do we count holes in a real map, where nobody can look at every piece? On a pixel grid a set is a union of square pixels, and χ can be computed by counting: $\chi = V - E + F$. Here V is the number of corners, E the number

of pixel edges and F the number of pixels of the set, each counted once. A single pixel has $4-4+1=1$. Two separate pixels have $8-8+2=2$. Now take a ring of eight pixels around an empty centre (a 3×3 block with the middle removed). It uses all $4\times4=16$ corners of the block, 12 horizontal and 12 vertical edges, and 8 pixels:

$$\chi = 16-24+8 = 0 = \beta_0-\beta_1 = 1-1.$$

So local counting finds a hole without ever looking for it. That is how $\chi(\nu)$ is computed on real maps (Chapter 12).

What this bought us. The ladder of summaries is a ladder of questions. Two fields can agree on the bottom two rungs and differ above them. And some topological summaries are exactly unchanged by a class of distortions that change every rung below.

Two fields with one power spectrum

The script `04_same_spectrum.py` builds the two universes from the opening of Section 0.4: one clumpy, one not, with the same power spectrum. Field A drops 60 points at random on a 256×256 periodic grid and smooths them into blobs. Field B is A with its phases randomised, exactly as in Example 0.9:

Listing 0.5: Keeping every $|\tilde{\phi}_k|$ and replacing the phases (`code/ch00/04_same_spectrum.py`)

```
# ---- field B: keep every |A_k|, replace the phases by those of white noise ----
#      rfft2 of a real white-noise map has exactly the Hermitian symmetry a real field needs
Ak = np.fft.rfft2(A)
phase = np.exp(1j * np.angle(np.fft.rfft2(rng.standard_normal((NPIX, NPIX)))))
Bk = np.abs(Ak) * phase
Bk[0, 0] = Ak[0, 0]                                  # keep the (zero) mean
B = np.fft.irfft2(Bk, s=A.shape)
```

The random phases are taken from the Fourier transform of a real white-noise map. Such phases automatically satisfy the condition $\alpha_{-\mathbf{k}} = -\alpha_{\mathbf{k}}$, so B is real. Pieces are counted with the function `scipy.ndimage.label`, which labels connected groups of pixels above the threshold.

The run shows the lower rungs agreeing and the upper ones not. The variances are $\mathrm{Var}(A) = 1$ and $\mathrm{Var}(B) = 1$, and the two binned power spectra differ by at most a fraction 1.500×10^{-12}, which is round-off. The skewness separates the fields: 2.455 for the clumps of A, 0.02076 for B, which is close to Gaussian. The topology separates them more sharply. At $\nu = 3$ (three standard deviations) A has $\beta_0 = 51$ separate pieces, one per surviving blob, and B has 3. At $\nu = 0$ the counts are 34 and 19.

Topology that survives observation, and topology that records dynamics

The detector with a monotonic response (Example 0.10) is the simplest protected case. A more physical one is CMB polarisation. The linear polarisation is described by the two Stokes parameters Q and U, which combine into $P = Q + iU$. At isolated points where $Q = U = 0$ the polarisation direction is undefined. Walk once round such a **polarisation singularity**, and the phase of P turns by a whole multiple of 2π. This whole number, the winding index or charge, cannot change under a smooth one-to-one remapping of the sky such as weak lensing. Lensing certainly changes the polarisation map, converting E modes into B modes. But it can only move and distort singularities; it cannot change their charges continuously [1–3]. The protection fails where its assumptions fail: pairs of singularities can be created or annihilated, and noise and finite resolution can hide them.

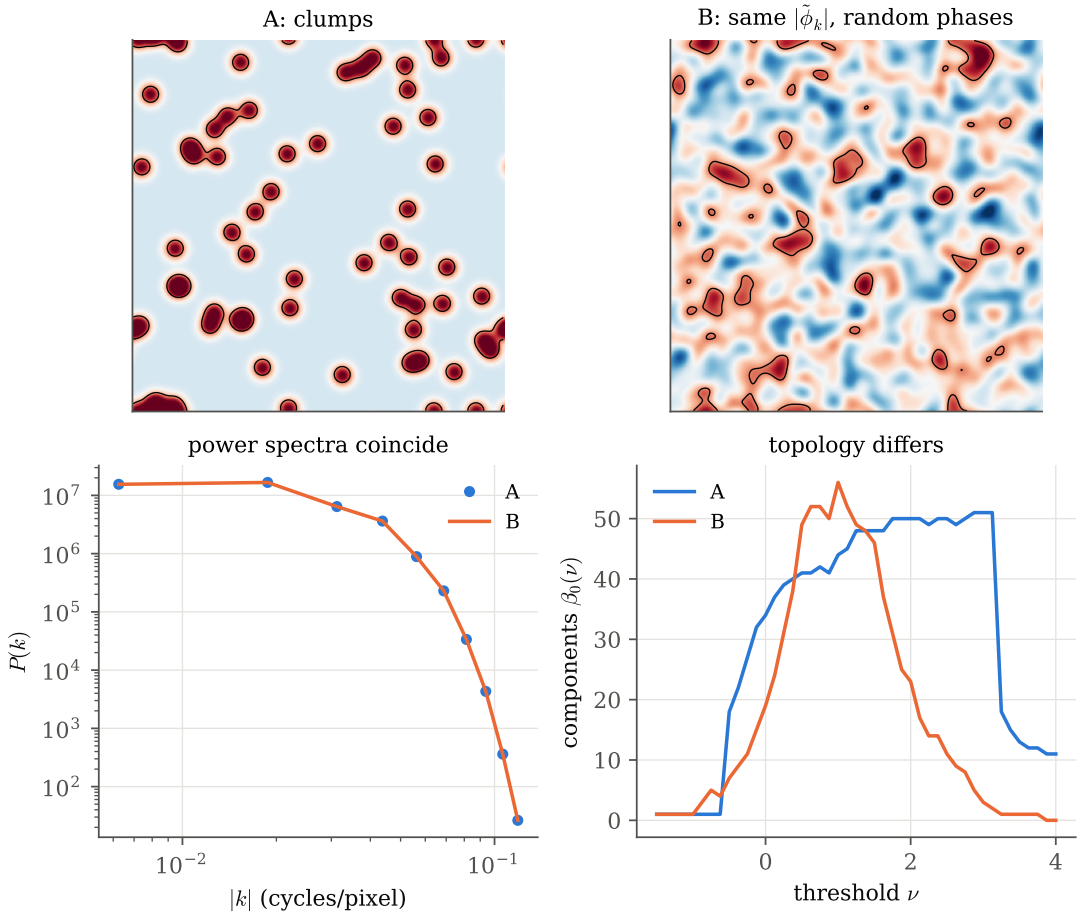

Figure 0.9: Top: the clumpy field A and its phase-randomised twin B, with the contour at $\nu = 1.5$. Bottom left: their power spectra coincide point by point. Bottom right: the number of connected pieces of the excursion set as the threshold is raised. B behaves like a Gaussian field, with most pieces near $\nu \approx 1$ and few at high threshold; A keeps one piece per blob right up to the blob peaks, so its curve stays high until $\nu \approx 3$.

A count at a single threshold is fragile, since nothing makes $\nu = 1\sigma$ special. The remedy is to follow each piece and hole as ν is lowered. Record the threshold where each feature appears (its birth) and the one where it merges or fills in (its death). This gives **persistence**. A feature with a long lifetime $\Delta\nu = \nu_{\text{death}} - \nu_{\text{birth}}$ is a real structure; a short-lived one is likely noise. Chapter 12 builds this with a union–find algorithm.

Watch out: topology is not conserved by dynamics

Invariance holds under a stated class of deformations, not under physics in general. Gravitational collapse is not a monotonic remapping of the initial density: it moves matter, merges clumps and opens voids, and the Betti numbers of the cosmic web change with time [4, 5]. There the changing topology is the *signal*. The scientific question is either "what survives the nuisance?" or "what changes because of the physics?". Both are legitimate; they are different questions. Note also that a mask cuts excursion sets at its edge and so changes their topology, just as it changes the covariance of $\widehat{C}_\ell$ (Chapter 8).

How research uses a topological summary. A CMB map is a function $T : S^2 \to \mathbb{R}$ from directions on the sphere to temperatures. To use its topology, generate many Gaussian skies

from the fiducial power spectrum C_ℓ. Pass each sky through the beam, the noise and the mask. Measure $\beta_0(\nu)$, $\beta_1(\nu)$ and $\chi(\nu)$ on every realisation. The mean and covariance of these curves over the realisations define a likelihood for the observed curves, and the posterior follows as for any other summary. This is the Monte Carlo study of Chapter 8 with $\widehat{C}_\ell$ replaced by a Betti curve, and it is where the book ends (Chapter 12).

0.5 One idea, several detectors

A collider experiment counts events in bins of invariant mass and asks whether there is a bump. A CMB satellite measures the temperature of the sky and asks for the cosmological parameters. A gravitational-wave interferometer records a strain time series and asks for the masses of an inspiralling binary. The instruments share nothing, and the statistics looks different in each community's papers: Poisson log-likelihoods, C_ℓ likelihoods, matched filters. Underneath, all three ask one question: *for a given set of parameters $\boldsymbol{\theta}$, how probable is the noise realisation that would turn the model's prediction into the data we actually recorded?* Because the question is the same, the idea needs to be developed only once. Writing it out for each detector, and for a topological summary, shows how it applies everywhere.

The noise you would need. The likelihood is the probability density of the noise that the data require. Put the model prediction $m(\boldsymbol{\theta})$ on one side and the data $\boldsymbol{d}$ on the other. The difference $\boldsymbol{d} - m(\boldsymbol{\theta})$ is the noise that nature *would have had to supply* if $\boldsymbol{\theta}$ were the truth. A value of $\boldsymbol{\theta}$ that needs a wildly improbable noise realisation is implausible. A value that needs only a typical fluctuation is plausible. What differs between detectors is only the statistics of their noise. Chapter 3 builds the likelihood from this picture one step at a time.

The same four questions for any detector.

1. What does the model predict, as a function of $\boldsymbol{\theta}$?
2. What is the noise: its distribution, and its correlations?
3. For a trial $\boldsymbol{\theta}$, how probable is the noise realisation $\boldsymbol{d} - m(\boldsymbol{\theta})$ (or, for counts, the observed counts given their expectation)?
4. Read that probability as a function of $\boldsymbol{\theta}$, and feed it to Bayes, MCMC or Fisher.

Working definition 0.5 (likelihood from a noise model)

If the data are prediction plus noise, $\boldsymbol{d} = m(\boldsymbol{\theta}) + \boldsymbol{\epsilon}$, and the noise has a known density p_ϵ, then

$$\mathcal{L}(\boldsymbol{\theta}) \equiv p(\boldsymbol{d} \mid \boldsymbol{\theta}) = p_\epsilon\big(\boldsymbol{d} - m(\boldsymbol{\theta})\big) \tag{0.9}$$

[the density of the noise realisation that is required, evaluated at the observed data and read as a function of $\boldsymbol{\theta}$]. The **likelihood** is not a probability distribution over $\boldsymbol{\theta}$: it need not integrate to one over $\boldsymbol{\theta}$, and only its shape and ratios matter.

The commonest case is independent Gaussian noise: each data point d_i has its own noise $\epsilon_i \sim \mathcal{N}(0, \sigma_i^2)$, a Gaussian with mean zero and standard deviation σ_i. Then (0.9) gives the

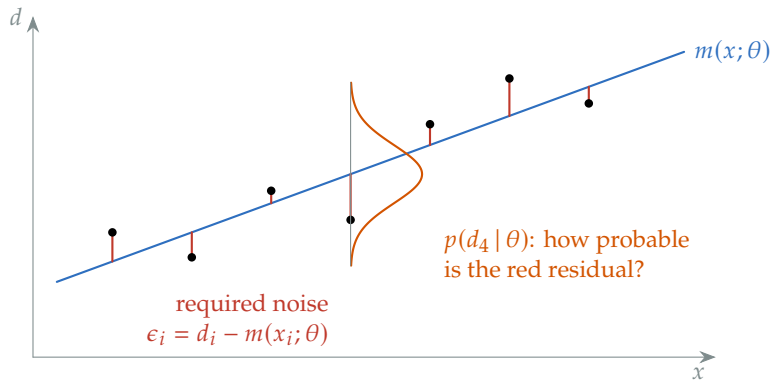

Figure 0.10: Data as prediction plus noise. The blue line is the model for one trial value of θ; the black points are the data; the red segments are the noise each point would need if that θ were true. The orange curve at the fourth point is the Gaussian noise density: a long red segment lands in its tail and costs a lot of probability. The likelihood multiplies these costs over all points; moving θ moves the line and changes every red segment.

workhorse of physics:

$$\ln \mathcal{L}(\boldsymbol{\theta}) \overset{(1)}{=} \ln \prod_{i=1}^{N} \frac{1}{\sqrt{2\pi\sigma_i^2}} \exp\Big[-\frac{(d_i - m_i(\boldsymbol{\theta}))^2}{2\sigma_i^2} \Big]$$

$$\overset{(2)}{=} -\frac{1}{2} \sum_{i=1}^{N} \frac{(d_i - m_i(\boldsymbol{\theta}))^2}{\sigma_i^2} - \frac{1}{2} \sum_{i=1}^{N} \ln(2\pi\sigma_i^2) \equiv -\frac{1}{2}\chi^2(\boldsymbol{\theta}) + \text{const.} \tag{0.10}$$

(1) Independent noise: the joint density is the product of one Gaussian per data point, evaluated at the required noise $d_i - m_i(\boldsymbol{\theta})$.

(2) The log of a product is the sum of logs, and $\ln e^u = u$.

If the noise in different data points is correlated, with covariance matrix $\mathbf{C}$, the product of separate Gaussians becomes one multivariate Gaussian: $\ln \mathcal{L} = -\frac{1}{2}(\boldsymbol{d} - m)^{\mathsf{T}} \mathbf{C}^{-1} (\boldsymbol{d} - m) - \frac{1}{2} \ln \det(2\pi\mathbf{C})$. The statistical logic is the same as before. Only the model for the probability of the data has changed.

With a whole data vector and many parameters, the backward question of Section 0.1 is still the same. The data vector is what we saw. Every value of $\boldsymbol{\theta}$ is a candidate explanation. The likelihood says how readily each candidate would have produced those data (Chapter 5). Reading the likelihood as the plausibility of the fluctuation needed to turn the model into the data is also how maximum likelihood is motivated [Wasserman p. 122].

Example 0.12 (the collider: a bump in Poisson counts). The data are event counts n_i in bins i of invariant mass. The question: how probable are these counts for a given signal strength μ? In bin i the expected count is $\lambda_i(\mu) = b_i + \mu s_i$: the background b_i plus a signal template s_i scaled by μ. Counts in different bins are independent Poisson variables. Then

$$\ln \mathcal{L}(\mu) \overset{(1)}{=} \ln \prod_i \frac{\lambda_i^{n_i} e^{-\lambda_i}}{n_i!} \overset{(2)}{=} \sum_i \big[n_i \ln \lambda_i(\mu) - \lambda_i(\mu) \big] - \sum_i \ln n_i!,$$

$$\frac{\mathrm{d} \ln \mathcal{L}}{\mathrm{d}\mu} \overset{(3)}{=} \sum_i s_i \Big(\frac{n_i}{\lambda_i(\mu)} - 1 \Big) = 0 \quad \text{at the maximum-likelihood } \hat{\mu}.$$

(1) Poisson probability of n_i events when λ_i are expected (Chapter 2), multiplied over independent bins.

Taxonomy: one question, four implementations

experiment	data	noise model	log-likelihood
collider	counts n_i in bins	Poisson with mean $\lambda_i(\mu) = b_i + \mu s_i$	$\sum_i [n_i \ln \lambda_i - \lambda_i]$
CMB	$a_{\ell m}$, or $\widehat{C}_\ell$	Gaussian random field on the sphere, variance C_ℓ per mode	$-\frac{1}{2}\sum_\ell (2\ell+1)\left[\widehat{C}_\ell/C_\ell + \ln C_\ell\right]$
GW detector	strain $d(t)$	stationary Gaussian noise with PSD $S_n(f)$	$-\frac{1}{2}(d-h \mid d-h)$
topology	Betti curves $S = \beta_0(\nu), \ldots$	unknown in closed form: simulated	$-\frac{1}{2}(S-\bar{S})^{\mathsf{T}}\widehat{\mathbf{C}}^{-1}(S-\bar{S})$ from simulations

(2) Log of a product; the last sum does not depend on μ and drops out of every ratio.
(3) $\mathrm{d}\lambda_i/\mathrm{d}\mu = s_i$; the chain rule on $n_i \ln \lambda_i$ gives $n_i s_i/\lambda_i$.

The condition says that at the best fit the observed counts match the expected ones on average, with each bin weighted by its signal s_i. There is no σ_i anywhere. The Poisson distribution carries its own noise: its variance equals its mean.

Example 0.13 (the CMB: the full-sky C_ℓ likelihood). The data are the harmonic coefficients of the sky (Example 0.8); the parameters are the power spectrum values C_ℓ. The question: how probable is the observed sky for given C_ℓ? Write the sky in a real orthonormal basis of spherical harmonics, so that at each multipole ℓ there are $2\ell+1$ real coefficients $r_{\ell j}$. For a Gaussian isotropic sky they are independent, and each is $\mathcal{N}(0, C_\ell)$. Then

$$\begin{aligned}\ln \mathcal{L}(\{C_\ell\}) &\overset{(1)}{=} \sum_\ell \sum_{j=1}^{2\ell+1} \Big[-\frac{r_{\ell j}^2}{2C_\ell} - \frac{1}{2}\ln(2\pi C_\ell)\Big] \\ &\overset{(2)}{=} -\frac{1}{2}\sum_\ell \Big[\frac{(2\ell+1)\widehat{C}_\ell}{C_\ell} + (2\ell+1)\ln C_\ell\Big] + \text{const} \\ &= -\frac{1}{2}\sum_\ell (2\ell+1)\Big[\frac{\widehat{C}_\ell}{C_\ell} + \ln C_\ell\Big] + \text{const.}\end{aligned}$$

(1) (0.10) with $d_i \to r_{\ell j}$, zero mean and variance C_ℓ.
(2) $\sum_j r_{\ell j}^2 = (2\ell+1)\widehat{C}_\ell$, the definition of $\widehat{C}_\ell$ in Example 0.8 (a real orthonormal basis is a rotation of the complex one, so the sum of squares is unchanged); $\ln 2\pi$ goes into the constant.

Three things follow. First, the data enter only through $\widehat{C}_\ell$, so $\widehat{C}_\ell$ is sufficient in the sense of (0.6), as claimed in Example 0.8. Second, setting $\partial \ln \mathcal{L}/\partial C_\ell = \frac{1}{2}(2\ell+1)[\widehat{C}_\ell/C_\ell^2 - 1/C_\ell] = 0$ gives $C_\ell = \widehat{C}_\ell$: the measured spectrum is the best fit. Third, $(2\ell+1)\widehat{C}_\ell/C_\ell = \sum_j (r_{\ell j}/\sqrt{C_\ell})^2$ is a sum of $2\ell+1$ squared unit Gaussians, which is a $\chi^2_{2\ell+1}$ variable (Chapter 2). That is how the script below simulates one sky's spectrum without making a map.

Example 0.14 (the GW detector: Gaussian noise with a PSD). The detector records a strain $d(t) = h(t;\boldsymbol{\theta}) + n(t)$ for a time T: a signal h from the binary with parameters $\boldsymbol{\theta}$, plus noise n. The question: how probable is the required noise $d-h$ for given $\boldsymbol{\theta}$? The noise is simplest in frequency space, so Fourier transform, $\tilde{d}(f) = \int d(t) e^{-2\pi i f t}\mathrm{d}t$, at the frequencies $f_k = k/T$, and

write $\tilde{d}_k = \tilde{d}(f_k)$. Stationary Gaussian noise has independent Fourier modes. Its one-sided power spectral density $S_n(f)$ [the noise power per unit frequency, counting positive frequencies only] fixes their size, $\mathbb{E}\,|\tilde{n}_k|^2 = \frac{T}{2} S_n(f_k)$. We also need one fact about complex Gaussians. A complex Gaussian z with $\mathbb{E}\,|z|^2 = \sigma^2$ has density $\frac{1}{\pi\sigma^2} e^{-|z|^2/\sigma^2}$ (its real and imaginary parts are independent, each with variance $\sigma^2/2$). So

$$\ln \mathcal{L}(\boldsymbol{\theta}) \overset{(1)}{=} -\sum_k \frac{|\tilde{d}_k - \tilde{h}_k(\boldsymbol{\theta})|^2}{\frac{T}{2} S_n(f_k)} + \text{const} \overset{(2)}{=} -2 \sum_k \Delta f \, \frac{|\tilde{d}_k - \tilde{h}_k|^2}{S_n(f_k)} + \text{const}$$
$$\overset{(3)}{=} -2 \int_0^\infty \frac{|\tilde{d}(f) - \tilde{h}(f)|^2}{S_n(f)} \, \mathrm{d}f + \text{const} \overset{(4)}{=} -\frac{1}{2} (d - h \,|\, d - h) + \text{const},$$

(1) The required noise in mode k is $\tilde{d}_k - \tilde{h}_k$; the product of independent complex Gaussians becomes a sum in the log. The $-\ln(\pi\sigma^2)$ terms do not depend on $\boldsymbol{\theta}$.
(2) The mode spacing is $\Delta f = 1/T$, so $\frac{1}{T/2} = 2\Delta f$.
(3) For long T the sum over modes becomes an integral over positive frequencies.
(4) Definition of the noise-weighted inner product $(a \,|\, b) = 4\,\mathrm{Re} \int_0^\infty \tilde{a}(f) \tilde{b}^*(f) / S_n(f) \, \mathrm{d}f$.

This is the χ^2 of (0.10) in the frequency domain, with each frequency weighted by how noisy the detector is there. Maximising it over $\boldsymbol{\theta}$ is matched filtering. Its curvature gives the Fisher matrix of Chapter 10.

What this bought us. Poisson counts, a Gaussian sky and coloured detector noise give three formulas that look unrelated. Each one is (0.9): the probability of the fluctuation that would turn the prediction into the data.

The three detectors in code

The script `05_three_detectors.py` generates data for all three and checks the noise model of each. For the collider and the GW detector the key lines are:

Listing 0.6: Collider: Poisson data and a scan of $\ln \mathcal{L}(\mu)$ (`code/ch00/05_three_detectors.py`)

```
n_obs = rng.poisson(bkg + 1.0 * sig_shape)                  # the data: one Poisson draw per bin
mus = np.linspace(0, 3, 3001)
# ln L(mu) = sum_i [ n_i ln(lambda_i) - lambda_i ]  (+ const, the ln n_i! term)
lam = bkg[None, :] + mus[:, None] * sig_shape[None, :]
lnL = np.sum(n_obs * np.log(lam) - lam, axis=1)
i_best = np.argmax(lnL)
inside = mus[lnL >= lnL.max() - 0.5]                        # Delta lnL = 1/2 interval
```

Listing 0.7: GW: coloured Gaussian noise drawn in the frequency domain (`code/ch00/05_three_detectors.py`)

```
sd = np.sqrt(T * Sn / 4)                                    # Re and Im each get half of T S_n/2
n_k = sd * (rng.standard_normal(f.size) + 1j * rng.standard_normal(f.size))
h_k = np.zeros_like(n_k); f_sig = 40.0
h_k[np.argmin(abs(f - f_sig))] = 12 * np.sqrt(T * Sn[np.argmin(abs(f - f_sig))])   # a weak line
d_k = n_k + h_k
pgram = 2 * np.abs(d_k) ** 2 / T                            # periodogram: E[pgram] = S_n off the line
```

Collider. The first block draws one Poisson count per bin. The expected counts are a falling background plus a peak at 125 GeV with $\mu = 1$. It then evaluates the $\ln \mathcal{L}$ of Example 0.12 on a grid of μ. With 4769 events in total, the maximum is at $\hat{\mu} = 0.959$. The values of μ whose $\ln \mathcal{L}$ lies within $\frac{1}{2}$ of the maximum run from 0.805 to 1.116; for a nearly Gaussian likelihood this is the $\pm 1\sigma$ interval (Chapter 3). The true $\mu = 1$ is inside.

GW detector. The second block draws each Fourier mode with real and imaginary parts of variance $TS_n/4$, so that $\mathbb{E}\,|\tilde{n}_k|^2 = TS_n/2$. The periodogram $2|\tilde{d}_k|^2/T$ should then scatter around S_n. Averaged over 8192 frequency bins away from the injected line, its ratio to S_n is 1.006.

CMB. One full sky is simulated as $\widehat{C}_\ell = C_\ell\, \chi^2_{2\ell+1}/(2\ell+1)$ around the Planck best fit, using the third result of Example 0.13. The mean of $\widehat{C}_\ell/C_\ell$ over $2 \le \ell \le 1500$ is 1.002. Its scatter is 0.2324 for $\ell \le 30$ but only 0.02923 for $\ell > 1000$, as the cosmic-variance formula $\sqrt{2/(2\ell+1)}$ predicts.

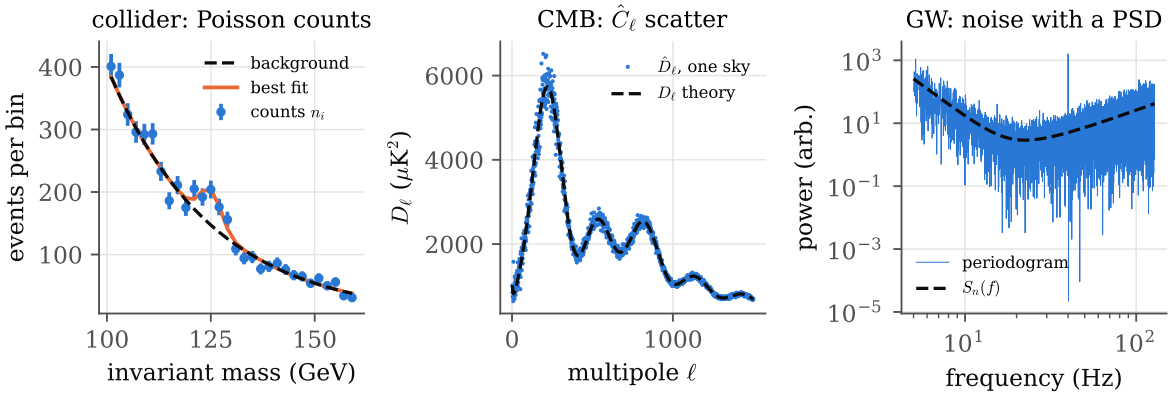

Figure 0.11: The same logic in three instruments. Left: Poisson counts with $\sqrt{n}$ error bars over a falling background, and the best-fit background plus signal. Middle: one simulated sky's $\hat{D}_\ell$ scattering around the theory curve; the scatter is large at low ℓ, where there are few modes, and small at high ℓ. Right: the periodogram of simulated detector noise, wildly fluctuating from bin to bin but centred on the power spectral density.

How research uses these likelihoods. Each simulation here verifies a known noise model: Poisson counts, χ^2 scatter of $\widehat{C}_\ell$, a periodogram centred on S_n. In research the closed forms break. A galactic mask couples multipoles and makes the C_ℓ likelihood non-diagonal. Real interferometer noise has glitches and is not stationary. A Betti curve has no known distribution at all. The fix is always the fourth row of the taxonomy (topology): simulate the forward model, estimate the mean and covariance of the summary from the simulations, and use the Gaussian form. The price is that the estimated covariance $\widehat{\mathbf{C}}$ is itself noisy and must be corrected [6] (Chapter 8).

Watch out: the likelihood is not the posterior

$\mathcal{L}(\boldsymbol{\theta}) = p(\boldsymbol{d} \mid \boldsymbol{\theta})$ is a function of $\boldsymbol{\theta}$, but it is not a density in $\boldsymbol{\theta}$. Here is a test that shows the difference. Change variables from C_ℓ to $\ln C_\ell$. The likelihood's values stay the same, but a density would pick up a Jacobian factor. Only after multiplying by a prior and normalising (Chapter 5) do we get a probability distribution for $\boldsymbol{\theta}$.

0.6 How to run the code

Months from now we will change one line in the Monte Carlo of Chapter 8. A quoted covariance will then move, and we will want to know why: because of the change, or because the random numbers were different this time? That question has an answer only if two things hold. Every simulation in the book must give the same numbers, bit for bit, when it is rerun. And every number in the text must be traceable to the script that printed it. A small amount of machinery guarantees both, so that one command regenerates every figure and every simulated number.

A lab notebook with a calibration source. An experimentalist keeps a notebook that records which run produced which plot, and keeps a calibration source that gives the same signal every time it is measured. The code does both. Each script is one notebook entry: it writes its figure and its numbers to files named after itself. And each script draws its random numbers from a generator seeded by its own name, a calibration source that reproduces the same "noise" on every run.

What we need from the code.

1. Where does each script live, and how is it run?
2. Where do its figures and numbers go, and how do they get into the text?
3. How are random numbers made reproducible, and different scripts independent?
4. How do all figures share one visual style?

```

```

Figure 0.12: The layout of the Notes directory. Every script is run from the top directory, reads nothing but its own inputs, and writes its outputs into the `figures` and `results` folders of its own chapter.

Everything is Python with numpy, scipy, matplotlib and healpy, and every sampler in the book is written from scratch. The choice of language does not matter for the statistics; "any computing language can be used" [Wasserman p. ix]. Simulation makes a probability tangible: we watch the empirical frequency settle on the theoretical value, as in the right panel of Figure 0.5 [SeeingTheory pp. 5–7].

Every script is run from the Notes directory, for example

```
python3 code/ch00/02_coin_questions.py
```

and starts with a docstring stating the question it answers, what it computes and what it writes. All scripts share one module, `code/common.py`. Its first part sets the environment, the paths and the colours:

Listing 0.8: Environment, paths and the colour palette (`code/common.py`)

```
import hashlib
import os
import pathlib

# keep numerical libraries from oversubscribing the machine when several scripts run at once
for _v in ("OMP_NUM_THREADS", "OPENBLAS_NUM_THREADS", "MKL_NUM_THREADS"):
    os.environ.setdefault(_v, "4")

import matplotlib

matplotlib.use("Agg")
import matplotlib.pyplot as plt  # noqa: E402
import numpy as np  # noqa: E402

NOTES = pathlib.Path(__file__).resolve().parents[1]
FIG = NOTES / "figures"
RES = NOTES / "results"
# Seed test: SEED_SALT=1 (or 2, ...) shifts every seed and sends figures and numbers to
# build/seedtest_<salt>/ so the book's own results are untouched. Unset: the book's seeds.
SEED_SALT = os.environ.get("SEED_SALT", "")
if SEED_SALT:
    FIG = NOTES / "build" / f"seedtest_{SEED_SALT}" / "figures"
    RES = NOTES / "build" / f"seedtest_{SEED_SALT}" / "results"
DATA = NOTES / "data"          # cached expensive products (CAMB spectra, simulated maps, chains)

# Categorical order is fixed: slot 1 is always the first series, never cycled.
SERIES = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300", "#4a3aa7", "#e34948"]
INK = "#0b0b0b"           # primary text
INK2 = "#52514e"          # secondary text, axes
GRID = "#e4e3df"          # recessive grid
THEORY = "#0b0b0b"        # analytic / theoretical curve: black, dashed
SEQ = "Blues"             # sequential colormap (magnitude)
DIV = "RdBu_r"            # diverging colormap (correlations, residuals), centred on zero
```

Lines 24–25 cap the linear-algebra libraries at four threads, so several scripts can run side by side without fighting for cores. Line 29 selects a non-interactive plotting backend, so scripts run without a display. The paths are computed from the location of `common.py` itself. That is why a script finds `figures/` and `results/` whatever directory it is started from. Lines 36–41 are a switch for testing the book itself: setting `SEED_SALT` changes every seed and sends the figures and numbers to a separate folder, so a run with different random numbers can be compared with the book's own without overwriting it. `SERIES` is the fixed order of categorical colours: the first data series in every figure is the same blue, the second the same orange, and colours are never recycled. The function `setup()` (lines 54–80, not shown) applies one matplotlib style: serif fonts, a light grid, no top and right axes. The second part of the module holds the functions every script calls:

Listing 0.9: Figures, numbers, random streams and theory curves (`code/common.py`)

```
def savefig(fig, chapter: str, name: str):

```

There are four functions. `savefig(fig, "ch00", "name")` writes `figures/ch00/name.pdf`, which the text includes with `\includegraphics`. `save_numbers` writes a file of LaTeX macros, one per number, formatted by `_fmt` (four significant figures, and $m \times 10^{e}$ for very large or small values). The text loads that file with `\input` and writes `$\PiHat$` where the number belongs. `rng_for` builds a random generator whose seed is a hash of the script's name. `theory_line` draws every analytic curve the same way, black and dashed, on top of the simulation it is compared with.

Working definition 0.6 (pseudo-random stream, seed, results macro)

A **pseudo-random generator** is a deterministic algorithm whose output passes statistical tests for independent uniform draws [PCG64 here, built in Chapter 6]. Its whole output is fixed by an integer, the **seed**. `rng_for(chapter, name, stream)` takes the first 8 bytes of the SHA-256 hash of `"chapter/name"` as a 64-bit seed and feeds it, together with the `stream` index, to numpy's `SeedSequence`, which scrambles the pair into a full generator state. Same name and stream [same seed] give the identical stream; different names give streams with no detectable correlation. A **results macro** is a LaTeX command such as `\PiHat` defined in `results/chNN/name.tex` by the script, so that the text quotes the number the

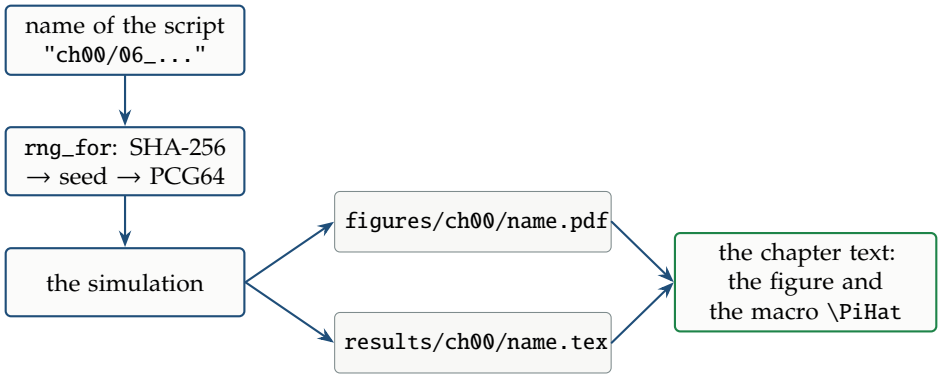

Figure 0.13: How a random number becomes a number in the text. The script's own name fixes the seed, the seed fixes every random draw, and the outputs are written to files that the chapter reads. Rerunning the script regenerates the figure and the quoted numbers together, so they cannot drift apart.

code actually produced.

Example 0.15 (can two scripts share a seed by accident?). If two scripts got the same seed, their "independent" random numbers would be identical. How likely is that? The hash scatters names over 2^{64} possible seeds, effectively at random. With M scripts, the probability that some pair collides is bounded as in the birthday problem:

$$\begin{aligned}\mathrm{P}(\text{some collision}) &\overset{(1)}{\le} \sum_{\text{pairs}} \mathrm{P}(\text{this pair collides}) \overset{(2)}{=} \binom{M}{2} 2^{-64} \\ &\overset{(3)}{\le} \frac{M^2}{2}\, 2^{-64} \overset{(4)}{=} \frac{10^6}{2} \times 5.4 \times 10^{-20} = 2.7 \times 10^{-14}\end{aligned}$$

for $M = 1000$.

(1) The probability of a union is at most the sum of the probabilities (the union bound).
(2) Two independent uniform seeds agree with probability 2^{-64}; there are $\binom{M}{2}$ pairs.
(3) $\binom{M}{2} = M(M-1)/2 \le M^2/2$.
(4) $M = 1000$ and $2^{-64} = 5.4 \times 10^{-20}$.

So with a thousand scripts a clash is, for practical purposes, impossible. And because `SeedSequence` mixes in the `stream` index as well, one script can take several independent streams; the three detectors of Section 0.5 use streams $0, 1, 2$.

Example 0.16 (a Monte Carlo number with its error bar: π from darts). Every Monte Carlo number in the book comes with an error bar; here is the simplest case. Throw N points uniformly in the unit square. The fraction $\hat{q}$ that lands inside the quarter disc $x^2 + y^2 < 1$ estimates the disc's area, $q = \pi/4$, so $\hat{\pi} = 4\hat{q}$ estimates π. How far off is it likely to be? A fraction of N independent trials scatters by $\sqrt{q(1-q)/N}$ (Example 0.4), so

$$\sigma_{\hat{\pi}} \overset{(1)}{=} 4\,\sigma_{\hat{q}} \overset{(2)}{=} 4\sqrt{\frac{q(1-q)}{N}} \overset{(3)}{=} 4\sqrt{\frac{0.7854 \times 0.2146}{10^6}} = 4 \times 4.106 \times 10^{-4} = 1.642 \times 10^{-3}.$$

(1) Multiplying a random variable by 4 multiplies its standard deviation by 4.
(2) The scatter of a fraction of N independent trials, Example 0.4.
(3) $q = \pi/4 = 0.7854$ and $N = 10^6$.

The script `06_reproducible_seeds.py` does exactly this with $N = 1000000$. It finds $\hat{\pi} = 3.143$ with estimated error 0.001641, within about one standard error of $\pi = 3.14159$. One more decimal digit means an error ten times smaller, and since the error falls like $1/\sqrt{N}$ that costs 100 times more darts. This $1/\sqrt{N}$ law dominates every Monte Carlo budget in the book.

Example 0.17 (the results file). The same script also checks the seeding. It builds two generators from the same name and one from a different name. The first draw is 0.217 for both generators with the same name (the streams are identical: yes), and 0.4034 for the other name. The file the script wrote, which the text reads, is:

Listing 0.10: The generated macro file (`results/ch00/06_reproducible_seeds.tex`)

```
% generated by code/ch00/06_reproducible_seeds.py -- do not edit
\providecommand{\SeedIdentical}{}\renewcommand{\SeedIdentical}{yes}
\providecommand{\SeedFirstDraw}{}\renewcommand{\SeedFirstDraw}{0.217}
\providecommand{\SeedOtherFirstDraw}{}\renewcommand{\SeedOtherFirstDraw}{0.4034}
\providecommand{\PiHat}{}\renewcommand{\PiHat}{3.143}
\providecommand{\PiErr}{}\renewcommand{\PiErr}{0.001641}
\providecommand{\PiN}{}\renewcommand{\PiN}{1000000}
```

Each line is `\providecommand` followed by `\renewcommand`. The first defines the macro if it does not exist yet; the second sets its value. So the file can be loaded twice without error, and the latest values always win. Macro names contain letters only, because LaTeX requires it, and `save_numbers` enforces this with an assertion.

What this bought us. Rerunning a script regenerates its figure and its numbers together, with the same random draws. The text never contains a simulated number typed by hand.

Watch out: reproducible is not the same as correct

A fixed seed makes a wrong answer reproducible too. Reproducibility lets us see *whether* a change in the code changed a result. It does not replace two other checks. One is the test of Chapter 6: does the generator pass statistical tests? The other is the comparison of every simulation with a known analytic limit. That is why every script in the book plots a black dashed theory curve wherever one exists.

Running everything. To regenerate every figure and number, run each script from the Notes directory, e.g. `for f in code/ch*/[0-9]*.py; do python3 "$f"; done`. Then build the book with `latexmk -pdf main.tex`. Expensive products (the fiducial CAMB spectrum, large simulated map sets, long chains) are cached in `data/` and reused. To force a recomputation, delete the cache file. One part can be built on its own with `./tools/testpart.sh`.

Chapter summary

concept	operational meaning	used later in
prediction, $\mathrm{P}(E \mid H)$	forward: fraction of the H-world in which E happens; compute along a tree path	Chapters 1 and 2
inference, $\mathrm{P}(H \mid E)$	backward: keep the paths that end at E, renormalise	Chapter 5
Bayes' theorem	posterior $\propto$ likelihood $\times$ prior; the evidence E shrinks the sample space	Chapters 5 and 9
odds form	posterior odds = likelihood ratio $\times$ prior odds; independent data multiply	Chapters 4 and 5
estimator, sampling distribution	a function of data; its histogram over repeated experiments, with bias and variance	Chapter 3
p-value	tail probability under H_0 of "this or more extreme in this direction"	Chapter 4
Monte Carlo error	a simulated fraction scatters by $\sqrt{q(1-q)/N}$	Chapters 6 and 8
Fisher information	minus the expected curvature of $\ln \mathcal{L}$; best possible variance $1/I$	Chapter 10
pipeline	model $\to$ data $\to$ what matters $\to S \to P(S \mid \boldsymbol{\theta}) \to P(\boldsymbol{\theta} \mid S)$	every chapter
sufficient summary	likelihood depends on the data only through S; compression is free	Chapters 3 and 7
summary ladder	amplitude, correlation, higher order, morphology, topology	Chapters 7 and 12
excursion set, β_0, β_1, χ	region above ν; pieces, holes, $\chi = \beta_0 - \beta_1 = V - E + F$	Chapter 12
robust observable	$T[\mathcal{N}[\phi]] = T[\phi]$ for a stated class of nuisances	Chapter 12
likelihood from noise	density of the required noise $\boldsymbol{d} - m(\boldsymbol{\theta})$, read as a function of $\boldsymbol{\theta}$	Chapters 3 and 5
Poisson, C_ℓ, Whittle likelihoods	$\sum[n \ln \lambda - \lambda]$; $-\frac{1}{2}\sum(2\ell+1)[\widehat{C}_\ell / C_\ell + \ln C_\ell]$; $-\frac{1}{2}(d-h \mid d-h)$	Chapters 4, 7 and 10
reproducible streams	seed from the script name; numbers reach the text as macros	every chapter

Chapter T0

Python for This Book

Where this chapter is going

Every result in this book is printed by a short Python script, and every figure is drawn by one. A reader who has never programmed may open one of those scripts, see a page of unfamiliar words (`np.linspace`, `ax.loglog`, `rng.standard_normal`, `optimize.brentq`) and conclude that programming is a second subject to be learned before the statistics can begin. It is not. The scripts are written in a small, repetitive subset of Python. The same two dozen names do half of all the work, and a reader who knows about a hundred of them can follow almost every line in the book.

That claim is not a guess. The code can be asked directly: a program can read every script in the book, without running any of them, and count which pieces of the language they use and which functions they call. The answer says what to learn, in what order, and what can safely be skipped on a first reading.

A script is read from the top down (Figure T0.1). It opens with a docstring that states its question, then a fixed block of imports, then the computation, then a figure and a file of numbers. The computation is written in plain Python (numbers, text, lists and dictionaries, loops and conditions, functions) and almost all of its arithmetic is done by NumPy, the array library: arrays, indexing, masks, broadcasting, random numbers, linear algebra and Fourier transforms. On top of NumPy sit a few SciPy tools (integrals, roots, minimisers, probability distributions) and the few Matplotlib calls that draw every figure. A handful of features appear in only a few scripts, and two physics libraries, healpy and CAMB, can be read as black boxes with known inputs and outputs. And a few traps catch every newcomer once.

Knowing the syntax is not the end. A script can run without an error message and still print a number that is partly noise: rounding error, a step size chosen badly, a Monte Carlo average from too few draws. So every printed number deserves one more question: *is it real?* Telling numerical noise from signal, knowing when sixteen digits are not enough, and predicting how long a computation will take before starting it are part of the same small toolkit.

The book's pipeline (Chapter 0) runs from a physical model to a dataset, to a summary of the data, to the sampling distribution of that summary, and back to the physics. Every arrow of it is a computation, and the same small toolkit serves all of them. With it, every script in the book reads like a derivation written in a slightly different notation.

T0.1 How much Python does the book use? A census

Suppose we want to learn just enough French to read one particular novel. A sensible first step is to count the words in the novel itself. Most of the text will turn out to be made of a few

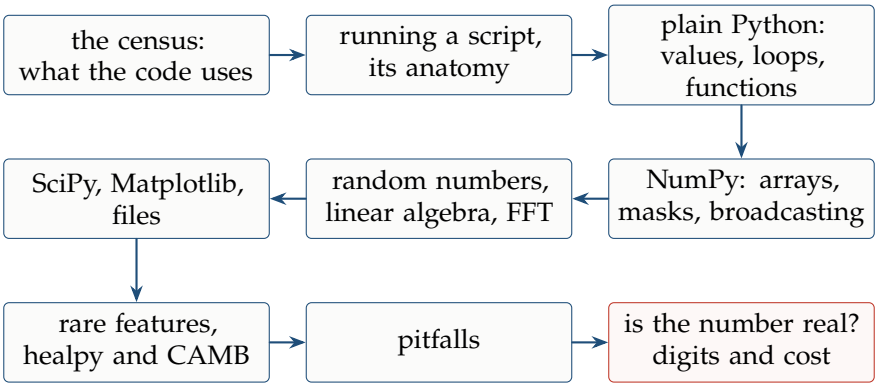

Figure T0.1: From the census to trusting a number. The census (top left) decides what is worth learning. The blue boxes are the language and its libraries, in the order a reader meets them in a script. The red box asks whether a printed number can be trusted, how many of its digits are real, and how long it took to compute.

hundred very common words, and the rare ones can be looked up when we meet them. We can treat the book's code the same way. There are 345 Python files under `code/`, with 45734 lines between them. The question is how much of the language they actually use.

The question, in words. Three counts answer it.

1. Which pieces of Python *syntax* (loops, conditions, function definitions, . . .) appear, and in what share of the scripts?
2. Which *libraries* do the scripts import?
3. Which *functions* do they call, how often each, and how many distinct names are needed to cover most of the calls?

Reading code without running it. A Python program is text. Before Python runs it, a part of Python called the **parser** turns the text into a tree of statements, much as a grammar teacher turns a sentence into subject, verb and object. The tree for the line `x = np.sqrt(2.0)` says: an assignment, whose target is the name `x`, and whose value is a call; the thing called is the attribute `sqrt` of the name `np`; the call has one argument, the number 2.0. Python's standard module `ast` ("abstract syntax tree") gives a program access to this tree. So a census script can read every file, build its tree, and walk through the tree counting what it finds, without executing a single line of the code it is counting. Nothing is run, so nothing can go wrong, and the census of all 345 files takes a few seconds.

Figure T0.2 shows the tree for that one line. The census script's job is to visit every node of every such tree. For a node that is a call it writes down the name of the thing being called, the way a reader would see it on the page. The function that does this is short:

Listing T0.1: Turning the called object into the name a reader sees (`code/chT0/01_census.py`)

```
def dotted(node):
    """Turn the function part of a call into text: np.linalg.solve, ax.plot, len."""
    if isinstance(node, ast.Name):
        return node.id
    if isinstance(node, ast.Attribute):
        inner = dotted(node.value)
        return f"{inner}.{node.attr}" if inner else f"obj.{node.attr}"
    return None                                  # e.g. axes[0].plot -> an object, handled above
```

If the called thing is a plain name, like `len` or `print`, the name is the answer (line 38–39). If it is an attribute, like `np.sqrt`, the function calls itself on the part before the dot and glues the pieces back together with a dot (lines 40–42). So `np.linalg.solve` is rebuilt piece by piece, from `np` outwards. Calls on an object that has no simple name, such as `axes[0].plot`, are filed under the method name, as `x.plot`. Elsewhere the script maps the local short names back to their libraries: `from scipy import stats` followed by `stats.norm.pdf` is counted as `scipy.stats.norm.pdf`. Calls of functions that the book defines itself are counted separately, because they are part of the book's own vocabulary, not of Python's.

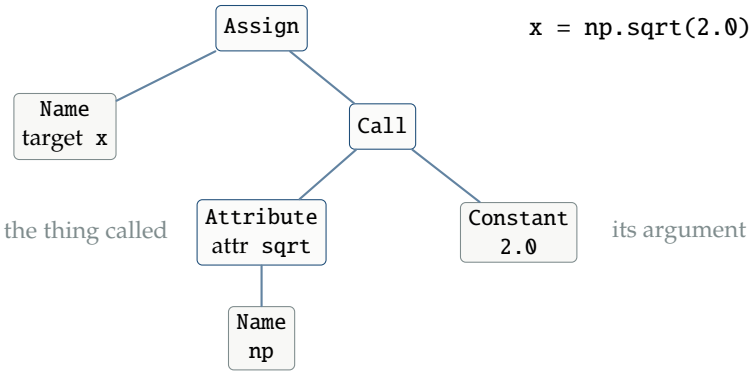

Figure T0.2: The tree that Python's parser builds from the line `x = np.sqrt(2.0)`, before anything is run. The census counts one call here, named `np.sqrt` by reading the `Attribute` node from the bottom up. Grey boxes are the leaves: names and numbers.

What the count found. The scripts make 27297 calls to functions that are not the book's own, and those calls use 759 distinct names. That sounds like a lot of names to learn. It is not, because the calls are very unevenly shared among the names. Sort the names from the most used to the least used. The first five are `np.sqrt` (1255 calls), `x.mean` (836), `x.plot` (826), `np.array` (721) and `x.set_xlabel` (707). Then ask: how many names, taken from the top of that list, are needed before they account for a given share of all the calls?

Working definition T0.1 (coverage of a vocabulary)

Rank the distinct names by the number of times they are called, $n_1 \geq n_2 \geq \cdots \geq n_D$, where D is the number of distinct names [here $D = 759$]. The **coverage** of the top K names is the share of all calls they make,

$$c(K) = \frac{\sum_{k=1}^{K} n_k}{\sum_{k=1}^{D} n_k}.$$

The number of names needed for a share q is the smallest K with $c(K) \geq q$, written K_q.

Example: the top five names. How much of the code do the five most used names cover on their own? We add their counts and divide by the total:

$$c(5) \overset{(1)}{=} \frac{n_1 + n_2 + n_3 + n_4 + n_5}{\sum_k n_k} \overset{(2)}{=} \frac{4345}{27297} = 15.9\,\%.$$

(1) The definition of $c(K)$ with $K = 5$.
(2) The five counts quoted above add up to 4345; the total number of calls is 27297.

So one call in about every six or seven in the whole book is one of five names: a square root, a mean, a plot command, the creation of an array, and the label of a horizontal axis.

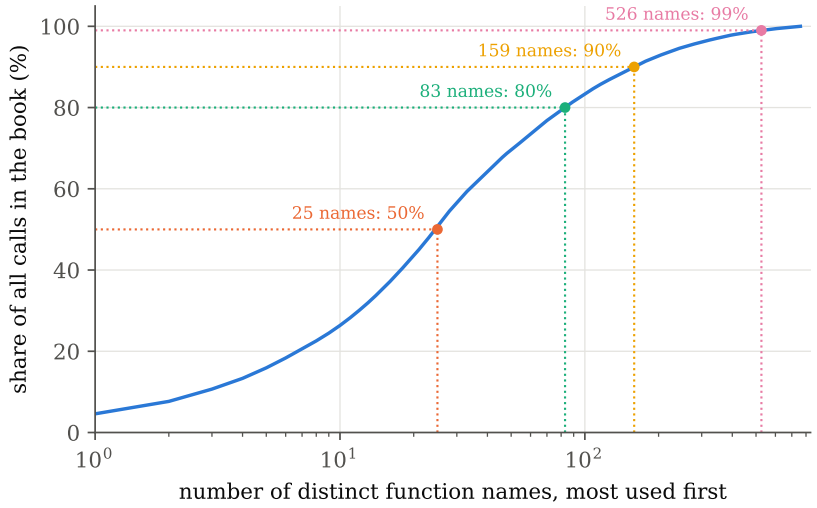

Figure T0.3: The share of all the book's library calls made by the most used names. The horizontal axis counts distinct names, most used first, on a logarithmic scale. Half of all calls use only 25 names; 83 names cover 80%, 159 cover 90%, and the last 1% of calls is spread over hundreds of names that each appear a handful of times.

Figure T0.3 is the whole answer. Half of all calls use $K_{0.5} = 25$ names. Eighty per cent use $K_{0.8} = 83$. Ninety per cent use $K_{0.9} = 159$. The curve then flattens: to reach 99% takes $K_{0.99} = 526$ names, because the last per cent is a long tail of names that each appear once or twice. There are 362 names called three times or fewer in the whole book, and together they make only 2.1% of the calls. Those are exactly the names it is pointless to learn in advance. Each is used once, for one special job, and the script's comment or the text next to it says what it does.

Example: what the eighty per cent means for one script. A typical script calls 36 distinct library names (the median over all files). Suppose a reader knows the 83 most used names. How many unfamiliar calls will a script of a hundred calls contain? If the script's calls are drawn like the book's as a whole, each call is one of the known names with probability $c(83) \approx 0.8$. The expected number of unknown calls is then

$$\mathbb{E}[\text{unknown calls}] \overset{(1)}{=} \sum_{i=1}^{100} \mathrm{P}(\text{call } i \text{ is unknown}) \overset{(2)}{=} 100 \times \big(1 - c(83)\big) \approx 100 \times 0.2 = 20.$$

(1) The expectation of a count is the sum of the probabilities of the events it counts (each call contributes 1 if unknown, 0 if not).
(2) Each call is unknown with probability $1 - c(K)$, the share of calls outside the known names.

Twenty calls sounds like many, but most of them repeat: a script that calls `hp.anafast` once usually calls it inside a loop or several times with different arguments. In practice the unfamiliar part of a script is one or two library functions, and the comment on that line usually says what they return.

Syntax: the same story, more strongly. The census also asks, for each piece of syntax, what share of the scripts use it at least once (Figure T0.4). Some pieces are everywhere: assignment, function calls, imports, indexing, keyword arguments and tuple unpacking appear in practically every file, `for` loops in 88%, f-strings (a way of putting numbers into text) in 84%, slices in 79%,

the definition of a function in 72%. Then comes a sharp drop. The `while` loop appears in 6% of the scripts, `try/except` in 3%, classes in 2%, decorators in 2%, generators (`yield`) in none. A course on Python spends weeks on classes, inheritance, generators, exceptions and decorators. The book barely uses them.

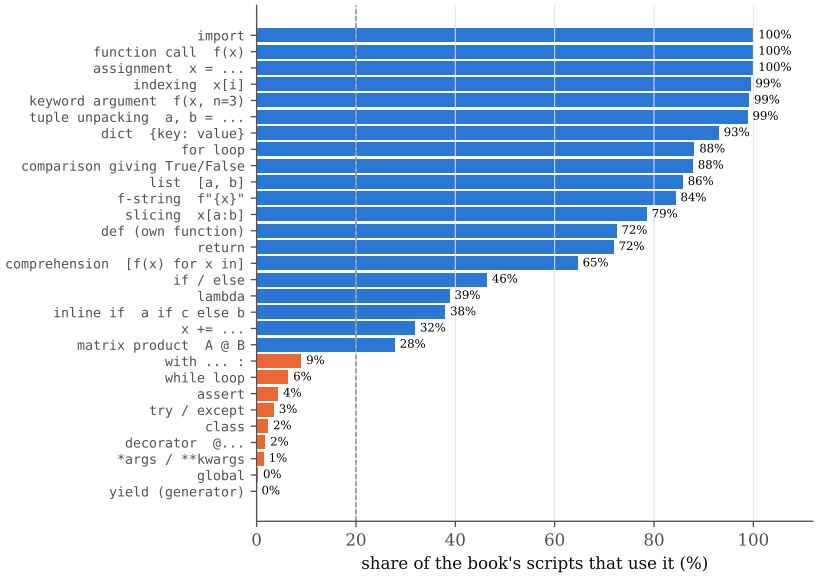

Figure T0.4: For each piece of Python syntax, the share of the book's scripts that use it at least once. Blue bars (at least 20% of the scripts) are the core every reader needs; orange bars are rare and are collected in Section T0.8. The dashed line marks 20%.

Libraries. The import statements tell the same story. NumPy is imported by 99% of the scripts and Matplotlib's plotting module by 88%. SciPy is used by 53%, almost always for one or two functions. healpy, the library for maps on the sphere, appears in 10%, and CAMB, the cosmology code, in 5%; numba and the multiprocessing module in about 1% each. By number of calls, NumPy names make 34% of all library calls, plotting calls about 22% and SciPy only 3%: SciPy functions are powerful, so one call does a lot. The rest are Python's own built-in functions, such as `len`, `range`, `print`, and methods of arrays and lists, such as `x.mean()` or `results.append(...)`.

Figure T0.5 lists the forty most used names, coloured by library. It is worth reading slowly once: together these forty names cover more than half of everything the book's code does, and each of them reappears below with an example.

Key idea: A small vocabulary does almost everything

About 25 names cover half of all the function calls in the book, about 83 cover 80%, and the syntax needed is the core of the language: assignment, calls with keyword arguments, indexing and slicing, `for` and `if`, short functions, lists, tuples and dictionaries. Everything else is rare and can be looked up when met.

That vocabulary is best learned in the order in which a reader meets it inside a script, each idea with its minimal syntax, a real excerpt from one of the book's scripts, and the one mistake most often made with it.

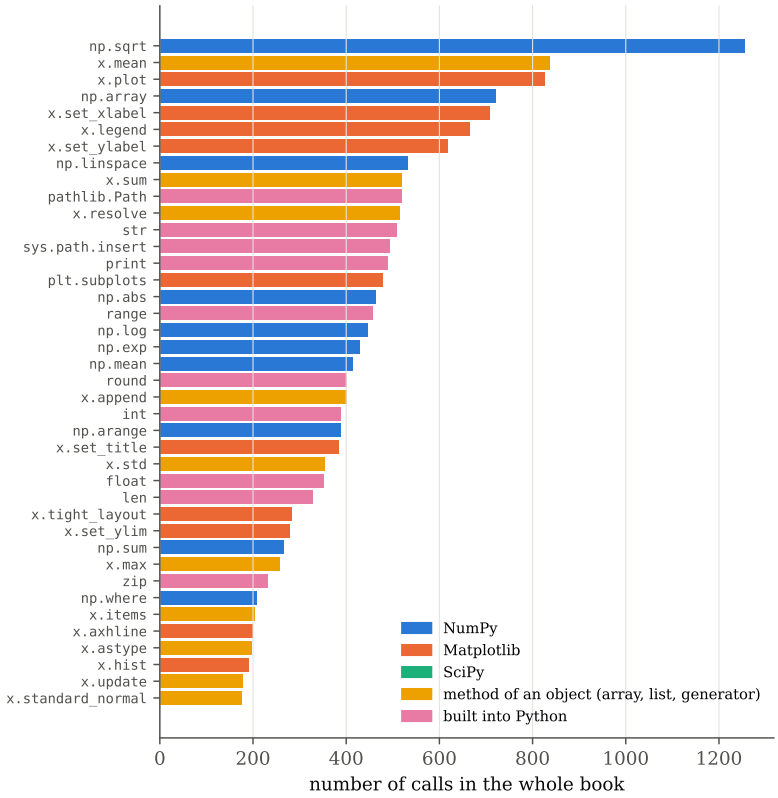

Figure T0.5: The forty most used names in the book's code, by number of calls. `x.` stands for a method called on some object: `x.mean` is the mean of an array, `x.plot` draws on a set of axes, `x.append` adds an item to a list. Blue are NumPy functions, orange Matplotlib, green SciPy, yellow methods of arrays, lists and random generators, pink Python's built-in functions.

T0.2 Running a script and reading what it prints

A script is a recipe for an experiment that the computer carries out. Like a lab procedure, it has a fixed shape: what it is for, what equipment it uses, the measurement itself, and where the results are written down. Every script in the book follows the same shape, so once one script has been read closely, the others look familiar. We read one closely here: `code/ch02/02_binomial.py`, which checks the binomial distribution of Section 2.2 by simulation. Its question is: if we repeat a yes/no trial with success probability p a number n of times and count the successes, does the histogram of that count match the binomial formula $\binom{n}{k}p^k(1-p)^{n-k}$?

Running it. From the top directory of the book (the folder `Notes`), one types in a terminal

```
python3 code/ch02/02_binomial.py
```

Python reads the file from the top and carries out its lines one after another. When it finishes, two new files exist: the figure `figures/ch02/02_binomial.pdf` and the numbers file `results/ch02/02_binomial.tex`. The terminal shows what the script chose to print, here two short lines naming those files. The book's own runs were made the same way, on a computing cluster, and the two files copied back. The random numbers are seeded by the script's name (Section 0.6), so the outputs are identical wherever the script runs.

When it fails. If something goes wrong, Python stops and prints a **traceback**: a list of the lines that were being executed, innermost last, followed by one line naming the error. The last

line is the one to read first. For example, adding an array of three numbers to an array of four numbers stops a script with

```
ValueError: operands could not be broadcast together with shapes (3,) (4,)
```

which says exactly what is wrong: two arrays whose shapes do not fit (Section T0.4.4). The line above it in the traceback gives the file and line number where it happened. Reading the traceback from the bottom up is the single most useful debugging habit.

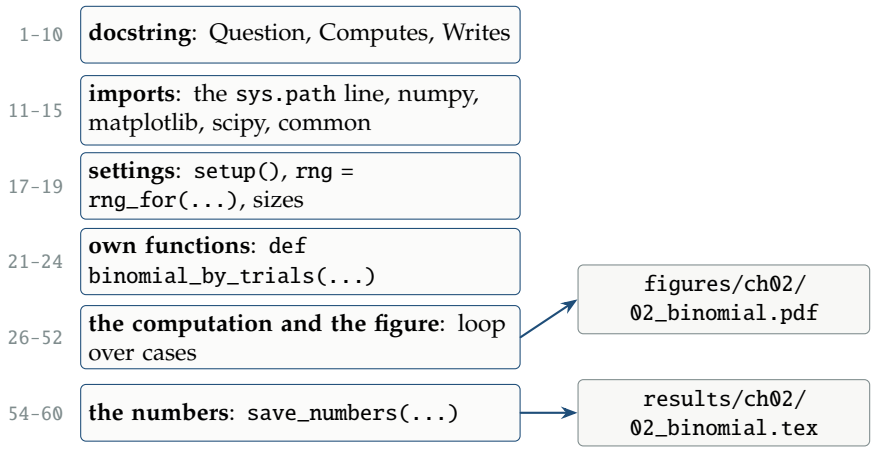

Figure T0.6: The six blocks of every script in the book, with the line numbers they occupy in `02_binomial.py`. The two grey boxes are the files the script writes: the chapter text includes the figure and reads its numbers from the second file.

The whole script. Here it is, all sixty lines.

Listing T0.2: A complete book script: the binomial distribution by simulation (`code/ch02/02_binomial.py`)

```
"""Many successive trials: the binomial distribution from counting paths.

Question:  if we repeat a Bernoulli(p) trial n times and count the successes,
           does the histogram of that count match C(n,k) p^k (1-p)^(n-k)?
Computes:  (a) 20000 repetitions of "n trials, count successes" for six (n,p)
           pairs, compared with the pmf; (b) a 3-out-of-4 coincidence trigger
           with per-layer efficiency 0.95, exact and simulated; (c) the sample
           mean and variance for n=20, p=0.2 against np and np(1-p).

})
```

We walk through it block by block (Figure T0.6).

The docstring (lines 1–10). Text between triple quotes at the top of a file is the file's **docstring**. Python stores it but does not execute it. Every script in the book states three things there: the *Question* it answers, what it *Computes*, and what it *Writes*. Reading the docstring first tells us what to look for in the rest.

The imports (lines 11–15). Line 11 is the same in every script and is explained once below. Lines 12–14 load NumPy under the short name `np`, Matplotlib's plotting module as `plt`, and the binomial distribution from SciPy. Line 15 loads four helpers from the book's own module `common.py`: `setup` (the figure style), `savefig` (write a figure into the right folder), `save_numbers` (write numbers for the text) and `rng_for` (a random generator seeded by the script's name). What each helper does inside is described in Section 0.6; here it is enough to know what goes in and what comes out.

The settings (lines 17–19). `setup(6.4, 4.6)` sets the figure size in inches and the house style. `rng = rng_for("ch02", "02_binomial")` creates the random generator. Every random number in the script comes from `rng`. `reps = 20_000` fixes the number of repetitions; the underscore only makes the number easier to read.

The script's own function (lines 21–24). `binomial_by_trials(n, p, reps)` draws a table of uniform random numbers with `reps` rows and `n` columns, marks each entry `True` when it is below p (a success), and counts the successes in each row. Line 24 does the counting with `trials.sum(axis=1)`: adding `True` as 1 and `False` as 0 along each row. Every idea in these four lines (arrays, comparisons that make masks, sums along an axis) appears again in Section T0.4.

The computation and the figure (lines 26–52). Line 27 lists six pairs (n, p). Line 28 creates a figure with a 3×2 grid of panels. Line 29 walks through the panels and the pairs side by side: for each panel `ax` and each pair `(n, p)`, line 30 simulates, line 32 turns the counts into frequencies, and lines 33–34 draw the simulated bars and the exact probabilities as short black marks. Line 43 saves the figure. Lines 46–52 then compute two more checks: a trigger that fires when at least three of four detector layers fire, exactly and by simulation, and the mean and variance of the count.

The numbers (lines 54–60). `save_numbers` writes the five numbers to `results/ch02/02_binomial.tex`, each as a LaTeX command, for example `\twoaTrigExact`. The chapter text writes that command where the number belongs, so the number in the text is always the one the script printed.

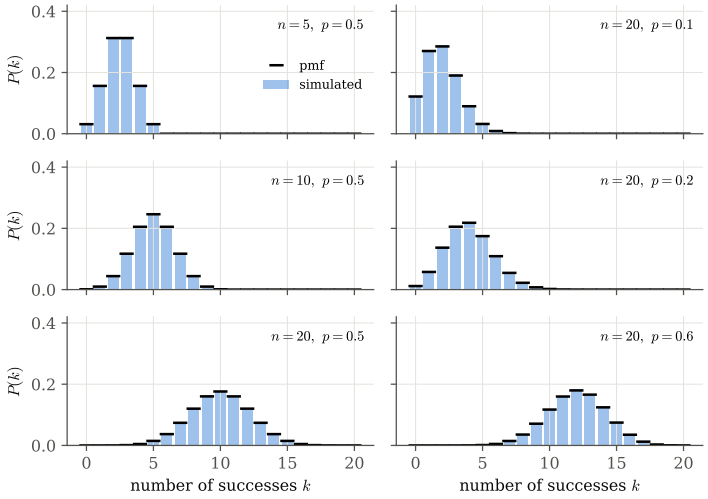

Figure T0.7: What `02_binomial.py` draws: for six choices of the number of trials n and the success probability p, the frequencies of k successes in 20 000 simulated experiments (blue bars) and the binomial probabilities (black marks). The left column grows n at $p = 0.5$; the right column grows p at $n = 20$.

The one line that is the same everywhere. Line 11 reads

```
import sys, pathlib; sys.path.insert(0,
str(pathlib.Path(__file__).resolve().parents[1]))
```

It looks cryptic, but it is a chain of small steps, each turning one thing into the next. Its job is to tell Python where `common.py` lives, so that line 15 can import it. Python looks for modules in a list of folders called `sys.path`, and the folder `code/` is not on that list by default. So the line computes the path of `code/` and puts it at the front of the list. For this script, read inside out:

`__file__` (1) = `"code/ch02/02_binomial.py"`

`pathlib.Path(__file__).resolve()` (2) = `/.../Notes/code/ch02/02_binomial.py`

`....parents[0]` (3) = `/.../Notes/code/ch02`

`....parents[1]` (4) = `/.../Notes/code`

`sys.path.insert(0, str(...))` (5) = put that folder first in the search list.

(1) Python sets `__file__` to the path by which the script was started.

(2) `pathlib.Path` turns the text into a path object, and `resolve()` makes it a full path from the root of the disk, whichever folder we started from.
(3) `parents[0]` is the folder that contains the file.
(4) `parents[1]` is one folder further up: `code/`, where `common.py` is.
(5) `str` turns the path object back into text, and `insert(0, ...)` puts it at position 0, the front, so it is searched first.

The tour script `code/chT0/06_python_tour.py` prints the last names of these folders for itself: `here.parents[0].name` is `'chT0'` and `here.parents[1].name` is `'code'`. Because the path is computed from the script's own location, the script runs correctly whether it is started from `Notes`, from `Notes/code`, or from anywhere else. Library files of one chapter used by another (such as `code/ch07/lib_fields.py`) are reached the same way, with one more `sys.path.insert` line naming their folder.

Example: reading a printed summary. Some scripts print a short report as they run. The census script of Section T0.1 prints three lines and keeps them in a text file:

```
345 files, 45734 lines, 27297 library calls, 759 distinct names
names covering 50/80/90/99 %: 25 83 159 526
names used at most 3 times: 362, carrying 2.1% of calls
```

The first line gives the size of the job (files, lines, calls, distinct names). The second gives $K_{0.5}$, $K_{0.8}$, $K_{0.9}$, $K_{0.99}$ of Figure T0.3, in that order. The third gives the long tail. Printing a few such lines, with words next to the numbers, is what makes a script's output readable a month later.

Watch out: Never edit a results file by hand

The files in `results/` are written by the scripts. If a number in the text looks wrong, the fix is in the script: change it, rerun it, and the text updates itself. A number changed by hand in `results/` is silently overwritten at the next run, and until then the text disagrees with the code.

T0.3 Plain Python: values, containers, loops and functions

Strip away the libraries and a script is a sequence of small instructions: give a number a name, collect several numbers together, repeat something for each item of a collection, do one thing or another depending on a condition, and package a recipe so that it can be used again. That is the whole of the plain Python the book needs. Every block below was run by `code/chT0/06_python_tour.py`, and each block shows a few lines of that script followed by exactly what they printed. The helper `say` prints a line and keeps a copy for the book; many lines use the f-string form `f"{x = }"`, which prints the expression itself followed by its value (Section T0.3.2).

T0.3.1 Numbers and names

The line `n = 20` does not state an equation. It is an instruction: compute the right-hand side and attach the name on the left to the result. The **assignment** `n = n + 1` is therefore perfectly sensible: take the current value of `n`, add one, and attach the name `n` to the new value.

Python has two kinds of number that matter here. An **integer** (type `int`) is a whole number, exact and of any size: a count of events, an index, a number of simulations. A **float** is a real

number stored with about sixteen significant digits (Section T0.10 says exactly how many and why). `20` is an integer, `20.0` and `0.2` are floats, and `1.5e-3` means 1.5×10^{-3}.

Listing T0.3: The tour: numbers and names (`code/chT0/06_python_tour.py`)

```
n = 20                                  # an integer: a count
p = 0.2                                 # a float: a real number, about 16 significant
    digits
say(f"{n * p = }")
say(f"{n / 8 = }")                      # / always gives a float
say(f"{n // 8 = }   {n % 8 = }")        # whole-number division, and the remainder
say(f"{2 ** 10 = }   {1.5e-3 * 2 = }")  # powers, and scientific notation
say(f"{1_000_000 = }")                  # underscores only make long numbers readable
say(f"{type(n) = }   {type(p) = }")
```

It prints:

```
n * p = 4.0
n / 8 = 2.5
n // 8 = 2   n % 8 = 4
2 ** 10 = 1024   1.5e-3 * 2 = 0.003
1_000_000 = 1000000
type(n) = <class 'int'>   type(p) = <class 'float'>
```

The operators are `+ - * /`, `**` for powers (2^{10} is `2 ** 10`, never `2^10`, which means something else), `//` for whole-number division and `%` for the remainder. Division with `/` always gives a float, even for two integers: 20/8 = 2.5. Underscores inside a number are ignored, so `1_000_000` is a million written readably. The book uses this everywhere for sizes of simulations: `reps = 20_000` in Section T0.2, `M = 200_000` below.

Watch out: The caret is not a power

`2 ** 10` is 1024. `2 ^ 10` is 8: the caret combines the bits of two integers, an operation the book never needs. A formula copied from paper with `^` for powers runs without complaint and gives nonsense.

T0.3.2 Text and f-strings

Text is a **string**: characters between quotes, single or double. Strings are used for file names, labels on axes and lines of printed output. Two operations cover most uses. Strings can be joined with +, and single characters or pieces can be taken out by position, exactly as for lists (Section T0.3.3).

Listing T0.4: The tour: text (`code/chT0/06_python_tour.py`)

```
name = "binomial"                       # text goes between quotes, single or double
say(f"{len(name) = }   {name.upper() = }")
say(f"{'02_' + name = }")               # + joins two strings
say(f"{name[0] = }   {name[-1] = }   {name[:3] = }")
```

It prints:

```
len(name) = 8   name.upper() = 'BINOMIAL'
'02_' + name = '02_binomial'
name[0] = 'b'   name[-1] = 'l'   name[:3] = 'bin'
```

The operation that the book uses constantly is the **f-string**: a string with an `f` before the opening quote, in which anything between curly braces is computed and written into the text. A colon inside the braces sets the format: `:.3f` means three digits after the decimal point, `:.2e` scientific notation with two digits after the point, `:,` thousands separators. Writing = at the

end, as in `f"{n = }"`, prints the expression and its value; the tour script uses this for every line it prints.

Listing T0.5: The tour: formatting numbers in f-strings (`code/chT0/06_python_tour.py`)

```
tau_hat, sig = 1.0234567, 0.1447
say(f"tau = {tau_hat:.3f} +/- {sig:.2f}")       # :.3f -> three digits after the point
say(f"p-value = {2.87e-7:.2e}")                  # :.2e -> scientific notation
say(f"N = {1000000:,}")                          # :,   -> thousands separators
say(f"$n={n},\\ p={p}$")                         # a plot label; a backslash is written
    twice
```

It prints:

```
tau = 1.023 +/- 0.14
p-value = 2.87e-07
N = 1,000,000
$n=20,\ p=0.2$
```

Here is how a real script uses f-strings. `code/ch01/01_events_as_masks.py` (Section 1.1) sends its numbers to the text, rounding some of them to four digits on the way:

Listing T0.6: Numbers sent to the text, some formatted by f-strings (`code/ch01/01_events_as_masks.py`)

```
save_numbers("ch01", "1a_events_masks", {
    "OneAMaskN": N,
    "OneAMaskFreqA": A.mean(), "OneAMaskFreqB": B.mean(),
    "OneAMaskFreqAB": A_and_B.mean(), "OneAMaskFreqAorB": A_or_B.mean(),
    "OneAMaskExA": f"{pA:.4f}", "OneAMaskExB": f"{pB:.4f}",
    "OneAMaskExAB": f"{pAB:.4f}", "OneAMaskExAorB": f"{pAorB:.4f}",
    "OneAMaskDeMorgan": int(demorgan_violations), "OneAMaskIEGap": int(ie_gap),
})
```

The keys on the left (`"OneAMaskExA"` and so on) become the names of LaTeX commands. The values are either numbers, which `save_numbers` formats itself, or strings already formatted with f-strings, such as `f"{pA:.4f}"`, which writes the probability `pA` with four decimals. Plot labels are f-strings too: line 35 of the binomial script writes `f"$n={n},\\ p={p}$"`, which becomes the label $n = 20,\ p = 0.2$ in the figure.

Watch out: Backslashes in labels

A backslash inside an ordinary Python string starts a special character: `"\n"` is a new line and `"\t"` a tab. So the LaTeX label `"$\theta$"` arrives as a tab followed by `heta`. Either double every backslash (`"$\\theta$"`) or put an `r` before the quote (`r"$\theta$"`), which tells Python to leave backslashes alone. The book's scripts use both forms.

T0.3.3 Lists, tuples and dictionaries

Three containers hold several values under one name.

A **list** is an ordered sequence in square brackets, `[1, 2, 5, 30]`, which can grow. Its items are numbered from 0, not from 1, so `ns[0]` is the first item. Negative positions count from the end: `ns[-1]` is the last item. A **slice** `ns[a:b]` takes the items from position `a` up to, but not including, position `b`. `.append(x)` adds an item at the end. The method `.append` is called 400 times in the book's code, almost always in one pattern: start with an empty list, and append one result each time round a loop.

Listing T0.7: The tour: a list, and the start-empty-then-append pattern (`code/chT0/06_python_tour.py`)

```
ns = [1, 2, 5, 30]                          # a list: an ordered sequence that can grow
say(f"{ns[0] = }   {ns[-1] = }   {len(ns) = }")
say(f"{ns[1:3] = }")                        # a slice: positions 1 and 2, stopping before 3
ns.append(100)                              # add one item at the end
say(f"{ns = }")
results = []                                # the usual pattern: start empty, append in a loop
for k in ns:
    results.append(k * k)
say(f"{results = }")
```

It prints:

```
ns[0] = 1   ns[-1] = 30   len(ns) = 4
ns[1:3] = [2, 5]
ns = [1, 2, 5, 30, 100]
results = [1, 4, 25, 900, 10000]
```

The rule "from `a`, stopping before `b`" becomes obvious once positions are pictured as the *gaps between items*, not the items themselves (Figure T0.8). Then `ns[1:3]` is everything between gap 1 and gap 3: two items. The length of a slice is `b - a`, and `ns[:k]` followed by `ns[k:]` gives back the whole list with nothing repeated and nothing lost.

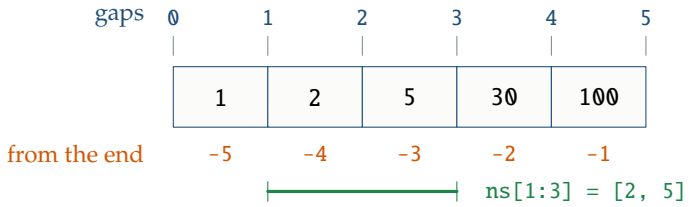

Figure T0.8: The list `ns = [1, 2, 5, 30, 100]`. Blue numbers mark the gaps between items: a slice `ns[a:b]` runs from gap `a` to gap `b`, so `ns[1:3]` holds two items. An index `ns[i]` is the item just after gap `i`; orange numbers are the negative indices, counting back from the end.

A **tuple** is a fixed group of values in round brackets, `(20, 0.2)`, which cannot be changed after it is made. The book uses tuples to keep things together that belong together, such as the pair (n, p) of a binomial distribution. Its most useful property is **unpacking**: `n, p = case` gives one name to each entry. Unpacking works in `for` loops too, and is used in practically every script.

Listing T0.8: The tour: tuples and unpacking (`code/chT0/06_python_tour.py`)

```
case = (20, 0.2)                            # a tuple: a fixed group of values
n, p = case                                 # unpacking: one name for each entry
say(f"{n = }   {p = }")
cases = [(5, 0.5), (20, 0.1)]               # a list of tuples, as in the binomial script
for n, p in cases:                          # unpack each tuple as the loop meets it
    say(f"n = {n}, p = {p}, mean n p = {n * p}")
```

It prints:

```
n = 20   p = 0.2
n = 5, p = 0.5, mean n p = 2.5
n = 20, p = 0.1, mean n p = 2.0
```

A **dictionary** (`dict`) is a table that maps *keys* to *values*, written `{"H0": 67.36, "ns": 0.9649}`. A value is fetched by its key, `fid["H0"]`, not by a position. New entries are added by assignment, `fid["tau"] = 0.0544`, and `.items()` walks through the (key, value) pairs.

Listing T0.9: The tour: a dictionary (`code/chT0/06_python_tour.py`)

```
82 fid = {"H0": 67.36, "ombh2": 0.02237, "ns": 0.9649}    # a dictionary: names -> values
83 say(f"{fid['H0'] = }")
84 fid["tau"] = 0.0544                        # add a new entry
85 say(f"{len(fid) = }   {'tau' in fid = }")
86 for key, value in fid.items():            # walk through (name, value) pairs
87     say(f"{key:>6} = {value}")
```

It prints:

```
fid['H0'] = 67.36
len(fid) = 4   'tau' in fid = True
    H0 = 67.36
 ombh2 = 0.02237
    ns = 0.9649
   tau = 0.0544
```

All three containers appear together in the binomial script of Section T0.2, lines 27–30: a list of tuples `cases = [(5, 0.5), (10, 0.5), ...]`, walked through with unpacking, `for ax, (n, p) in zip(...)`. The dictionary `{...}` handed to `save_numbers` on line 54 is the commonest dictionary in the book. A slightly richer use is in `code/ch03/01_sampling_distribution.py` (Section 3.1.4), which compares four ways of estimating g from ten readings:

Listing T0.10: A dictionary of estimators, and a dictionary built from it (`code/ch03/01_sampling_distribution.py`)

```
27
28 # ---------- (A) ten Gaussian readings of g ----------
29 g_true, sigma, N = 9.81, 0.05, 10
30 x = g_true + sigma * rng.standard_normal((M, N))      # each row = one experiment
31 est = {
32     "sample mean": x.mean(axis=1),
33     "sample median": np.median(x, axis=1),
34     "mid-range": 0.5 * (x.min(axis=1) + x.max(axis=1)),
35     "first reading": x[:, 0],
36 }
37 sd = {k: v.std(ddof=1) for k, v in est.items()}
```

The dictionary `est` maps a name (a string) to an array of 200 000 estimates, one per simulated experiment. Line 37 builds a second dictionary from the first: for every key `k` and value `v`, the standard deviation of `v`. That one-line construction is a *comprehension* (Section T0.3.4).

Example: why a dictionary and not a list? The four estimators could be kept in a list, `[mean, median, midrange, first]`. Then the standard deviation of the median would be `sd[1]`, and anyone reading the code must remember that position 1 is the median. With a dictionary it is `sd["sample median"]`: the code says what it means, and adding a fifth estimator does not shift the positions of the others. The rule of thumb is: a list when the items are of the same kind and their order matters (a sequence of sizes N), a dictionary when each item has a name (estimators, parameters, numbers for the text).

Watch out: Counting from zero

The first item is `x[0]` and the last is `x[len(x) - 1]`, also written `x[-1]`. `x[len(x)]` does not exist and stops the script with `IndexError`. When a formula on paper runs over $i = 1, \ldots, N$, the code runs over `i = 0, ..., N-1`.

T0.3.4 Doing things repeatedly, and conditionally

A `for` loop repeats a block of lines once for each item of a collection. The block is marked by **indentation**: the lines that belong to the loop are shifted to the right by four spaces, and the first line that is not shifted is the first line after the loop. Python has no `end` statement; the indentation *is* the structure.

`range(n)` produces the integers $0, 1, \ldots, n-1$ (`n` numbers, stopping before `n`), and `range(a, b)` those from `a` up to `b - 1`. `enumerate(xs)` gives the position together with each item, and `zip(xs, ys)` walks two collections side by side.

Listing T0.11: The tour: three kinds of for loop (`code/chT0/06_python_tour.py`)

```
total = 0
for k in range(1, 6):                    # k = 1, 2, 3, 4, 5  (stops before 6)
    total += k                           # the same as total = total + k
say(f"{total = }")
for i, n in enumerate([5, 10, 20]):      # enumerate: the position and the item
    say(f"i = {i}, n = {n}")
for n, p in zip([5, 10], [0.5, 0.1]):    # zip: walk two lists side by side
    say(f"n = {n}, p = {p}")
```

It prints:

```
total = 15
i = 0, n = 5
i = 1, n = 10
i = 2, n = 20
n = 5, p = 0.5
n = 10, p = 0.1
```

An `if` statement runs a block only when a condition is true. `elif` ("else if") adds further conditions, tried in order, and `else` catches everything left. Conditions are comparisons (<, <=, == for "is equal to", != for "is not equal to") joined by `and`, `or`, `not`.

Listing T0.12: The tour: if, elif, else (`code/chT0/06_python_tour.py`)

```
for z in [0.5, 3.4, 5.3]:
    if z >= 5:
        verdict = "discovery"
    elif z >= 3:
        verdict = "evidence"
    else:
        verdict = "nothing yet"
    say(f"z = {z}: {verdict}")
say(f"{(2 < 3) and (3 < 1) = }   {not (3 < 1) = }")
```

It prints:

```
z = 0.5: nothing yet
z = 3.4: evidence
z = 5.3: discovery
(2 < 3) and (3 < 1) = False   not (3 < 1) = True
```

Both appear together in the dice script of Section 1.1, which colours the 36 outcomes of two dice according to the two events "first die even" and "sum at least 9":

Listing T0.13: Two nested loops and a three-way condition (`code/ch01/01_events_as_masks.py`)

```
for i in range(1, 7):
    for j in range(1, 7):
        inA, inB = (i % 2 == 0), (i + j >= 9)
        colour = "white"
```

```
66          if inA and inB:
67              colour = SERIES[2]
68          elif inA:
69              colour = SERIES[0]
70          elif inB:
71              colour = SERIES[1]
72          ax0.add_patch(Rectangle((i - 0.45, j - 0.45), 0.9, 0.9, facecolor=colour,
73                                  edgecolor="#52514e", lw=0.6, alpha=0.75))
```

Lines 62–63 are two loops, one inside the other: for each value `i` of the first die, for each value `j` of the second, so the inner block runs $6 \times 6 = 36$ times. Line 64 computes two true/false values. Lines 66–71 choose a colour: both events (green), only A (blue), only B (orange), and otherwise the white set on line 65 stays. Line 72 draws one square.

A `while` loop repeats as long as a condition holds, for when the number of repetitions is not known in advance. It is rare in the book (6% of the scripts). A typical use is accept–reject sampling (Chapter 6): keep drawing until enough draws have been accepted. `code/ch03/10_angular_ml.py` (Section 3.9.3) does exactly that:

Listing T0.14: Draw until there are enough: a while loop (`code/ch03/10_angular_ml.py`)

```
27 def sample(size):
28     """accept-reject from the flat envelope on [xmin, xmax]"""
29     out = np.empty(0)
30     gmax = 1 + abs(a_true) + abs(b_true)
31     while out.size < size:
32         x = rng.uniform(xmin, xmax, 2 * size)
33         keep = rng.uniform(0, gmax, 2 * size) < 1 + a_true * x + b_true * x**2
34         out = np.concatenate([out, x[keep]])
35     return out[:size]
```

Line 31 says: while fewer than `size` values have been collected, draw another batch of 2×`size` candidates, keep those that pass the test (line 33), and add them to the collection (line 34). Line 35 returns exactly `size` of them.

A **comprehension** is a loop that builds a list (or a dictionary) in one line: `[k ** 2 for k in range(5)]` is the list of the squares of $0, \ldots, 4$. An `if` at the end keeps only some items. The same construction inside `sum(...)` or `max(...)` needs no brackets.

Listing T0.15: The tour: comprehensions (`code/chT0/06_python_tour.py`)

```
142 squares = [k ** 2 for k in range(5)]              # a list built by a loop in one line
143 evens = [k for k in range(10) if k % 2 == 0]      # ... keeping only some items
144 lengths = {s: len(s) for s in ["pi", "K", "p"]}  # the same for a dictionary
145 say(f"{squares = }")
146 say(f"{evens = }")
147 say(f"{lengths = }")
148 say(f"{sum(k ** 2 for k in range(5)) = }")       # inside a function call, no brackets needed
```

It prints:

```
squares = [0, 1, 4, 9, 16]
evens = [0, 2, 4, 6, 8]
lengths = {'pi': 2, 'K': 1, 'p': 1}
sum(k ** 2 for k in range(5)) = 30
```

Comprehensions are in 65% of the scripts. Line 37 of the sampling-distribution excerpt above, `{k: v.std(ddof=1) for k, v in est.items()}`, is one. A one-line `if` also exists for values: `a if condition else b`. It is how the book's code writes a default, as in `rng = np.random.default_rng() if rng is None else rng`.

Example: the same sum three ways. The sum $\sum_{k=1}^{5} k$ is computed by an explicit loop in the tour (`total = 15`). With a comprehension it is `sum(k for k in range(1, 6))`. With NumPy (Section T0.4) it is `np.arange(1, 6).sum()`. All three give 15. The loop is the clearest; the NumPy form is the fastest for long sums, by a factor of about 137 for a million terms (Section T0.4.5).

Watch out: Indentation is part of the program

Moving a line four spaces to the left takes it out of the loop: it then runs once, after the loop, instead of once per item. Python cannot warn about this, because both versions are valid programs. When a result looks like "only the last case was used", check the indentation of the line that stores the result.

T0.3.5 Functions

A **function** packages a recipe with inputs and outputs, so that it can be used many times and read once. It starts with `def`, its name and its inputs (the **parameters**) in brackets; the indented block is the recipe; `return` hands back the result. A string on the first line of the block is the function's docstring. Parameters can have **default values**, used when the caller does not give them; and a caller can give any parameter by name, as a **keyword argument**, in any order. To return several results, a function returns them separated by commas, which makes a tuple, and the caller unpacks it.

Listing T0.16: The tour: two functions and a lambda (`code/chT0/06_python_tour.py`)

```
def gaussian(x, mu=0.0, sigma=1.0):
    """Normal density at x; mu and sigma have default values."""
    return np.exp(-0.5 * ((x - mu) / sigma) ** 2) / (sigma * np.sqrt(2 * np.pi))

def mean_and_error(x):
    """Two answers at once: the sample mean and its standard error."""
    return np.mean(x), np.std(x, ddof=1) / np.sqrt(len(x))

say(f"{gaussian(0.0) = :.4f}")                    # defaults used: mu = 0, sigma = 1
say(f"{gaussian(1.0, sigma=2.0) = :.4f}")        # sigma given by name, mu left at 0
m, e = mean_and_error(np.array([9.80, 9.71, 9.86, 9.83]))
say(f"m = {m:.3f} +/- {e:.3f}")
square = lambda t: t ** 2                        # a one-line function without a name
say(f"{square(3) = }")
```

It prints:

```
gaussian(0.0) = 0.3989
gaussian(1.0, sigma=2.0) = 0.1760
m = 9.800 +/- 0.032
square(3) = 9
```

The first two lines call `gaussian(x, mu=0.0, sigma=1.0)`: once with both defaults, once giving `sigma` by name and leaving `mu` at its default. The third calls `mean_and_error`, which returns two values, unpacked into `m, e`. The last line uses a **lambda**: a one-line function without a name, `lambda t: t ** 2`, convenient when a function is needed only once, as an argument to another function.

Every one of these features is in daily use in the book. The log-likelihood of the decay-time example (Section 3.12.4) is a two-line function, and the function whose root gives the likelihood interval is a lambda:

Listing T0.17: A function, and lambdas handed to SciPy (`code/ch03/09_mle_decay.py`)

```
27 def lnL(tau, t):
28     """log-likelihood of mean life tau for decay times t (constants dropped)."""
29     return -len(t) * np.log(tau) - t.sum() / tau
30
31
32 # ---------- one experiment ----------
33 t = rng.exponential(tau_true, n)
34 tau_hat = t.mean()                                  # analytic MLE
35 tau_num = optimize.minimize_scalar(lambda s: -lnL(s, t), bounds=(0.1, 5),
       method="bounded").x
36 sig_curv = tau_hat / np.sqrt(n)                     # 1/sqrt(-d2 lnL/dtau2) at tau_hat
37 lmax = lnL(tau_hat, t)
38 f = lambda s: lnL(s, t) - lmax + 0.5                # zero where ln L has dropped by 1/2
39 lo = optimize.brentq(f, 0.3 * tau_hat, tau_hat)
40 hi = optimize.brentq(f, tau_hat, 3 * tau_hat)
```

Line 29 is the whole recipe: $\ln \mathcal{L}(\tau) = -n \ln \tau - \sum_i t_i/\tau$ for decay times t_i, with `len(t)` giving n and `t.sum()` the sum. Line 35 hands a lambda to SciPy's minimiser: "the function of `s` that returns minus the log-likelihood at `s`". Line 38 builds the function whose zeros are the points where $\ln \mathcal{L}$ has dropped by $\frac{1}{2}$ from its maximum, and lines 39–40 find those zeros (Section T0.6).

Library functions in the book use defaults and keyword arguments to stay flexible. The Gaussian-field simulator of Section 7.4.2 begins

Listing T0.18: Defaults and keyword arguments in a library function (`code/ch07/lib_fields.py`)

```
45 def gaussian_field(P, N: int, L: float, d: int = 2, rng=None, nsim: int | None = None):
46     """Gaussian random field(s) with power spectrum P(k) on a periodic box.
47
48     P    : callable P(kmag) (vectorised), in units of length^d
49     nsim : if given, return an array of nsim independent fields (axis 0)
50     The k = 0 mode is set to zero, so each box has exactly zero mean.
51     """
52     rng = np.random.default_rng() if rng is None else rng
53     D = L / N
```

The parameters `d`, `rng` and `nsim` have defaults (2 dimensions, no generator given, one field), so the simplest call is `gaussian_field(P, N, L)`, and a three-dimensional batch of fields is `gaussian_field(P, N, L, d=3, nsim=100, rng=rng)`. The words after the colons (`N: int`, `L: float`) are **type hints**: notes for the reader saying what kind of value is expected. Python ignores them.

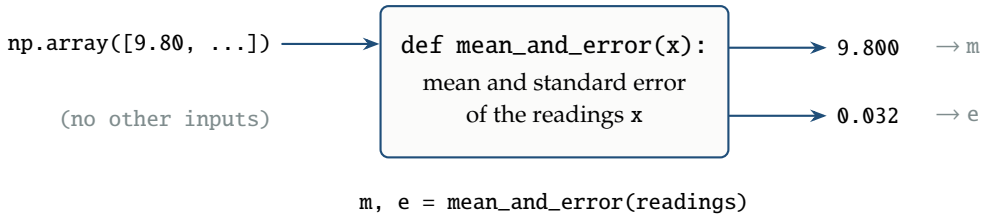

Figure T0.9: A function as a box with a name: an array of readings goes in, two numbers come out as a tuple, and the caller gives each a name by unpacking. Nothing inside the box is visible to the caller except what `return` hands back.

Example: why a function at all? The binomial script of Section T0.2 simulates the binomial count three times: for the six panels (line 30), for the trigger (line 48) and for the moments (line

52). Without the function `binomial_by_trials`, its two lines would be written three times, and a correction (say, < instead of <=) would have to be made in three places. With the function, it is made once. This is the reason almost three quarters of the scripts (72%) define at least one function of their own.

Watch out: A function that forgets to return

A function without a `return` line returns the special value `None`. The mistake looks like this: the last line computes the answer, `chi2 = np.sum(r ** 2)`, but never returns it. The caller then gets `None`, and the error appears later, somewhere else, as `TypeError: unsupported operand type(s) ... 'NoneType'`. When that word appears in an error message, look for a missing `return`.

T0.3.6 Modules and imports

A **module** is a file of Python code whose functions can be used elsewhere. `import numpy as np` loads the module `numpy` and calls it `np` inside the script, so its square root is `np.sqrt`. `from scipy import stats` loads one part of SciPy under its own name, and `from math import comb` loads a single function. The book's short names are fixed: `np` for NumPy, `plt` for Matplotlib's plotting module, `hp` for healpy.

Listing T0.19: The tour: imports (`code/chT0/06_python_tour.py`)

```
152 import math                                          # a whole module: use as math.something
153 from math import comb                                # one name from a module
154 say(f"{math.pi = }   {comb(10, 3) = }")
155 here = pathlib.Path(__file__).resolve()             # the full path of this script
156 say(f"{here.name = }")
157 say(f"{here.parents[0].name = }   {here.parents[1].name = }")
```

It prints:

```
math.pi = 3.141592653589793   comb(10, 3) = 120
here.name = '06_python_tour.py'
here.parents[0].name = 'chT0'   here.parents[1].name = 'code'
```

The book's own modules (`common.py`, `camb_fiducial.py` and the `lib_*.py` files of each chapter) are imported the same way once their folder is on `sys.path` (Section T0.2). One more construction appears at the bottom of a few of them. `code/camb_fiducial.py` ends with

Listing T0.20: Run main() only when the file is started as a script (`code/camb_fiducial.py`)

```
40 if __name__ == "__main__":
41     main()
```

Python sets the name `__name__` to `"__main__"` in the file that was started, and to the module's own name in a file that was imported. So `python3 code/camb_fiducial.py` computes and saves the CAMB spectra, while `from camb_fiducial import load_fiducial` in another script only makes the function available, without running anything.

T0.4 NumPy: computing with whole arrays

A physicist writes $\chi^2 = \sum_i (d_i - m_i)^2/\sigma_i^2$ without thinking about the order in which the terms are added. The formula is about whole vectors: the data vector $\boldsymbol{d}$, the model vector $\boldsymbol{m}$, the vector of errors. NumPy lets code be written the same way. Its central object is the **array**: a block of numbers, all of the same kind, laid out in a grid of one or more dimensions, on which

arithmetic acts element by element. `(d - m) / s` is the vector of normalised residuals, and `np.sum(((d - m) / s) ** 2)` is χ^2. NumPy names make 34% of all library calls in the book, and NumPy is imported by 99% of the scripts: this section is the heart of the toolkit. The printed lines below come from `code/chT0/07_numpy_tour.py`.

T0.4.1 Arrays, shape and type

An array is made from a list with `np.array([...])`, or directly by a function that fills it: `np.zeros`, `np.ones`, `np.full`, `np.arange`, `np.linspace`, or a random generator. Three attributes describe it. Its **shape** is a tuple giving the length along each dimension: `(4,)` for four readings, `(2, 3)` for two rows of three. `ndim` is the number of dimensions, and `dtype` the kind of number stored, almost always `float64` (a real number in double precision) or `int64` (a whole number). Arithmetic and functions such as `np.sqrt`, `np.exp`, `np.log` act on every element.

```
g.shape = (4,)   g.dtype = dtype('float64')   g.ndim = 1
counts.dtype = dtype('int64')
X.shape = (2, 3)   X.size = 6
np.arange(5) = array([0, 1, 2, 3, 4])
np.linspace(0, 1, 5) = array([0.  , 0.25, 0.5 , 0.75, 1.  ])
np.logspace(0, 3, 4) = array([   1.,   10.,  100., 1000.])
g * 2 = array([19.6 , 19.42, 19.72, 19.66])
np.sqrt(g) = array([3.1305, 3.1161, 3.1401, 3.1353])
```

Three ways of making evenly spaced numbers need to be told apart, because they are used constantly. `np.arange(a, b, step)` starts at `a` and adds `step` until it reaches `b`, which it does *not* include; it is meant for integers. `np.linspace(a, b, n)` gives `n` points from `a` to `b` *including* both ends; it is the right choice for a grid of real numbers, such as the x values at which a density is plotted. `np.logspace(p, q, n)` gives `n` points from 10^p to 10^q, evenly spaced in the logarithm, and `np.geomspace(a, b, n)` the same between `a` and `b` themselves; they are the right choice for sample sizes, scales and frequencies that span several decades.

Example: how many points, and what spacing? A grid of θ from 0 to 1 with steps of 0.1 has eleven points, $0, 0.1, \ldots, 1$. With `np.linspace(0, 1, 11)` the spacing is

$$\Delta\theta \overset{(1)}{=} \frac{b-a}{n-1} = \frac{1-0}{11-1} = 0.1,$$

(1) n points with both ends included leave $n-1$ gaps between them.

and the last point is exactly 1. With `np.arange(0, 1, 0.1)` one gets only ten points, stopping at 0.9; and because 0.1 is not exactly representable in binary (Section T0.10), `np.arange` with a fractional step can occasionally include or exclude the end by rounding. Hence the rule: `arange` for integers, `linspace` for real grids.

T0.4.2 Indexing and slicing

Indexing an array works like indexing a list (Figure T0.8), with one addition: an array with several dimensions takes one index per dimension, separated by commas. `A[1, 2]` is the element in row 1, column 2 (both counted from 0). A colon on its own means "all of this dimension", so `A[:, 0]` is the first column and `A[1]` (or `A[1, :]`) the second row. A slice `a:b:step` can take every second or third element, and `::-1` reverses.

```
v[0] = 0   v[-1] = 90   v[2:5] = array([20, 30, 40])
v[::3] = array([ 0, 30, 60, 90])   v[::-1][:3] = array([90, 80, 70])
```

```
A =
[[ 0  1  2  3]
 [ 4  5  6  7]
 [ 8  9 10 11]]
A[1, 2] = 6   A[1] = array([4, 5, 6, 7])   A[:, 0] = array([0, 4, 8])
A[0:2, 1:3] =
[[1 2]
 [5 6]]
```

The book stores many repetitions of an experiment as the *rows* of a two-dimensional array: one row per simulated experiment, one column per reading. Then `x[:, 0]` is "the first reading of every experiment", which is how the sampling-distribution script of Section 3.1.4 builds its fourth estimator (line 34 of the excerpt in Section T0.3.3).

T0.4.3 Masks: selecting by a condition

A comparison between an array and a number, such as `x > 0`, does not give one `True` or `False`. It gives an array of them, one per element: a **boolean mask**. A mask can do three things. Used as an index, `x[m]` keeps only the elements where the mask is `True`. Summed, `m.sum()` counts the `True` entries, because `True` counts as 1 and `False` as 0. Averaged, `m.mean()` is the fraction of `True` entries, which is how a simulated probability is computed. Masks combine with `&` (and), `|` (or) and `~` (not). `np.where(m, a, b)` takes `a` where the mask is true and `b` elsewhere.

```
m = array([ True, False,  True,  True, False])
x[m] = array([0.3, 2.5, 0.8])   m.sum() = 3   m.mean() = 0.6
np.where(x > 0, x, 0.0) = array([0.3, 0. , 2.5, 0.8, 0. ])
x[(x > 0) & (x < 1)] = array([0.3, 0.8])
```

Masks are the bridge between probability and code, and the very first script of Chapter 1 is built on them (Section 1.1). An event is a set of outcomes; in a simulation, an event *is* a mask over the simulated outcomes:

Listing T0.21: Events as boolean masks over 100 000 simulated rolls of two dice (`code/ch01/01_events_as_masks.py`)

```
20 rng = rng_for("ch01", "1a_events_masks")
21 N = 100_000
22
23 # --- one row per repetition of the experiment: the outcome omega = (d1, d2)
24 d1 = rng.integers(1, 7, size=N)
25 d2 = rng.integers(1, 7, size=N)
26
27 # --- events are boolean arrays: A[i] is True when outcome i lies in A
28 A = (d1 % 2 == 0)            # first die even
29 B = (d1 + d2 >= 9)           # sum at least 9
30
31 # --- set operations are logical operations on the masks
32 A_and_B = A & B              # intersection
33 A_or_B = A | B               # union
34 not_A = ~A                   # complement
35
36 # De Morgan: (A u B)^c == A^c n B^c must hold outcome by outcome
37 demorgan_violations = np.count_nonzero(~A_or_B != (~A & ~B))
38
39 # inclusion-exclusion on counts: |A u B| = |A| + |B| - |A n B|  (exact identity)
40 ie_gap = A_or_B.sum() - (A.sum() + B.sum() - A_and_B.sum())
```

Lines 24–25 roll two dice $N = 100\,000$ times: `rng.integers(1, 7, size=N)` draws integers from 1 to 6 (the upper end 7 is excluded, as for `range`). Line 28 is the event "first die even" as a mask: `d1 % 2 == 0` is `True` where the remainder on division by 2 is zero. Lines 32–34 are

intersection, union and complement, written `&`, `|`, `~`. Line 40 checks the inclusion–exclusion identity $|A \cup B| = |A| + |B| - |A \cap B|$ on the counts, each count being a `.sum()` of a mask. The frequency of A is then `A.mean()`, which estimates $\mathrm{P}(A)$.

Example: a probability as the mean of a mask. Why is `A.mean()` an estimate of $\mathrm{P}(A)$? Write $I_i = 1$ if roll i lies in A and $I_i = 0$ otherwise; the mask `A` is the array $(I_1, \dots, I_N)$. Then

$$\texttt{A.mean()} \overset{(1)}{=} \frac{1}{N}\sum_{i=1}^{N} I_i \overset{(2)}{=} \frac{\#\{i :\ \text{roll } i \in A\}}{N}, \qquad \mathbb{E}[\texttt{A.mean()}] \overset{(3)}{=} \frac{1}{N}\sum_{i=1}^{N} \mathbb{E}[I_i] \overset{(4)}{=} \mathrm{P}(A).$$

(1) `.mean()` adds the entries and divides by their number, with `True` counted as 1.
(2) The sum of the indicators counts the rolls that land in A.
(3) The expectation of a sum is the sum of the expectations.
(4) Each indicator has expectation $1 \cdot \mathrm{P}(A) + 0 \cdot (1 - \mathrm{P}(A)) = \mathrm{P}(A)$.

So the mean of a mask is the relative frequency, an unbiased estimate of the probability, with the binomial standard error $\sqrt{\mathrm{P}(A)(1-\mathrm{P}(A))/N}$ (Section T0.10).

Watch out: and is not &

For masks, write `(x > 0) & (x < 1)`, with the brackets. The word `and` works only for single `True/False` values and stops with `ValueError: The truth value of an array with more than one element is ambiguous`. Without the brackets, `x > 0 & x < 1` is read as `x > (0 & x) < 1`, because `&` binds more tightly than `>`.

T0.4.4 Broadcasting: arrays of different shapes

`g * 2` multiplies every element of `g` by 2: the single number is "stretched" to the shape of the array. NumPy generalises this to arrays of different shapes, and the generalisation, called **broadcasting**, is what lets the book write tables of pairs without loops.

Working definition T0.2 (broadcasting)

Two arrays can be combined element by element when their shapes are compatible. Compare the shapes from the right (the last dimension first). Two lengths are compatible if they are equal or if one of them is 1 [a length-1 dimension is copied as often as needed]. A missing dimension on the left counts as length 1. The result has, in each dimension, the larger of the two lengths.

The tool for making a length-1 dimension on purpose is `None` as an index. If `r` has shape `(3,)`, then `r[:, None]` has shape `(3, 1)` (a column) and `r[None, :]` has shape `(1, 3)` (a row). Their difference has shape `(3, 3)`, and its entry (i, j) is $r_i - r_j$ (Figure T0.10).

```
r[:, None].shape = (3, 1)   r[None, :].shape = (1, 3)
r[:, None] - r[None, :] =
[[ 0. -1. -3.]
 [ 1.  0. -2.]
 [ 3.  2.  0.]]
(A - A.mean(axis=0)).mean(axis=0) = array([0., 0., 0., 0.])
```

The book uses exactly this to build covariance matrices that depend on the distance between two points. The correlated one-dimensional field of Section 6.9.2 has covariance $C_{ij} = e^{-|x_i - x_j|/\ell}$ between grid points x_i and x_j, and the whole 200×200 matrix is one line:

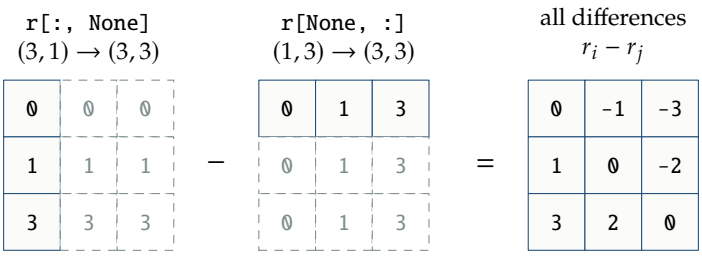

Figure T0.10: Broadcasting a column against a row. The column of shape $(3, 1)$ is copied sideways and the row of shape $(1, 3)$ is copied downwards (dashed copies are never actually stored), so the difference is the full 3×3 table of $r_i - r_j$.

Listing T0.22: A covariance matrix from all pairwise distances, by broadcasting (`code/ch06/23_cholesky_field.py`)

```
38 # ------------------------------------------------------------- 2. a correlated 1-D field
39 n, Lbox, ell, M = 200, 20.0, 2.0, 4000
40 xg = np.linspace(0, Lbox, n)
41 C = np.exp(-np.abs(xg[:, None] - xg[None, :]) / ell)
42 L = np.linalg.cholesky(C)
```

Line 39 sets the sizes and line 40 makes the 200 grid positions. In line 41, `xg[:, None] - xg[None, :]` is the 200×200 table of differences, `np.abs` takes their absolute values, and the exponential is applied to every entry. Line 42 factorises the matrix (Section T0.5.2).

Example: when shapes do not fit. Adding `r` of shape `(3,)` to `np.ones(4)` of shape `(4,)` compares the last lengths, 3 and 4. They differ and neither is 1, so the operation is refused with the error quoted in Section T0.2. The error is a friend: NumPy refuses to guess what was meant. The dangerous case is the opposite one, when the shapes *do* fit but not in the way intended. Subtracting a vector of 3 column means from a 3×3 matrix, `A - A.mean(axis=0)`, subtracts each column's mean from its column, as intended; `A - A.mean(axis=1)` subtracts the *row* means from the *columns*, also without complaint. For square arrays, only the numbers reveal the mistake. Writing `A.mean(axis=1, keepdims=True)`, which keeps the reduced dimension with length 1 (shape $(3, 1)$), makes the intention explicit.

T0.4.5 Vectorisation: why loops are avoided

Python can of course compute χ^2 with a loop over the data points. The question is how much slower it is, and why. `code/chT0/02_vectorise.py` computes the same χ^2 in both ways for N from 10 to 10^6 or 10^7:

Listing T0.23: The same sum, one element at a time and as one array expression (`code/chT0/02_vectorise.py`)

```
19 def chi2_loop(d, m, s):
20     """One element at a time, the way one would write it on paper."""
21     total = 0.0
22     for i in range(len(d)):
23         total += ((d[i] - m[i]) / s[i]) ** 2
24     return total
25
26
27 def chi2_vec(d, m, s):
28     """The same sum as one expression on whole arrays."""
29     return np.sum(((d - m) / s) ** 2)
```

For $N = 10^6$ the loop takes 0.3575 s and the array expression 2.614 ms, a factor of 137; the two answers agree to a relative difference of 3.731×10^{-15}, which is rounding error from adding the terms in a different order (Figure T0.11).

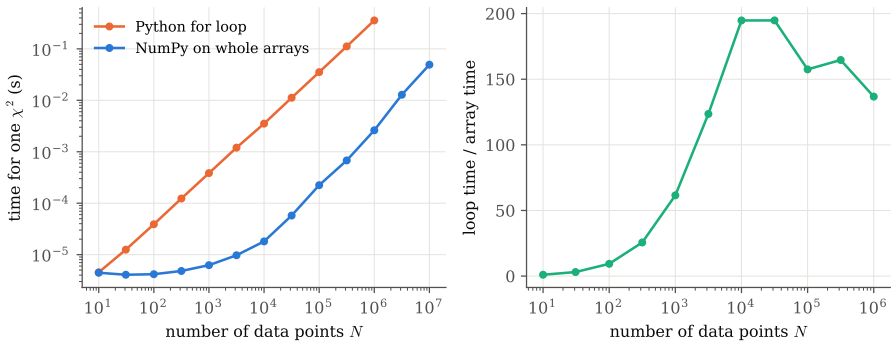

Figure T0.11: Left: the time to compute one χ^2 of N data points with a Python loop (orange) and with one NumPy expression (blue). Both grow in proportion to N, but the loop pays far more per point. Right: the ratio of the two times, close to 1 for a handful of points and about a hundred for large N.

Where the factor comes from. Both versions do the same arithmetic, so the difference must be in the overhead around it. In the loop, Python handles each number as a separate object: it looks up `d[i]`, checks its type, creates a new object for each intermediate result, and only then does the floating-point operation, which itself takes a nanosecond or less. In the array expression, Python is consulted once per *array*; the loop over elements runs inside NumPy's compiled code, on numbers stored side by side in memory. A simple cost model makes this quantitative. Let each version cost a fixed overhead plus a cost per element, $T_{\text{loop}} = o_{\text{loop}} + c_{\text{loop}} N$ and $T_{\text{vec}} = o_{\text{vec}} + c_{\text{vec}} N$. Then

$$\frac{T_{\text{loop}}}{T_{\text{vec}}} \overset{(1)}{=} \frac{o_{\text{loop}} + c_{\text{loop}} N}{o_{\text{vec}} + c_{\text{vec}} N} \xrightarrow{N \to \infty} \frac{c_{\text{loop}}}{c_{\text{vec}}} \overset{(2)}{=} \frac{358\ \text{ns}}{2.6\ \text{ns}} \approx 137.$$

(1) For large N the overheads are negligible next to the terms proportional to N.
(2) The measured costs per element at $N = 10^6$: the total times divided by 10^6.

For $N = 10$ the ratio is about 1: both versions are dominated by the fixed overhead of a function call, and vectorising buys nothing. The lesson is practical: a loop over a few dozen cases (six binomial panels, ten sample sizes) is fine and often clearest; a loop over a million data points or simulated values is written as an array expression.

T0.4.6 Reductions along an axis

A **reduction** turns many numbers into fewer: `sum`, `mean`, `std`, `var`, `min`, `max`, `median`, `percentile`. On a two-dimensional array, the keyword `axis` says which dimension is reduced, that is, which dimension *disappears*. With experiments in rows and readings in columns, `E.mean(axis=1)` averages along each row and leaves one mean per experiment; `E.mean(axis=0)` averages down each column and leaves one mean per reading slot; with no `axis`, all numbers are averaged (Figure T0.12).

```
E.mean() = 9.8067
E.mean(axis=1) = array([9.8  , 9.805, 9.815])
E.mean(axis=0) = array([9.83 , 9.7667, 9.8167, 9.8133])
E.std(axis=1, ddof=1) = array([0.0648, 0.0342, 0.0661])
E.max() = 9.9   E.argmax() = 8   np.cumsum([1, 2, 3]) = array([1, 3, 6])
```

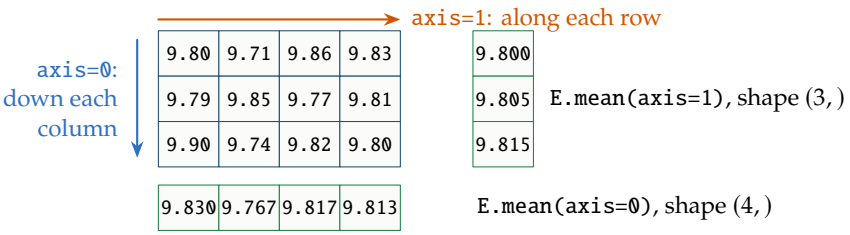

Figure T0.12: Reducing a 3×4 array of readings (three experiments in rows, four readings each). The axis named in the call is the one that disappears: `axis=1` leaves one mean per experiment, `axis=0` one mean per column.

This is how the book studies sampling distributions: simulate M experiments of N readings each as one $M \times N$ array, reduce along `axis=1` to get M estimates, and histogram them. The $1/\sqrt{N}$ study of Section 3.3.5 does it for several parent distributions and several N:

Listing T0.24: Many experiments at once: an $M \times N$ array reduced along its rows (`code/ch03/03_one_over_sqrtN.py`)

```
34 for N in Ns:
35     for k, (draw, _) in parents.items():
36         m = draw((M, N)).mean(axis=1)
37         var_of_mean[k].append(m.var(ddof=1))
38         if k == "Exponential(1)":
39             q = np.percentile(m, [25, 75]); iqr[k].append(0.5 * (q[1] - q[0]))
40     mc = rng.standard_cauchy((M, N)).mean(axis=1)
41     q = np.percentile(mc, [25, 75]); iqr["Cauchy"].append(0.5 * (q[1] - q[0]))
```

Line 36 is the whole simulation for one parent distribution and one N: `draw((M, N))` returns $M = 20\,000$ rows of N draws, and `.mean(axis=1)` turns each row into its sample mean. Line 37 stores the variance of those M means. Line 39 computes two percentiles at once from a list, `[25, 75]`. The loop over N (line 34) and over the three parents (line 35) stays a Python loop, because it runs only 11×3 times; the $M \times N$ work inside it is vectorised.

Example: the standard error from one array. Four readings of g are in the first row of the array `E` above. Their mean and its standard error are

$$\bar{g} = \texttt{E[0].mean()}, \qquad \sigma_{\bar{g}} \overset{(1)}{=} \frac{s}{\sqrt{n}} \overset{(2)}{=} \texttt{E[0].std(ddof=1) / np.sqrt(E.shape[1])}.$$

(1) The standard error of a mean of n independent readings with sample standard deviation s (Chapter 3).

(2) `ddof=1` divides by $n - 1$ instead of n (the unbiased sample variance of Section 2.13.4); `E.shape[1]` is the number of columns, $n = 4$.

Forgetting `ddof=1` is a common slip. NumPy's default is `ddof=0`, the divide-by-n version, which is the maximum-likelihood estimate of the variance and is biased low by the factor $(n-1)/n$.

T0.4.7 Grids in two and more dimensions

A function of two variables, such as a likelihood $\mathcal{L}(a, b)$ or a Fourier-space amplitude $P(|\boldsymbol{k}|)$, is evaluated on a grid. `np.meshgrid(xs, ys, indexing="ij")` returns two arrays of the same two-dimensional shape: in the first, entry (i, j) is `xs[i]`; in the second, it is `ys[j]`. Any formula in `XX` and `YY` is then evaluated at every grid point at once. The keyword `indexing="ij"` makes the first index run over `xs`, as in matrix notation; without it, NumPy uses the plotting convention, with the axes swapped, which is a classic source of transposed images.

```
XX =
[[-1. -1. -1.]
 [ 0.  0.  0.]
 [ 1.  1.  1.]]
YY =
[[0. 1. 2.]
 [0. 1. 2.]
 [0. 1. 2.]]
np.hypot(XX, YY) =
[[1.     1.4142 2.2361]
 [0.     1.     2.    ]
 [1.     1.4142 2.2361]]
```

The Gaussian random fields of Chapter 7 need $|\boldsymbol{k}|$ on the grid of the fast Fourier transform. The library function that builds it is short:

Listing T0.25: The grid of wavenumbers for a d-dimensional box (`code/ch07/lib_fields.py`)

```
24 def kgrid(N: int, L: float, d: int, real: bool = True):
25     """|k| on the FFT grid (rfft layout if real=True), and the list of component arrays."""
26     k1 = 2 * np.pi * np.fft.fftfreq(N, d=L / N)
27     kl = 2 * np.pi * np.fft.rfftfreq(N, d=L / N) if real else k1
28     axes = [k1] * (d - 1) + [kl]
29     comps = np.meshgrid(*axes, indexing="ij")
30     kmag = np.sqrt(sum(c ** 2 for c in comps))
31     return kmag, comps
```

Line 26 gives the wavenumbers $k = 2\pi n/L$ in the order the FFT uses (Section T0.5.3). Line 28 builds a list with one copy for each dimension: `[k1] * (d - 1)` repeats a list, and `+` joins two lists. Line 29 hands that list to `np.meshgrid`; the star in `*axes` unpacks the list into separate arguments. Line 30 computes $|\boldsymbol{k}| = \sqrt{k_x^2 + k_y^2 + \dots}$ at every grid point with a generator expression inside `sum`. Line 31 returns two things.

T0.5 Random numbers, linear algebra and Fourier transforms

Three parts of NumPy carry the physics of most chapters. Random numbers make the simulated experiments of every Monte Carlo study. Linear algebra handles covariance matrices, least-squares fits and Fisher matrices. The Fourier transform turns a field or a time series into its modes, where Gaussian random fields and detector noise become simple. Each takes only a few names.

T0.5.1 Random numbers with a seed

A computer cannot toss a coin. It runs a deterministic recipe, a **pseudo-random generator**, whose output passes every statistical test for independent uniform draws (Chapter 6 builds such generators from scratch). The whole sequence is fixed by one integer, the **seed**: the same seed gives the same sequence, every time, on every machine. NumPy packages a generator as an object of type `Generator`, and every random draw is a method of that object:

call	draws
`rng.random(n)`, `rng.uniform(a, b, n)`	uniform on $[0,1)$ or $[a,b)$
`rng.standard_normal(n)`, `rng.normal(mu, s, n)`	Gaussian, $\mathcal{N}(0,1)$ or $\mathcal{N}(\mu, s^2)$
`rng.integers(a, b, n)`	integers from a to `b-1`
`rng.poisson(lam, n)`, `rng.exponential(tau, n)`	Poisson counts, exponential waiting times
`rng.choice(x, n)`, `rng.permutation(x)`	resampling, shuffling

The last argument may be a shape instead of a number: `rng.standard_normal((M, N))` is an $M \times N$ array, the "M experiments of N readings" layout of Section T0.4.6.

The book never creates a generator by hand. It calls `rng_for(chapter, name)` from `common.py`, which makes the seed from the script's own name (Section 0.6). The seeding script of Chapter 0 shows the consequence in four lines:

Listing T0.26: Same name, same random numbers; different name, unrelated ones (`code/ch00/06_reproducible_seeds.py`)

```
14 r1 = rng_for("ch00", "06_reproducible_seeds")     # seed = hash of
       "ch00/06_reproducible_seeds"
15 r2 = rng_for("ch00", "06_reproducible_seeds")     # same name -> same seed -> same stream
16 r3 = rng_for("ch00", "some_other_script")          # different name -> unrelated stream
17 a, b, c = r1.random(5), r2.random(5), r3.random(5)
```

Lines 14 and 15 build two generators from the same name, so `a` and `b` are identical arrays. Line 16 uses another name, so `c` is unrelated. An optional third argument, the **stream**, gives one script several independent generators: `rng_for("ch00", "05_three_detectors", 1)` is a different sequence from stream 0 (Section 6.5 shows why streams from one seed are independent).

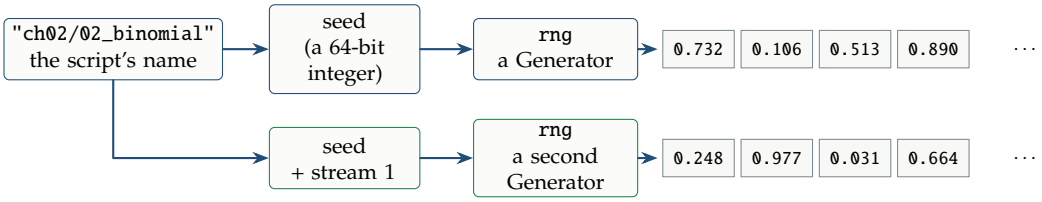

Figure T0.13: Where the random numbers of a script come from. The script's name fixes a seed, the seed fixes a generator, and the generator's sequence of draws (the numbers shown are only illustrative) is the same on every run. A stream number mixed into the seed gives a second, independent sequence.

The census checks that the book keeps this rule. Of the 216 files that draw random numbers, 197 create their generator with `rng_for`; nearly all of the rest are library files (`lib_*.py`, 15 of them) that receive a generator from the script that calls them, as `gaussian_field(..., rng=rng)` does in Section T0.3.5. A generator without a seed, `np.random.default_rng()`, appears 3 times, almost always as the fallback `if rng is None`. The old style of NumPy, a global generator set by `np.random.seed(...)` and used through `np.random.normal(...)`, appears 3 times.

Example: why a fixed seed matters for a comparison. Suppose we change the mask of a CMB simulation and the estimated variance of $\hat{C}_{100}$ moves by 2%. Is that the mask, or just different random skies? If both runs use the same seed, every sky is the same in the two runs, so the random part of the two estimates is largely shared and cancels in the difference; what remains is the mask effect plus whatever random part the two estimators do not share. If they use unrelated seeds, the 2% is the mask plus the Monte Carlo noise of two independent runs, of the same order. Fixed seeds do not make the comparison exact. They make the two runs share their noise, which shrinks the noise of the difference, and Section T0.10.5 shows the size of the gain.

Watch out: A generator made inside a loop

Writing `rng = rng_for(...)` *inside* a loop restarts the sequence at every pass, so every "independent" repetition gets the same random numbers. The generator is made once, at the top of the script, and then drawn from repeatedly. (When fresh but reproducible streams

are wanted per repetition, pass the repetition number as the stream: `rng_for(chapter, name, i)`.)

T0.5.2 Linear algebra

Matrices are two-dimensional arrays, and the matrix product is the operator `@`: `A @ B`, `A @ x`, `x @ C @ x` for $x^\mathsf{T}Cx$ (`x.T` or `A.T` is the transpose, which does nothing to a one-dimensional array). It appears in 28% of the scripts. The star `A * B` is *not* the matrix product: it multiplies element by element. Four functions from `np.linalg` do the rest:

- `np.linalg.solve(A, b)` returns the x with $Ax = b$;
- `np.linalg.cholesky(C)` returns the lower-triangular L with $LL^\mathsf{T} = \mathbf{C}$, for a symmetric positive-definite $\mathbf{C}$ such as a covariance matrix;
- `np.linalg.eigh(C)` returns the eigenvalues (in increasing order) and the eigenvectors (as columns) of a symmetric matrix;
- `np.linalg.inv(A)` returns the inverse matrix.

```
L =
[[2.     0.    ]
 [0.9    0.4359]]
np.allclose(L @ L.T, C) = True
lam = array([0.1569, 4.8431])
np.linalg.solve(C, b) = array([-3.4211,  8.1579])
np.linalg.inv(C) @ b = array([-3.4211,  8.1579])
np.linalg.cond(C) = 30.9
Hilbert n = 10: cond = 1.6e+13, residual solve = 8.5e-17, inv = 3.6e-05, error of x =
    2.3e-05
n = 2000: solve 44 ms, inv @ b 180 ms, cholesky 57 ms
```

Cholesky: making correlated noise. The commonest use of `cholesky` in the book is to draw correlated Gaussian vectors with a given covariance $\mathbf{C}$. Draw a vector z of independent standard Gaussians and set $x = Lz$. Why does x have covariance $\mathbf{C}$? Because

$$\mathrm{Cov}(x) \overset{(1)}{=} \mathbb{E}[xx^\mathsf{T}] \overset{(2)}{=} \mathbb{E}[Lzz^\mathsf{T}L^\mathsf{T}] \overset{(3)}{=} L\,\mathbb{E}[zz^\mathsf{T}]\,L^\mathsf{T} \overset{(4)}{=} L\,\mathbb{1}\,L^\mathsf{T} \overset{(5)}{=} \mathbf{C}.$$

(1) x has zero mean, because z does, so its covariance is $\mathbb{E}[xx^\mathsf{T}]$.
(2) $x^\mathsf{T} = (Lz)^\mathsf{T} = z^\mathsf{T}L^\mathsf{T}$.
(3) L is a fixed matrix, so it comes out of the expectation.
(4) Independent standard Gaussians have unit variances and zero covariances.
(5) The defining property of the Cholesky factor.

In code, with many draws stored as the rows of an array `z`, the product Lz for every row at once is `z @ L.T`. That is exactly line 32 of the correlated-field script of Section 6.9.2:

Listing T0.27: Correlated Gaussian pairs from independent ones (`code/ch06/23_cholesky_field.py`)

```
29 C2 = np.array([[1.0, 1.6], [1.6, 4.0]])
30 L2 = np.linalg.cholesky(C2)
31 z = rng.standard_normal((50_000, 2))
32 xy = z @ L2.T                                    # each row is L z
33 S2 = np.cov(xy, rowvar=False)
```

Line 31 draws 50 000 rows of two independent Gaussians, line 32 turns each row into a correlated pair, and line 33 checks the result with `np.cov(..., rowvar=False)`, the sample covariance when the variables are the columns.

Solve, do not invert. The quantity $\boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}$ appears in every Gaussian likelihood and every Fisher matrix. It is tempting to write `d @ np.linalg.inv(C) @ d`. The better form is `d @ np.linalg.solve(C, d)`: it asks for $\boldsymbol{y} = \mathbf{C}^{-1}\boldsymbol{d}$ by solving $\mathbf{C}\boldsymbol{y} = \boldsymbol{d}$, without ever forming the inverse. The Fisher matrix of the CMB forecast in Section 10.6.1 is written this way:

Listing T0.28: A Fisher matrix summed over multipoles, with solve instead of inv (`code/ch10/lib_fisher10.py`)

```
183 def fisher_spectra(dC, C, NT, NP, fsky, lmin, lmax):
184     """The same T+E Fisher matrix written as sum_l dC^T Cov^-1 dC, with Cov the 3x3
        covariance of the
185     estimated (TT, EE, TE) spectra (Verde 2010, eq. 27 with noise added)."""
186     F = np.zeros((6, 6))
187     for l in range(lmin, lmax + 1):
188         a = C["TT"][l] + NT[l]; b = C["TE"][l]; e = C["EE"][l] + NP[l]
189         nu = (2 * l + 1) * fsky
190         cov = np.array([[2 * a * a, 2 * b * b, 2 * a * b],
191                         [2 * b * b, 2 * e * e, 2 * e * b],
192                         [2 * a * b, 2 * e * b, b * b + a * e]]) / nu
193         d = np.array([dC["TT"][:, l], dC["EE"][:, l], dC["TE"][:, l]])
194         F += d.T @ np.linalg.solve(cov, d)
195     return F
```

For each multipole ℓ (line 187), lines 190–192 build the 3×3 covariance of the estimated TT, EE and TE spectra, line 193 stacks the derivatives of the three spectra with respect to the six parameters into a 3×6 array `d`, and line 194 adds $\boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}$, a 6×6 matrix, to the running sum.

Why is `solve` better? There are two reasons. The first is speed: solving needs one factorisation of $\mathbf{C}$, about $\frac{2}{3}n^3$ operations, while inverting needs about $2n^3$ and then a matrix product. The tour measured, for $n = 2000$, 44 ms for `solve` against 180 ms for `inv` followed by a product. The second is accuracy, and it matters for badly conditioned matrices, where small rounding errors are amplified. The tour tried both on the Hilbert matrices $H_{ij} = 1/(i+j+1)$, which become nearly singular as their size grows (Figure T0.14, left). For $n = 10$, with condition number $\kappa \approx 1.602\times10^{13}$ (Section T0.10.4 explains this number), `solve` returns an $\boldsymbol{x}$ that satisfies the equations to 8.502×10^{-17} in relative terms, the best that double precision allows, while `inv` leaves a residual of 3.584×10^{-5}. Neither recovers $\boldsymbol{x}$ itself better than 2.272×10^{-5}, because no method can beat the conditioning of the problem.

So when is `inv` right? When the inverse matrix itself is the answer wanted. Turning a Fisher matrix $\mathbf{F}$ into the covariance of the parameters, $\mathbf{F}^{-1}$, is the commonest case, and it accounts for most of the 105 calls of `np.linalg.inv` in the book (against 29 of `solve`, 22 of `cholesky` and 13 of `eigh`). Those matrices are small (6×6 or so) and well conditioned, and there `inv` is harmless. The rule is: `inv` when the matrix A^{-1} is the result, `solve` (or `cholesky`) when A^{-1} only stands inside a formula such as $A^{-1}\boldsymbol{b}$ or $\boldsymbol{b}^{\mathsf{T}}A^{-1}\boldsymbol{b}$.

Example: eigenvectors as the axes of an ellipse. For the covariance $\mathbf{C} = \left(\begin{smallmatrix} 4 & 1.8 \\ 1.8 & 1 \end{smallmatrix}\right)$ of the tour, `eigh` returns the eigenvalues $\lambda_1 \approx 0.157$ and $\lambda_2 \approx 4.843$. Their sum is $5 = \operatorname{tr}\mathbf{C}$ and their product $0.76 = \det\mathbf{C} = 4 - 1.8^2$, as they must be. The 1σ contour of a two-dimensional Gaussian with this covariance is an ellipse whose axes point along the eigenvectors, with half-lengths $\sqrt{\lambda_1} \approx 0.40$ and $\sqrt{\lambda_2} \approx 2.20$. Section 1.13 draws it with exactly this recipe (the function `ellipse` in `code/ch01/18_covariance_transform.py`).

T0.5.3 The fast Fourier transform

The discrete Fourier transform of N numbers $x_0, \dots, x_{N-1}$ is

$$X_k = \sum_{n=0}^{N-1} x_n \, e^{-2\pi i k n / N}, \qquad k = 0, \dots, N-1,$$

the same sign convention as $\tilde{h}(f) = \int h(t) e^{-2\pi i f t}\, \mathrm{d}t$. Computed term by term it costs N^2 operations. The **fast Fourier transform** (FFT) computes the same numbers in about $N \log_2 N$ operations, by splitting the sum into its even and odd terms again and again; for a million points that is fifty thousand times less work, which is why every power-spectrum calculation of the book is done in Fourier space. NumPy's functions live in `np.fft`:

- `np.fft.fft(x)` gives all N complex X_k; `np.fft.ifft` inverts it.
- For real data, $X_{N-k} = X_k^*$, so half of the numbers are redundant. `np.fft.rfft(x)` returns only $k = 0, \dots, N/2$, that is $N/2 + 1$ numbers, and `np.fft.irfft` inverts it. `rfftn` and `irfftn` do the same in several dimensions (the random fields of Chapter 7).
- `np.fft.rfftfreq(N, d=dt)` gives the frequency of each entry, $f_k = k/(N\,\Delta t)$, and `fftfreq` the same for the full transform, with the negative frequencies in the second half.

```
t.size = 2000   F.size = 1001   f[1] = 0.5   f[-1] = 500.0
peak at f = 50.0 Hz
Parseval: sum x^2 = 2105.229,  sum |X|^2 / N = 2105.229
```

The tour puts a weak tone, amplitude 0.5 at 50 Hz, into Gaussian noise of standard deviation 1, samples it at 1000 Hz for 2 s, and transforms (Figure T0.14, right). Two numbers follow from the sampling alone. The frequency step is $\Delta f = 1/T = 0.5$ Hz and the highest frequency is the Nyquist frequency $f_s/2 = 500$ Hz, which is why `f[1] = 0.5` and `f[-1] = 500.0`. The tone, invisible by eye in the time series, stands out at 50.0 Hz, about 180 times above the median noise power. The last printed line checks Parseval's theorem in NumPy's convention, $\sum_n x_n^2 = \frac{1}{N}\sum_k |X_k|^2$: the factor $1/N$ is where conventions differ between libraries and books, and checking Parseval is the quickest way to find out which one a function uses.

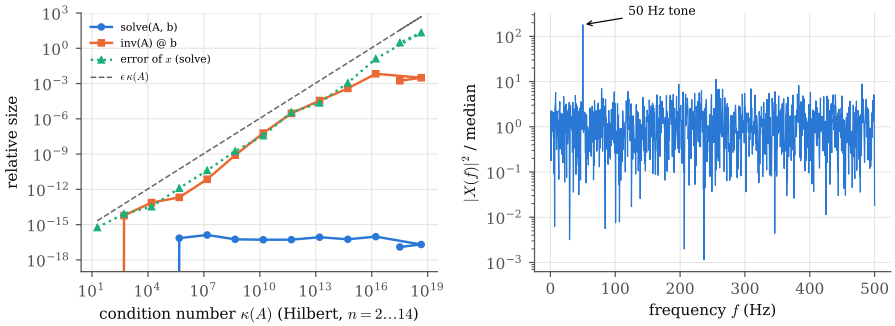

Figure T0.14: Left: solving $A\boldsymbol{x} = \boldsymbol{b}$ for Hilbert matrices of growing size. With `solve` (blue) the residual stays at the rounding level for every condition number; with `inv` followed by a product (orange) it grows with the condition number. The error of $\boldsymbol{x}$ itself (green) follows $\epsilon\kappa$ (dashed) whatever the method. Right: the power spectrum of 2 s of noise containing a weak 50 Hz tone, normalised to its median: one Fourier coefficient carries the tone.

In the book, a typical FFT is two lines inside a larger recipe. The autocorrelation of a Markov chain (Section 9.12.2) is computed with the Wiener–Khinchin theorem: the autocorrelation is the inverse transform of the power spectrum.

Listing T0.29: The autocorrelation of a chain through two FFTs (`code/ch09/lib_mcmc9c.py`)

```
74 def acf(x, maxlag=None):
75     """Normalised autocorrelation rho(k) of a 1-D series, via FFT (zero padding)."""
76     x = np.asarray(x, dtype=float) - np.mean(x)
77     n = x.size
78     f = np.fft.rfft(x, n=2 * n)
79     r = np.fft.irfft(f * np.conj(f))[:n]
80     r /= r[0]
81     return r if maxlag is None else r[: maxlag + 1]
```

Line 76 subtracts the mean. Line 78 transforms with `n=2 * n`, which pads the series with zeros to twice its length, so that the circular wrap-around of the discrete transform does not mix the end of the chain with its beginning. Line 79 multiplies the transform by its complex conjugate (the power) and transforms back; the first n entries are the autocovariance at lags $0, \ldots, n-1$. Line 80 divides by the value at lag 0, so that $\rho(0) = 1$. Done directly, this would cost n^2 operations, about 10^{10} for a chain of 10^5 steps; through the FFT it takes milliseconds.

T0.6 SciPy: distributions, integrals, roots and minima

NumPy does arithmetic on arrays. SciPy adds the classic numerical recipes that a physicist would otherwise copy from a handbook: the densities and tail probabilities of the standard distributions, numerical integration, root finding, minimisation, special functions and interpolation. It is used in 53% of the scripts but makes only 3% of the calls, because one SciPy call does a lot of work. Six tools cover almost all of it. Each is shown answering one small physics question in `code/chT0/03_scipy_tour.py`, with an answer we can check by hand, and then in a real script.

T0.6.1 Probability distributions

`scipy.stats` contains one object per distribution: `stats.norm`, `stats.poisson`, `stats.binom`, `stats.chi2`, `stats.t`, `stats.expon`, and about a hundred more. Every object answers the same five questions, which are the five things the earlier chapters ask of a distribution (Figure T0.16, left):

method	question	formula
`pdf(x)` (`pmf` if discrete)	how dense is the probability at x?	$p(x)$
`cdf(x)`	how likely is a value at most x?	$F(x) = \mathrm{P}(X \le x)$
`sf(x)`	how likely is a value above x?	$1 - F(x)$, computed directly
`ppf(q)`	below which value lies a fraction q?	$F^{-1}(q)$
`rvs(size=n)`	give me n random draws	

Shape parameters come first (`stats.poisson.pmf(k, mu)`, `stats.chi2.sf(x, df)`), and every continuous distribution also takes `loc` and `scale`, which shift and stretch it: `stats.norm.pdf(x, loc=mu, scale=sigma)` is the Gaussian of mean μ and standard deviation σ. The logarithmic versions `logpdf`, `logpmf` and `logsf` are what likelihoods use, because a product of many small densities underflows while a sum of their logarithms does not (Section T0.11).

Listing T0.30: One distribution object, several questions (`code/chT0/03_scipy_tour.py`)

```
24 # (a) one distribution object, five questions
25 z95 = stats.norm.ppf(0.975)                    # where does the cdf reach 0.975?
26 p5 = stats.norm.sf(5.0)                        # P(Z > 5) = 1 - cdf(5), computed without
       cancellation
```

```
27 x = stats.norm.rvs(loc=2.0, scale=0.5, size=10_000, random_state=rng)
28 out.update(TzZninetyfive=f"{z95:.4f}", TzPfive=p5, TzBackCdf=f"{stats.norm.cdf(z95):.4f}",
29             TzRvsMean=f"{x.mean():.4f}", TzRvsStd=f"{x.std(ddof=1):.4f}")
```

Line 25 asks where the Gaussian cdf reaches 0.975: the answer, 1.9600, is the familiar "1.96σ" of a two-sided 95% interval, and `cdf` of it gives back 0.9750. Line 26 asks for the probability of a fluctuation above 5σ: 2.867×10^{-7}, the discovery threshold of particle physics. Line 27 draws 10^4 values from $\mathcal{N}(2, 0.5^2)$ using the book's generator (`random_state=rng`); their sample mean and standard deviation are 2.0049 and 0.5039.

The same two functions do the work of the p-value-to-sigma conversion of Section 4.9.1:

Listing T0.31: Sigmas to one- and two-sided p-values (`code/ch04/09_p_to_z.py`)

```
23 Z = np.arange(1, 7)
24 p1 = stats.norm.sf(Z)
25 p2 = 2 * stats.norm.sf(Z)
```

`stats.norm.sf(Z)` acts on the whole array $Z = 1, \ldots, 6$ at once, like any NumPy function. The reverse direction, from a p-value to a number of sigmas, is `stats.norm.isf(p)`, the inverse of `sf`.

Watch out: `1 - cdf` in the tail

For x far in the upper tail, $F(x)$ is a number like 0.9999999997, and $1 - F(x)$ keeps only the few digits that differ from 1. `sf(x)` computes the tail directly and keeps all sixteen. At 5σ the difference is still small; beyond about 8σ, `1 - cdf` returns exactly 0 while `sf` is still accurate (Section T0.11).

T0.6.2 Integrals

`integrate.quad(f, a, b)` integrates a function of one variable from `a` to `b` (either limit may be `np.inf`) and returns *two* numbers: the value and an estimate of its absolute error. It evaluates `f` at cleverly chosen points, compares two rules of different order on each piece of the interval, and keeps subdividing the pieces where they disagree. The tour checks it against the 5σ tail of line 26:

Listing T0.32: The 5σ tail again, by integrating the density (`code/chT0/03_scipy_tour.py`)

```
31 # (b) the same tail by integrating the density from 5 to infinity
32 tail, tail_err = integrate.quad(stats.norm.pdf, 5.0, np.inf)
33 out.update(TzQuadTail=tail, TzQuadErr=tail_err, TzQuadRel=abs(tail - p5) / p5)
```

quad returns 2.867×10^{-7} with an error estimate of 8.853×10^{-10}, and the value differs from `sf(5)` by a relative 5.328×10^{-9}. The comma on the left, `tail, tail_err = ...`, unpacks the two returned numbers. Many scripts keep only the value, writing `quad(...)[0]`, as the detector-smearing check of Section 1.10 does:

Listing T0.33: Expected counts per histogram bin from integrals of a density (`code/ch01/13_detector_smearing.py`)

```
60 frac_neg_exact = quad(p_meas, -np.inf, 0)[0]
61 counts, edges = np.histogram(E_meas, bins=140, range=(-20, 120))
62 expected = np.array([N * quad(p_meas, a, b)[0] for a, b in zip(edges[:-1], edges[1:])])
```

Line 62 is a list comprehension that integrates the density over every bin, `zip(edges[:-1], edges[1:])` pairing each left edge with the next one. Section T0.10.3 shows how the error estimate can be wrong, and what to do about it.

T0.6.3 Roots

Many statistical answers are the solution of one equation in one unknown: the parameter value where $\ln \mathcal{L}$ has dropped by $\frac{1}{2}$, the mean μ at which observing so few events would have probability 5%, the Lagrange multiplier of a maximum-entropy problem. `optimize.brentq(f, a, b)` finds a zero of `f` between `a` and `b`. It requires a **bracket**: `f(a)` and `f(b)` must have opposite signs, so that a continuous `f` must cross zero in between. It then shrinks the bracket, combining halving (always safe) with interpolation steps (fast when f is smooth), until the zero is pinned to about 10^{-12} (Figure T0.15).

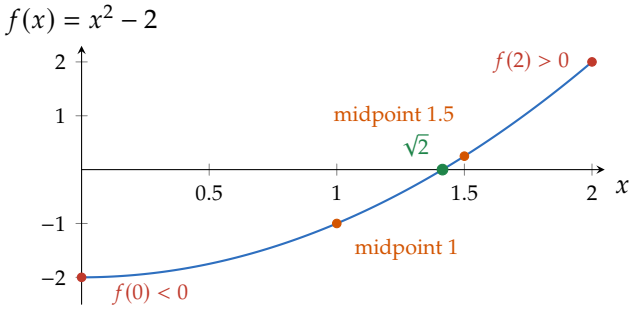

Figure T0.15: A bracket and its shrinking. $f(0) = -2 < 0$ and $f(2) = 2 > 0$ (red points), so a zero lies in $[0, 2]$. The midpoint 1 has $f < 0$, so the zero is in $[1, 2]$; the next midpoint 1.5 has $f > 0$, so it is in $[1, 1.5]$ (orange points). `brentq` mixes such halvings with faster interpolation steps and stops at $\sqrt{2}$ (green) to twelve digits. On $[0, 1]$ there is no sign change and `brentq` refuses to start.

The tour computes the 95% upper limit on a Poisson mean after observing n events: the μ at which $\mathrm{P}(N \le n \mid \mu) = 0.05$.

Listing T0.34: An upper limit as the root of an equation (`code/chT0/03_scipy_tour.py`)

```
35 # (c) Poisson upper limit: the mean mu at which seeing n or fewer events has probability
       0.05
36 def upper_limit(n, cl=0.95):
37     return optimize.brentq(lambda mu: stats.poisson.cdf(n, mu) - (1 - cl), 1e-6, 50.0)
38 mu0, mu3 = upper_limit(0), upper_limit(3)
39 out.update(TzUpperZero=f"{mu0:.4f}", TzUpperZeroExact=f"{np.log(20):.4f}",
       TzUpperThree=f"{mu3:.3f}")
```

For $n = 0$ the equation is $e^{-\mu} = 0.05$, whose exact root is $\ln 20 = 2.9957$; `brentq` gives 2.9957. For $n = 3$ it gives 7.754 (Figure T0.16, right). The likelihood interval of the decay-time example (Section T0.3.5, lines 39–40 there) is the same pattern, with two brackets, one on each side of the maximum.

T0.6.4 Minima

Maximum likelihood means finding the parameters that make $-\ln \mathcal{L}$ smallest. `optimize.minimize(f, x0)` starts at the guess `x0` and walks downhill. It returns a result object whose most useful entries are `res.x` (the minimising parameters), `res.fun` (the value there), `res.success` (whether the method believes it converged) and `res.nit` (how many iterations it took). The `method` keyword chooses the walk: `"Nelder-Mead"` needs only function values and is robust; `"BFGS"` and `"L-BFGS-B"` use gradients (estimated numerically if not given) and are faster on smooth problems; `"L-BFGS-B"` also accepts `bounds`. Extra fixed inputs, such as the data, are handed over with `args=(...,)`.

Listing T0.35: Maximum likelihood for Gaussian data by minimisation (`code/chT0/03_scipy_tour.py`)

```
# (d) maximum likelihood by minimising minus the log-likelihood over (mu, ln sigma)
def neg_lnL(theta, data):
    mu, ln_sig = theta
    return -np.sum(stats.norm.logpdf(data, mu, np.exp(ln_sig)))
res = optimize.minimize(neg_lnL, x0=[0.0, 0.0], args=(x,), method="Nelder-Mead")
mu_hat, sig_hat = res.x[0], np.exp(res.x[1])
out.update(TzMinMu=f"{mu_hat:.4f}", TzMinSig=f"{sig_hat:.4f}",
    TzMeanCheck=f"{x.mean():.4f}",
           TzStdCheck=f"{x.std(ddof=0):.4f}", TzMinIters=res.nit)
```

Two habits are visible here. The width is fitted as $\ln\sigma$ (line 43), so that any real number is an allowed value and the minimiser cannot wander to a negative σ. And the result is checked against an answer known in closed form: for Gaussian data the maximum-likelihood estimates are the sample mean and the divide-by-n standard deviation. The minimiser finds $\hat{\mu} = 2.0050$ and $\hat{\sigma} = 0.5039$ in 69 iterations; the closed forms give 2.0049 and 0.5039.

The Poisson-binned fit of Section 3.11.4 wraps `minimize` in a small function, so that three different goodness-of-fit functions can be minimised with the same call:

Listing T0.36: A minimiser wrapped in a function, with tightened tolerances (`code/ch03/12_poisson_bins.py`)

```
def fit(fun, n):
    start = np.array([n.sum(), 1.0])
    r = optimize.minimize(fun, start, args=(n,), method="Nelder-Mead",
                          options=dict(xatol=1e-7, fatol=1e-9, maxiter=4000))
    return r.x, r.fun
```

The function to minimise, `fun`, is itself an argument (functions can be passed around like numbers). `options=dict(xatol=..., fatol=..., maxiter=...)` tightens the stopping rules, because the default tolerances of Nelder–Mead are loose for a study that compares estimators to many digits. Section T0.10.3 shows what happens when a minimiser stops too early, and how `res.success` reports it.

T0.6.5 Special functions and interpolation

`scipy.special` contains the functions of mathematical physics: Γ and its logarithm `gammaln`, the beta function, binomial coefficients `comb`, error functions, Bessel functions, the Voigt profile. The one the book uses most is `gammaln`, because likelihoods of counts contain factorials, and factorials overflow: $200! \approx 10^{375}$ is far beyond the largest double, about 1.8×10^{308}. Its logarithm is a modest number:

Listing T0.37: $\ln 200!$ is fine; 200! as a float is not (`code/chT0/03_scipy_tour.py`)

```
# (e) logs of huge numbers: ln(200!) is fine, 200! as a float is not
ln_fact = special.gammaln(201)
try:
    float(math.factorial(200))
    overflow = "no"
except OverflowError:
    overflow = "yes"
out.update(TzLnFact=f"{ln_fact:.3f}", TzLnFactCheck=f"{math.lgamma(201):.3f}",
    TzFactOverflow=overflow)
```

$\ln 200! = \ln\Gamma(201) = 863.232$, and Python's own `math.lgamma` agrees (863.232). Converting 200! itself to a float overflows (`OverflowError`: yes); the `try`/`except` block of lines 52–56 catches that error and records it instead of stopping (Section T0.8). The de Moivre–Laplace check of Section 2.9.4 uses `special.gammaln(n_st + 1)` for exactly this reason.

Interpolation estimates a function between tabulated points. `np.interp(x, xt, yt)` joins the table (x_t, y_t) by straight lines; `interpolate.CubicSpline(xt, yt)` by smooth cubic pieces whose first and second derivatives are continuous. For a coarse table of six values of $\sin x$ on $[0, \pi]$ the tour finds a largest error of 0.0489 for straight lines and 0.0027 for the spline (lines 59–66). Straight lines are the right choice when the table is fine and the curve may have kinks; a spline when the table is coarse and the curve is smooth. `np.interp` is the one the book calls most often, typically to read a tabulated CAMB spectrum or a transfer function at new multipoles.

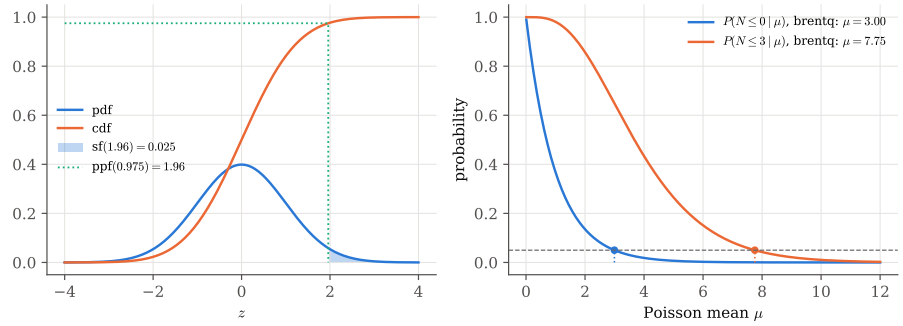

Figure T0.16: Left: the standard Gaussian's density (pdf) and cumulative distribution (cdf). The shaded tail above 1.96 is `sf(1.96)` = 0.025, and the dotted path from 0.975 on the cdf down to the axis is `ppf(0.975)` = 1.96. Right: the probability of observing at most n events as a function of the Poisson mean, for $n = 0$ and 3; `brentq` finds where each curve crosses 0.05 (dashed), the 95% upper limits.

T0.7 Matplotlib, files and folders

Every figure drawn from data in the book is made by a dozen Matplotlib calls, and every expensive result is kept on disk by two NumPy calls. Both are learned once.

T0.7.1 A figure is a canvas holding axes

Matplotlib thinks of a picture in two layers (Figure T0.17). The **figure** is the whole canvas, the thing saved to a PDF file. On it sit one or more **axes**: rectangular panels, each with its own coordinate system, ticks, labels and legend. Everything that is drawn is drawn *on an axes*. The book always creates both at once,

```
fig, ax = plt.subplots()      or      fig, axes = plt.subplots(2, 3)
```

which returns the figure and one axes, or the figure and a 2×3 array of axes, `axes[row, column]`. Everything else is a method of `ax`:

call	draws
`ax.plot(x, y)`, `ax.plot(x, y, "o")`	a line through the points, or markers only
`ax.loglog`, `ax.semilogx`, `ax.semilogy`	the same with logarithmic axes
`ax.hist(data, bins=40, density=True)`	a histogram, normalised to a density
`ax.errorbar(x, y, yerr=s, fmt="o")`	points with error bars
`ax.fill_between(x, lo, hi, alpha=0.3)`	a shaded band
`ax.imshow(image, origin="lower")`	a two-dimensional array as an image
`ax.axhline(y)`, `ax.axvline(x)`	a horizontal or vertical reference line
`ax.set_xlabel`, `set_ylabel`, `set_title`, `set_xlim`	labels and ranges
`ax.legend()`	a key built from the `label=...` of each curve

Finally `fig.tight_layout()` packs the panels so that labels do not overlap, and the book's `savefig(fig, "chNN", "name")` writes the PDF into `figures/chNN/` (Section 0.6). Colours come from the house palette set by `setup()`, and every analytic curve is drawn by `theory_line(ax, x, y)` as a black dashed line on top of the simulation it is compared with.

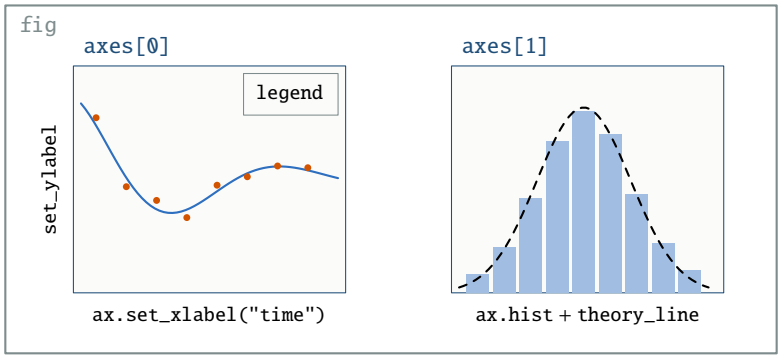

Figure T0.17: The two layers of a Matplotlib picture. The figure (`fig`) is the canvas that is saved; each axes is one panel with its own coordinates, and everything is drawn by a method of an axes. `plt.subplots(1, 2)` creates this layout and returns the figure and the array of the two axes.

The gallery script `code/chT0/04_plot_gallery.py` draws one panel of each common kind from simulated data (Figure T0.18). A real figure of the book is the same calls in a slightly longer sequence. Here is the log-likelihood plot of the decay-time example (Section 3.12.4):

Listing T0.38: A complete figure: curve, theory, reference lines, labels, legend, save (`code/ch03/09_mle_decay.py`)

```
42 fig, ax = plt.subplots(figsize=(5.2, 3.2))
43 ss = np.linspace(0.6 * tau_hat, 1.6 * tau_hat, 400)
44 ax.plot(ss, lnL(ss, t) - lmax, color=SERIES[0],
       label=r"$\ln\mathcal{L}(\tau)-\ln\mathcal{L}_{\max}$")
45 theory_line(ax, ss, -0.5 * ((ss - tau_hat) / sig_curv) ** 2, label="parabola, curvature at
       max")
46 ax.axhline(-0.5, color=SERIES[1], lw=1, ls=":")
47 for v in (lo, hi):
48     ax.axvline(v, color=SERIES[1], lw=0.8, ls=":")
49 ax.set_ylim(-3, 0.3)
50 ax.set_xlabel(r"$\tau$"); ax.set_ylabel(r"$\Delta\ln\mathcal{L}$")
51 ax.legend(fontsize=7, loc="lower center")
52 fig.tight_layout()
53 savefig(fig, "ch03", "mle_decay_lnL")
```

Line 42 makes one axes of 5.2×3.2 inches. Line 44 plots $\ln \mathcal{L}(\tau) - \ln \mathcal{L}_{\max}$ on a grid of 400 values of τ, with a LaTeX label for the legend (the `r` before the string keeps the backslashes, Section T0.3.2). Line 45 overlays the parabola that has the same curvature at the maximum. Lines 46–48 add a dotted horizontal line at $-\frac{1}{2}$ and vertical lines at the two roots found by `brentq`. Lines 49–51 set the range, the axis labels and the legend; line 53 saves.

Example: why a histogram needs `density=True`. A histogram of 5000 draws in bins of width Δx has heights n_j that add up to 5000. A density $p(x)$ integrates to 1. To compare them, the heights must be divided by the number of draws and by the bin width:

$$\hat{p}_j \overset{(1)}{=} \frac{n_j}{N\,\Delta x}, \qquad \sum_j \hat{p}_j\,\Delta x \overset{(2)}{=} \frac{1}{N}\sum_j n_j \overset{(3)}{=} 1.$$

(1) The fraction of draws in bin j, n_j/N, estimates $\int_{\text{bin}} p\,\mathrm{d}x \approx p(x_j)\,\Delta x$; divide by Δx.

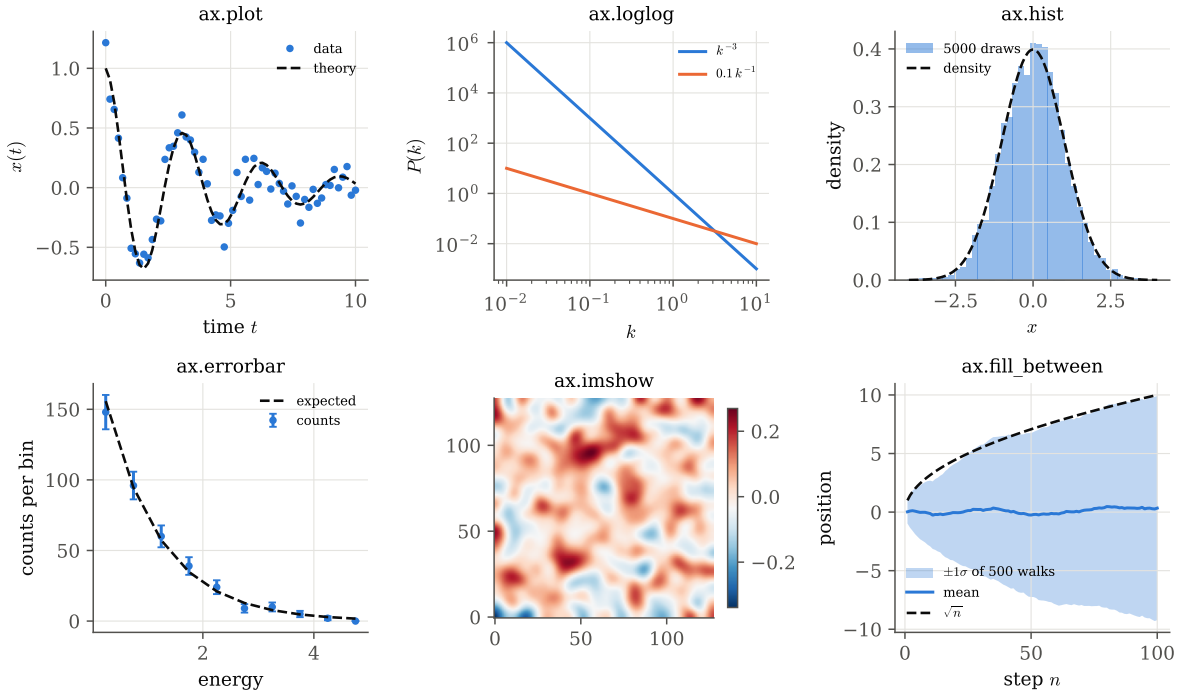

Figure T0.18: Six kinds of panel and the call that draws each, from simulated data: noisy samples of a damped oscillation with the curve they scatter around (`plot`), two power laws as straight lines on logarithmic axes (`loglog`), 5000 Gaussian draws against their density (`hist`), Poisson counts with $\sqrt{n}$ error bars (`errorbar`), a smoothed random field (`imshow`), and the $\pm1\sigma$ band of 500 random walks around their mean, against $\sqrt{n}$ (`fill_between`).

(2) Multiply each height by its bin width and add.
(3) Every draw falls in some bin (if the bins cover the data), so the counts add up to N.

`ax.hist(x, bins=40, density=True)` does exactly this division, which is why the histogram and the black dashed density in the third panel of Figure T0.18 lie on top of each other. Without `density=True` the bars would be $N\,\Delta x \approx 5000 \times 0.2 = 1000$ times taller than the curve (for 40 bins over a range of about 8, $\Delta x \approx 0.2$).

Watch out: `plt` versus `ax`

Many examples on the internet draw with `plt.plot(...)`, which draws on "the current axes" that Matplotlib keeps in the background. With several panels, "current" is easily not the panel intended. The book always draws with `ax.plot(...)` on an axes it holds by name, and calls `plt` only to create the figure.

T0.7.2 Files, folders and caches

Some results cost minutes or hours: a thousand simulated CMB skies, a long Markov chain, a hundred calls of a Boltzmann code. They are computed once and kept in the folder `data/`, in NumPy's own file format. Two calls do it. `np.savez(path, name1=array1, name2=array2)` writes several arrays into one `.npz` file, each under a name. `z = np.load(path)` opens it, and `z["name1"]` gives back the first array, bit for bit.

Paths are handled by Python's `pathlib`. A `Path` is a file or folder name that knows its structure: `NOTES / "data" / "ch08"` joins names with the operator `/`, whatever the operating system's separator; `path.exists()` asks whether the file is there; `path.mkdir(parents=True,`

`exist_ok=True`) creates a folder (and any missing folders above it) unless it already exists; `path.parents[1]` is two levels up (Section T0.2).

The two combine into the **cache** pattern: if the file exists, load it; otherwise compute, save, and return. The Monte Carlo library of Section 8.5 writes it once, as a function that takes the computation itself as an argument:

Listing T0.39: Compute once, then load: a cache in eleven lines (`code/ch08/lib_cmbsim.py`)

```
252 def cached(name: str, make, force: bool = False):
253     """Load data/ch08/<name>.npz if it exists, else run make() -> dict, save it and return
        it."""
254     DATA.mkdir(parents=True, exist_ok=True)
255     path = DATA / f"{name}.npz"
256     if path.exists() and not force:
257         z = np.load(path)
258         return {k: z[k] for k in z.files}
259     d = make()
260     np.savez(path, **d)
261     print(f"[cache] wrote {path}")
262     return d
```

`make` is a function that returns a dictionary of arrays (line 252 receives it without calling it). Line 254 makes sure `data/ch08` exists. If the file is already there and recomputing was not forced (line 256), lines 257–258 load it and turn it back into a dictionary with a comprehension over `z.files`, the list of the names stored in it. Otherwise line 259 calls `make()`, line 260 saves every entry of the dictionary with `**d` (which hands each key–value pair to `np.savez` as a keyword argument), and line 262 returns the result. A thousand skies are simulated the first time; every later run of every script that needs them reads them in a fraction of a second (Figure T0.19).

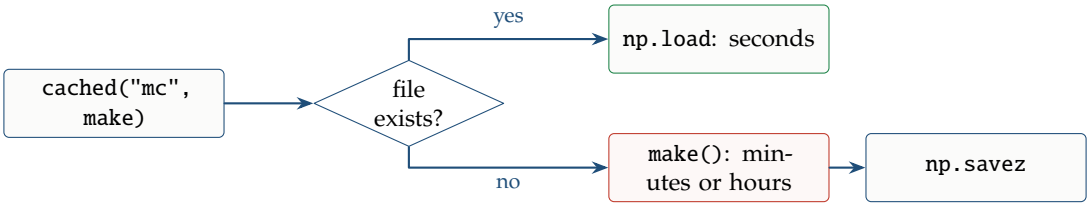

Figure T0.19: The cache pattern of `lib_cmbsim.cached`. The expensive branch (red) runs once and leaves a file behind; every later call takes the cheap branch (green). Deleting the file, or passing `force=True`, forces a fresh computation.

The fiducial CMB spectra shared by the whole book are cached the same way, in `code/camb_fiducial.py`:

Listing T0.40: Load the cached CAMB spectra, computing them on first use (`code/camb_fiducial.py`)

```
25 def load_fiducial(spec="TT"):
26     if not PATH.exists():
27         main()
28     z = np.load(PATH)
29     return z["ell"], z[spec]
30
31
32 def main():
33     ell, tot = compute()
34     PATH.parent.mkdir(exist_ok=True)
35     np.savez(PATH, ell=ell, TT=tot[:, 0], EE=tot[:, 1], BB=tot[:, 2], TE=tot[:, 3],
36              **{f"param_{k}": v for k, v in FIDUCIAL.items()})
37     print(f"wrote {PATH}")
```

`load_fiducial()` computes and saves the spectra only if `data/camb_fiducial.npz` is missing (lines 26–27), and otherwise loads them (line 28) and returns the multipoles and the requested spectrum (line 29). Line 36 shows one more use of **: it unpacks a dictionary built on the spot, so that the parameters of the fiducial model are stored in the same file as `param_H0`, `param_ombh2`, and so on, and anyone opening the file can see which model produced it.

Watch out: A stale cache

A cache does not know that the code which produced it has changed. If a simulation is corrected but its cache file is left in place, every script keeps reading the old, wrong results. After changing a computation that feeds a cache, delete the file (or run once with `force=True`).

T0.8 Seen a few times: rare features and two black boxes

The census (Figure T0.4) found a sharp drop after the core of the language: a few constructions appear in fewer than one script in ten. They can be skipped on a first reading and looked up here when met. The same holds for the two physics libraries, healpy and CAMB, which the book uses as black boxes: we need to know what goes in and what comes out, not how they work inside.

T0.8.1 Classes and data classes

A **class** bundles data together with the functions that act on it. The book defines classes in only 2% of its scripts, always for the same reason: a group of settings that belong together and some quantities derived from them. The clearest example is the description of a CMB experiment in the Monte Carlo library of Section 8.2.1:

Listing T0.41: An experiment as a data class: settings, and quantities derived from them (`code/ch08/lib_cmbsim.py`)

```
68 @dataclass
69 class Experiment:
70     """A full-sky temperature experiment: resolution, depth and the analysis band limit."""
71     nside: int = 256
72     fwhm_arcmin: float = 30.0
73     depth_uK_arcmin: float = 200.0      # Delta_T: white-noise level per square arcminute
74     lmax: int = 512                     # analysis band limit, 2 nside (trusted range, ch.
       7)
75     pixwin: bool = True
76
77     @property
78     def lmax_sim(self) -> int:          # synthesis band limit, 3 nside - 1
79         return 3 * self.nside - 1
80
81     @property
82     def npix(self) -> int:
83         return hp.nside2npix(self.nside)
84
85     @property
86     def omega_pix(self) -> float:       # sr
87         return 4.0 * np.pi / self.npix
88
89     @property
90     def sigma_pix(self) -> float:       # muK per pixel: Delta_T / pixel side
91         return self.depth_uK_arcmin * ARCMIN / np.sqrt(self.omega_pix)
```

Read it as a form with blanks. Line 68, `@dataclass`, is a **decorator**: a line starting with `@` that modifies the definition below it, here by writing the routine parts of the class automatically. Lines 71–75 list the settings, each with a type hint and a default value: the HEALPix resolution, the beam width, the noise level, the band limit, and whether to include the pixel window. Then `exp = Experiment(nside=128, fwhm_arcmin=10.0)` creates one experiment with two settings changed and the rest left at their defaults, and `exp.nside` reads a setting back. Lines 77–91 define quantities computed from the settings. The decorator `@property` makes each of them look like a setting: `exp.npix` or `exp.sigma_pix` without brackets, recomputed every time it is read, so it can never disagree with the settings. Inside the class, `self` means "this particular experiment". Lines 92 onwards are ordinary functions of the experiment, called as `exp.nl()`.

T0.8.2 Errors on purpose, and `with`

`try:` followed by `except SomeError:` runs a block and, if that particular error occurs, runs the second block instead of stopping. It appears in 3% of the scripts, typically to record that something failed. The SciPy tour uses it to show that 200! cannot be a float (Section T0.6.5), and Section T0.10.4 uses it to detect a matrix that is not positive definite. Catching errors to hide them is never done: a script that fails should fail loudly.

`with ... as name:` sets something up for the duration of an indented block and tidies it away afterwards, even if the block fails. It appears in 9% of the scripts, in three forms: opening a file, starting a pool of worker processes (below), and `with np.errstate(divide="ignore"):`, which silences NumPy's warning about a division by zero that the code is about to repair anyway (line 54 of `lib_fields.py`, where $P(k)$ is evaluated at $k = 0$ and then set to zero).

T0.8.3 Several cores at once

A Monte Carlo study runs the same function on many independent random seeds, and those runs can go on different processor cores at the same time. Python's `multiprocessing.Pool` does this with one call: `pool.map(f, jobs)` applies `f` to every item of the list `jobs`, spreads the items over the workers, and returns the results in the original order. The topology study of Section 12.23.1 is the clearest case:

Listing T0.42: Hundreds of independent simulations spread over four cores (`code/ch12/c02_mc_fnl.py`)

```
50 def one(args):
51     stream, eps_list = args
52     rng = rng_for("ch12", "c02_mc_fnl", stream)
53     g = model.gauss(rng)                                  # one Gaussian field per seed
54     res = []
55     for eps in eps_list:                                  # common random numbers across eps
56         u = model.draw(eps, g=g)
57         s = summaries(u, model)
58         s["sk"] = skew_params(u)
59         res.append(s)
60     return res
61
62
63 def run():
64     jobs = ([(i, [0.0]) for i in range(N_NULL)]
65             + [(10_000 + i, [0.0]) for i in range(N_CHECK)]
66             + [(20_000 + i, list(EPS_GRID)) for i in range(N_GRID)])
67     t0 = time.time()
68     with Pool(4) as pool:
69         out = pool.map(one, jobs, chunksize=8)
```

Each job (lines 64–66) is a tuple: a stream number and a list of non-Gaussianity amplitudes ϵ. The function `one` (lines 50–60) makes its own generator from the stream number (line 52), draws one Gaussian field, and measures it at every ϵ in the list. Line 68 starts four workers, and line 69 runs all the jobs. Two details make this safe. Every job builds its generator from its own stream number, so the result does not depend on which worker ran which job or in what order (Section T0.5.1); a generator shared between workers would make the results depend on the scheduling. And the function given to `pool.map` is defined at the top level of the module, because each worker process imports the script to find it.

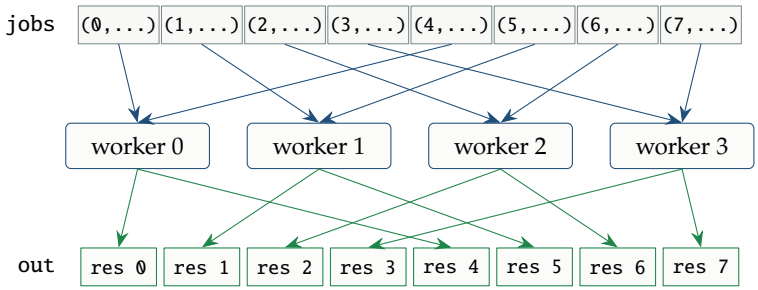

Figure T0.20: `pool.map(one, jobs)` with four workers. Each job carries its own stream number, so it produces the same result whichever worker runs it, and the list of results comes back in the order of the jobs.

T0.8.4 Compiled loops: numba

Vectorisation (Section T0.4.5) needs the elements to be independent, so that one operation can act on all of them. Some algorithms are sequential by nature: in a Metropolis sweep of the Ising model each spin's update depends on its neighbours' *current* values, which earlier steps of the same sweep may have just changed. Such a loop cannot be written as one array expression. The library numba solves this by compiling a Python function into machine code the first time it is called: the decorator `@njit` on top of the function is the only change. Five files use it (1%). The Ising sweep of Section 9.15.3 is one:

Listing T0.43: A sequential Metropolis sweep, compiled by numba (`code/ch09/20_ising.py`)

```
19 @njit(cache=True)
20 def sweep(s, beta, u):
21     """One sweep: visit every site once (in order) and propose to flip its spin.
22     dE = 2 J s_i (sum of the 4 neighbours), J = 1.  Accept with min(1, exp(-beta dE)).
23     Each single-site update satisfies detailed balance, so each preserves the Boltzmann
       law."""
24     L = s.shape[0]
25     acc = 0
26     k = 0
27     for i in range(L):
28         for j in range(L):
29             nb = s[(i + 1) % L, j] + s[(i - 1) % L, j] + s[i, (j + 1) % L] + s[i, (j - 1) %
       L]
30             dE = 2.0 * s[i, j] * nb
31             if dE <= 0.0 or u[k] < np.exp(-beta * dE):
32                 s[i, j] = -s[i, j]
33                 acc += 1
34             k += 1
35     return acc
```

Apart from line 19 this is plain Python with two nested loops: visit every site, sum its four neighbours with periodic wrap-around (the `% L` on line 28), compute the energy change, and

accept the flip with the Metropolis probability. Uncompiled, the L^2 inner steps would run at Python's speed of a few hundred nanoseconds each; compiled, at a few nanoseconds. A compiled function accepts only NumPy arrays and plain numbers, which is why the random numbers u are drawn outside, by the book's generator, and passed in.

T0.8.5 healpy and CAMB as black boxes

Two libraries do physics that the book does not reimplement. **healpy** handles maps on the sphere in the HEALPix pixelisation [7]: $12N_{\text{side}}^2$ pixels of equal area, and the spherical-harmonic transforms between a map and its coefficients $a_{\ell m}$. **CAMB** [8] solves the linearised Boltzmann equations of a cosmological model and returns its predicted spectra. Neither needs to be understood inside. Each can be used as a box with known inputs and outputs (Figure T0.21), and checked from outside on a case with a known answer.

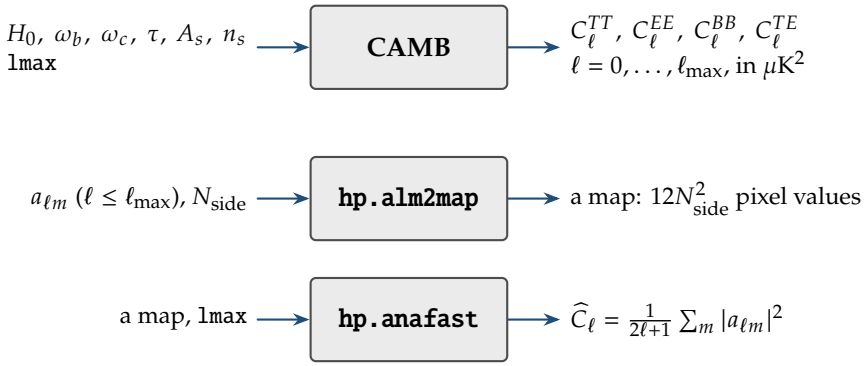

Figure T0.21: Three black boxes and what crosses their walls. CAMB turns six cosmological parameters into the predicted CMB spectra. healpy's `alm2map` turns harmonic coefficients into a pixelised map, and `anafast` turns a map back into the estimated power spectrum. A round trip through the last two must return the spectrum that went in, which is how the book checks them.

The whole CAMB interface the book uses is three calls in `code/camb_fiducial.py`:

Listing T0.44: Six parameters in, four spectra out (`code/camb_fiducial.py`)

```
16 def compute(params=FIDUCIAL, lmax=LMAX):
17     import camb
18     p = camb.set_params(**params, lmax=lmax + 200, lens_potential_accuracy=1)
19     r = camb.get_results(p)
20     cls = r.get_cmb_power_spectra(p, CMB_unit="muK", raw_cl=True)
21     tot = cls["total"][: lmax + 1]
22     return np.arange(lmax + 1), tot  # columns TT, EE, BB, TE
```

Line 18 collects the parameters into one object (the `**params` unpacks the dictionary `FIDUCIAL` of line 13 into keyword arguments such as `H0=67.36`); `lmax` is set 200 above the multipoles wanted, because the lensing calculation needs a margin. Line 19 runs the Boltzmann code, which takes several seconds. Line 20 asks for the spectra in μK^2 as raw C_ℓ (not D_ℓ), and line 21 keeps the total (lensed) spectra, an array with one row per ℓ and four columns TT, EE, BB, TE. Because this costs seconds per call, the result is cached (Section T0.7.2) and CAMB is called again only by the few scripts that vary the parameters (Section T1.3, Section 10.5.2).

healpy calls look like this round trip, from Section 7.11.1:

Listing T0.45: From $a_{\ell m}$ to a map and back: healpy as two black boxes (`code/ch07/24_camb_healpix.py`)

```
61 def roundtrip(lm, it):
```

```
62      """Draw a_lm up to lm, make the N_side = 256 map, analyse it again; return
        |C_map/C_input - 1|."""
63      a = lh.synalm(cl, lm, rng)
64      sky = hp.alm2map(a, NS, lmax=lm)                # = synfast with our own random numbers
65      c_in = lh.alm2cl(a, lm)
66      c_map = hp.anafast(sky, lmax=lm, iter=it)
67      return sky, a, c_in, np.abs(c_map[2:] / c_in[2:] - 1)
```

Line 63 draws the coefficients with the book's own generator (`lh.synalm`, written from scratch in Section 7.8.2). Line 64 is `hp.alm2map`: coefficients in, map of $N_{\text{side}} = 256$ out. Line 66 is `hp.anafast`: map in, $\widehat{C}_\ell$ out; `iter` sets how many refinement passes it makes on the transform. Line 67 compares the result with the spectrum of the input coefficients. The few other healpy calls in the book are of the same kind: `hp.nside2npix` (pixels from resolution), `hp.map2alm` (map to coefficients), `hp.smoothing` (convolve with a beam), `hp.pixwin` (the pixel window), `hp.mollview` (draw the sphere on a page). Each is a documented box, and the book checks each once against a case with a known answer before relying on it.

T0.9 Seven traps that catch everyone once

A program does exactly what it says, which is not always what its author meant. Most mistakes stop the script with an error message, and those are the friendly ones: Python names the line, and the fix is usually obvious. The dangerous mistakes are the ones that run to the end and print a plausible number. Take the smallest example. A script estimates the variance of each of M simulated experiments, stored as the rows of an $M \times N$ array `x`, by subtracting each row's mean. If it writes `x - x.mean(axis=1)`, the means form an array of shape `(M,)`, and NumPy lines that shape up against the *columns* of `x`, not its rows (Section T0.4.4). When $M \neq N$ the shapes do not fit and the script stops; when by bad luck $M = N$, it subtracts the mean of experiment j from reading j of every experiment, runs to the end, and prints a variance that is simply wrong. The good version, `x - x.mean(axis=1, keepdims=True)`, keeps the means as a column of shape `(M, 1)` and is correct for every M and N; its price is eleven characters. The lesson: the traps worth knowing are the silent ones.

There are seven of them, and each is a fact about how Python or NumPy stores numbers. The script `code/chT0/05_pitfalls.py` runs each one in two or three lines and prints what happens, and the book's own scripts show how each is avoided.

T0.9.1 Comparing real numbers

A computer stores a real number in binary with a fixed number of digits, so most decimal fractions are stored only approximately. 0.1 in binary is 0.000110011001100…, repeating for ever, and it is cut off after 53 binary digits. The first lines of the script show the consequence:

```
# 1. floats
0.1 + 0.2 == 0.3          -> False
0.1 + 0.2 - 0.3           -> 5.551e-17
np.isclose(0.1 + 0.2, 0.3) -> True
```

The stored 0.1 + 0.2 and the stored 0.3 differ by 5.551×10^{-17}, so the test == says they are different. Nothing is broken: each number is correct to about sixteen significant digits, and they disagree in the seventeenth. The consequence is a rule. Real numbers computed in two different ways are compared with a tolerance, never with ==. `np.isclose(a, b)` asks whether $|a - b| \leq 10^{-8} + 10^{-5}\,|b|$ (both tolerances can be changed with `atol=` and `rtol=`), and `np.allclose` asks the same of every element of two arrays.

The book's scripts compare in exactly this way when they check one method against another. The exact binomial confidence interval of Section 4.10.4 is found twice, once by solving two equations with `brentq` and once from a closed formula that uses the beta distribution:

Listing T0.46: Two routes to the same interval, compared with a tolerance (`code/ch04/11_test_inversion.py`)

```
40 lo = optimize.brentq(lambda t: p_upper_tail(t) - alpha / 2, 1e-6, z / N)
41 hi = optimize.brentq(lambda t: p_lower_tail(t) - alpha / 2, z / N, 1 - 1e-6)
42 # the same numbers from the binomial-beta identity (a check)
43 lo_beta = stats.beta.ppf(alpha / 2, z, N - z + 1)
44 hi_beta = stats.beta.ppf(1 - alpha / 2, z + 1, N - z)
45 assert abs(lo - lo_beta) < 1e-6 and abs(hi - hi_beta) < 1e-6
```

Line 45 is the comparison: the two lower ends must agree to within 10^{-6}, and so must the two upper ends. The tolerance is set by the less accurate of the two routes, here the root finder, whose default stopping rule pins the root to about 10^{-12}; 10^{-6} leaves a wide margin while still catching any real mistake, which would show up in the second or third digit. How large a tolerance must be in general, and why, is the subject of Section T0.10.1.

T0.9.2 Whole numbers and real numbers

Python and NumPy keep two kinds of number apart: integers (`int`, whole numbers, exact) and floating-point numbers (`float`, real numbers, approximate). Two consequences surprise newcomers:

```
# 2. integer arrays
a = np.array([1, 2, 3]); a[0] = 0.7  -> a = [0 2 3], a.dtype = int64
7 / 2 -> 3.5,   7 // 2 -> 3
```

The first line is the dangerous one. `np.array([1, 2, 3])` is made from integers, so its `dtype` is `int64`, and an integer array can only hold integers: writing 0.7 into it silently stores 0, the integer part. The second line is the reassuring one: in Python 3, `/` always divides as real numbers, `7 / 2` is 3.5, and only the explicit floor division `//` throws the fraction away.

Integer arrays arise naturally in the book, because counts are integers: `rng.poisson` and `rng.integers` return them, and so does `np.histogram` for its counts. The iterative unfolding of Section 6.14.5 works on simulated Poisson counts, and converts them to real numbers the moment they are drawn:

Listing T0.47: Counts converted to real numbers before any arithmetic, and a default of `None` (`code/ch06/30_unfolding.py`)

```
172 def ibu(n, iters, prior=None):
173     """D'Agostini iterations; n may be (..., M).  Returns the estimate after 'iters'
        steps."""
174     p = np.full(M, 1.0 / M) if prior is None else prior / prior.sum()
175     m_hat = np.broadcast_to(p * n.sum(axis=-1, keepdims=True), n.shape).copy()
176     for _ in range(iters):
177         nu_hat = m_hat @ R.T                                  # sum_j R_ij mu_j
178         m_hat = m_hat / eff * ((n / nu_hat) @ R)              # mu_j/eps_j sum_i R_ij n_i / nu_i
179     return m_hat
180
181
182 iters_grid = np.array([1, 2, 3, 4, 5, 6, 8, 10, 15, 20, 30, 50, 100, 200, 500])
183 toys = rng.poisson(nu, size=(1000, M)).astype(float)
```

Line 183 draws 1000 toy data sets of Poisson counts and immediately applies `.astype(float)`, which returns a copy of the array with `dtype` `float64`. The update of line 178 then divides

these counts by the predicted ones and multiplies by efficiencies; with real numbers there is no risk that an intermediate result is cut to an integer anywhere along the way. (Lines 172 and 174 show another habit, the default value `None`, which Section T0.9.6 explains.) The rule: when an array will hold real numbers, make it a float array from the start, with `np.zeros(n)` (which is float by default), `np.array(..., float)` or `.astype(float)`.

T0.9.3 Views and copies

A slice of a NumPy array is not a new array. It is a **view** [a second name for part of the same block of memory]: `y = x[1:3]` makes `y` a window onto elements 1 and 2 of `x`, and writing through the window changes `x` (Figure T0.22). NumPy does this on purpose, because slicing a large array would otherwise copy it every time. The script shows both behaviours:

```
# 3. views and copies
x = np.zeros(5); y = x[1:3]; y[:] = 9  -> x = [0. 9. 9. 0. 0.]
same with y = x[1:3].copy()            -> x = [0. 0. 0. 0. 0.]
```

With the view, the two nines appear inside `x`; with `.copy()`, `y` is an independent array and `x` stays zero. The same is true of plain assignment: `y = x` gives the same array a second name and copies nothing. Python lists behave the same way for assignment, though their slices *are* copies.

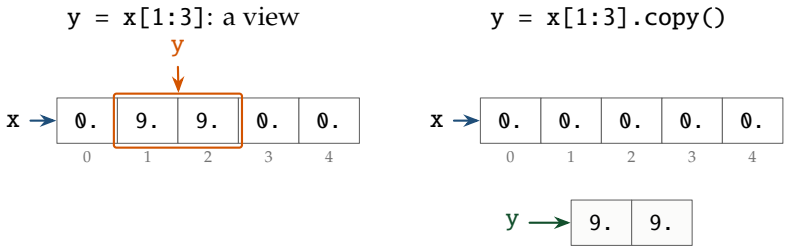

Figure T0.22: Two names for one block of memory, or two blocks. Left: the slice `y` is a window (orange) onto elements 1 and 2 of `x`, so `y[:] = 9` writes into `x`. Right: `.copy()` makes a new block (green) for `y`, and `x` is untouched.

Where does this matter in practice? When a loop records the history of something it keeps changing. Newton's method for the maximum-likelihood angle fit of Section 3.9.3 stores every step it takes, so that the path can be drawn:

Listing T0.48: Recording the path of an iteration: a copy at every step (`code/ch03/10_angular_ml.py`)

```
62 def newton(x, th0, tol=1e-10, maxit=50):
63     th, path = np.array(th0, float), [np.array(th0, float)]
64     for it in range(maxit):
65         g, H = grad_hess(th, x)
66         step = -np.linalg.solve(H, g)              # theta_{j+1} = theta_j - H^{-1} grad
67         th = th + step
68         path.append(th.copy())
69         if np.max(np.abs(step)) < tol:
70             break
71     return th, np.array(path)
```

Line 63 makes the starting point a float array (the previous trap) and starts the list `path` with a *separate* copy of it. Line 66 computes the Newton step, line 67 moves to the new point, and line 68 appends a copy of it to the list. Here line 67 happens to build a new array, because `th + step` always creates one, so the copy is a safeguard rather than a necessity. It becomes a necessity the moment someone "simplifies" line 67 to `th += step`: the operator += updates the

existing array in place, and without the copy every entry of `path` would be the same array, so the plotted path would collapse to its final point. The rule: when an array is stored and then changed, store a `.copy()`.

T0.9.4 Where ranges and slices stop

Python counts from zero and stops *before* the end:

```
# 4. where ranges stop
list(range(5))            -> [0, 1, 2, 3, 4]
len(np.arange(0, 1, 0.1)) -> 10   (1.0 is not included)
len(np.linspace(0, 1, 11)) -> 11  (both ends included)
v = np.arange(10); v[2:5] -> [2 3 4],  v[-1] -> 9
```

`range(5)` is 0, 1, 2, 3, 4: five numbers, and 5 is not among them. A slice `v[2:5]` takes elements 2, 3, 4. `np.arange(0, 1, 0.1)` stops before 1 and has ten points, while `np.linspace(0, 1, 11)` includes both ends and has eleven. The convention has a reward: `v[a:b]` has exactly $b - a$ elements, and `v[:k]` and `v[k:]` split `v` into two pieces without overlap or gap. Its cost is that every formula written on paper with $i = 1, \ldots, N$ must be translated to `i = 0, ..., N-1`.

The commonest form of the trap in the book is the **fencepost** [n bins need $n + 1$ edges, as n fence panels need $n + 1$ posts] of every histogram (Figure T0.23). The density-histogram script of Section 1.9 builds its bins like this:

Listing T0.49: Bin edges with `arange`, and the centres between them (`code/ch01/11_density_histogram.py`)

```
34    E = E_all[:N]
35    bins = np.arange(mu - 4 * sigma, mu + 4 * sigma + w / 2, w)
36    counts, edges = np.histogram(E, bins=bins)
37    centres = 0.5 * (edges[1:] + edges[:-1])
```

Line 35 wants edges from $\mu - 4\sigma$ to $\mu + 4\sigma$ *inclusive*, in steps of the bin width w. Because `np.arange` stops before its end point, and because $8\sigma/w$ steps of a fractional w may land a hair above or below $\mu + 4\sigma$ by rounding, the end is given as $\mu + 4\sigma + w/2$: half a step beyond the last edge wanted, so that the last edge is included and nothing beyond it is. Line 36 returns the counts, one per bin, and the edges, one more than the counts. Line 37 makes the bin centres by averaging each edge with the next: `edges[1:]` drops the first edge and `edges[:-1]` drops the last, so the two arrays have the same length, the number of bins, and their average is the midpoint of every bin.

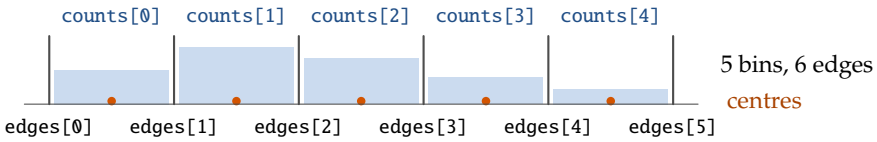

Figure T0.23: The fencepost. Five bins (blue) are bounded by six edges (black). `np.histogram` returns five counts and six edges; the five centres (orange dots) are the averages of `edges[:-1]` (the left edges) and `edges[1:]` (the right edges).

T0.9.5 Shapes that do not fit, or fit by accident

Broadcasting (Section T0.4.4) compares the shapes of two arrays from the right, and stretches any axis of length one. Two outcomes are printed by the script:

```
# 5. shapes
(r - r[:, None]).shape    -> (3, 3)
```

```
r + np.ones(4)            -> ValueError: operands could not be broadcast together with
    shapes (3,) (4,)
```

Subtracting a column (shape `(3, 1)`, made by `r[:, None]`) from a row (shape `(3,)`) gives the 3×3 table of all differences, which is often exactly what is wanted. Adding arrays of lengths 3 and 4 fails with a message that names both shapes. The failure is the friendly case. The unfriendly case is the one of the opening paragraph: two axes that happen to have the same length, so that the shapes fit even though the meaning does not.

The sample-variance study of Section 3.4.4 has exactly that structure, M simulated experiments of N readings each, stored as an $M \times N$ array, with N running over a list of sample sizes:

Listing T0.50: Each row minus its own mean: `keepdims=True` (code/ch03/04_sample_variance.py)

```
29 mse = {"N-1": [], "N": [], "N+1": []}
30 for N in Ns:
31     x = rng.standard_normal((M, N))                  # sigma = 1
32     ss = ((x - x.mean(axis=1, keepdims=True)) ** 2).sum(axis=1)
33     mean_biased.append((ss / N).mean())
```

Line 31 subtracts each row's mean from that row. `x.mean(axis=1)` alone would have shape `(M,)`, a row of M means, which broadcasting would line up against the N columns: an error if $M \neq N$, and a silently wrong answer if $M = N$. With `keepdims=True` the result keeps the averaged axis with length one, shape `(M, 1)`, a column, and broadcasting stretches it across each row. The habit that catches the rest: print `.shape` of every array in a new formula once, and check that it is what the paper formula says.

T0.9.6 A default value that remembers

A default value in a function definition (Section T0.3.5) is created *once*, when Python reads the `def` line, and shared by every call that does not supply that argument. For a number or a string this never matters, because they cannot be changed in place. For a list it does:

```
# 6. mutable default argument
append_bad(1); append_bad(2)   -> [1, 2]
append_good(1); append_good(2) -> [2]
```

`append_bad(value, store=[])` appends to its default list, and since that list is the same object at every call, the second call returns [1, 2]: it remembers the first. `append_good(value, store=None)` uses the conventional cure: the default is the special value `None`, and the first line of the function makes a fresh list whenever `store` is `None`. The unfolding function `ibu` of the excerpt in Section T0.9.2 uses the same pattern for an array: `prior=None` on line 172, and on line 174 a flat prior made fresh at each call when none is given. The book never uses a list, a dictionary or an array as a default value.

T0.9.7 Forgetting the seed

A generator made without a seed takes one from the computer's clock and its internal noise, so its numbers differ at every run:

```
# 7. seeds
default_rng() twice        -> equal: False
rng_for(same name) twice   -> equal: True  (0.858458)
```

Two generators made with `np.random.default_rng()` give different first draws; two made with `rng_for` and the same name give the same draw, 0.858458, at every run and on every

machine (Section T0.5.1). The difference matters for three reasons. A number quoted in the text must be the number the script prints, every time it is rerun. A bug that appears for one random sample can be chased only if the same sample can be produced again. And two settings can be compared on the same random numbers, which makes their difference far more precise than either one (Section T0.10.5).

The census counts of Section T0.5.1 show how faithfully the book keeps the rule: of the 216 files that draw random numbers, 197 make their generator with `rng_for`, and nearly all of the others are libraries that receive a generator from the script that calls them. The script above is one of the very few places where an unseeded generator is made on purpose, to show what it does.

Watch out: A trap that hides in an average

Each of the seven traps can hide inside a Monte Carlo average, where a wrong number looks like noise. The cure is the same for all of them: run the code once on a case whose answer is known, and compare with a tolerance (Section T0.10.7).

T0.10 Is this number real? Numerical noise and how to check

A script finishes and prints a number. It ran without an error, the number has the right size, and it carries twelve digits. How many of those digits mean anything? The question is not idle, because every number a computer produces has passed through three filters that each blur it. Every real number is stored with about sixteen significant digits and rounded after every operation. Every method that replaces calculus by arithmetic (a derivative by a difference, an integral by a sum, an equation by an iteration) makes an error of its own that depends on a step size or a tolerance. And every Monte Carlo number is an average of random draws, which a different seed would change.

The smallest example. The probability that a standard Gaussian variable exceeds 2 is $\mathrm{P}(Z > 2) = 0.02275$. A script estimates it from $N = 10^4$ draws as the fraction of draws above 2, and with the first seed prints 0.0226. Read naively, that is a number with three significant digits, and it does not match the truth to all three. Which of the three filters set the error? Rounding contributes about one part in 10^{16}, and the method (counting) is exact. The Monte Carlo filter is the whole story: the count of draws above 2 is binomial, so the fraction has standard deviation $\sqrt{q(1-q)/N} = 0.00149$ for $q = 0.02275$. The printed value should therefore be read as 0.0226 ± 0.00149: one and a half significant digits, and entirely consistent with the truth: the difference is -0.10 standard deviations. The naive reading would call a correct computation wrong; with only 10^2 draws it would just as readily call a wrong one right. The good habit, quoting every number with its error, costs one more line of code. *The lesson: a number without an error estimate has not yet been measured.*

The checks are a short list, one for each source of error: the floating-point facts that set the limit of every computation, the step-size balance of numerical derivatives, the reports and silences of SciPy's integrators, root finders and minimisers, the condition number of a matrix, the $1/\sqrt{N}$ of Monte Carlo, convergence studies, validation against known answers, and finally a single rule for deciding whether a difference between two numbers is real. Every one of them is already used somewhere in the book, and each is shown at work on a small problem by `code/chT0/08_trust.py`.

T0.10.1 Sixteen digits, and how to lose them

How a real number is stored. NumPy's `float64`, Python's `float`, is a number in binary scientific notation, packed into 64 bits (Figure T0.24):

$$x = (-1)^s \left(1 + \sum_{k=1}^{52} b_k\, 2^{-k}\right) 2^e, \qquad b_k \in \{0,1\}, \quad -1022 \le e \le 1023. \tag{T0.1}$$

One bit holds the sign s, eleven the exponent e, and fifty-two the binary digits b_k of the fraction, the **mantissa**. Between 1 and 2 (that is, $e = 0$) the numbers that can be stored are 1, $1 + 2^{-52}$, $1 + 2 \cdot 2^{-52}$, and so on: they are evenly spaced, and the gap is

$$\epsilon = 2^{-52} \approx 2.22 \times 10^{-16}, \tag{T0.2}$$

the **machine epsilon** [the gap between 1 and the next larger storable number]. Between 2^e and 2^{e+1} the same 2^{52} steps are stretched by 2^e, so the gap is $\epsilon\, 2^e$: the *relative* spacing is about ϵ everywhere. A real number is rounded to the nearest storable one, so its stored value is $x(1+\delta)$ with $|\delta| \le \epsilon/2$, and so is the result of every arithmetic operation. That is what "sixteen significant digits" means: $\log_{10}(1/\epsilon) \approx 15.7$ [9]. NumPy reports these facts itself, through `np.finfo(np.float64)`:

```
eps = 2.2204e-16   largest = 1.7977e+308   smallest normal = 2.2251e-308
1.0 + eps == 1.0 -> False;   1.0 + eps/2 == 1.0 -> True
0.1 + 0.2 == 0.3 -> False;   np.isclose -> True
```

$1 + \epsilon$ is the next number after 1, so it differs from 1; $1 + \epsilon/2$ lies exactly halfway and is rounded back to 1. The largest storable number is about 1.798×10^{308} and the smallest with full precision about 2.225×10^{-308}, so overflow and underflow are rare in practice, though not impossible (Section T0.11).

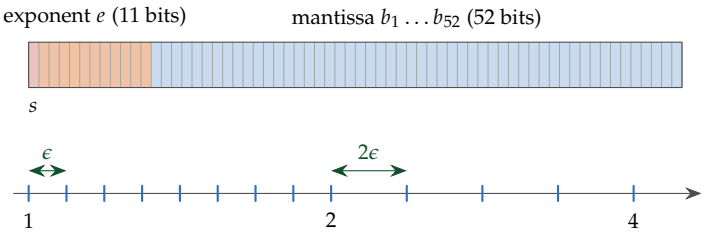

Figure T0.24: A `float64`. Top: one sign bit, eleven exponent bits and fifty-two mantissa bits. Bottom: the storable numbers near 1, with the spacing exaggerated (there are really 2^{52} of them between 1 and 2). The gap is ϵ between 1 and 2 and doubles at every power of two, so the relative gap stays near ϵ.

Comparing with a tolerance. Because every result carries a relative error of order ϵ, two routes to the same quantity agree to about ϵ times its size, not exactly, and the comparison must be relative. The dark-matter halo of Section T2.9 is built from its virial mass and radius, and the script checks that the mass enclosed by the profile at r_{200} really is the mass put in:

Listing T0.51: A relative comparison: the ratio minus one (`code/chT2/04_dm_profile.py`)

```
40 # check: the mean density inside r200 is 200 rho_crit
41 M_nfw = lambda r: 4 * np.pi * rho_s * rs**3 * (np.log(1 + r / rs) - (r / rs) / (1 + r / rs))
42 assert abs(M_nfw(r200) / M200 - 1) < 1e-10
```

Line 41 is the enclosed mass of the profile, from its closed form, and line 42 compares the ratio of the two masses with 1. Written as $|M/M_{200} - 1| < 10^{-10}$ the test is relative: it does not

care whether masses are measured in grams or in solar masses, while `abs(M - M200) < 1e-10` would be meaningless for numbers of order 10^{12}. The tolerance sits well above the rounding level (a cube root, two logarithms and a few products, each adding about ϵ) and far below any error that would matter.

Cancellation. Rounding errors of order ϵ are harmless as long as they stay of order ϵ. One operation can magnify them enormously: the subtraction of two nearly equal numbers. Suppose a and b are stored as $a(1+\delta_a)$ and $b(1+\delta_b)$, with $|\delta_a|, |\delta_b| \le \epsilon/2$. What is the relative error of the computed difference?

$$\frac{|a(1+\delta_a) - b(1+\delta_b) - (a-b)|}{|a-b|} \overset{(1)}{=} \frac{|a\delta_a - b\delta_b|}{|a-b|} \overset{(2)}{\le} \frac{\epsilon}{2}\,\frac{|a|+|b|}{|a-b|}. \tag{T0.3}$$

(1) Expand: the exact $a-b$ cancels, and the two rounding errors remain.
(2) The triangle inequality, $|a\delta_a - b\delta_b| \le |a|\,|\delta_a| + |b|\,|\delta_b|$, and $|\delta| \le \epsilon/2$.

The inputs' relative error $\epsilon/2$ is multiplied by $(|a|+|b|)/|a-b|$, which is about $2a/(a-b)$ when $a \approx b$. If a and b agree in their first ten digits, ten of the sixteen digits are lost: the result is the difference of two numbers whose leading digits cancelled, leaving the uncertain trailing ones. This is **catastrophic cancellation**, and it needs no long calculation: a single subtraction is enough.

Example: $1-\cos x$ for small x. The ratio $(1-\cos x)/x^2$ tends to $\frac{1}{2}$ as $x \to 0$. At $x = 10^{-5}$, $\cos x \approx 1 - 5\times10^{-11}$, so the subtraction $1-\cos x$ cancels ten digits. Since 1 is stored exactly and $\cos x$ with a relative error of at most $\epsilon/2$, (T0.3) bounds the relative error of the result by $(\epsilon/2)/(x^2/2) = \epsilon/x^2 \approx 2\times10^{-6}$. The script prints:

```
x = 1e-5: (1 - cos x)/x^2 = 0.5000000414,  2 sin^2(x/2)/x^2 = 0.5000000000
x = 1e-8: naive = 0.0,  rewritten = 0.5000000000
```

At $x = 10^{-5}$ the naive formula gives 0.5000000414, wrong in the eighth digit, within the bound. At $x = 10^{-8}$ it gives exactly 0. There $\cos x = 1 - 5\times10^{-17}$; just below 1 the storable numbers are spaced by $\epsilon/2 \approx 1.1\times10^{-16}$, and 5×10^{-17} is less than half of that spacing, so $\cos x$ is stored as exactly 1 and the difference vanishes. The cure is to rewrite the formula so that nothing nearly equal is subtracted. The double-angle identity $\cos x = 1 - 2\sin^2(x/2)$ gives $1-\cos x = 2\sin^2(x/2)$, a product of small numbers each known to sixteen digits, and the rewritten form returns 0.5000000000 at both values. Figure T0.25 (left) shows the relative error of both forms against x: the naive one follows the bound ϵ/x^2 up to order one, and the rewritten one stays at the rounding floor.

Example: the variance in one pass. The variance of a set of readings is $\langle x^2\rangle - \langle x\rangle^2$, and that formula needs only one pass through the data. Try it on 10^4 readings $10^8 + z_i$, with z_i standard Gaussian: times in nanoseconds measured from some epoch would look like this. Both $\langle x^2\rangle$ and $\langle x\rangle^2$ are about 10^{16}, and near 10^{16} the storable numbers are spaced by $\epsilon\cdot 2^{53} = 2$ (since $2^{53} \approx 9\times10^{15}$). Each of the two terms is therefore known only to the nearest even number, and their difference, which should be about 1, can only come out as a multiple of 2:

```
variance of 1e8 + N(0,1): one-pass = 2.0000,  two-pass = 0.9919,  np.var = 0.9919
```

The one-pass formula returns 2.00; the two-pass form, which first subtracts the mean and then squares, returns 0.9919, and so does `np.var`, which works the same way. By (T0.3) the amplification factor is about 2×10^{16}, enough to destroy all sixteen digits. The book always computes variances in two passes: the sample-variance excerpt of Section T0.9.5 subtracts each

row's mean before squaring (line 31 there), and elsewhere `np.var` and `np.cov` do it internally. *The lesson: never subtract two large, nearly equal numbers; rewrite the formula, or subtract the large common part first.*

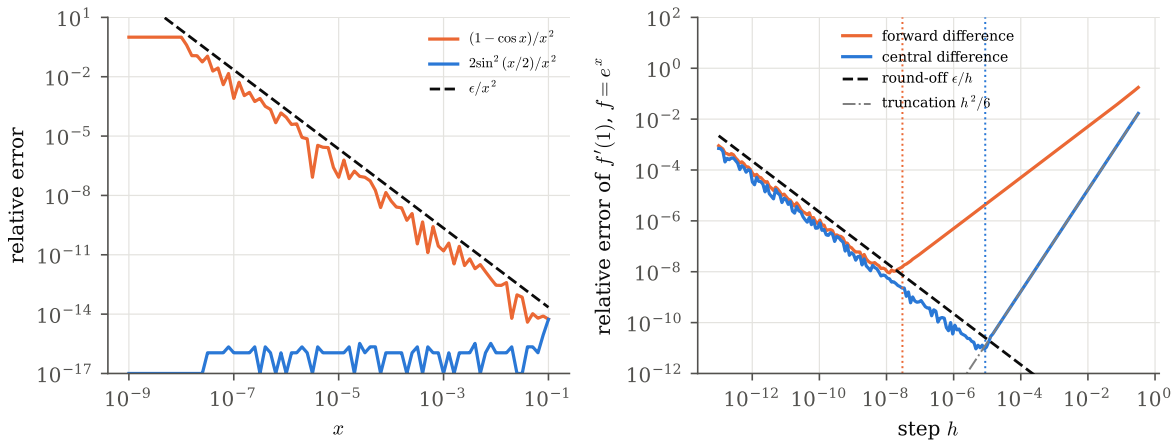

Figure T0.25: Where digits go. Left: relative error of $(1-\cos x)/x^2$ computed naively (orange) and as $2\sin^2(x/2)/x^2$ (blue). The naive form loses digits along the dashed line ϵ/x^2 and is useless below $x \approx 10^{-8}$; the rewritten form stays at the rounding floor. Right: relative error of the numerical derivative of e^x against the step h, for the forward and central differences, as the root-mean-square over 101 points between 0.5 and 1.5. To the right of each minimum the truncation error grows (grey line, $h^2/6$ for the central difference); to the left the round-off error grows as ϵ/h (dashed). Dotted verticals: the best steps predicted by (T0.5) and its forward analogue.

T0.10.2 Derivatives: the step that is neither too large nor too small

Fisher matrices (Chapter 10), emulators (Section 9.20) and Newton's method all need derivatives of functions that are known only as code. The obvious approach is the definition of the derivative with a small but finite step h. How small? Intuition says "as small as possible", and Figure T0.25 (right) shows that intuition to be wrong: the error falls as h shrinks, reaches a minimum, and then rises again. Two errors compete, and the best step is where they balance.

The truncation error. Take the **central difference** $D(h) = [f(x+h) - f(x-h)]/2h$. Taylor's theorem gives $f(x \pm h) = f \pm hf' + \frac{1}{2}h^2 f'' \pm \frac{1}{6}h^3 f''' + \ldots$, all derivatives at x. Subtracting the two expansions cancels the even powers, and dividing by $2h$ leaves

$$D(h) = f'(x) + \frac{h^2}{6} f'''(x) + O(h^4). \tag{T0.4}$$

The error $h^2 f'''/6$ shrinks as h shrinks: this is the part intuition sees.

The round-off error. The two function values are computed with relative errors of order ϵ, so each is off by up to about $\epsilon\,|f|$, and in the worst case the two errors have opposite signs and add. Their difference is then off by $2\epsilon\,|f|$, and dividing by $2h$ leaves $\epsilon\,|f|\,/h$. This part *grows* as h shrinks: for a tiny h, $f(x+h)$ and $f(x-h)$ are nearly equal, and their difference is the cancellation of (T0.3).

The balance. The total error and its minimum follow in three lines:

$$
\begin{aligned}
E(h) &\overset{(1)}{=} \frac{\epsilon\,|f|}{h} + \frac{h^2}{6}\,|f'''|\,, \\
\frac{\mathrm{d}E}{\mathrm{d}h} &\overset{(2)}{=} -\frac{\epsilon\,|f|}{h^2} + \frac{h}{3}\,|f'''| = 0 \quad\Longrightarrow\quad h_{\mathrm{opt}} \overset{(3)}{=} \left(\frac{3\epsilon\,|f|}{|f'''|}\right)^{1/3} \sim \epsilon^{1/3}, \\
E(h_{\mathrm{opt}}) &\overset{(4)}{=} \frac{3}{2}\,\frac{\epsilon\,|f|}{h_{\mathrm{opt}}} \sim \epsilon^{2/3}.
\end{aligned}
\tag{T0.5}
$$

(1) Round-off plus truncation, the two estimates above.
(2) The smallest error is where the slope of E vanishes.
(3) Multiply by $3h^2/|f'''|$: $h^3 = 3\epsilon\,|f|\,/|f'''|$, and take the cube root.
(4) At h_{opt}, $\frac{h^2}{6}\,|f'''| = \frac{h^3}{6h}\,|f'''| = \frac{3\epsilon|f|}{6h} = \frac{1}{2}\,\frac{\epsilon|f|}{h}$: the truncation term is half the round-off term, and the sum is $\frac{3}{2}$ of it. Since $h_{\mathrm{opt}} \sim \epsilon^{1/3}$, this is $\epsilon/\epsilon^{1/3} = \epsilon^{2/3}$.

For $f = e^x$, where $f = f'''$, the best step is $(3\epsilon)^{1/3} = 8.733\times10^{-6}$ and the best relative error about $\epsilon^{2/3} \approx 3.814\times10^{-11}$: two-thirds of the sixteen digits, about ten, survive. The same reasoning for the **forward difference** $[f(x+h)-f(x)]/h = f' + \frac{1}{2}hf'' + \ldots$, whose truncation error is first order in h, gives $E = 2\epsilon\,|f|\,/h + \frac{1}{2}h\,|f''|$, $h_{\mathrm{opt}} = 2\sqrt{\epsilon\,|f|\,/|f''|} \sim \epsilon^{1/2}$ and an error of order $\epsilon^{1/2}$: only eight digits. The script scans h and finds:

```
best h: forward 1.2e-08 (predicted 3.0e-08),  central 8.2e-06 (predicted 8.7e-06)
smallest error: forward 9.0e-09 (predicted 3.0e-08),  central 9.0e-12 (predicted 3.8e-11)
```

The measured best steps sit where (T0.5) puts them. The measured errors are a few times smaller than predicted, because the prediction assumed the worst case, with the two rounding errors adding; on average they partly cancel.

The plateau check. For a function whose third derivative is unknown, (T0.5) cannot be evaluated. The practical test is to compute the derivative for steps a factor of ten apart and look for a **plateau**, a range of h over which the result does not change:

```
h = 1e-02:  central difference = 2.718327133383
h = 1e-03:  central difference = 2.718282281506
h = 1e-04:  central difference = 2.718281832990
h = 1e-05:  central difference = 2.718281828518
h = 1e-06:  central difference = 2.718281828296
h = 1e-08:  central difference = 2.718281821856
h = 1e-10:  central difference = 2.718281155722
h = 1e-12:  central difference = 2.718492098097
```

The exact value is $e = 2.718281828459$. From $h = 10^{-2}$ to 10^{-4} the digits settle (truncation shrinking a hundredfold per step); at $h = 10^{-5}$ and 10^{-6} the results agree with each other to ten digits; below that, round-off takes over, and at $h = 10^{-12}$ only four digits survive. The digits that stay fixed while h changes by a factor of ten are the ones to trust.

The book chooses its steps in exactly this spirit. The emulator of Section 9.20.2 replaces CAMB by a second-order Taylor expansion in the six cosmological parameters, and its first derivatives are central differences with a fixed step for each parameter:

Listing T0.52: Central differences of $\ln C_\ell$, one parameter at a time (`code/ch09/lib_cmbemu.py`)

```
57      E = np.eye(d) * STEPS
58      plus = [lnc(FID + E[i]) for i in range(d)]
59      minus = [lnc(FID - E[i]) for i in range(d)]
60      D = np.array([(plus[i] - minus[i]) / (2 * STEPS[i]) for i in range(d)])
```

Line 57 builds a diagonal matrix whose row i moves parameter i alone by its step (the array `STEPS`, set on line 29 of the same file to 0.02 in $\ln(10^{10}A_s)$, 0.01 in n_s, 0.5 in H_0, and so on). Lines 58–59 run CAMB at each shifted point, and line 60 is (T0.4). These steps are far larger than $\epsilon^{1/3}$, and rightly so. CAMB's output is not accurate to sixteen digits but to perhaps six, so its ϵ is about 10^{-6}, and (T0.5) then asks for steps of order 10^{-2} in relative terms. Section 10.5.1 redoes the balance with such a "code noise" and with the four-point rule, and Section 10.5.2 runs the plateau check on CAMB itself, multiplying all six steps by factors from $\frac{1}{64}$ to 4 and confirming that the forecast does not move over the middle of that range. *The lesson: a numerical derivative is trustworthy only on a plateau; find it by changing h by factors of ten.*

T0.10.3 Integrals, roots and minima: what the black boxes report

`quad`, `brentq` and `minimize` (Section T0.6) are iterations that stop when an internal test is satisfied. Each one reports something about its own reliability, and each can be fooled. The three ways they go wrong are different: `quad` can be confidently wrong, `brentq` refuses loudly, and `minimize` stops quietly.

quad is only as good as the points it looked at. `quad` returns a value and an error estimate (Section T0.6.2). The estimate is the disagreement between two integration rules applied to the same function values, and so it says nothing about regions where the function was never evaluated. The script integrates a Gaussian of width 0.01 centred at 37.3, whose integral is exactly 1, over $[0, 100]$, and then tries four remedies:

```
quad narrow peak on [0, 100]: 0.000e+00 (claimed error 0.0e+00);  tighter tolerance:
    0.000e+00;  points=[37.3]: 4.951e-14;  points=[37.25, 37.35]: 0.9999994267 (claimed
    8.7e-10);  on [37.2, 37.4]: 1.0000000000 (claimed 8.7e-10)
```

Over $[0, 100]$ `quad` first applies a 21-point rule to the whole interval. No point lands within the peak, every value is zero or astronomically small, both rules agree on zero, and `quad` reports 0 with a claimed error of 0. Tightening the tolerance changes nothing, because by `quad`'s own estimate the answer is already exact. Telling it that something happens at 37.3, with `points=[37.3]`, still fails, and instructively: the peak now sits on the boundary between two pieces, and the integration rules never evaluate the function at the ends of a piece. An interval exactly as wide as the peak, `points=[37.25, 37.35]`, nearly works, and yet the answer is too small by 5.7×10^{-7} while the claimed error is 10^{-9}: the missing amount is the probability beyond $\pm 5\sigma$ (twice the 2.867×10^{-7} of Section T0.6.1), which lives in the two long outer pieces where `quad` once again saw nothing. Only an interval that contains the whole peak with room to spare gives 1.0000000000.

The book's integrals are chosen with this in mind: the limits and break points are put where the function lives. The posterior mean of a location parameter with a Student-t likelihood, in the self-normalised importance-sampling study of Section 6.12.4, is one ratio of two integrals:

Listing T0.53: Integration limits wide enough for heavy tails, and a larger subdivision limit (`code/ch06/27_importance.py`)

```
114 xdat = np.array([-4.0, 0.5, 1.0])
115 like = lambda th: np.prod(stats.t.pdf(xdat[:, None] - th[None, :], df=3), axis=0)
116 num = integrate.quad(lambda t: t * like(np.array([t]))[0], -60, 60, limit=400)[0]
117 den = integrate.quad(lambda t: like(np.array([t]))[0], -60, 60, limit=400)[0]
```

Line 115 is the likelihood of three data points at -4, 0.5 and 1, a product of three t densities with three degrees of freedom. The range $[-60, 60]$ is far wider than the data, because t tails fall only as a power of the distance and a short range would cut off a noticeable part of the integral; `limit=400` lets `quad` subdivide up to 400 times instead of the default 50, so that it can resolve

the structure near the data within that wide range. The checks for any quad result follow from the example: plot the integrand once; tighten `epsabs` and `epsrel` and see whether the value moves; split the range or change its ends and see whether the value moves. A value that moves was never as accurate as claimed.

`brentq` needs a bracket, and says so. `brentq(f, a, b)` requires $f(a)$ and $f(b)$ to have opposite signs (Section T0.6.3). If they do not, it stops at once:

```
brentq on [0, 1] for x^2 - 2: ValueError: f(a) and f(b) must have different signs
brentq on [0, 2]: 1.414213562373136   (sqrt 2 = 1.414213562373095)
```

On $[0, 1]$ the function $x^2 - 2$ is negative at both ends, so there is no guaranteed root and `brentq` refuses; on $[0, 2]$ it finds $\sqrt{2}$ to fourteen digits. This failure is friendly. The care goes into choosing the bracket so that it contains exactly the root wanted: the exact binomial interval of Section T0.9.1 (lines 40–41 of that excerpt) brackets the lower end between 10^{-6} and the estimate z/N, and the upper end between z/N and $1 - 10^{-6}$, because each tail probability crosses its target exactly once on its own side of the estimate.

`minimize` can stop early, and reports it only if asked. A minimiser stops when its steps become small, when it runs out of iterations, or when it can no longer find a way downhill. Only the first is success. The script minimises the five-dimensional Rosenbrock function, a long curved valley whose minimum is at $(1, 1, 1, 1, 1)$, twice:

Listing T0.54: A minimiser stopped early, and one allowed to finish (`code/chT0/08_trust.py`)

```
105 rosen = optimize.rosen                                  # a curved valley, minimum at (1, 1,
        1, 1, 1)
106 x_start = np.zeros(5)
107 short = optimize.minimize(rosen, x_start, method="Nelder-Mead", options=dict(maxiter=200))
108 full = optimize.minimize(rosen, x_start, method="BFGS", jac=optimize.rosen_der)
109 say(f"Nelder-Mead, 200 iterations: success = {short.success}, message = '{short.message}', "
110     f"x = {np.round(short.x, 3)}, |grad| =
        {np.linalg.norm(optimize.rosen_der(short.x)):.2e}")
111 say(f"BFGS with gradient: success = {full.success}, x = {np.round(full.x, 6)}, "
112     f"|grad| = {np.linalg.norm(optimize.rosen_der(full.x)):.2e}")
```

Line 107 runs Nelder–Mead with at most 200 iterations, line 108 runs BFGS with the exact gradient, and lines 109–112 print, for each, the flag `success`, the point found, and the length of the gradient there:

```
Nelder-Mead, 200 iterations: success = False, message = 'Maximum number of iterations has
    been exceeded.', x = [ 0.714  0.497  0.248  0.065 -0.023], |grad| = 7.60e+00
BFGS with gradient: success = True, x = [1. 1. 1. 1. 1.], |grad| = 5.00e-06
```

The first result looks like an answer, a point with a function value of 1.868, but `success` is `False`, the message says the iteration limit was reached, and the gradient there has length 7.598, far from zero. At a true minimum the gradient vanishes, as it does for BFGS, 5.001×10^{-6}. Three checks catch an early stop: read `res.success` and `res.message`; evaluate the gradient (numerically if need be) at `res.x`; and restart from `res.x`, or from a different starting point, to see whether the answer moves. For a likelihood, also check that the curvature there gives a sensible error bar (Chapter 3).

T0.10.4 Linear algebra: the condition number

The question. Solving $A\boldsymbol{x} = \boldsymbol{b}$ is the most common linear-algebra task in the book: every χ^2, every Gaussian likelihood and every Fisher matrix contains one. The data $\boldsymbol{b}$ is never exact: it

carries at least rounding error, usually measurement noise. How much does a small relative change of $\boldsymbol{b}$ change $\boldsymbol{x}$?

The smallest example. Take $A = \mathrm{diag}(1,\ 10^{-6})$. The equation splits into $x_1 = b_1$ and $x_2 = 10^6\, b_2$. A change of $\boldsymbol{b}$ by 10^{-16} in its second component changes x_2 by 10^{-10}, while $\boldsymbol{x}$ itself may be of order 1: a relative change 10^6 times that of $\boldsymbol{b}$. The matrix stretches some directions a million times more than others, and inverting it magnifies whatever lies along the weak direction. That ratio of stretches is the whole story.

The general bound. For any perturbation $\delta\boldsymbol{b}$ the solution changes by $\delta\boldsymbol{x} = A^{-1}\delta\boldsymbol{b}$. Write $\|A\|$ for the largest factor by which A stretches any vector (its largest singular value, which for a symmetric positive-definite matrix is its largest eigenvalue), so that $\left\|A^{-1}\right\|$ is one over the smallest. Then

$$\frac{\|\delta\boldsymbol{x}\|}{\|\boldsymbol{x}\|} \overset{(1)}{=} \frac{\left\|A^{-1}\delta\boldsymbol{b}\right\|}{\|\boldsymbol{x}\|} \overset{(2)}{\le} \frac{\left\|A^{-1}\right\|\,\|\delta\boldsymbol{b}\|}{\|\boldsymbol{x}\|} \overset{(3)}{\le} \left\|A^{-1}\right\|\,\|A\|\,\frac{\|\delta\boldsymbol{b}\|}{\|\boldsymbol{b}\|} \equiv \kappa(A)\,\frac{\|\delta\boldsymbol{b}\|}{\|\boldsymbol{b}\|}. \tag{T0.6}$$

(1) $A(\boldsymbol{x} + \delta\boldsymbol{x}) = \boldsymbol{b} + \delta\boldsymbol{b}$ and $A\boldsymbol{x} = \boldsymbol{b}$ give $\delta\boldsymbol{x} = A^{-1}\delta\boldsymbol{b}$.
(2) No vector is stretched by A^{-1} more than $\left\|A^{-1}\right\|$.
(3) $\|\boldsymbol{b}\| = \|A\boldsymbol{x}\| \le \|A\|\,\|\boldsymbol{x}\|$, so $1/\|\boldsymbol{x}\| \le \|A\|\,/\|\boldsymbol{b}\|$.

The **condition number** $\kappa(A) = \|A\|\,\left\|A^{-1}\right\|$ is the ratio of the largest to the smallest stretch, $\lambda_{\max}/\lambda_{\min}$ for a symmetric positive-definite matrix, and 10^6 in the example. NumPy computes it as `np.linalg.cond(A)`. Since $\delta\boldsymbol{b}$ is at least rounding, of relative size ϵ, the solution can carry a relative error up to $\kappa\epsilon$. In digits: *about* $\log_{10}\kappa$ *of the sixteen digits are lost*. The tour of Section T0.5.2 solved a 10×10 Hilbert system, whose condition number is 1.602×10^{13}: thirteen digits lost, three left. The recovered $\boldsymbol{x}$ was indeed wrong by 2.272×10^{-5}, inside the bound $\kappa\epsilon/2 \approx 2\times10^{-3}$, whether computed with `solve` or with `inv`. No algorithm can do better than the problem allows. What `solve` does achieve is a tiny residual, 8.502×10^{-17}: its $\boldsymbol{x}$ solves a problem extremely close to the one posed, which is the most any method can promise. `inv` followed by a product does not even achieve that (3.584×10^{-5}), the second reason, after speed, for the rule "solve, do not invert".

The book measures condition numbers where it matters. The mode-coupling matrix of the pseudo-C_ℓ method (Section 8.11.2) must be inverted for every mask, and the script that builds it records its condition number for each:

Listing T0.55: The condition number of the coupling matrix, measured (`code/ch08/22_coupling.py`)

```
74      sub = M[2:, 2:]
75      cond = np.linalg.cond(sub)
```

Line 74 keeps the multipoles $\ell \ge 2$ (the monopole and dipole are removed from the maps), and line 75 computes κ. For the full sky it is 1.1, for the 70% cap 1.8: harmless. For the 30% and 10% caps it is 1.3×10^{16} and 1.3×10^{17}, beyond $1/\epsilon$: all sixteen digits lost, the matrix singular to machine precision. Section 8.11.2 explains why, and what is done instead (binning, which keeps only the well-determined combinations).

Cholesky failing is a message. `np.linalg.cholesky` succeeds only for a symmetric matrix whose eigenvalues are all positive, and stops with `LinAlgError` otherwise. When a covariance matrix fails it, the matrix is telling us something. The script estimates the covariance of a 50-bin data vector from 30 and from 200 simulations:

```
30 simulations of 50 bins: smallest eigenvalue -1.3e-15, rank 29, cholesky fails
    (LinAlgError)
200 simulations of 50 bins: smallest eigenvalue 2.7e-01, rank 50, cholesky succeeds
```

Why does 30 fail? The sample covariance $\hat{\mathbf{C}} = \frac{1}{n-1}\sum_{i=1}^{n}(\boldsymbol{x}_i - \bar{\boldsymbol{x}})(\boldsymbol{x}_i - \bar{\boldsymbol{x}})^{\mathsf{T}}$ is a sum of n matrices of the form $\boldsymbol{u}\boldsymbol{u}^{\mathsf{T}}$, each of which stretches only along its own vector $\boldsymbol{u}$. And the n vectors $\boldsymbol{x}_i - \bar{\boldsymbol{x}}$ are not independent: they sum to zero, so any one is minus the sum of the others. So $\hat{\mathbf{C}}$ stretches at most $n-1$ directions and is exactly zero along the remaining $p-(n-1)$. With $n = 30$ and $p = 50$ the rank is 29, twenty-one eigenvalues are zero (computed as $\pm 10^{-15}$, rounding around zero), and the Cholesky factor does not exist. With $n = 200$ all 50 eigenvalues are positive and it succeeds. The failure says: not enough simulations to estimate this covariance. Even when $n > p$ the inverse of $\hat{\mathbf{C}}$ is biased, and the Hartlap factor $(n-p-2)/(n-1)$ of Section 8.13.2 corrects it; Section 8.13 asks how many simulations are enough.

A script that might meet such a matrix catches the error instead of crashing. The bootstrap of Hubble's 1929 galaxies (Section 11.14.3) refits a model with a solar-motion term to each resampled set of twenty-four galaxies:

Listing T0.56: A resample whose fit is singular is recorded as missing, not hidden (`code/ch11/08_hubble1929.py`)

```
119     for i in range(nb):
120         j = rng.integers(0, N, N)
121         Kb_a[i] = fit_origin(r[j], v[j])[0]
122         try:
123             Kb_b[i] = fit_solar(r[j], v[j], ra[j], dec[j])[0][0]
124         except np.linalg.LinAlgError:
125             Kb_b[i] = np.nan
126     Kb_b = Kb_b[np.isfinite(Kb_b)]
```

Line 120 draws N galaxy indices with replacement, and line 121 refits the simple model. A resample can repeat a few galaxies so often that their directions on the sky no longer determine the four parameters of the fit, and the linear solve inside `fit_solar` (`np.linalg.solve` on the normal equations) then fails. Lines 122–125 catch exactly that error and record the resample as `np.nan`; line 126 removes those before any statistic is formed, and the number removed can be printed. *The lesson:* $\log_{10}\kappa$ *digits are lost to the matrix; a failed Cholesky factor is a diagnosis, not a nuisance.*

T0.10.5 Monte Carlo noise: every simulated number has an error bar

A Monte Carlo estimate is an average of N independent draws, so its standard deviation is $\sigma/\sqrt{N}$, with σ the standard deviation of a single draw: the variance of an average is the single-draw variance divided by N, derived in Section 6.11.2. The rule that follows is simple: every simulated number is quoted with its $\sigma/\sqrt{N}$, which is estimated from the same draws. The first Monte Carlo of the book, the estimate of π from random points in a square (Section 0.6), does exactly that:

Listing T0.57: A Monte Carlo estimate and its standard error, side by side (`code/ch00/06_reproducible_seeds.py`)

```
21 # a one-line Monte Carlo: fraction of darts in the unit quarter-disc -> pi/4
22 N = 1_000_000
23 x, y = r1.random(N), r1.random(N)
24 frac = np.mean(x**2 + y**2 < 1.0)
25 pi_hat = 4 * frac
26 pi_err = 4 * np.sqrt(frac * (1 - frac) / N)       # binomial error of a fraction, times 4
```

Line 24 is the fraction of points inside the quarter disc, line 25 the estimate $\hat{\pi} = 4\times$fraction, and line 26 its standard error: a fraction of N independent yes/no draws has variance $q(1-q)/N$, and multiplying by 4 multiplies the standard deviation by 4. With $N = 10^6$ the script finds $\hat{\pi} = 3.143 \pm 0.001641$, which is within one standard error of π.

Rerunning with a different seed. The error bar is a prediction: other seeds should scatter by about that much. That prediction can be tested directly. The script estimates $\mathrm{P}(Z > 2)$ with $N = 10^4$ draws for eight different streams:

```
P(Z>2) exact 0.02275;  N = 10^4, eight seeds: [0.0226 0.0203 0.0229 0.0196 0.0251 0.0229
    0.0227 0.0223];  predicted spread 0.00149, observed 0.00169
```

The eight estimates scatter by 0.00169 against the predicted 0.00149, the agreement expected for eight values, whose own standard deviation is uncertain by about $1/\sqrt{2\times 7} \approx 27\%$ (Section 7.12.3). Figure T0.26 (left) shows the same for N from 10^2 to 10^6: the estimates converge onto the exact value inside a band that narrows as $1/\sqrt{N}$. Each factor of ten in accuracy costs a factor of a hundred in draws.

Common random numbers. Often the question is not a number but a difference: how much does a probability change when a parameter changes? Two independent Monte Carlo runs each carry their own noise, and the noise of the difference is larger than either. The cure is to run both settings on the *same* random draws. Why that helps follows from the variance of a difference of two estimates A and B:

$$\mathrm{Var}(A - B) \overset{(1)}{=} \mathrm{Var}\, A + \mathrm{Var}\, B - 2\,\mathrm{Cov}(A, B). \tag{T0.7}$$

(1) Expand $\mathbb{E}[(A - B - \mathbb{E}\,A + \mathbb{E}\,B)^2]$: the two squares give the variances, and the cross term gives $-2\,\mathrm{Cov}(A, B)$.

With independent draws, $\mathrm{Cov}(A, B) = 0$ and the variances add. With the same draws, the two estimates rise and fall together, $\mathrm{Cov}(A, B)$ is positive and nearly as large as the variances, and most of the noise cancels in the difference. This is the method of **common random numbers**. The script compares $\mathrm{P}(X > 2)$ for $X \sim \mathcal{N}(\mu, 1)$ at $\mu = 0$ and at $\mu = 0.1$, repeating the comparison 400 times with 10000 draws each:

Listing T0.58: The same change estimated with fresh draws, and with the same draws shifted (`code/chT0/08_trust.py`)

```
147 delta, M, R = 0.1, 10_000, 400
148 diff_ind, diff_crn = [], []
149 r5 = rng_for("chT0", "08_trust", 99)
150 for _ in range(R):
151     z1, z2 = r5.standard_normal(M), r5.standard_normal(M)
152     diff_ind.append(np.mean(z2 + delta > 2) - np.mean(z1 > 2))    # fresh draws for the
        second setting
153     diff_crn.append(np.mean(z1 + delta > 2) - np.mean(z1 > 2))    # the same draws, shifted
```

Line 151 draws two independent sets of standard Gaussians. Line 152 estimates the change with fresh draws for the second setting; line 153 uses the first set for both settings, shifting it by $\delta = 0.1$ for the second. The exact change is 0.00597. Its scatter over the repetitions is 0.00224 with independent draws and 0.00076 with common ones, a variance 9 times smaller, worth 9 times as many draws (Figure T0.26, right). With independent draws a single comparison measures the change at only 2.7 standard deviations; with common random numbers, at 7.9.

The book uses common random numbers wherever it compares settings. The CMB pipeline of Section 8.5 computes seven different spectra from the *same* simulated sky, so that the bias of

one estimator relative to another is measured to a fraction of a per cent. The simulated Fisher matrices of Section 12.20.2 and Section 12.26.1 take each derivative from maps that share their random seed, so that the maps differ only through the change of cosmology. *The lesson: quote $\sigma/\sqrt{N}$ with every simulated number, and compare settings on the same random numbers.*

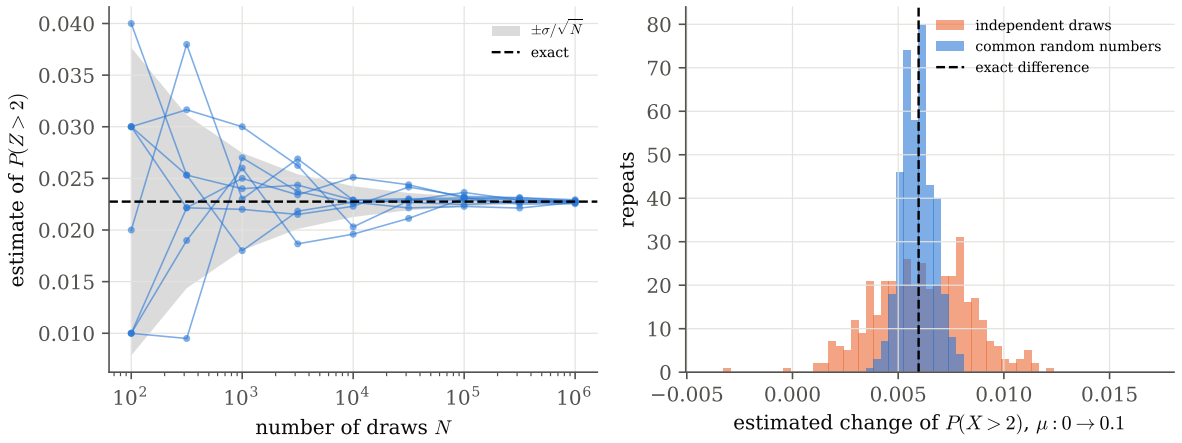

Figure T0.26: Monte Carlo noise. Left: estimates of $\mathrm{P}(Z > 2)$ from eight independent streams (blue lines) against the number of draws; the grey band is the predicted $\pm\sigma/\sqrt{N}$ around the exact value (dashed). Right: the estimated change of $\mathrm{P}(X > 2)$ when the mean moves from 0 to 0.1, over 400 repetitions of 10^4 draws each. Independent draws for the two settings (orange) scatter about three times more widely than common random numbers (blue) around the exact change (dashed).

T0.10.6 Convergence: change the resolution until nothing changes

Every computation in the book has a resolution: a grid spacing, a number of points per axis, a HEALPix N_{side}, a maximum multipole $\ell_{\max}$, a number of simulations or of chain steps. The answer at finite resolution differs from the answer the resolution is meant to approximate. The test is a **convergence study**: compute at two or three resolutions, and accept the answer only when it changes by less than its other errors.

Example: the trapezoid rule. The integral $\int_0^\pi \sin x \, \mathrm{d}x = 2$ computed by the trapezoid rule with n intervals:

```
trapezoid n =  8: 1.9742316019   error -2.58e-02
trapezoid n = 16: 1.9935703438   error -6.43e-03
trapezoid n = 32: 1.9983933610   error -1.61e-03
```

Each halving of the step divides the error by 4.008, almost exactly 4. That number is itself information: an error that falls as h^2 is what the trapezoid rule should give (for a smooth function the trapezoid value exceeds the integral by $\frac{(b-a)h^2}{12}\overline{f''}$, with $\overline{f''}$ an average of the second derivative, here $-\sin x < 0$, hence the negative errors), so the code behaves as its theory says. An error ratio far from the expected one is the sign of a bug or of a function that is not smooth.

Richardson extrapolation. Knowing that the error falls as h^2 allows it to be removed. Write the result with step h as its limit plus the leading error, and do the same for $h/2$:

$$T(h) \overset{(1)}{=} I + ch^2 + O(h^4), \qquad T(h/2) \overset{(2)}{=} I + \tfrac{1}{4}ch^2 + O(h^4),$$
$$\frac{4T(h/2) - T(h)}{3} \overset{(3)}{=} \frac{4I + ch^2 - I - ch^2}{3} + O(h^4) = I + O(h^4). \tag{T0.8}$$

(1) The trapezoid error expanded in powers of the step. For a smooth function only even powers appear.
(2) The same with h replaced by $h/2$: the coefficient c is the same, so the h^2 term is a quarter as large.
(3) Four times the second line minus the first: the h^2 terms cancel and $3I$ remains; divide by 3.

The script prints the result:

```
Richardson (4 T16 - T8)/3 = 2.0000165910   error 1.66e-05
```

From the two cheap values at $n = 8$ and 16, whose errors are -0.02577 and -0.00643, the combination gives an error of 1.659×10^{-5}: about four hundred times smaller than at $n = 16$, for no new function evaluations. The four-point derivative of Section 10.5.1 is the same trick applied to (T0.4).

The book's convergence studies follow this pattern. The brute-force evidence of a four-parameter model in Section 5.19.1 is computed with n points per axis for seven values of n:

Listing T0.59: The same integral at seven resolutions, each timed (`code/ch05/27_grid_cost.py`)

```
50 ns = [8, 12, 16, 24, 32, 48, 64]
51 times, lnBs = [], []
52 for n in ns:
53     t0 = time.perf_counter()
54     lnZ = ln_Z_bump_bruteforce(y, n)
55     times.append(time.perf_counter() - t0)
56     lnBs.append(lnZ - lnZ0)
57     print(n, times[-1], lnBs[-1])
```

Line 50 lists the resolutions, and the loop of lines 52–57 computes the log Bayes factor at each, timing it with `time.perf_counter` (Section T0.12). The answer moves from 4.558 at $n = 12$ to 2.379 at $n = 24$ and 2.1 at $n = 64$, against the exact 2.096: only the finest grids have converged. Section 8.6.5 does the same with the number of simulated skies, watching the estimated bias and error bar settle inside the band $\pm\sigma/\sqrt{N}$. *The lesson: an answer is converged when doubling the resolution changes it by less than its other errors.*

T0.10.7 Validation: test the code where the answer is known

The checks so far estimate the size of an error. None of them catches a plain mistake in the code: a sign, a factor of two, a wrong index. Those are caught by one habit, used throughout the book: before a method is trusted on a problem with no known answer, it is run on a problem with one. The Monte Carlo variance of simulated $\widehat{C}_\ell$ is compared with the cosmic variance $2C_\ell^2/(2\ell+1)$ before simulations are used for masked skies (Section 7.12.3); the exact binomial interval found by root finding is compared with the closed formula in terms of the beta distribution (Section T0.9.1); the healpy round trip of Section T0.8.5 must return the spectrum that went in; the Fisher forecast is checked against an MCMC run on the same likelihood (Chapter 10).

A comparison can be written into the script as an `assert`: `assert condition` does nothing when the condition is true and stops the script with an error when it is false. The tiny-image study of Section 12.22.1 enumerates every one of the $2^9 = 512$ black-and-white 3×3 images and checks three facts about each:

Listing T0.60: Three identities checked on every one of 512 images (`code/ch12/c01_tiny.py`)

```
29 configs = []
30 for bits in itertools.product([0, 1], repeat=9):
31     m = np.array(bits, bool).reshape(3, 3)
```

```
32      b0, b1 = betti_plane(m)
33      chi = euler_cubical(m)
34      assert chi == b0 - b1                                   # the Euler relation, checked
        512 times
35      # scikit-image: 8-connected pieces, Euler number with 8-connectivity (connectivity=2)
36      assert measure.label(m, connectivity=2).max() == b0
37      assert measure.euler_number(np.pad(m, 1), connectivity=2) == chi
38      configs.append((b0, b1, chi, m.sum()))
```

Line 30 runs through all 512 patterns of nine bits, line 31 turns each into a 3×3 image, and lines 32–33 count its pieces and holes and compute its Euler characteristic with the book's own functions. Line 34 asserts the Euler relation $\chi = \beta_0 - \beta_1$; lines 36–37 assert that scikit-image's independent implementation finds the same number of pieces and the same χ. If any of the 1536 checks failed, the script would stop at that image. These are exact integer comparisons, so == is right here; between real numbers the comparison is made with a tolerance (Section T0.10.1).

The census of Section T0.1 counts how often the book writes such checks into its code: 19 `assert` statements in 15 files, and 13 calls of `np.isclose`, `np.allclose` and similar comparison functions in 9. That is a small number, and it understates the validation, because most of the book's checks are not asserts. They are a figure in which the simulation is drawn over the analytic curve (the black dashed `theory_line` of Section T0.7), or a pair of numbers saved by the script and quoted side by side in the text. A comparison in a figure or in the text is read by a person, who notices a discrepancy that no one thought to assert. *The lesson: a method is trusted where its answer is unknown only after it has reproduced an answer that is known.*

How this is used in real research: Verification first, then research

The same simulation code plays two roles. Run on an ideal full-sky Gaussian field, it *verifies*: its variance of $\widehat{C}_\ell$ must reproduce $2C_\ell^2/(2\ell+1)$ within its Monte Carlo error. Run with a mask, a beam and inhomogeneous noise, where no formula exists, it is the *research instrument*: the covariance it produces feeds a likelihood (Chapter 8). Research codes follow this order as a rule, and publish their validation tests next to their results.

T0.10.8 The decision rule: is a difference real?

Every check above ends with a comparison of two numbers: a simulation and a formula, two resolutions, two methods, two settings. They never agree exactly. When is a difference real, and when is it noise? The rule is the one every physicist uses for measurements. Collect the uncertainty of each number from every source, numerical and Monte Carlo, add the independent ones in quadrature, and divide the difference by the result:

$$z = \frac{|x_1 - x_2|}{\sqrt{\sigma_1^2 + \sigma_2^2}}, \qquad \sigma_i^2 = \sigma_{i,\mathrm{MC}}^2 + \sigma_{i,\mathrm{num}}^2. \tag{T0.9}$$

If the two numbers really estimate the same quantity and the errors are roughly Gaussian, z is the absolute value of a standard Gaussian variable: below 1 two times in three, below 2 nineteen times in twenty, above 3 about once in four hundred. So $z \lesssim 2$ means "consistent"; z between 2 and 3 means "look again", with more draws or another seed; $z \gtrsim 3$, in a single planned comparison, means that the difference is real, which may mean a bug. When many comparisons are made at once, a few values of z near 2 to 3 are expected by chance alone, exactly the look-elsewhere problem of Section 4.14.

Example: the Monte Carlo variance at the quadrupole. Section 7.12.3 estimates the variance of $\widehat{C}_\ell$ from 20,000 simulated skies and compares it with the cosmic variance $2C_\ell^2/(2\ell+1)$. At $\ell = 2$ the ratio of the two is 1.021, a 2% excess. Is the formula wrong, or the simulation, or neither? The analytic answer has no numerical error worth mentioning, and the simulated one has the Monte Carlo error derived there, 0.01483 in units of the ratio. So

$$z = \frac{1.021 - 1}{0.01483} \approx 1.4,$$

well inside the range of chance: neither is wrong. Had the excess been 10%, z would have been about 7, and the code would have been searched for the bug.

Example: a change seen with and without common random numbers. In Section T0.10.5, a single comparison of $P(X > 2)$ at $\mu = 0$ and $\mu = 0.1$ with independent draws measures the true change 0.00597 against a noise of 0.00224: $z \approx 2.7$, a "look again". Over the 400 repeats, 60% of such single comparisons fall short of 3σ, so one of them alone often would not establish that the probability changed at all. With common random numbers the noise is 0.00076 and $z \approx 7.9$, and 0% fall short: a difference beyond doubt, from the same number of draws.

Key idea: When a computed number can be trusted

A computed number is trusted to the extent that its error budget is known: rounding (ϵ times the amplification of cancellation or of the condition number), the method (step size, tolerance, resolution, checked by changing them), and Monte Carlo noise ($\sigma/\sqrt{N}$, checked by changing the seed). A difference is real when it is large compared with the combined budget, $z \gtrsim 3$; and a method is trusted on an unknown answer only after it has reproduced a known one.

Table 1 collects the checks in the form in which they are needed: a symptom, the check that diagnoses it, the fix, and a place in the book where it is done.

T0.11 When sixteen digits are not enough: mpmath

A double-precision number carries about sixteen significant digits and spans magnitudes from about 10^{-308} to 10^{308} (Section T0.10.1). For almost everything in the book that is ample. Occasionally it is not, and the failure has a recognisable shape: a probability so small that it underflows to zero, a sum whose terms cancel so completely that no digit of the answer survives, a factorial or a Gamma function so large that it overflows. The library **mpmath** computes with as many digits as we ask for, and the question is when to reach for it, how many digits to ask for, and what it costs.

The smallest example: the significance of a large excess. The one-sided p-value of a $z\sigma$ excess is the Gaussian tail $P(Z > z)$ (Chapter 4). There are three ways to compute it in SciPy: `1 - norm.cdf(z)`, `norm.sf(z)` (the survival function, which computes the tail directly) and `norm.logsf(z)`, its natural logarithm. The script `code/chT0/09_mpmath.py` compares all three with mpmath at fifty digits:

```
z =  5: 1-cdf = 2.8665e-07   sf = 2.8665e-07   log10 sf =   -6.5426   mpmath log10 =
    -6.5426
z =  8: 1-cdf = 6.6613e-16   sf = 6.2210e-16   log10 sf =  -15.2061   mpmath log10 =
    -15.2061
z =  9: 1-cdf = 0.0000e+00   sf = 1.1286e-19   log10 sf =  -18.9475   mpmath log10 =
    -18.9475
```

symptom	check	fix	in the book
== between real numbers fails	print the difference; compare it with ϵ times the size	`np.isclose`, or a relative tolerance	Sections T0.9.1 and T2.9
digits lost in a small difference	count the leading digits that cancel, (T0.3)	rewrite the formula; subtract the large common part first	Sections T0.10.1 and 3.4.4
derivative changes with the step	scan h by factors of ten; look for a plateau	a step on the plateau; four-point rule	Sections 9.20.2 and 10.5.2
integral with a tiny claimed error	plot the integrand; tighten the tolerance; change the range	limits and `points` where the function lives	Section 6.12.4
`brentq` raises `ValueError`	evaluate f at both ends	a bracket with a sign change around the wanted root	Section 4.10.4
minimiser result looks plausible	`res.success`, `res.message`, gradient at `res.x`	more iterations; restart from `res.x`; a gradient-based method	Section T0.6.4
solution of $A\boldsymbol{x} = \boldsymbol{b}$ unstable	`np.linalg.cond(A)`; $\log_{10}\kappa$ digits are lost	`solve`, not `inv`; bin or regularise	Section 8.11.2
`cholesky` raises `LinAlgError`	eigenvalues of the matrix; rank against the number of simulations	more simulations; Hartlap factor	Sections 8.13 and 8.13.2
simulated number without an error bar	$\sigma/\sqrt{N}$ from the same draws; another seed	quote it; increase N	Sections 6.11.2 and 7.12.3
noisy difference of two simulations	scatter of the difference over seeds	common random numbers	Sections 8.5 and 12.20.2
answer depends on grid, N_{side}, $\ell_{\max}$	halve the step or double the size	finer resolution; Richardson extrapolation	Sections 5.19.1 and 8.6.5
a new method on a new problem	run it where the answer is known	find the bug before trusting the result	Sections 7.12.3 and 12.22.1
two numbers disagree	z of (T0.9) with all errors	$z \lesssim 2$: noise; $z \gtrsim 3$: real, or a bug	Section 7.12.3

Table 1: Is the number real? Thirteen symptoms, the check that diagnoses each, the usual fix, and a place in the book where it is done.

```
z = 20: 1-cdf = 0.0000e+00   sf = 2.7536e-89   log10 sf =  -88.5601   mpmath log10 =
    -88.5601
z = 37: 1-cdf = 0.0000e+00   sf = 5.7256e-300   log10 sf = -299.2422   mpmath log10 =
    -299.2422
z = 38: 1-cdf = 0.0000e+00   sf = 0.0000e+00   log10 sf = -315.5398   mpmath log10 =
    -315.5398
z = 39: 1-cdf = 0.0000e+00   sf = 0.0000e+00   log10 sf = -332.2714   mpmath log10 =
    -332.2714
z = 40: 1-cdf = 0.0000e+00   sf = 0.0000e+00   log10 sf = -349.4370   mpmath log10 =
    -349.4370
```

At 5σ, the discovery threshold of particle physics, all three are fine: even the naive `1 - cdf` is accurate to a relative 1.547×10^{-10}. At 8σ the naive form is already 7% wrong, and from 8.5σ on it returns exactly 0. The reason is the spacing of storable numbers just below 1, which is $\epsilon/2 \approx 1.1 \times 10^{-16}$: the cdf is stored as the nearest of these, so a tail much smaller than 10^{-16}

cannot be represented as "1 minus something" at all. `sf` avoids the subtraction and stays accurate down to about 10^{-300}, but at 38.0σ the tail itself, about 10^{-316}, is below the smallest number with full precision, 2.225×10^{-308}, and the function returns 0. `logsf` never forms the tiny number: it computes $\ln \mathrm{P}(Z > z)$ directly, a modest negative number, and agrees with mpmath to every printed digit all the way to 40σ, where $\log_{10} \mathrm{P} = -349.44$ (Figure T0.27, left). The naive choice fails silently at 8σ; the good choice, `sf` or `logsf`, costs nothing. *The lesson: rewrite first; reach for more digits only when no rewriting will do, and then mostly to check.*

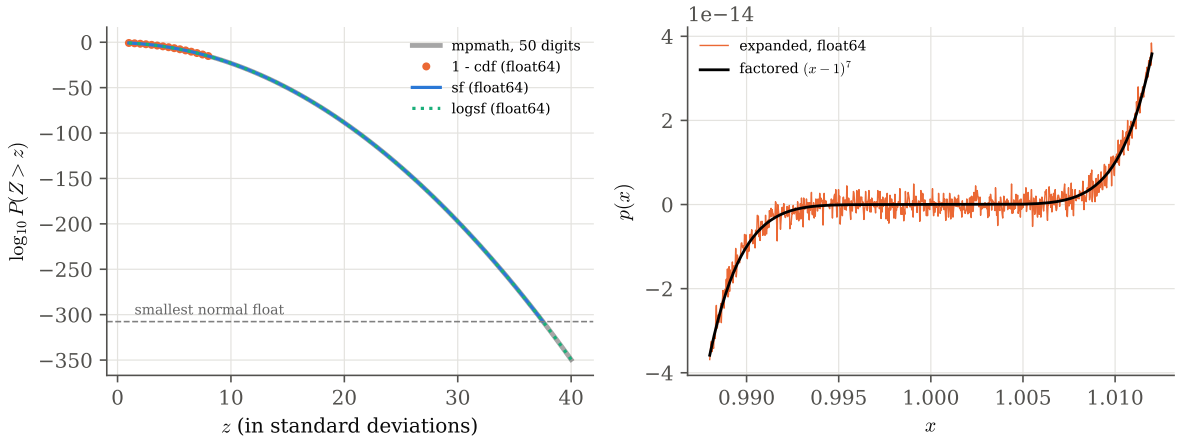

Figure T0.27: Where double precision breaks. Left: $\log_{10} \mathrm{P}(Z > z)$ from mpmath at fifty digits (thick grey) and from three float64 routes. `1 - cdf` (orange points) stops near 8.5σ, `sf` (blue) at 38σ, where the tail falls below the smallest normal float (dashed); `logsf` (dotted) follows mpmath to the end. Right: the polynomial $(x-1)^7$ near its root, evaluated from its expanded coefficients in float64 (orange) and in factored form (black). The expanded form returns rounding noise of size about 10^{-14} instead of a smooth curve.

T0.11.1 Log space first

Most overflows and underflows in statistics come from products of many factors (likelihoods), from factorials and Gamma functions (binomial and Poisson probabilities, normalising constants), and from exponentials of large numbers (evidences, Boltzmann weights). All of them disappear when the computation is done with logarithms, which turn products into sums and keep every intermediate number of modest size. SciPy supplies the two tools that make this painless.

`gammaln`. `scipy.special.gammaln(x)` returns $\ln \Gamma(x)$ without forming $\Gamma(x)$. Since $n! = \Gamma(n+1)$, $\ln 200!$ is `gammaln(201)`, which is 863.232, while $200!$ itself, about 10^{375}, overflows (Section T0.6.5). A ratio of Gamma functions is the exponential of a difference of `gammaln`s. The bias factor $c_4(N) = \sqrt{2/(N-1)}\,\Gamma(N/2)/\Gamma\big((N-1)/2\big)$ of the sample standard deviation (Section 3.4.1) is computed this way:

Listing T0.61: A ratio of Gamma functions as the exponential of a difference of logarithms (`code/ch03/04_sample_variance.py`)

For $N = 5$ the direct ratio would be harmless, but $\Gamma(N/2)$ overflows above $N \approx 344$, while the line as written works for any N: the logarithms stay of order $N \ln N$, and their difference, the logarithm of c_4, is close to zero.

`logsumexp`. An evidence, a mixture density or a normalisation is a sum of exponentials, $\ln \sum_i e^{a_i}$, and the a_i are log-likelihoods, often in the hundreds or thousands. For $a_1 = -1000$ and $a_2 = -1001$, `np.exp` underflows both to 0 and the logarithm of the sum is $-\infty$. Factoring out the largest term $m = \max_i a_i$ removes the problem:

$$\ln \sum_i e^{a_i} \overset{(1)}{=} \ln\Big(e^m \sum_i e^{a_i - m}\Big) \overset{(2)}{=} m + \ln \sum_i e^{a_i - m}. \tag{T0.10}$$

(1) $e^{a_i} = e^m e^{a_i - m}$ for every i; take the common factor out of the sum.
(2) The logarithm of a product is the sum of the logarithms, and $\ln e^m = m$.

Now every exponent $a_i - m$ is at most 0, the largest term is exactly 1, nothing overflows, and the terms that underflow are those too small to matter. For the example, $-1000 + \ln(1 + e^{-1}) = -999.687$. `scipy.special.logsumexp` does exactly this. The posterior probabilities of three competing models in Section 5.18.3 are their evidences normalised to sum to one, computed in log space throughout:

Listing T0.62: Posterior model probabilities from log-evidences (`code/ch05/25_how_many_bumps.py`)

```
66      lnZ = np.array([lnZ0, lnZ0 + lnB1, lnZ0 + lnB2])
67      lnp[key] = lnZ - logsumexp(lnZ)
```

Line 66 collects the three log-evidences, for no bump, one bump and two bumps. Line 67 subtracts $\ln \sum_k e^{\ln Z_k}$ from each, which is the logarithm of $Z_k / \sum_j Z_j$, the posterior probability of model k when the three are equally probable a priori. The evidences themselves are never formed. The tail probability above is the same idea in SciPy's distributions: `logpdf`, `logcdf` and `logsf` exist for every distribution, and a likelihood of many data points is built as a sum of `logpdf` values rather than a product of `pdf` values, which underflows to zero once there are a few hundred points.

T0.11.2 Cancellation that cannot be rewritten away

Sometimes no rewriting is available, because the formula arrives as given. A polynomial from a series expansion or a fit comes as its coefficients, not in factored form. The script takes the polynomial $(x-1)^7$ in its expanded form, $x^7 - 7x^6 + 21x^5 - 35x^4 + 35x^3 - 21x^2 + 7x - 1$, evaluates it near $x = 1$ by Horner's rule (multiply by x, add the next coefficient, repeat), and compares with the factored form:

```
x = 1.01: float64 expanded = 7.993606e-15   factored = 1.000000e-14
          mpmath 15 digits = 7.9936058e-15   30 digits = 1.0e-14   exact (x = 1.01 as
    decimal) = 1.0e-14
```

At $x = 1.01$ the exact value is 10^{-14}; float64 returns 7.994×10^{-15}, wrong by 20%. Figure T0.27 (right) shows the expanded form near the root: not a curve but a band of rounding noise. mpmath with fifteen digits reproduces the float64 answer digit for digit, because it is making the same rounding errors with the same number of digits; with thirty digits it returns 1.000×10^{-14}.

How many digits survive? The question is the one answered for a single subtraction by (T0.3), now for a sum of many terms. Suppose each term t_k of a sum $p = \sum_k t_k$ is computed with relative error at most u, the working precision: $u \approx \epsilon/2$ in float64, and $u \approx 10^{-d}$ when mpmath

carries d decimal digits. Then

$$\frac{|\hat{p}-p|}{|p|} \overset{(1)}{=} \frac{|\sum_k t_k\delta_k|}{|\sum_k t_k|} \overset{(2)}{\le} u\,\frac{\sum_k |t_k|}{|\sum_k t_k|} \equiv u\,\kappa,$$
$$\text{digits trusted} \overset{(3)}{=} -\log_{10}(u\kappa) \approx d - \log_{10}\kappa. \tag{T0.11}$$

(1) Each computed term is $t_k(1+\delta_k)$, so the error of the sum is $\sum_k t_k\delta_k$.
(2) The triangle inequality and $|\delta_k| \le u$.
(3) A relative error 10^{-j} means j correct digits; with $u = 10^{-d}$, $-\log_{10} u = d$.

The **condition number** of the sum, $\kappa = \sum_k |t_k| \,/\, |\sum_k t_k|$, is the ratio of the size of the terms to the size of the result. For two terms, a and $-b$, it is $(|a|+|b|)/|a-b|$, the amplification factor of (T0.3); for a linear system it is the $\kappa(A)$ of (T0.6). The rule reads the same each time: *working digits minus* $\log_{10}\kappa$. (Rounding inside Horner's rule adds a factor of order the number of terms, a fraction of a digit to one digit; the rule is a guide, not a guarantee.)

For the expanded polynomial the terms are the binomial coefficients times powers of x, so $\sum_k |t_k| = (x+1)^7$ by the binomial theorem, and

$$\kappa = \frac{(x+1)^7}{|x-1|^7} = \left(\frac{2.01}{0.01}\right)^7 \approx 1.3\times 10^{16} \quad \text{at } x = 1.01,$$

which the script confirms, $\kappa = 1.33e+16$ ($\log_{10}\kappa = 16.1$). With $d \approx 16$ working digits, (T0.11) predicts that *no* digit survives, and indeed none of the float64 answer is right. To keep ten digits we need $d \approx 16.1 + 10 \approx 26$; asking for thirty leaves a margin.

The practical test: d against $2d$. The condition number is rarely known in advance. The practical rule is to compute the same quantity twice, at d and at $2d$ digits, and keep the digits on which the two agree. Why does this work? The error of the $2d$ result is about 10^{-d} times smaller than that of the d result, so the difference between the two is, to a good approximation, the error of the d result itself:

Listing T0.63: The same sum at d and at $2d$ digits, and the number of digits on which they agree (`code/chT0/09_mpmath.py`)

```
77 xs_dec = "1.01"
78 rows = []
79 for dps in (10, 15, 20, 30):
80     mp.mp.dps = dps
81     a = expanded(mp.mpf(xs_dec))
82     mp.mp.dps = 2 * dps
83     b = expanded(mp.mpf(xs_dec))
84     mp.mp.dps = 4 * dps
85     agree = max(float(-mp.log10(abs((a - b) / b))), 0.0) if a != b else float(4 * dps)
86     rows.append((dps, a, b, agree))
87     say(f"dps = {dps:2d}: {mp.nstr(a, 12):>18}   dps = {2 * dps:2d}: {mp.nstr(b, 12):>18}
       agree to "
88         f"{agree:5.1f} digits")
```

Line 80 sets the working precision to `dps` decimal digits, and line 81 evaluates the polynomial at 1.01; line 82 doubles the precision and line 83 evaluates again. The input is given as the string `"1.01"`, so mpmath reads the decimal number exactly to the working precision; `mp.mpf(1.01)` would inherit the binary rounding of the float 1.01. Line 85 converts the relative difference into a number of agreeing digits. The result:

```
dps = 10:  2.18278728426e-10   dps = 20:  9.99999982452e-15   agree to   0.0 digits
dps = 15:   7.9936057773e-15   dps = 30:            1.0e-14   agree to   0.7 digits
```

```
dps = 20:  9.99999982452e-15   dps = 40:            1.0e-14   agree to   7.8 digits
dps = 30:            1.0e-14   dps = 60:            1.0e-14   agree to  16.4 digits
condition number of the expanded sum at x = 1.01: 1.325e+16  (log10 = 16.1)
```

At $d = 10$ and $d = 15$ the two results disagree completely: no digit of the d-digit answer can be trusted, as (T0.11) predicted for $d < 16$. At $d = 20$ they agree on 7.8 digits, and at $d = 30$ on 16.4; the rule, $d - 16$, predicted four and fourteen, so it is conservative, because it assumes that all rounding errors line up. *The lesson: the digits that survive a doubling of the precision are the digits to keep.*

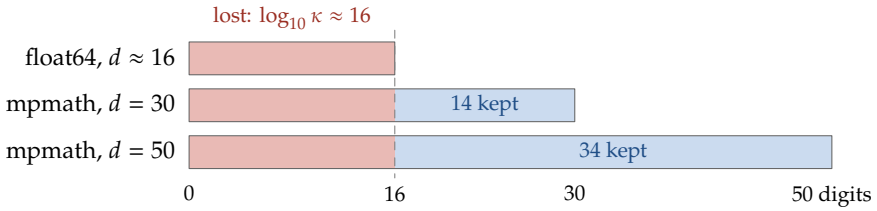

Figure T0.28: The digit budget of the expanded polynomial at $x = 1.01$. Each bar is the working precision; cancellation consumes the first $\log_{10}\kappa \approx 16$ digits (red), whatever the precision, and only the rest (blue) can be trusted. In float64 nothing is left. The kept digits are the guaranteed minimum of (T0.11); the d-against-$2d$ test usually finds a few more.

T0.11.3 What it costs, and when to use it

An mpmath number is a Python object, and every operation on it runs Python code rather than a single machine instruction; nor does mpmath work on whole arrays. The script times one exponential each way:

```
time per exp: numpy 13.0 ns, math 332 ns, mpmath (15 digits) 11330 ns, mpmath (50 digits)
    21097 ns
```

NumPy, working on a whole array at once, needs 13.0 ns per exponential; Python's `math.exp`, one number at a time, 332 ns; mpmath, at the same fifteen digits, 11330 ns, about 870 times slower than NumPy, and slower again at fifty digits. A Monte Carlo study of 10^8 draws that takes a second in NumPy would take more than a day in mpmath. So mpmath is a tool for checking, not for running.

It is the right tool in four situations, in order of how often they arise.

1. *As a reference.* A float64 routine whose accuracy is in doubt is compared, at a few points, with the same formula in mpmath at thirty or fifty digits: if the two agree to the digits that matter, the float64 routine is trusted everywhere it is fast. This is how Figure T0.27 judges SciPy's tail functions.
2. *Extreme tails*, beyond about 38σ, where even `sf` underflows. In practice `logsf` already covers this, and mpmath is needed only for the tail of a distribution that has no log-survival function.
3. *Cancellation that no rewriting removes*, as in the expanded polynomial, with d chosen by (T0.11) and checked by the d-against-$2d$ test.
4. *Huge or tiny intermediate numbers that log space cannot handle*, such as a sum of terms of alternating sign each larger than 10^{308} (logarithms cannot represent the signs that make such a sum cancel).

No script of the book needs mpmath for its results; the census of Section T0.1 finds it only here. Every case the book meets is handled by a rewrite or by log space, and those are what to try first.

T0.12 How long will it run? Counting operations

Before a long computation is started, two questions deserve an answer: how long will it take, and will it fit in memory? A script that finishes in a second for a test case may need a day, or a terabyte, for the real one, and it is far better to know that before pressing the key than after a night of waiting.

The smallest example: counting close pairs. The galaxy correlation function of Section 13.17 needs the number of pairs of points closer than some distance r. The obvious program compares every point with every other. The script `code/chT0/10_cost.py` times that brute-force count for N random points in a cube: for $N = 16\,000$ it takes 16.89 s. How long for a catalogue of a million galaxies? The naive extrapolation scales the time with the number of points: $10^6/16\,000 = 62.5$ times longer, about 18 minutes. That is wrong, because the work is not proportional to the number of points but to the number of *pairs*, $N(N-1)/2 \approx N^2/2$. Sixty-two and a half times more points means $62.5^2 \approx 3900$ times more pairs, and the honest estimate is about 18 hours; the script's fit to its measured times gives 22.6 hours. The good choice is to count first: how does the work grow with N? Its price is a minute of thought, and the same thought shows the way out. A k-d tree (Section 13.17.1) groups the points into boxes and counts whole boxes of pairs at once, and it counts 256 000 points in 1.36 s. *The lesson: how the cost grows with the size matters far more than how fast the computer is.*

T0.12.1 Counting how the work grows

The cost of a computation, its run time or the number of arithmetic operations, depends on the size N of the problem: the number of data points, pixels, grid points, simulations. For large N it is usually close to a power law, $T(N) \approx cN^p$, possibly with a logarithm. The exponent p comes from the structure of the algorithm and can be found by counting; the constant c depends on the computer and the implementation and is found by timing. One writes $T(N) = O(N^p)$, read "of order N^p", to say that the cost grows no faster than a constant times N^p. Only the fastest-growing term is kept, and constant factors are dropped: $3N^2 + 100N$ is $O(N^2)$, because for large N the first term dominates, whatever the constants.

The exponent answers the most useful practical question directly: *if the problem gets ten times bigger, how much longer does it take?* For $O(N)$, ten times; for $O(N^2)$, a hundred times; for $O(N^3)$, a thousand times. The book's heavy computations fall into a handful of classes, each found by a count that fits in a line or two.

$O(N)$: anything done once per element. Adding two vectors, evaluating a density on a grid, summing a χ^2, drawing N random numbers: one operation, or a fixed few, per element. Every vectorised NumPy expression of Section T0.4.5 is of this kind.

$O(N \log N)$: halving, again and again. The fast Fourier transform (Section T0.5.3) splits a transform of length N into two transforms of length $N/2$, one for the even-numbered and one for the odd-numbered points, and combines them with about cN further operations. How

many operations does that make in all? Apply the split repeatedly:

$$T(N) \overset{(1)}{=} 2\,T(N/2) + cN \overset{(2)}{=} 4\,T(N/4) + 2cN \overset{(3)}{=} 2^k\,T(N/2^k) + k\,cN \overset{(4)}{=} N\,T(1) + cN\log_2 N. \quad \text{(T0.12)}$$

(1) One split: two half-size transforms plus the combination.
(2) Split each half again: $2[2T(N/4) + cN/2] + cN$.
(3) After k splits there are 2^k transforms of length $N/2^k$, and each level of splitting has added cN.
(4) The splitting stops at length one, after $k = \log_2 N$ levels.

A direct sum would need N^2 operations (every output frequency from every input point). For $N = 10^6$ the difference between N^2 and $N\log_2 N \approx 2\times 10^7$ is a factor of fifty thousand. Sorting a list (`np.sort`, used for quantiles and empirical distribution functions) is $O(N\log N)$ for the same reason.

$O(N^2)$: all pairs. N points have $N(N-1)/2$ pairs, so anything that visits every pair, such as the brute-force pair count, the pairwise-distance matrix of the correlated field in Section 6.9.2, or the Vietoris–Rips complex of Chapter 12, is $O(N^2)$ in time, and $O(N^2)$ in memory if the pairs are stored. Trees and grids bring pair counting down by never visiting pairs that are obviously too far apart or that can be counted as a block.

$O(N^3)$: dense linear algebra. Solving $A\boldsymbol{x} = \boldsymbol{b}$, the Cholesky factor, the determinant, the inverse and the eigenvalues of an $N \times N$ matrix all cost $O(N^3)$. For the Cholesky factor the count is short. Column k of L is found from the entries to its left, after which every entry of the remaining $(N-k)\times(N-k)$ block below and to the right is updated once, with one multiplication and one addition; the block is symmetric, so only the entries on and below its diagonal are computed:

$$\text{operations} \overset{(1)}{=} \sum_{k=1}^{N} 2\cdot\frac{(N-k)(N-k+1)}{2} \overset{(2)}{=} \sum_{j=0}^{N-1}\left(j^2+j\right) \overset{(3)}{=} \frac{(N-1)N(2N-1)}{6} + \frac{(N-1)N}{2} \approx \frac{N^3}{3}. \quad \text{(T0.13)}$$

(1) An $m\times m$ symmetric block has $m(m+1)/2$ entries on and below its diagonal, with $m = N-k$; each costs two operations.
(2) Rename $j = N-k$, which runs from $N-1$ down to 0.
(3) The sum of the first n squares is $n(n+1)(2n+1)/6$ and of the first n integers $n(n+1)/2$, with $n = N-1$; for large N only the $N^3/3$ of the first term matters.

Every covariance matrix, every Gaussian likelihood in pixel space and every Fisher matrix of many parameters lives in this class.

$O(\ell_{\max}^3)$: spherical-harmonic transforms. A HEALPix map at resolution $N_{\rm side}$ has $N_{\rm pix} = 12N_{\rm side}^2$ pixels on about $4N_{\rm side}$ rings of constant latitude, and is analysed up to $\ell_{\max} \approx 3N_{\rm side}$. On each ring an FFT separates the azimuthal modes m, which is cheap; then for every ring and every m the transform sums over all $\ell \geq m$:

$$\underbrace{4N_{\rm side}}_{\text{rings}} \times \underbrace{\ell_{\max}}_{m} \times \underbrace{\ell_{\max}}_{\ell} \sim N_{\rm side}^3 \sim N_{\rm pix}^{3/2}.$$

Doubling $N_{\rm side}$ makes `map2alm` and `alm2map` eight times slower [7].

Simulations and chains. A Monte Carlo study costs the number of simulations times the cost of one; an MCMC run costs the number of steps times the cost of one likelihood evaluation. These multiply. A chain of 10^5 steps with a Boltzmann code that takes a second per call takes more than a day; with the emulator of Section 9.20, which evaluates in microseconds, it takes seconds. That is the whole reason the emulator exists.

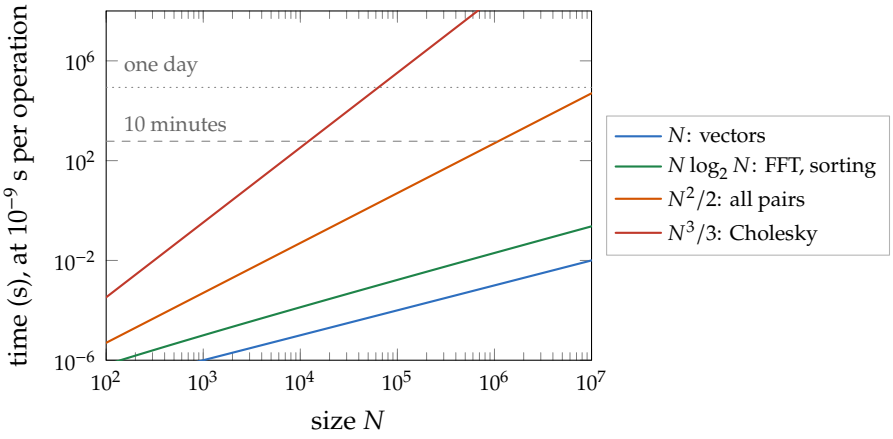

Figure T0.29: How the four commonest costs grow, at an illustrative 10^{-9} s per operation. At $N = 10^4$ all four are affordable; at $N = 10^6$ an N^2 computation takes about ten minutes and an N^3 one about ten years. The horizontal lines mark the ten-minute budget of a laptop script and one day.

Memory. Time is not the only limit. A `float64` occupies 8 bytes, so an array of N numbers takes $8N$ bytes and an $N \times N$ matrix $8N^2$. A covariance matrix of 10^4 bins takes 800 MB; one of 4×10^4 bins, 12.8 GB, more than a laptop can spare. The pixel covariance of a map at $N_{\mathrm{side}} = 256$, with 786 432 pixels, would take $8 \times 786\,432^2 \approx 4.9 \times 10^{12}$ bytes, almost five terabytes. Memory can also be estimated before running: count the largest arrays, multiply by eight bytes per element, and remember that NumPy expressions create temporary arrays of the same size as their inputs.

T0.12.2 Estimating a run time: time small, fit, extrapolate

Counting gives the exponent; timing gives the constant. The recipe has four steps: time the computation at a few small sizes; fit a straight line to $\log T$ against $\log N$, whose slope is the measured exponent; extrapolate the line to the size wanted; and multiply by a safety factor. The script does the first two steps with two small functions:

Listing T0.64: Timing: the best of a few runs, and the slope on log-log axes (`code/chT0/10_cost.py`)

```
def best_time(f, repeats=3):
    """Shortest of a few runs: the least disturbed by whatever else the machine is doing."""
    t = []
    for _ in range(repeats):
        t0 = time.perf_counter()
        f()
        t.append(time.perf_counter() - t0)
    return min(t)

def slope(sizes, times, last=4):
    """Least-squares slope and intercept of log10(time) against log10(size), from the
    largest sizes."""
```

```
48      b, a = np.polyfit(np.log10(sizes[-last:]), np.log10(times[-last:]), 1)
49      return b, a
```

`time.perf_counter()` (lines 40 and 42) reads a clock with sub-microsecond resolution, and the difference of two readings is the time spent in between. `best_time` runs the computation three times and keeps the shortest time (line 43), the run least disturbed by whatever else the computer was doing. `slope` fits a straight line to the logarithms with `np.polyfit` (line 48); for $T = cN^p$, $\log T = \log c + p \log N$, so the slope is p. Only the largest sizes are used (`last=4`), because at small sizes fixed overheads, such as the call itself, distort the power law. The census finds such timing in 11% of the scripts, with 32 calls of `time.perf_counter` and 98 of the coarser `time.time`.

The script times four representative operations on a single processor core: the FFT, the Cholesky factor, pair counting by brute force and with a tree, and `healpy.map2alm`. For two of them it then measures a size beyond the fitted range, to see whether the prediction holds. Figure T0.30 shows the result, and the printed summary is:

```
FFT:        slope 1.35   (N log N alone would give 1.07)
Cholesky:   slope 2.45;  n = 6000: predicted 3.25 s, measured 3.21 s
pairs:      brute-force slope 2.04, k-d tree slope 1.69;  same counts: True
            brute force for 10^6 points, predicted 22.6 h;  tree at 256000 points 1.36 s
map2alm:    slope in N_side 3.06;  N_side = 512: predicted 2.01 s, measured 1.43 s
Cholesky of the 786432 x 786432 pixel covariance at N_side = 256: fitted slope 6 days,
    exponent 3 84 days, memory 4.9 TB
```

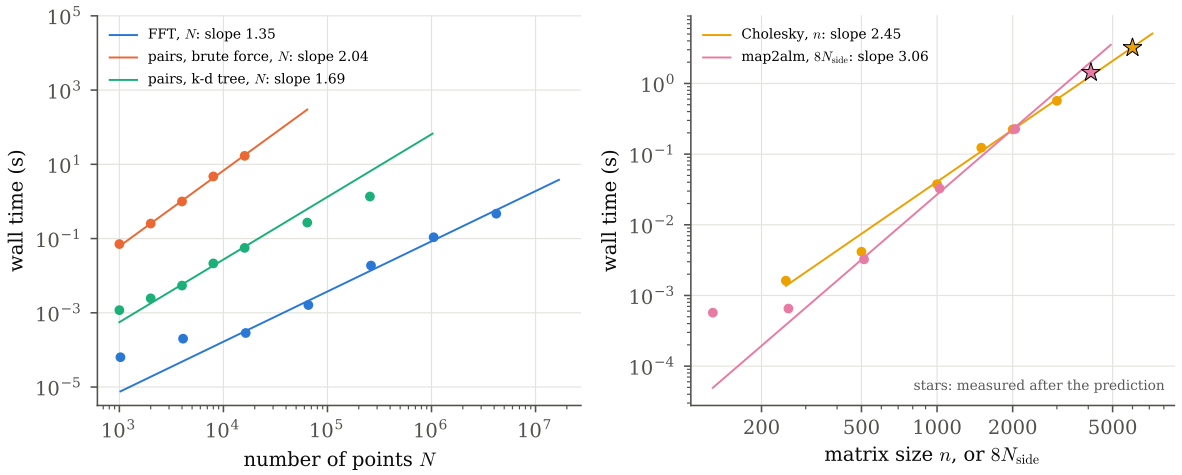

Figure T0.30: Measured run times on one core (points) and power-law fits (lines), with the fitted exponents in the legends. Left: FFT, brute-force pair counting and k-d-tree pair counting against the number of points. Right: the Cholesky factor of an $n \times n$ matrix, and `map2alm` against $8N_{\text{side}}$ (a rescaling that puts both on one axis). Stars: sizes beyond the fitted range, measured after the prediction was made.

What do the measured exponents say? Brute-force pair counting has slope 2.04, the counted 2. `map2alm` has slope 3.06 in N_{side}, the counted 3, and its prediction for $N_{\text{side}} = 512$, 2.01 s, compares with a measured 1.43 s. The Cholesky fit predicts 3.25 s for $n = 6000$ and the measurement is 3.21 s. These are successes. Two exponents differ from the count, and both differences teach something. The FFT's slope is 1.35, steeper than the 1.07 that $N \log N$ alone would give over the same range: at the largest sizes the arrays no longer fit in the processor's fast cache memory, and every operation waits longer for its data. The Cholesky slope, 2.45, is shallower than the counted 3: for small matrices the fixed overheads are a large part of the time, and the optimised linear-algebra library also runs more efficiently on larger blocks, so

the time grows more slowly than the operation count until the matrix is large. A fitted slope describes the range it was fitted on, and nothing guarantees it beyond.

Example: recalling the likelihood that cannot be evaluated. Section 8.1.1 asked how long one evaluation of the exact Gaussian likelihood of a CMB map would take. It needs the Cholesky factor of the $N_{\mathrm{pix}} \times N_{\mathrm{pix}}$ pixel covariance, and its script times that factor up to $n = 6000$:

Listing T0.65: The cost study of Section 8.1.1: time at the largest size, exponent fixed by counting (`code/ch08/03_cost_scaling.py`)

```
# dense likelihood: Cholesky of a positive-definite N x N matrix
Ns = np.array([1000, 2000, 3000, 4500, 6000])
t_chol = []
for n in Ns:
    A = rng.standard_normal((n, n)); C = A @ A.T / n + np.eye(n)
    t_chol.append(best_time(lambda: np.linalg.cholesky(C)))
t_chol = np.array(t_chol)
a3 = t_chol[-1] / Ns[-1] ** 3          # t = a3 N^3, normalised at the largest N (closest
    to asymptotic)
```

Lines 30–35 time the Cholesky factor of random positive-definite matrices, with the same best-of-three function as above. Line 36 is the instructive one: rather than fitting a slope, it fixes the exponent at the counted 3 and uses only the largest, most nearly asymptotic, measurement to set the constant. From 0.80 s at $n = 6000$ it predicted about 21 days for the 786 432 pixels of $N_{\mathrm{side}} = 256$, and 4.9 TB of memory. The script of this section, on a single core, measured 3.21 s at $n = 6000$, about 4 times longer, because the earlier study let the linear-algebra library use up to four cores. With the counted exponent it predicts 84 days, about 4 times longer for the same reason: the two studies agree on the exponent and differ only in the constant. With its own fitted slope of 2.45, however, it would predict only 6 days, an underestimate by more than a factor of ten, because a slope fitted where overheads still matter is extrapolated far beyond the range in which it was measured. When the asymptotic exponent is known by counting, use it, and take the constant from the largest size measured. Either way the conclusion of Section 8.1.1 stands: the exact pixel likelihood is out of reach, while a spherical-harmonic transform of the same map takes a fraction of a second.

Example: a Monte Carlo before it is run. Suppose a study needs 1000 simulated skies at $N_{\mathrm{side}} = 256$, each analysed with three `map2alm` calls (temperature and two noise halves, say). One call took 0.227 s on one core, so the whole study needs about $3000 \times 0.227\,\mathrm{s} \approx 11$ minutes of transforms. That is within a laptop's budget on a few cores; at $N_{\mathrm{side}} = 512$ it would be eight times longer, and at $N_{\mathrm{side}} = 2048$, the resolution of the Planck maps, 512 times longer, which is why the book's simulations stay at $N_{\mathrm{side}} \leq 512$ and say what the full-resolution version would cost. The grid evidence of Section 5.19.1 is the same kind of estimate in a more dramatic form: an n^4 grid that takes 9.43 s at $n = 64$ would take $1.784e+04$ years in six dimensions with a thousand points per axis.

The safety factor. Extrapolation is uncertain in both directions: the exponent may change beyond the fitted range (the FFT and the Cholesky factor above), and a large run shares the computer with other work. A factor of two to three on the predicted time is prudent, and a prediction that is still uncomfortable after it is a prediction that the computation should not be run as planned. It should be made cheaper (a tree, an FFT, a coarser grid, an emulator), split over cores (Section T0.8.3), or sent to a bigger machine.

Key idea: Estimate before you run

Count how the work and the memory grow with the size of the problem; time the computation at a few small sizes; extrapolate with the counted exponent, the time measured at the largest size, and a safety factor of two or three. Anything that the estimate puts beyond about ten minutes or a few gigabytes is redesigned or moved to a bigger computer before it is started.

T0.13 The whole toolkit on one page

Table 2 is the toolkit in the order a script uses it: each concept, the smallest piece of syntax that does it, the subsection that explains it, and a place in the book where it does real work. The syntax column is meant to be read as a reminder of something already understood, not learned from.

The census, once more. The table has thirty-six rows. The census of Section T0.1 explains why that is enough. The book's 345 scripts make 27297 calls to 759 distinct library functions, but the calls are very unevenly shared: 25 names make half of them, 83 make 80%, and 159 make 90%. The other 362 names are each used at most three times and together make only 2.1% of the calls; each of those can be looked up in the documentation on the one occasion it is met. The syntax is more concentrated still: loops, function definitions, f-strings, slices, dictionaries and keyword arguments appear in most scripts, and classes, `try`, `while` and decorators in a few percent of them. A reader who knows the rows of Table 2, and the habits of Sections T0.10 to T0.12, can read every script in the book line by line, change it, and judge whether what it prints can be believed.

Chapter summary

Every number and figure in the book comes from a short script, and the scripts are written in a small, repetitive part of Python: a fixed anatomy, plain Python for the bookkeeping, NumPy for all arithmetic on arrays, a few SciPy tools, and a few Matplotlib calls. In the book's pipeline,

$$\text{physical model} \to \text{field or dataset} \to \text{summary } S \to P(S \mid \theta) \to \text{infer physics},$$

the code is the instrument that carries out every arrow, and the second half of the chapter is the instrument's calibration: what limits a computed number (rounding, the method, Monte Carlo noise), how to check each, when sixteen digits are not enough, and how to predict the cost of a computation before running it.

concept	syntax	here	at work in
A script and plain Python			
run a script	`python3 code/ch02/02_binomial.py`	§T0.2	§2.2
docstring, helpers	`"""Question: ..."""; setup(), save_numbers(...)`	§T0.2	§0.6

compare reals	`np.isclose(a, b); abs(a / b - 1) < 1e-10`	§T0.10.1	§T2.9
Monte Carlo error	`x.std(ddof=1) / np.sqrt(len(x))`	§T0.10.5	§0.6
condition number	`np.linalg.cond(A)`	§T0.10.4	§8.11.2
more digits	`mp.mp.dps = 30; mp.mpf("1.01")`	§T0.11	checks only
timing	`t0 = time.perf_counter()`	§T0.12.2	§5.19.1

Table 2: The toolkit on one page. "Here" points to the subsection that explains it; "at work in" to a place where the book uses it on a real problem.

concept	operational meaning	used later in
the census	read every script's syntax tree without running it; count features, imports and calls; a few dozen names make most of the calls	every chapter
anatomy of a script	docstring (question, computes, writes), imports, settings, functions, computation and figure, numbers saved for the text	every chapter
vectorisation	one array expression instead of a Python loop; 137 times faster for a million elements	every chapter
broadcasting	arrays of different shapes combined by stretching axes of length one, compared from the right	Chapters 6, 7 and 13
seeded generator	`rng_for(chapter, name)`: the same numbers on every run; streams for independent sequences	Chapters 6, 8, 9 and 12
solve, do not invert	$A^{-1}\boldsymbol{b}$ by `solve` or Cholesky; `inv` only when the inverse itself is wanted	Chapters 8 and 10
the seven traps	float equality, integer arrays, views, ranges, shapes, mutable defaults, missing seeds	every chapter
machine epsilon	$\epsilon = 2^{-52} \approx 2.2 \times 10^{-16}$, the relative spacing of `float64` numbers; compare with tolerances	Chapters 4 and 10
cancellation	subtracting nearly equal numbers multiplies the relative error by $(\lvert a\rvert + \lvert b\rvert)/\lvert a - b\rvert$; rewrite the formula	Chapters 3 and 4
finite-difference step	central difference: best $h \sim \epsilon^{1/3}$, error $\sim \epsilon^{2/3}$; trust the plateau	Chapters 9, 10 and 12
condition number	$\kappa = \lambda_{\max}/\lambda_{\min}$; $\log_{10}\kappa$ digits lost; failed Cholesky means too few simulations or a singular matrix	Chapters 8 and 10
Monte Carlo error	$\sigma/\sqrt{N}$ quoted with every simulated number; common random numbers for differences	Chapters 6 to 8 and 12
convergence and validation	change the resolution until the answer stops moving; reproduce a known answer before trusting an unknown one	every chapter
decision rule	$z = \lvert\Delta\rvert / \sqrt{\sigma_1^2 + \sigma_2^2}$ with all errors; $z \gtrsim 3$ is real (or a bug)	Chapters 4 and 7
log space and mpmath	`logsf`, `gammaln`, `logsumexp` first; mpmath at d and $2d$ digits to check; trusted digits $\approx d - \log_{10}\kappa$	Chapters 4 and 5
cost $O(N^p)$	count the exponent, time small sizes for the constant, extrapolate with a safety factor; $8N^2$ bytes for an $N \times N$ matrix	Chapters 5, 8 and 13

Recap: Python for this book

- The book's code uses a small vocabulary: 25 names make half of all library calls and 159 make 90%. Learn those; look up the rest when they appear.
- A script reads like a derivation: question, imports, settings, computation, figure, numbers. Its numbers reach the text through `save_numbers`, never by hand.
- NumPy does the arithmetic on whole arrays: shapes, slices, masks, broadcasting, reductions along an axis. Loops are kept for what is truly sequential.
- Randomness always comes from a seeded generator; matrices are solved, not inverted; real numbers are compared with tolerances.
- Every computed number has an error budget: rounding, the method, Monte Carlo noise. Check each by changing what controls it, validate on a known answer, and call a difference real only when it is large compared with the budget.

- Rewrite and use log space before asking for more digits; when asking, compare d with $2d$.
- Count how the cost grows before running; time small sizes and extrapolate with a safety factor.

Reading the literature

- **The libraries.** The NumPy paper [10] explains the array model (shapes, strides, views, broadcasting, vectorised operations) on which everything here rests; the NumPy user guide, especially its pages on indexing, broadcasting and random generators, is the reference for exact behaviour. The SciPy paper [11] describes the algorithms behind `quad` (QUADPACK), `brentq`, `minimize` and the distributions, and the SciPy reference guide gives every option and every returned field. Matplotlib is described in [12]; its gallery is the quickest way to find how a particular kind of plot is drawn.
- **The physics libraries.** HEALPix is described in [7] and its Python interface healpy in [13]; CAMB in [8], with the CAMB Python documentation for the call pattern. numba is described in [14].
- **Floating point.** Goldberg's survey [9] is the classic account of how real numbers are stored and rounded, why cancellation happens, and how to rewrite formulas to avoid it. The mpmath documentation explains working precision (`mp.dps`) and the functions available at arbitrary precision.

Chapter 1

Probability: The Language of Uncertain Events

Where this chapter is going

Every analysis in this book ends with a sentence of the form "the probability of this is that". The probability that a muon passing through a detector fires the trigger. The probability that a background fluctuation looks as large as the bump we saw. The probability that Ω_m, the fraction of the cosmic energy density in matter, lies between 0.30 and 0.32, given a CMB map. Before we can say any of these, three questions need answers. What exactly is the "this" that has a probability? What rules must the numbers obey? How does a probability change when we learn something?

The answers come in two steps. The first step works with *events*: yes-or-no statements about the outcome of an experiment, such as "the track was tagged as a kaon". The second step, in the next part, turns outcomes into numbers, called *random variables*, and brings in densities, marginals and moments.

One picture runs through both steps: probability is area inside a box that holds every possible outcome. Learning that something happened (conditioning) shrinks the box. Conditioning several times in a row draws a tree. Adding the branches of the tree that end in an observation gives the total probability of that observation. Reading the tree backwards, from the observation to the branch that produced it, is Bayes' theorem. Bayes' theorem links the two directions of probability of Chapter 0: prediction, $\mathrm{P}(E \mid H)$, which goes from a hypothesis H to the event E it produces, and inference, $\mathrm{P}(H \mid E)$, which goes from the event we saw back to the hypothesis that produced it.

Events are the language in which the last two steps of the book's pipeline are written. The pipeline (Chapter 0) runs: a theory with parameters θ; the data it produces; a statistic S that compresses the data; how S scatters from one dataset to the next, $P(S \mid \theta)$; and what the observed S says about θ. A *sampling distribution* is a list of probabilities of events ("S lands in this bin"), each computed assuming a hypothesis is true. That is the forward direction. *Inference* reads the same joint structure backwards. Every later chapter, from p-values (Chapter 4) to Metropolis–Hastings (Chapter 9) and Fisher forecasts (Chapter 10), is built from three rules about events: the axioms, the definition of conditional probability, and the law of total probability.

Questions about events.

1. What is the thing that has a probability? (An event, a subset of all possible outcomes.)
2. What must any assignment of probabilities satisfy, and what follows from that alone?

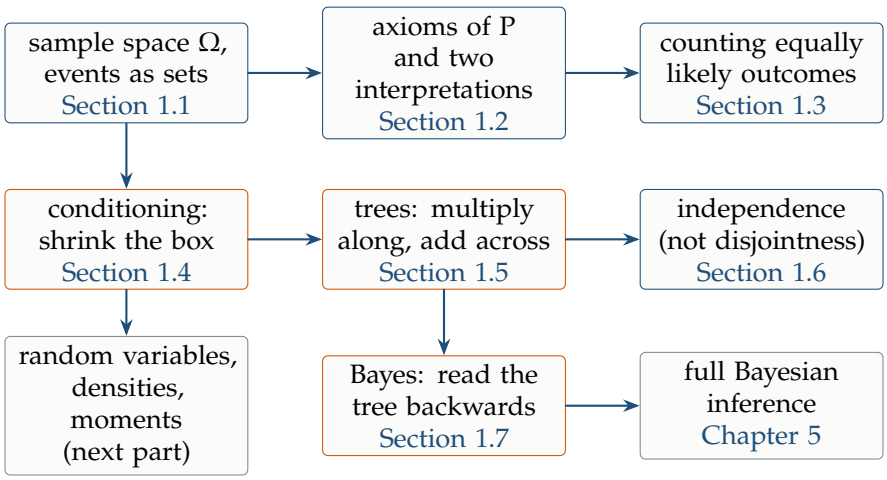

Figure 1.1: The route through the ideas. The top row builds the objects (events, the rules for their probabilities, and the special case in which probability is counting). The orange boxes are the core machine: conditioning shrinks the space of possibilities, trees chain conditionings together, and Bayes' theorem runs a tree in reverse. Grey boxes are where the ideas go next.

3. When every outcome is equally likely, how do we count?
4. How does learning "B happened" change the probability of A?
5. How do we compute the probability of an observation that can be produced in several ways?
6. When does learning B tell us nothing about A?
7. Having seen the observation, which of the ways produced it?

1.1 Sample spaces and events: probability needs a list of possibilities

A cosmic-ray muon telescope is three flat scintillator paddles stacked above each other. When a charged particle crosses a paddle, the paddle may or may not give a signal. For each passage we record which paddles fired: a pattern like $(1, 0, 1)$ means "top fired, middle did not, bottom fired". The trigger logic writes the passage to disk if *at least two* paddles fired.

Before we can ask "how often does the trigger fire?", we must say two things precisely: what could have happened, and which of those possibilities count as "the trigger fired". The first is the sample space, the second is an event. Once both are written down, every trigger condition, every selection cut and every hypothesis in the book is a *subset* of one fixed list. Combining conditions then becomes set algebra, which we can check by drawing pictures and by counting in code.

A box of possibilities. Picture a box. Every point in it is one complete description of how the experiment could turn out. Nature picks one point, the outcome ω. A yes-or-no statement about the result ("at least two paddles fired") is a region drawn in the box. The statement is true exactly when the chosen point lands inside the region. Probability will be the area of a region, and conditioning will mean throwing away part of the box.

Setting up any probability problem. Every problem in this book starts with the same four questions, asked in words before any symbol appears.

1. What is one run of the experiment? (One muon passage, one pair of die rolls, one collision.)
2. What is the complete list of its possible results, described finely enough that everything we will ask about can be read off?
3. Which statement about the result do we care about?
4. Which results make that statement true? That collection is the event.

Working definition 1.1 (sample space, outcome, event)

The **sample space** Ω is the set of all possible outcomes of an experiment [one entry per distinguishable result of one run, and exactly one entry is realised each time]. A point $\omega \in \Omega$ is called a **sample outcome**, **realization** or **element** [one complete description of how this run turned out]. A subset $A \subseteq \Omega$ is an **event** [a collection of outcomes, for example all patterns with at least two paddles fired]. We say "A happened" or "A occurred" when the realised outcome satisfies $\omega \in A$. *Operational test:* write down Ω as a list (or a formula), then write the event as $\{\omega \in \Omega : \text{ condition on } \omega\}$ and check that you can decide the condition for every ω.

The notation $\{\omega \in \Omega : \text{ condition}\}$ is **set-builder notation**. Read it as "the set of all ω in Ω such that the condition holds".

Example 1.1 (The telescope). One run is one muon passage. Each paddle either fires (1) or not (0), so

$$\Omega = \{000,\ 001,\ 010,\ 011,\ 100,\ 101,\ 110,\ 111\}, \qquad |\Omega| = 8,$$

where the digits are (top, middle, bottom) and $|\Omega|$ is the number of elements. The trigger event is

$$T = \{\omega : \text{ at least two digits of } \omega \text{ are } 1\} = \{011,\ 101,\ 110,\ 111\}.$$

The event "the top paddle fired" is $U = \{100, 101, 110, 111\}$. Both are subsets of the same Ω, which is what will let us combine them.

Example 1.2 (Three examples from Wasserman). *(a) Two coin tosses.* $\Omega = \{HH, HT, TH, TT\}$. "The first toss is heads" is $A = \{HH, HT\}$.

(b) A temperature measurement. The outcome is a real number, so we may take $\Omega = \mathbb{R} = (-\infty, \infty)$. Temperature is bounded below (by absolute zero), so $\mathbb{R}$ is larger than needed, but a sample space that is too big does no harm: the extra outcomes will simply get probability zero. "The reading is larger than 10 but at most 23" is the interval $A = (10, 23]$.

(c) Tossing a coin forever. An outcome is an infinite sequence,

$$\Omega = \big\{\omega = (\omega_1, \omega_2, \omega_3, \dots) : \ \omega_i \in \{H, T\}\big\}.$$

"The first head appears on the third toss" is

$$E = \big\{(\omega_1, \omega_2, \omega_3, \dots) : \ \omega_1 = T,\ \omega_2 = T,\ \omega_3 = H,\ \omega_i \in \{H, T\} \text{ for } i > 3\big\}.$$

E contains infinitely many outcomes, since tosses $4, 5, \dots$ are unrestricted. An event is a condition, not a single sequence.

Outcome versus event, and a sample space that is too coarse. Two cautions. First, an outcome and an event are different objects. The outcome 4 of a die is a point; the event $\{4\}$ is a set containing that point. Probabilities belong to events. Second, Ω must be fine enough to answer every question we will ask. Suppose we roll two dice but record only their *sum*, so

$\Omega = \{2, \dots, 12\}$. Then we can no longer ask whether the first die was even, because the sum does not say. The eleven sums are also not equally likely. The finer space of 36 ordered pairs (first die, second die) answers every question and makes each point equally likely. The sample space is fixed by the measurement we make [Kruschke §4.1].

1.1.1 Operations on events

Statements combine with "not", "or" and "and". Events combine in exactly the same way, through set operations.

Working definition 1.2 (complement, union, intersection, difference)

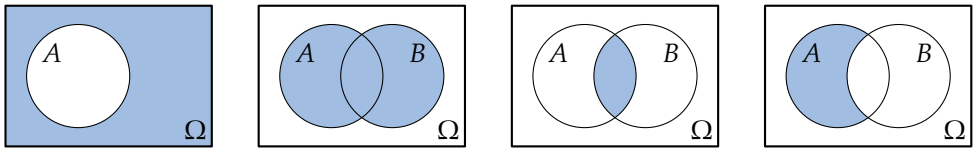
For events $A, B \subseteq \Omega$:

- the **complement** $A^c = \{\omega \in \Omega : \ \omega \notin A\}$ ["not A", every outcome outside A]. Note $\Omega^c = \varnothing$, the **empty set**.
- the **union** $A \cup B = \{\omega : \ \omega \in A$ or $\omega \in B$ or both$\}$ ["A or B", the inclusive or].
- the **intersection** $A \cap B = \{\omega : \ \omega \in A$ and $\omega \in B\}$ ["A and B", both conditions true for the same outcome]. It is also written AB or (A, B).
- the **set difference** $A - B = \{\omega : \ \omega \in A, \ \omega \notin B\} = A \cap B^c$ [in A but not in B].
- **inclusion** $A \subset B$ [every outcome in A is also in B, so "A happened" forces "B happened"]. Equivalently $B \supset A$.

For a sequence $A_1, A_2, \dots$ the countable union and intersection are

$$\bigcup_{i=1}^{\infty} A_i = \{\omega : \ \omega \in A_i \text{ for at least one } i\}, \qquad \bigcap_{i=1}^{\infty} A_i = \{\omega : \ \omega \in A_i \text{ for all } i\}.$$

The shorthand AB for $A \cap B$ will be used constantly, as in $\mathrm{P}(AB)$ for "the probability that A and B both happen". It is the same convention as the comma in $p(x, y)$ for a joint density in the next part.



A^c $\quad A \cup B$ $\quad A \cap B$ $\quad A - B$

Figure 1.2: Venn diagrams: the rectangle is the sample space Ω, the discs are the events A and B, and the shaded region is the event named underneath. Shading the complement leaves a hole where A is. The union is everything touched by either disc, the intersection only the lens where they overlap, the difference the part of A outside B.

Four languages for the same thing.

sets	logic	detector / trigger	numpy mask
Ω	always true	every passage	`np.ones(N, bool)`
$\varnothing$	always false	impossible pattern	`np.zeros(N, bool)`
A^c	not A	veto on A	`~A`
$A \cup B$	A or B	OR of two trigger bits	`A | B`
$A \cap B$, AB	A and B	coincidence (AND)	`A & B`
$A - B$	A and not B	A with B as veto	`A & ~B`
$A \subset B$	A implies B	tighter cut	`np.all(B[A])`
$A \cap B = \varnothing$	cannot both hold	mutually exclusive patterns	`not np.any(A & B)`

Example 1.3 (Operations in the telescope). With T (trigger) and U (top fired) from Example 1.1:

$$
\begin{aligned}
T \cap U &= \{101, 110, 111\} && \text{(trigger fired and top fired),}\\
T \cup U &= \{011, 100, 101, 110, 111\} && \text{(trigger fired or top fired),}\\
T - U &= \{011\} && \text{(trigger fired without the top paddle),}\\
T^c &= \{000, 001, 010, 100\} && \text{(at most one paddle fired).}
\end{aligned}
$$

Each line is read off by going through the eight patterns and checking the condition. The event $T - U = \{011\}$ is useful: it is the only way the trigger can fire if the top paddle is dead.

1.1.2 The rules of set algebra

Set algebra looks like ordinary algebra, with $\cup$ playing $+$ and $\cap$ playing $\times$ [SeeingTheory p. 20]. So $A \cap (B \cup C)$ should expand like $a(b + c) = ab + ac$. The analogy is not perfect: $A \cup A^c = \Omega$, whereas $a + (-a) = 0$. So each rule has to be proved, and the method is always the same. Take one outcome and show that it is in the left side if and only if it is in the right side.

Key idea: De Morgan's laws and the distributive laws

For any events A, B, C,

$$
(A \cup B)^c = A^c \cap B^c, \qquad (A \cap B)^c = A^c \cup B^c, \tag{1.1}
$$

$$
A \cap (B \cup C) = (A \cap B) \cup (A \cap C), \qquad A \cup (B \cap C) = (A \cup B) \cap (A \cup C). \tag{1.2}
$$

In words: "not (A or B)" is "not A and not B". A veto on an OR trigger is the coincidence of the two vetoes.

Take any outcome $\omega \in \Omega$. Then

$$
\begin{aligned}
\omega \in (A \cup B)^c &\overset{(1)}{\iff} \omega \notin A \cup B\\
&\overset{(2)}{\iff} \text{it is false that } (\omega \in A \text{ or } \omega \in B)\\
&\overset{(3)}{\iff} \omega \notin A \text{ and } \omega \notin B\\
&\overset{(4)}{\iff} \omega \in A^c \text{ and } \omega \in B^c\\
&\overset{(5)}{\iff} \omega \in A^c \cap B^c.
\end{aligned}
$$

(1) Definition of the complement.
(2) Definition of the union.
(3) An "or" statement is false exactly when both parts are false.
(4) Definition of the complement, applied to A and to B.

(5) Definition of the intersection.

Every step is an "if and only if", so the two sets contain exactly the same outcomes. The second De Morgan law follows from the first. Apply the first law to the events A^c and B^c; since taking the complement twice gives back the original event, this reads $(A^c \cup B^c)^c = A \cap B$. Taking the complement of both sides gives $A^c \cup B^c = (A \cap B)^c$.

For the distributive law,

$$\begin{aligned} \omega \in A \cap (B \cup C) &\overset{(1)}{\iff} \omega \in A \text{ and } (\omega \in B \text{ or } \omega \in C) \\ &\overset{(2)}{\iff} (\omega \in A \text{ and } \omega \in B) \text{ or } (\omega \in A \text{ and } \omega \in C) \\ &\overset{(3)}{\iff} \omega \in (A \cap B) \cup (A \cap C). \end{aligned}$$

(1) Definitions of intersection and union.
(2) "p and (q or r)" is true exactly when "p and q" or "p and r" is true. Check the eight combinations of truth values if in doubt.
(3) Definitions of intersection and union again.

The other distributive law is proved the same way with "and" and "or" exchanged. All four identities extend to any collection $\{A_i : i \in I\}$, for example $\left(\bigcup_{i\in I} A_i\right)^c = \bigcap_{i\in I} A_i^c$: the chain above goes through word for word with "for at least one i" in place of "or" and "for all i" in place of "and".

1.1.3 Disjoint events, partitions and indicator functions

Working definition 1.3 (disjoint, partition, indicator)

Events $A_1, A_2, \ldots$ are **disjoint** or **mutually exclusive** if $A_i \cap A_j = \varnothing$ whenever $i \neq j$ [no single outcome belongs to two of them, so at most one can happen]. A **partition** of Ω is a sequence of disjoint events with $\bigcup_i A_i = \Omega$ [every outcome lies in exactly one piece]. The **indicator function** of A is

$$I_A(\omega) = I(\omega \in A) = \begin{cases} 1 & \omega \in A, \\ 0 & \omega \notin A. \end{cases}$$

For example $[0,1), [1,2), [2,3), \ldots$ are disjoint, and together with $[-1,0), [-2,-1), \ldots$ they partition $\mathbb{R}$. The histogram bins of any analysis are a partition of the range of the measured quantity. In the telescope, "exactly k paddles fired" for $k = 0, 1, 2, 3$ is a partition of Ω into pieces of sizes $1, 3, 3, 1$.

Indicators turn set operations into arithmetic, which is how a computer does set algebra. For any outcome,

$$\begin{aligned} &I_{A\cap B} = I_A\, I_B, \qquad I_{A^c} = 1 - I_A, \\ &I_{A\cup B} \overset{(1)}{=} 1 - I_{(A\cup B)^c} \overset{(2)}{=} 1 - I_{A^c\cap B^c} \overset{(3)}{=} 1 - (1 - I_A)(1 - I_B) \overset{(4)}{=} I_A + I_B - I_A I_B. \end{aligned} \tag{1.3}$$

(1) The complement rule $I_{C^c} = 1 - I_C$ with $C = A \cup B$.
(2) De Morgan (1.1).
(3) The product rule for intersections, then the complement rule for each factor.
(4) Expand the product.

The product rule holds because $I_A I_B$ is one only if both factors are one. Now sum (1.3) over all the outcomes of a finite Ω (or over all rows of a simulation). The sum of I_A over outcomes

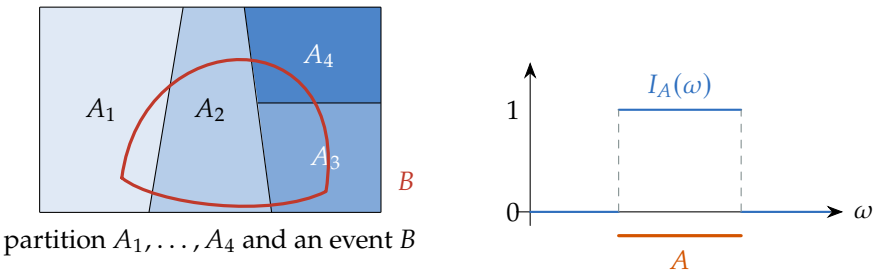


Figure 1.3: Left: a partition cuts Ω into non-overlapping pieces that cover it, so any event B (red outline) is cut into the disjoint pieces $B \cap A_i$. This picture is the law of total probability of Section 1.5. Right: the indicator of an event is a function on outcomes that equals one on the event and zero elsewhere.

counts the outcomes in A, which is $|A|$, the number of elements of A. So the sum gives the counting identity $|A \cup B| = |A| + |B| - |A \cap B|$. This is the seed of the inclusion–exclusion rule of Section 1.2.

1.1.4 Sequences of events and their limits

Some events are naturally the end of a sequence of events: "the detector is still alive after n hours" for $n = 1, 2, \dots$, or "the energy lies within $1/n$ of the peak". We need to say what the limit of such a sequence is.

Monotone sequences. A sequence $A_1, A_2, \dots$ is **monotone increasing** if $A_1 \subset A_2 \subset \cdots$ [each event is a looser condition than the one before], and then $\lim_{n\to\infty} A_n := \bigcup_{i=1}^{\infty} A_i$. It is **monotone decreasing** if $A_1 \supset A_2 \supset \cdots$ [each condition is tighter], and then $\lim_{n\to\infty} A_n := \bigcap_{i=1}^{\infty} A_i$. In either case we write $A_n \to A$.

Example 1.4 (Shrinking intervals: the endpoint matters). Let $\Omega = \mathbb{R}$ and $A_i = [0, 1/i)$. The sets shrink, $[0,1) \supset [0, \frac{1}{2}) \supset \cdots$. Their union is the biggest one, $\bigcup_i A_i = [0,1)$. For the intersection,

$$x \in \bigcap_{i=1}^{\infty} [0, 1/i) \overset{(1)}{\iff} 0 \le x < 1/i \text{ for every } i \ge 1$$
$$\overset{(2)}{\iff} 0 \le x \le 0$$
$$\overset{(3)}{\iff} x = 0,$$

(1) Definition of the intersection.
(2) $1/i$ can be made smaller than any positive number, so $x < 1/i$ for all i holds exactly when $x \le 0$.
(3) Combine $x \ge 0$ and $x \le 0$.

so $\bigcap_i A_i = \{0\}$. If instead $A_i = (0, 1/i)$, the same argument gives $\bigcup_i A_i = (0,1)$ and $\bigcap_i A_i = \varnothing$, because now $x = 0$ was never allowed. The limit of a decreasing sequence can be a single point or nothing at all, depending on one endpoint.

Try it: Infinitely often. Let $B_n = \bigcup_{i \ge n} A_i$ and $C_n = \bigcap_{i \ge n} A_i$. Show that $B_1 \supset B_2 \supset \cdots$ and $C_1 \subset C_2 \subset \cdots$; that $\omega \in \bigcap_n B_n$ exactly when ω lies in infinitely many of the A_i; and that $\omega \in \bigcup_n C_n$ exactly when ω lies in all but finitely many of them [Wasserman p. 14, Ex. 3]. *Answer*

sketch: $\omega \in \bigcap_n B_n$ means "for every n there is an $i \geq n$ with $\omega \in A_i$", which is "there is no last i with $\omega \in A_i$". If A_i is "a spark in the detector during hour i", $\bigcap_n B_n$ is "sparks never stop".

1.1.5 Events in code

In a simulation each row is one run of the experiment, so an event is simply a boolean array with one entry per row: `True` where the outcome lies in the event. The script below rolls two dice 100 000 times and builds A = "the first die is even" and B = "the sum is at least 9".

Listing 1.1: Events as boolean masks (`code/ch01/01_events_as_masks.py`)

```
20 rng = rng_for("ch01", "1a_events_masks")
21 N = 100_000
22
23 # --- one row per repetition of the experiment: the outcome omega = (d1, d2)
24 d1 = rng.integers(1, 7, size=N)
25 d2 = rng.integers(1, 7, size=N)
26
27 # --- events are boolean arrays: A[i] is True when outcome i lies in A
28 A = (d1 % 2 == 0)            # first die even
29 B = (d1 + d2 >= 9)           # sum at least 9
30
31 # --- set operations are logical operations on the masks
32 A_and_B = A & B              # intersection
33 A_or_B = A | B               # union
34 not_A = ~A                   # complement
35
36 # De Morgan: (A u B)^c == A^c n B^c must hold outcome by outcome
37 demorgan_violations = np.count_nonzero(~A_or_B != (~A & ~B))
38
39 # inclusion-exclusion on counts: |A u B| = |A| + |B| - |A n B|  (exact identity)
40 ie_gap = A_or_B.sum() - (A.sum() + B.sum() - A_and_B.sum())
41
42 # --- exact probabilities by counting the 36 equally likely outcomes
43 grid1, grid2 = np.meshgrid(np.arange(1, 7), np.arange(1, 7), indexing="ij")
44 Aex = (grid1 % 2 == 0)
45 Bex = (grid1 + grid2 >= 9)
46 pA, pB, pAB = Aex.mean(), Bex.mean(), (Aex & Bex).mean()
47 pAorB = (Aex | Bex).mean()
```

Lines 24–25 generate the outcomes, one pair (d_1, d_2) per row, where d_1 and d_2 are the two dice. Lines 28–29 turn the two conditions into masks. Lines 32–34 are the last column of the four-languages table above: `&`, `|` and `~` are intersection, union and complement. Line 37 checks De Morgan's law row by row and finds 0 violations, as it must, since (1.1) is an identity about every single outcome, not a statement that holds on average. Line 40 checks the counting identity $|A \cup B| = |A| + |B| - |A \cap B|$ and finds a gap of 0. Lines 43–47 compute exact probabilities by listing all 36 outcomes, which is the counting method of Section 1.3.

The simulated frequencies are 0.5004 for A (exact 0.5000), 0.2757 for B (exact $0.2778 = 10/36$), 0.1663 for $A \cap B$ (exact $0.1667 = 6/36$) and 0.6099 for $A \cup B$ (exact $0.6111 = 22/36$). The identities hold exactly, because they are true outcome by outcome. The frequencies only scatter around the exact probabilities, because they depend on which outcomes the simulation happened to draw. This difference, exact identity versus noisy estimate, returns throughout the book.

What this bought us. An event is a condition on outcomes, and in code it is a mask. Set identities such as De Morgan's hold outcome by outcome, so they hold exactly for simulated counts. Probabilities, which we define next, are what the frequencies of those masks approach.

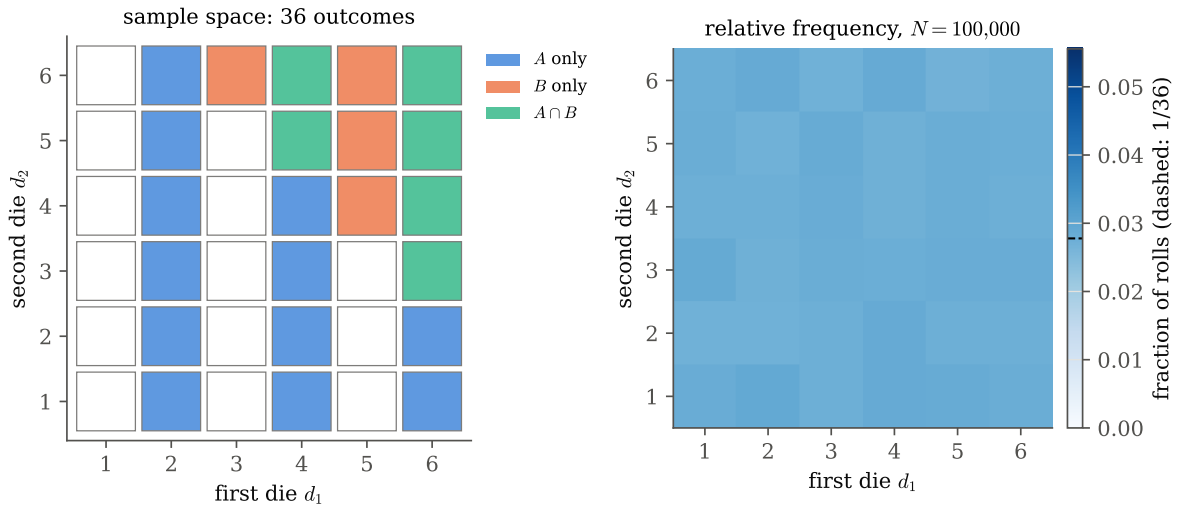

Figure 1.4: Left: the 36 outcomes of two dice as a grid, with the event A (first die even, blue), the event B (sum at least 9, orange) and their overlap (green). Counting cells gives the exact probabilities. Right: how often each cell was hit in the simulation. Every cell is close to the dashed value 1/36 on the colour bar, with small random differences.

1.2 The axioms of probability, and what they buy us

Return to the three-paddle muon telescope of Example 1.1. Analyst one has recorded a million muon passages and assigns to each of the eight patterns the fraction of passages that produced it. Analyst two has just installed a new middle paddle, has no data yet, and assigns numbers that express how strongly she expects each pattern, based on the data sheet of the photomultiplier. The two sets of numbers mean different things. Yet both analysts will add them, subtract them from one, and combine them into trigger probabilities in exactly the same way.

Whatever the numbers mean, any assignment of probabilities must obey three rules, the axioms. Every rule we compute with follows from these three: the complement rule, the inclusion–exclusion rule, the union bound that controls the look-elsewhere effect, and the continuity that lets us take limits. Only after the rules are in place do we ask what the numbers mean, and where each meaning is used.

Probability is a unit of sand spread over the box. Take the box of possibilities from Section 1.1 and pour exactly one kilogram of sand over it, as unevenly as you like. The probability of an event is the mass of sand lying inside its region. Mass is never negative. The whole box holds all of it. If two regions do not overlap, the sand inside their union is the sand in one plus the sand in the other. You would accept every one of these statements about sand without proof. The proofs below only check that three of them imply all the others.

What an assignment of probabilities must do. Stated in words, the demands are these.

1. To every event we can ask about, attach a number.
2. The number for "something happens" (Ω) must be the largest possible, and we fix the scale by calling it one.
3. No event may get a negative number.
4. Numbers for events that cannot happen together must add, also for an infinite list of such events.

5. Everything else (complements, overlaps, limits) must then follow, so that we never need another rule.

Working definition 1.4 (probability distribution)

A **probability distribution** or **probability measure** P is a rule that assigns a real number $\mathrm{P}(A)$ to each event A [each subset of Ω we are allowed to ask about, see Section 1.2.4] such that

Axiom 1: $\mathrm{P}(A) \geq 0$ for every event A.

Axiom 2: $\mathrm{P}(\Omega) = 1$.

Axiom 3: if $A_1, A_2, \ldots$ are disjoint [no outcome lies in two of them], then

$$\mathrm{P}\Big(\bigcup_{i=1}^{\infty} A_i\Big) = \sum_{i=1}^{\infty} \mathrm{P}(A_i).$$

Axiom 3 is called **countable additivity** [additivity for an infinite sequence of disjoint events, one for each $i = 1, 2, 3, \ldots$]. *Operational test:* a table of numbers $\mathrm{P}(\{\omega\})$ on a finite or countable Ω is a valid distribution exactly when every entry is nonnegative and the entries sum to one.

These three lines are Kolmogorov's axioms (1933). They say nothing about *how* to find the numbers. That is the job of physics, of data and of judgement. They only say which lists of numbers are internally consistent.

1.2.1 Consequences of the axioms

Five properties follow at once [Wasserman p. 6, (1.1)]:

$$\begin{aligned} &\mathrm{P}(\varnothing) = 0, \\ &A \subset B \implies \mathrm{P}(A) \leq \mathrm{P}(B), \\ &0 \leq \mathrm{P}(A) \leq 1, \\ &\mathrm{P}(A^c) = 1 - \mathrm{P}(A), \\ &A \cap B = \varnothing \implies \mathrm{P}(A \cup B) = \mathrm{P}(A) + \mathrm{P}(B). \end{aligned} \tag{1.4}$$

Each takes a few lines to prove, and each proof is one idea that we will use again, so we prove them all.

The empty event has probability zero. Take the sequence $A_1 = \Omega$, $A_2 = A_3 = \cdots = \varnothing$. These are disjoint (the empty set meets nothing) and their union is Ω. Then

$$1 \overset{(1)}{=} \mathrm{P}(\Omega) \overset{(2)}{=} \mathrm{P}\big(\Omega \cup \varnothing \cup \varnothing \cup \cdots\big) \overset{(3)}{=} \mathrm{P}(\Omega) + \sum_{i=2}^{\infty} \mathrm{P}(\varnothing) \overset{(4)}{=} 1 + \sum_{i=2}^{\infty} \mathrm{P}(\varnothing).$$

(1) Axiom 2.
(2) Adding empty sets to a union changes nothing.
(3) Axiom 3 for the disjoint sequence $\Omega, \varnothing, \varnothing, \ldots$.
(4) Axiom 2 again.

So $\sum_{i \geq 2} \mathrm{P}(\varnothing) = 0$. This is a sum of infinitely many copies of the same number, which is nonnegative by Axiom 1. It is zero only if that number is zero: $\mathrm{P}(\varnothing) = 0$.

Finite additivity. For disjoint $A_1, \dots, A_n$, pad the list with empty sets, $A_{n+1} = A_{n+2} = \cdots = \varnothing$. Axiom 3 then gives $\mathrm{P}(A_1 \cup \cdots \cup A_n) = \sum_{i=1}^{n} \mathrm{P}(A_i) + \sum_{i>n} 0$, which is the last line of (1.4) for $n = 2$.

Complement rule. A and A^c are disjoint and $A \cup A^c = \Omega$, so

$$1 \overset{(1)}{=} \mathrm{P}(\Omega) \overset{(2)}{=} \mathrm{P}(A \cup A^c) \overset{(3)}{=} \mathrm{P}(A) + \mathrm{P}(A^c). \tag{1.5}$$

(1) Axiom 2.
(2) Every outcome is either in A or not.
(3) Finite additivity.

This is the most used identity in the book: "at least one" is always computed as one minus "none".

Monotonicity, and the difference rule. If $A \subset B$, cut B into the part inside A and the part outside, $B = A \cup (B - A)$, which are disjoint. Then

$$\mathrm{P}(B) \overset{(1)}{=} \mathrm{P}(A) + \mathrm{P}(B - A) \overset{(2)}{\geq} \mathrm{P}(A). \tag{1.6}$$

(1) Finite additivity for the disjoint pieces A and $B - A$.
(2) Axiom 1 for the event $B - A$.

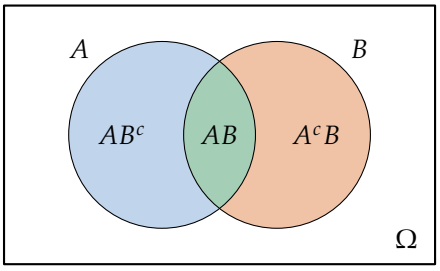
The first equality also says $\mathrm{P}(B - A) = \mathrm{P}(B) - \mathrm{P}(A)$ when $A \subset B$. In detector language: a tighter cut A inside a looser cut B can only lose outcomes, never gain them, so its probability cannot be larger. Finally $0 \leq \mathrm{P}(A)$ is Axiom 1, and $\mathrm{P}(A) \leq \mathrm{P}(\Omega) = 1$ is monotonicity with $B = \Omega$.

Key idea: Inclusion–exclusion

For any events A and B,

$$\mathrm{P}(A \cup B) = \mathrm{P}(A) + \mathrm{P}(B) - \mathrm{P}(AB). \tag{1.7}$$

Adding $\mathrm{P}(A)$ and $\mathrm{P}(B)$ counts the overlap twice, so we subtract it once.



$\mathrm{P}(A) = \mathrm{P}(AB^c) + \mathrm{P}(AB)$

$\mathrm{P}(B) = \mathrm{P}(AB) + \mathrm{P}(A^cB)$

sum: the green lens twice

$\mathrm{P}(A \cup B)$: each piece once

Figure 1.5: The union of two events is cut into three disjoint pieces: the part of A outside B (blue), the overlap (green) and the part of B outside A (orange). $\mathrm{P}(A)$ and $\mathrm{P}(B)$ between them contain the green overlap twice, and the union contains it once.

To prove (1.7), use the three disjoint pieces of Figure 1.5: $A \cup B = (AB^c) \cup (AB) \cup (A^cB)$.

Then

$$\begin{aligned}\mathrm{P}(A \cup B) &\overset{(1)}{=} \mathrm{P}(AB^c) + \mathrm{P}(AB) + \mathrm{P}(A^cB)\\ &\overset{(2)}{=} \mathrm{P}(AB^c) + \mathrm{P}(AB) + \mathrm{P}(A^cB) + \mathrm{P}(AB) - \mathrm{P}(AB)\\ &\overset{(3)}{=} \mathrm{P}\big((AB^c) \cup (AB)\big) + \mathrm{P}\big((A^cB) \cup (AB)\big) - \mathrm{P}(AB)\\ &\overset{(4)}{=} \mathrm{P}(A) + \mathrm{P}(B) - \mathrm{P}(AB).\end{aligned}$$

(1) Finite additivity for three disjoint pieces.
(2) Add and subtract the same number.
(3) Finite additivity backwards, for the disjoint pairs AB^c, AB and A^cB, AB.
(4) An outcome of A is either outside B or inside it, so $(AB^c) \cup (AB) = A$. Likewise $(A^cB) \cup (AB) = B$.

Example 1.5 (Two coin tosses). Let H_1 be "heads on toss 1" and H_2 "heads on toss 2". With the four outcomes HH, HT, TH, TT equally likely, $\mathrm{P}(H_1) = \mathrm{P}(\{HH, HT\}) = \frac{1}{2}$, $\mathrm{P}(H_2) = \mathrm{P}(\{HH, TH\}) = \frac{1}{2}$ and $\mathrm{P}(H_1H_2) = \mathrm{P}(\{HH\}) = \frac{1}{4}$. So

$$\mathrm{P}(H_1 \cup H_2) \overset{(1)}{=} \mathrm{P}(H_1) + \mathrm{P}(H_2) - \mathrm{P}(H_1H_2) = \tfrac{1}{2} + \tfrac{1}{2} - \tfrac{1}{4} = \tfrac{3}{4}.$$

(1) Inclusion–exclusion (1.7).

Check by the complement rule: "at least one head" fails only for TT, so the answer is $1 - \frac{1}{4} = \frac{3}{4}$. The two routes must agree, and they do.

Example 1.6 (A probability table for the telescope). On a finite sample space, finite additivity over single outcomes gives

$$\mathrm{P}(A) = \sum_{\omega \in A} \mathrm{P}(\{\omega\}), \tag{1.8}$$

so a distribution is just a table of nonnegative numbers that sum to one. Suppose the telescope patterns have the probabilities

pattern	000	001, 010, 100	011, 101, 110	111
probability (each)	0.001	0.009	0.081	0.729

They sum to $0.001 + 3(0.009) + 3(0.081) + 0.729 = 1$, so the table is legitimate. (Where such numbers come from is the subject of Section 1.6: they are what one gets if each paddle fires with probability 0.9 on its own.) For the trigger T and the event U (top fired) of Example 1.3,

$$\begin{aligned}\mathrm{P}(T) &= 3(0.081) + 0.729 = 0.972, \qquad \mathrm{P}(U) = 0.009 + 2(0.081) + 0.729 = 0.9,\\ \mathrm{P}(TU) &= \mathrm{P}(\{101, 110, 111\}) = 2(0.081) + 0.729 = 0.891,\\ \mathrm{P}(T \cup U) &\overset{(1)}{=} 0.972 + 0.9 - 0.891 = 0.981.\end{aligned}$$

(1) Inclusion–exclusion. Directly, $T \cup U = \{011, 100, 101, 110, 111\}$ has probability $0.081 + 0.009 + 0.081 + 0.081 + 0.729 = 0.981$, the same.

The trigger misses a muon with probability $\mathrm{P}(T^c) = 1 - 0.972 = 0.028$, by the complement rule.

Try it: Three events. Show that $\mathrm{P}(A \cup B \cup C) = \mathrm{P}(A) + \mathrm{P}(B) + \mathrm{P}(C) - \mathrm{P}(AB) - \mathrm{P}(AC) - \mathrm{P}(BC) + \mathrm{P}(ABC)$. *Hint:* apply (1.7) to $A \cup B$ and C, then use the distributive law $(A \cup B) \cap C = (AC) \cup (BC)$ and (1.7) once more, noting $(AC)(BC) = ABC$. In the telescope, the three events "paddle j fired" give $3(0.9) - 3(0.81) + 0.729 = 0.999$, which is $1 - \mathrm{P}(\{000\})$.

1.2.2 Two inequalities: Bonferroni and Boole

Often we cannot compute an overlap $\mathrm{P}(AB)$, but we can still bound it from below. Rearrange (1.7) and use $\mathrm{P}(A \cup B) \le 1$:

$$\mathrm{P}(AB) = \mathrm{P}(A) + \mathrm{P}(B) - \mathrm{P}(A \cup B) \;\ge\; \mathrm{P}(A) + \mathrm{P}(B) - 1. \tag{1.9}$$

This is the simplest **Bonferroni inequality** [CasellaBerger (1.2.9)]. *Example.* The tracker and the calorimeter are each fully operational in 95% of the luminosity blocks. Then both are operational in at least 95% + 95% − 100% = 90% of them, however their failures are correlated. When $\mathrm{P}(A) + \mathrm{P}(B) < 1$ the bound is negative: true, but useless.

Key idea: Boole's inequality, the union bound

For any events $A_1, A_2, \ldots$ (disjoint or not),

$$\mathrm{P}\Big(\bigcup_{n=1}^{\infty} A_n\Big) \le \sum_{n=1}^{\infty} \mathrm{P}(A_n). \tag{1.10}$$

The probability that at least one thing goes wrong is at most the sum of the probabilities of each thing going wrong.

Make the events disjoint by keeping only the part of each A_n that is new: $B_1 = A_1$ and $B_n = A_n - \bigcup_{i<n} A_i$ [Wasserman p. 14, Ex. 7]. An outcome in $\bigcup_n A_n$ has a *first* index n with $\omega \in A_n$, and it lies in B_n for that n only. So the B_n are disjoint, $\bigcup_n B_n = \bigcup_n A_n$, and $B_n \subset A_n$. Then

$$\mathrm{P}\Big(\bigcup_n A_n\Big) \overset{(1)}{=} \mathrm{P}\Big(\bigcup_n B_n\Big) \overset{(2)}{=} \sum_n \mathrm{P}(B_n) \overset{(3)}{\le} \sum_n \mathrm{P}(A_n).$$

(1) The two unions contain the same outcomes.
(2) Axiom 3 for the disjoint B_n.
(3) Monotonicity (1.6), term by term, since $B_n \subset A_n$.

In research: the look-elsewhere effect in one line. A bump hunt scans m mass bins. If background alone makes a given bin fluctuate up to the observed size with probability p_{local}, the probability that *some* bin does so is at most $m\, p_{\text{local}}$ by (1.10). This is the Bonferroni correction for multiple tests (Chapter 4). It is a bound, and it is loose when neighbouring bins are correlated. In real searches the actual "global" probability is obtained by simulating many background-only experiments and counting how often the largest fluctuation anywhere exceeds the observed one [15]. The union bound is what tells us in advance roughly how bad the effect can be.

Example 1.7 (Events of probability one). If $\mathrm{P}(A_i) = 1$ for every i, then $\mathrm{P}\big(\bigcap_i A_i\big) = 1$ [Wasserman p. 14, Ex. 8]:

$$\mathrm{P}\Big(\big(\textstyle\bigcap_i A_i\big)^c\Big) \overset{(1)}{=} \mathrm{P}\Big(\textstyle\bigcup_i A_i^c\Big) \overset{(2)}{\le} \sum_i \mathrm{P}(A_i^c) \overset{(3)}{=} \sum_i 0 = 0.$$

(1) De Morgan's law (1.1) for a countable family.
(2) Boole's inequality (1.10).
(3) Complement rule: $\mathrm{P}(A_i^c) = 1 - 1 = 0$.

A probability is nonnegative, so the complement has probability exactly zero and the intersection has probability one. Countably many "almost sure" statements hold almost surely all at once.

1.2.3 Continuity: probabilities of limits are limits of probabilities

Continuity of probability. If $A_n \to A$ (a monotone sequence, Section 1.1), then $\mathrm{P}(A_n) \to \mathrm{P}(A)$ as $n \to \infty$ [Wasserman p. 7, Thm 1.8].

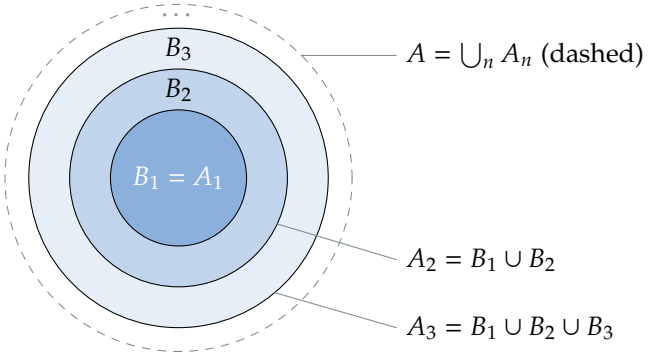


Figure 1.6: An increasing sequence of events drawn as nested discs. The rings B_n (the part of A_n that is new at step n) do not overlap, and the first n rings together make up A_n. The probability of the limit is the total mass of all rings, which is the limit of the partial sums.

Suppose $A_1 \subset A_2 \subset \cdots$ with $A = \bigcup_i A_i$. Define the rings of Figure 1.6: $B_1 = A_1$ and $B_n = \{\omega : \omega \in A_n,\ \omega \notin A_{n-1}\}$ for $n \geq 2$. Because the sets are nested, "not in A_{n-1}" already means "not in any earlier A_i", so this is the construction used for Boole's inequality. The B_n are disjoint, $A_n = \bigcup_{i=1}^{n} B_i$ and $\bigcup_{i=1}^{\infty} B_i = A$. Then

$$\lim_{n\to\infty} \mathrm{P}(A_n) \overset{(1)}{=} \lim_{n\to\infty} \mathrm{P}\Big(\bigcup_{i=1}^{n} B_i\Big) \overset{(2)}{=} \lim_{n\to\infty} \sum_{i=1}^{n} \mathrm{P}(B_i) \overset{(3)}{=} \sum_{i=1}^{\infty} \mathrm{P}(B_i) \overset{(4)}{=} \mathrm{P}\Big(\bigcup_{i=1}^{\infty} B_i\Big) \overset{(5)}{=} \mathrm{P}(A).$$

(1) A_n is the union of the first n rings.
(2) Finite additivity.
(3) An infinite sum is by definition the limit of its partial sums. It converges because the partial sums increase and never exceed one.
(4) Axiom 3, which is where *countable* additivity is essential.
(5) The rings together make up A.

For a decreasing sequence $A_1 \supset A_2 \supset \cdots$ with $A = \bigcap_i A_i$, the complements increase, $A_1^c \subset A_2^c \subset \cdots$, and by De Morgan $\bigcup_i A_i^c = \big(\bigcap_i A_i\big)^c = A^c$. The increasing case gives $\mathrm{P}(A_n^c) \to \mathrm{P}(A^c)$, so $\mathrm{P}(A_n) = 1 - \mathrm{P}(A_n^c) \to 1 - \mathrm{P}(A^c) = \mathrm{P}(A)$ [Wasserman p. 13, Ex. 1].

Example 1.8 (A detector that is alive forever). Let A_n be "the readout board has not failed during the first n hours". The events decrease, $A_1 \supset A_2 \supset \cdots$, and their intersection A is "the board never fails". Suppose a reliability model gives $\mathrm{P}(A_n) = e^{-n/\tau}$ with a mean lifetime of $\tau = 10^4$ hours. Continuity gives

$$\mathrm{P}(\text{never fails}) \overset{(1)}{=} \lim_{n\to\infty} \mathrm{P}(A_n) = \lim_{n\to\infty} e^{-n/\tau} = 0.$$

(1) Continuity for the decreasing sequence $A_n \to A$.

We could not have computed $\mathrm{P}(A)$ directly, since A is defined by an infinite number of conditions. Continuity turns it into an ordinary limit.

Example 1.9 (There is no uniform distribution on the integers). Can we pick a whole number "completely at random", so that every $n \in \{0, 1, 2, \dots\}$ has the same probability c

[Wasserman p. 14, Ex. 6]? The single-number events $\{0\}, \{1\}, \ldots$ are disjoint with union Ω, so

$$1 \overset{(1)}{=} \mathrm{P}(\Omega) \overset{(2)}{=} \sum_{n=0}^{\infty} \mathrm{P}(\{n\}) = \sum_{n=0}^{\infty} c = \begin{cases} 0 & c = 0, \\ \infty & c > 0. \end{cases}$$

(1) Axiom 2.
(2) Axiom 3.

Neither case equals one, so no such P exists. The same obstruction appears for a "flat prior" on an unbounded parameter range, such as a uniform distribution for a mass on $(0, \infty)$: it cannot be normalised. Such an *improper* prior can still be used as a device when the posterior turns out normalisable, and Chapter 5 explains when.

1.2.4 Which events are allowed? A word on σ-fields

On a finite or countable Ω every subset can be an event. On $\mathbb{R}$ this fails: one can prove that there is no way to give a "length" to *every* subset of $[0, 1]$ that is countably additive and unchanged by shifts. So probabilities are assigned only to a large, well-behaved class of subsets [Wasserman p. 13, §1.9].

σ-field, probability space. A **σ-field** (or σ-algebra) $\mathcal{A}$ is a collection of subsets of Ω with (i) $\varnothing \in \mathcal{A}$, (ii) if $A_1, A_2, \cdots \in \mathcal{A}$ then $\bigcup_i A_i \in \mathcal{A}$, and (iii) if $A \in \mathcal{A}$ then $A^c \in \mathcal{A}$ [the class of events is closed under not, and countable or]. Its members are called **measurable**. The pair $(\Omega, \mathcal{A})$ is a **measurable space**, and with a probability measure P on $\mathcal{A}$ the triple $(\Omega, \mathcal{A}, \mathrm{P})$ is a **probability space**. On $\mathbb{R}$ one uses the **Borel σ-field**, the smallest σ-field containing all open intervals [everything you can build from intervals by countably many unions, intersections and complements].

In practice this restriction never bites. Every event in this book (intervals, histogram bins, excursion sets of a smooth field, limits of monotone sequences) is Borel. A σ-field is also closed under countable intersections, by De Morgan: $\bigcap_i A_i = \left(\bigcup_i A_i^c\right)^c$, and the right side uses only complements and unions. So the limits of decreasing sequences from Section 1.1 stay inside it too.

1.2.5 What the numbers mean: frequency and degree of belief

The axioms fix the arithmetic. They do not say what $\mathrm{P}(A) = 0.3$ *means*. There are two standard answers [Wasserman p. 6], [Cowan §1.2], [Kruschke §4.2].

Working definition 1.5 (frequency and degree-of-belief interpretations)

In the **frequency interpretation**, $\mathrm{P}(A)$ is the long-run proportion of repetitions in which A happens,

$$\mathrm{P}(A) = \lim_{n \to \infty} \frac{n_A}{n}, \tag{1.11}$$

where n_A is the **count** of A [the number of runs, out of n identical and independent runs, in which A occurred]. In the **degree-of-belief** (subjective, Bayesian) interpretation, $\mathrm{P}(A)$ measures how strongly a given observer, with given information, believes that the statement A is true. Here Ω is often called the **hypothesis space** [a list of mutually exclusive statements, exactly one of which is true].

Both readings obey the same axioms, for different reasons. For frequencies the axioms are automatic. A frequency is never negative, the frequency of "some outcome" is one, and the frequency of one of several disjoint outcomes is the sum of their frequencies [Cowan p. 5].

For beliefs the axioms are a consistency requirement, and a bet shows why. Suppose you would pay 0.6 for a ticket that pays 1 if A happens, and also 0.6 for a ticket that pays 1 if A does not. Buying both costs 1.2. Exactly one of the tickets wins, so you get back exactly 1 whatever happens. Your beliefs $\mathrm{P}(A) = \mathrm{P}(A^c) = 0.6$ break the complement rule, and they lose money for sure. Beliefs that cannot be exploited this way must obey the axioms.

The same kind of comparison pins a belief down. Suppose you prefer a ticket on A to a ticket on drawing red from a bag with 1 red and 9 white marbles. Then your $\mathrm{P}(A)$ is above 0.1. Suppose you also prefer a ticket on a bag with 5 red and 5 white to the ticket on A. Then your $\mathrm{P}(A)$ is below 0.5. So it lies between 0.1 and 0.5 [Kruschke §4.2.2.1].

The frequency reading needs repetition, so it fails for a unique object. It is natural for anything that is repeated: collisions at a collider, photons in a detector, the simulated universes of a Monte Carlo. Now take the electron mass m_e. It is either inside the interval $[0.510, 0.512]$ MeV or not, and repeating the experiment does not change it. So the frequency of "m_e is in the interval" is either one (always inside) or zero (never), and we do not know which. A statement like "95% probability that m_e lies in this interval" only makes sense as a degree of belief [Cowan p. 6]. The same is true of "the probability that Ω_m lies between 0.30 and 0.32": there is one universe.

Taxonomy: Which interpretation, where in the book

Frequency	sampling distributions of data and statistics (Chapters 2 and 3), p-values and the coverage of confidence intervals (Chapter 4), Monte Carlo error bars (Chapter 6), cosmic variance of C_ℓ as scatter over hypothetical skies (Chapter 7), the transfer function and covariance of a masked pipeline (Chapter 8).
Degree of belief	priors and posteriors for parameters $p(\boldsymbol{\theta} \mid \boldsymbol{d})$ (Chapter 5), credible intervals from MCMC (Chapter 9), Fisher forecasts read as posterior widths (Chapter 10), systematic uncertainties.
Both, same rules	everything in the theory of probability. The calculus is shared, and in a Bayesian analysis the likelihood $\mathrm{P}(\boldsymbol{d} \mid \boldsymbol{\theta})$ is itself a frequency statement about repeated data.

1.2.6 A simulated long-run frequency

The frequency definition (1.11) is a limit, and a computer lets us watch the limit being approached [Wasserman p. 16, Ex. 21]. We flip a coin with P(heads) = p a thousand times and plot the proportion of heads so far.

Listing 1.2: Running proportion of heads (`code/ch01/02_running_frequency.py`)

```
for ax, p, tag in zip(axes, (0.3, 0.03), ("A", "B")):
    rng = rng_for("ch01", "1a_running_frequency", stream=int(1000 * p))
    ends = []
    for r in range(runs):
        flips = rng.random(n_max) < p          # True = heads, with probability p
        running = np.cumsum(flips) / n         # proportion of heads after n flips
        ax.plot(n, running, color=SERIES[r], lw=1.0, alpha=0.9)
        ends.append(running[-1])
```

```
    band = 2 * np.sqrt(p * (1 - p) / n)
    theory_line(ax, n, np.full_like(n, p, dtype=float), label=f"$p={p}$")
    ax.fill_between(n, p - band, p + band, color="0.85", zorder=0,
                    label=r"$p\pm2\sqrt{p(1-p)/n}$")
```

Line 27 is the whole simulation: `rng.random(n_max)` draws uniform numbers in $[0, 1)$, and a number lands below p with probability p, so the comparison is a coin with heads probability p. Line 28 divides the cumulative count of heads by the number of flips so far, which is n_A/n in (1.11). Line 31 draws the band $p \pm 2\sqrt{p(1-p)/n}$. Where that width comes from is the variance of the binomial distribution in Chapter 2. For now it is simply a rule of thumb: at any given n, a run lies outside the band only about one time in twenty.

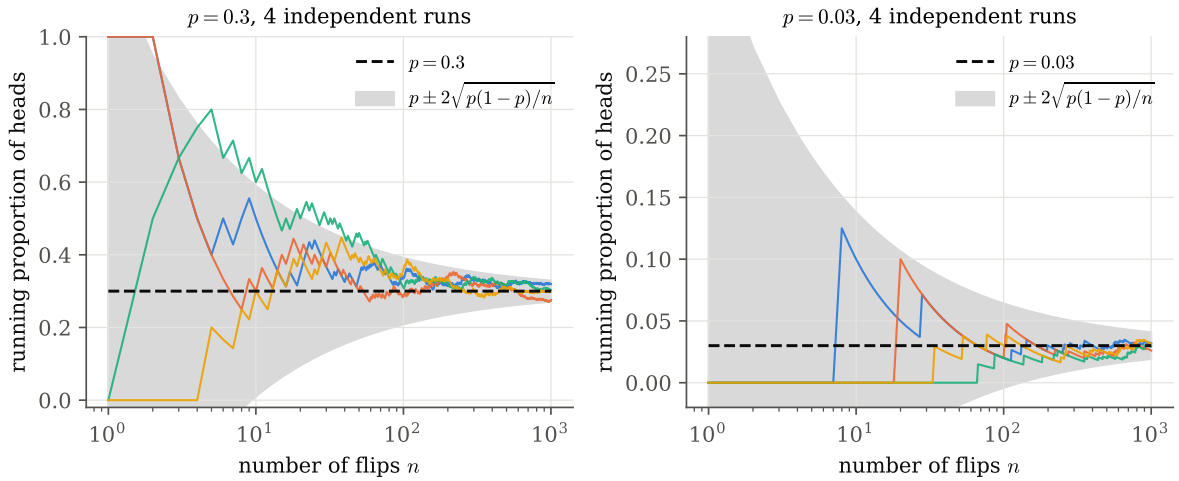

Figure 1.7: Running proportion of heads for four independent runs of 1000 flips, with $p = 0.3$ (left) and $p = 0.03$ (right). Early on the proportion jumps around wildly. As flips accumulate the runs settle towards the dashed value, and the shaded band $p \pm 2\sqrt{p(1-p)/n}$ narrows like $1/\sqrt{n}$.

A rare event is harder to pin down than a common one. After 1000 flips with $p = 0.3$, the first two runs end at 0.320 and 0.275, and 4 of the 4 runs end inside the band 0.3 ± 0.029. With $p = 0.03$ the first two end at 0.032 and 0.026, and 4 of the 4 end inside 0.03 ± 0.011. The band is narrower for the rare event in absolute terms. Relative to p, though, it is much wider: about 10% of p for $p = 0.3$, and almost 40% of p for $p = 0.03$. Dividing the half-width $2\sqrt{p(1-p)/n}$ by p gives the relative width $2\sqrt{(1-p)/(np)}$. It depends on np, the expected number of times the event occurs. So estimating a small probability to a given relative precision needs a number of trials proportional to $1/p$.

What this bought us. A finite run gives a frequency, not the probability. The frequency scatters around the probability, and the scatter shrinks like $1/\sqrt{(\text{number of occurrences})}$. This is the first appearance of the Monte Carlo error, which we will meet again every time a simulation estimates a number.

How this is used in real research: Verification here, instrument later

Here we *knew* p and the simulation only verified that frequencies approach it. In research the direction is reversed. Nobody can write down the probability that a pp collision at the LHC produces a muon that survives all selection cuts. It is obtained exactly this way, as a frequency over millions of simulated collisions, with the $1/\sqrt{n_A}$ scatter quoted as the "Monte Carlo statistical uncertainty".

The frequency definition is not a recipe for every probability. Equation (1.11) needs repeatable, identical runs. It gives no meaning to P(the Hubble tension is new physics). Conversely, a degree of belief is not arbitrary: once it is written as a probability it must obey all the rules above, and it must be updated by the rule of Section 1.7.

1.3 Equally likely outcomes: probability as counting

A silicon pixel sensor has $N = 10^4$ pixels. In one readout frame, $k = 100$ charged particles cross it, each landing on a pixel at random. If two particles hit the same pixel, the pixel reports one hit, the two tracks share it, and the tracking code may lose one of them. How often does at least one such merger happen in a frame? The occupancy is only $100/10^4 = 1\%$, so one expects "rarely". The answer is about 39%.

When every outcome is equally likely, a probability is a ratio of two counts, so all the work is in counting. Four basic counting formulas cover the cases: ordered or not, with or without replacement. Physicists know them as Maxwell–Boltzmann, Bose–Einstein and Fermi–Dirac counting. They settle the pixel problem, which is the birthday problem in disguise, and we solve it three ways: exactly, approximately and by simulation.

The microcanonical ensemble. In statistical mechanics an isolated system is equally likely to be in any of its $\Omega(E)$ microstates of energy E. The probability of a macrostate is then the number of microstates that realise it divided by $\Omega(E)$, and entropy $S = k_B \ln \Omega$ is a logarithm of a count. Probability on a finite sample space with equally likely outcomes is exactly this: fix the list of equally likely microstates, and every probability is a ratio of counts.

Solving a counting problem. Every counting problem here is solved by the same four steps.

1. Find a sample space in which every outcome is equally likely. (This is a physical statement about the mechanism, not a counting fact.)
2. Count all outcomes, $|\Omega|$.
3. Count the outcomes in the event, $|A|$. Break the count into a sequence of simple choices.
4. Divide. If counting A is hard, count A^c and use $1 - |A^c|/|\Omega|$.

Working definition 1.6 (uniform distribution on a finite set)

If $\Omega = \{\omega_1, \dots, \omega_N\}$ is finite and every outcome has the same probability, $\mathrm{P}(\{\omega_i\}) = 1/N$, then for every event

$$\mathrm{P}(A) = \frac{|A|}{|\Omega|}. \tag{1.12}$$

This is the **uniform probability distribution** on Ω [probability of A is the number of outcomes in A over the number of outcomes in Ω]. *Operational test:* can you argue, from symmetry of the mechanism, that no outcome is preferred? If not, (1.12) does not apply.

The equal value $1/N$ is forced: the N single-outcome events are disjoint with union Ω, so $N \cdot c = 1$. Then

$$\mathrm{P}(A) \overset{(1)}{=} \sum_{\omega \in A} \mathrm{P}(\{\omega\}) \overset{(2)}{=} \sum_{\omega \in A} \frac{1}{N} \overset{(3)}{=} \frac{|A|}{N}.$$

(1) Finite additivity over the outcomes in A, (1.8).

(2) Every outcome has probability $1/N$.
(3) The sum has $|A|$ equal terms.

Example 1.10 (Two dice). Roll a die twice. $\Omega = \{(i,j) : i,j \in \{1,\dots,6\}\}$ has 36 ordered pairs, all equally likely for fair dice rolled separately. The sum is 11 for $(5,6)$ and $(6,5)$, so $\mathrm{P}(\text{sum} = 11) = 2/36$. The sum is 7 for $(1,6),(2,5),\dots,(6,1)$, so $\mathrm{P}(\text{sum} = 7) = 6/36$. Here the pitfall of Section 1.1 bites: on the coarser space of sums $\{2,\dots,12\}$ the eleven values are *not* equally likely, and (1.12) would give the wrong answer $1/11$.

1.3.1 The multiplication principle

Fundamental theorem of counting. If a job consists of k separate choices, and the i-th choice can be made in n_i ways whatever the earlier choices were, the job can be done in $n_1 \times n_2 \times \cdots \times n_k$ ways.

For $k = 2$ choices, a table proves it. Write the possibilities with n_1 rows (first choice) and n_2 columns (second choice). Each cell is one way of doing the job, and there are $n_1 n_2$ cells. For k choices, treat the first $k-1$ as one job and apply the $k = 2$ case again and again. The phrase "whatever the earlier choices were" matters. The *number* of options at each step must not depend on what was chosen before, although the options themselves may: when dealing two cards, the second card has 51 options whichever card came first, but which 51 depends on the first card.

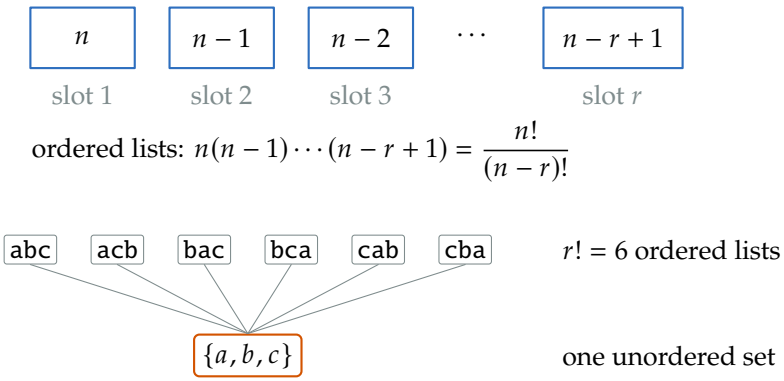

Figure 1.8: Top: filling r ordered slots from n distinct objects without putting any object back. The first slot has n options, the second $n-1$, and so on. Bottom: the $3! = 6$ ordered lists of the letters a, b, c all describe the same unordered set, so counting sets means dividing the ordered count by $r!$.

Permutations. The number of ways to arrange n distinct objects in a row is $n! = n(n-1)\cdots 2\cdot 1$. Call it P_n. There are n choices for the first position, and then the remaining $n-1$ objects can be arranged in P_{n-1} ways, so $P_n = n\,P_{n-1}$ with $P_1 = 1$ [SeeingTheory p. 22]. Unwinding the recursion gives $P_n = n!$. We set $0! = 1$: there is exactly one way to arrange nothing, and $P_1 = 1 \cdot P_0$ requires $P_0 = 1$.

Ordered selection without replacement. Filling r ordered slots from n objects (Figure 1.8, top) can be done in

$$n(n-1)\cdots(n-r+1) \overset{(1)}{=} \frac{n(n-1)\cdots(n-r+1)\,(n-r)!}{(n-r)!} \overset{(2)}{=} \frac{n!}{(n-r)!}$$

(1) Multiply and divide by $(n-r)! = (n-r)(n-r-1)\cdots 1$.

(2) The numerator is now the full product $n(n-1)\cdots 1$.

ways, by the multiplication principle with $n_i = n - i + 1$.

Unordered selection without replacement. Now we want the number of *sets* of r objects, ignoring order. Call it $\binom{n}{r}$. Every set of r objects can be put in order in $r!$ ways (Figure 1.8, bottom), and every ordered list arises from exactly one set. So we can count ordered lists in two ways:

$$\frac{n!}{(n-r)!} \overset{(1)}{=} \binom{n}{r} \times r! \quad \Longrightarrow \quad \binom{n}{r} = \frac{n!}{r!\,(n-r)!}. \tag{1.13}$$

(1) Choose the set first ($\binom{n}{r}$ ways), then its order ($r!$ ways), and apply the multiplication principle.

This is the **binomial coefficient**, read "n choose r" [Wasserman p. 8, (1.2)]. The method, counting something in two ways and equating, is the most useful trick in combinatorics.

Two properties follow. $\binom{n}{0} = \binom{n}{n} = 1$, since $0! = 1$: there is one way to choose nothing and one way to choose everything. And $\binom{n}{r} = \binom{n}{n-r}$, since choosing the r objects that are in is the same as choosing the $n - r$ that are out. Algebraically, swapping $r \leftrightarrow n - r$ in $n!/(r!(n-r)!)$ swaps the two factorials in the denominator.

Example 1.11 (Committees, and a poker hand). A class of 20 elects a committee of 3 [Wasserman p. 8]:

$$\binom{20}{3} \overset{(1)}{=} \frac{20!}{3!\,17!} \overset{(2)}{=} \frac{20 \times 19 \times 18}{3 \times 2 \times 1} = 1140.$$

(1) Definition (1.13).
(2) Cancel $17!$ from $20! = 20 \cdot 19 \cdot 18 \cdot 17!$.

A five-card poker hand is an unordered set of 5 of 52 cards, so there are $\binom{52}{5} = 2\,598\,960$ equally likely hands. "Four aces" fixes four cards and leaves 48 choices for the fifth, so $\mathrm{P}(\text{four aces}) = 48/2\,598\,960 \approx 1.8 \times 10^{-5}$. "Exactly one pair" is built by a sequence of choices [CasellaBerger (1.2.11)]: the pair's value (13 ways), its two suits ($\binom{4}{2} = 6$), the three other values, all different from each other and from the pair ($\binom{12}{3} = 220$), and a suit for each ($4^3 = 64$). So

$$\mathrm{P}(\text{exactly one pair}) = \frac{13 \cdot 6 \cdot 220 \cdot 64}{2\,598\,960} = \frac{1\,098\,240}{2\,598\,960} \approx 0.423.$$

Selection with replacement. If an object is put back after being chosen, every slot again has n options, and there are n^r ordered lists.

Unordered selection with replacement. This is the hardest case. An unordered choice of r objects from n types, repeats allowed, is fixed by how many of each type we took. Draw the n types as bins separated by $n - 1$ walls, and each chosen object as a star in its bin (Figure 1.9). A choice is then a row of r stars and $n - 1$ walls, and every such row is one choice. Counting rows means choosing which r of the $r + n - 1$ positions hold stars:

$$\#\{\text{unordered selections with replacement}\} = \binom{n+r-1}{r}. \tag{1.14}$$

Figure 1.9: Stars and bars. Four objects of four possible types are recorded as a row of four stars and three walls. The stars between consecutive walls are the objects of one type, so this row means one of type 1, two of type 2, none of type 3 and one of type 4. The two outer walls (grey) never move and are not counted.

Key idea: The four ways to choose r objects from n

	without replacement	with replacement
ordered	$\dfrac{n!}{(n-r)!}$	n^r
unordered	$\binom{n}{r}$	$\binom{n+r-1}{r}$

In the New York lottery (6 numbers from 44) these are 5 082 517 440, 7 256 313 856, 7 059 052 and 13 983 816 tickets [CasellaBerger Table 1.2.1].

Counting in statistical mechanics. Put r particles into n single-particle states.

particles	counting	configurations
distinguishable (Maxwell–Boltzmann)	ordered, with replacement	n^r
identical bosons (Bose–Einstein)	unordered, with replacement	$\binom{n+r-1}{r}$
identical fermions (Fermi–Dirac)	unordered, without replacement	$\binom{n}{r}$

"With replacement" means a state can hold more than one particle. "Unordered" means we only record occupation numbers, not which particle is where.

Watch out: The count of outcomes is not a statement about their probabilities

Take $r = 2$ items from $n = 3$ with replacement, by drawing, noting and putting back. The nine ordered pairs are equally likely. The six unordered outcomes $\{1,1\},\{2,2\},\{3,3\},\{1,2\},\{1,3\},\{2,3\}$ are *not*: $\{1,2\}$ comes from $(1,2)$ and $(2,1)$ and has probability $2/9$, while $\{1,1\}$ has $1/9$ [CasellaBerger Ex. 1.2.19]. Formula (1.14) counts the unordered outcomes, but only the mechanism decides which list is equally likely. Physics gives a striking instance. For two particles in two states, the chance that both sit in the same state is $1/2$ if they are distinguishable (states 11, 22 out of 11, 12, 21, 22), $2/3$ for identical bosons (the three occupations $(2,0),(1,1),(0,2)$ are the equally likely quantum states), and 0 for fermions. That bosons "bunch" and fermions "anti-bunch" is measured directly in Hanbury Brown–Twiss correlations. It is a fact about nature, not about counting.

Try it: Toss until two heads. A fair coin is tossed until the second head appears [Wasserman p. 14, Ex. 5]. Show that exactly k tosses are needed with probability $(k-1)/2^k$ for $k \geq 2$. *Answer:* every particular sequence of k tosses has probability 2^{-k}. The event requires toss k to be heads and exactly one head among the first $k-1$ tosses, which can be placed in $\binom{k-1}{1} = k-1$ ways. As a check, $\sum_{k\geq 2}(k-1)2^{-k} = 1$: differentiate $\sum_{k\geq 0} x^k = 1/(1-x)$ to get $\sum_{k\geq 1} kx^{k-1} = 1/(1-x)^2$, and set $x = \frac{1}{2}$ after multiplying by x^2.

1.3.2 The birthday problem, and merged hits

Now back to the pixel sensor from the start of this section: $N = 10^4$ pixels, $k = 100$ particles per frame. Each of the k particles lands on one of the N pixels, independently and uniformly. (Independence is made precise in Section 1.6. Here it means that all N^k ordered lists of pixels, one entry per particle, are equally likely.) Let D be the event "at least two particles share a pixel". Its complement D^c, "all k pixels are different", is easier to count, because it is an ordered selection without replacement.

$$\mathrm{P}(D) \overset{(1)}{=} 1 - \mathrm{P}(D^c) \overset{(2)}{=} 1 - \frac{N(N-1)\cdots(N-k+1)}{N^k} \overset{(3)}{=} 1 - \prod_{j=0}^{k-1}\Big(1 - \frac{j}{N}\Big). \tag{1.15}$$

(1) Complement rule (1.5).
(2) Uniform distribution on the N^k ordered lists (ordered, with replacement). D^c contains the lists with all entries different (ordered, without replacement).
(3) Divide each of the k factors $N - j$ of the numerator by one factor N of the denominator.

For $N = 365$ days this is the birthday problem. To see why the answer grows so fast, take the logarithm and use $\ln(1 - x) \approx -x$ for small x (the first term of the Taylor series $\ln(1 - x) = -x - x^2/2 - \cdots$):

$$\ln \mathrm{P}(D^c) \overset{(1)}{=} \sum_{j=0}^{k-1} \ln\Big(1 - \frac{j}{N}\Big) \overset{(2)}{\approx} -\sum_{j=0}^{k-1} \frac{j}{N} \overset{(3)}{=} -\frac{k(k-1)}{2N}. \tag{1.16}$$

(1) The logarithm of a product is the sum of the logarithms.
(2) $\ln(1 - x) \approx -x$, valid when $j/N \ll 1$, i.e. $k \ll N$.
(3) Arithmetic series, $0 + 1 + \cdots + (k-1) = k(k-1)/2$.

So $\mathrm{P}(D) \approx 1 - e^{-k(k-1)/2N}$. The exponent has a meaning: $k(k-1)/2 = \binom{k}{2}$ is the number of *pairs* of particles, and each pair shares a pixel with probability $1/N$. The number of pairs grows like k^2, which is why coincidences come early. The probability reaches one half when $k(k-1)/2N \approx \ln 2$, i.e. $k \approx \sqrt{2N \ln 2} \approx 1.18\sqrt{N}$.

Example 1.12 (Birthdays and pixels). For $N = 365$ and $k = 23$, $\binom{23}{2} = 253$ pairs, and (1.15) gives $\mathrm{P}(D) = 0.5073$, while the approximation gives $1 - e^{-253/365} = 0.5000$. The smallest group with better than even odds has $k = 23$ people, close to $1.18\sqrt{365} \approx 22.5$. With 50 people the probability is 0.970. For the pixel sensor, $N = 10^4$ and $k = 100$ give $\binom{100}{2} = 4950$ pairs, and P(some merged hit) = 0.3914 exactly (approximation 0.3904), at a mean occupancy of only 1%.

Listing 1.3: Exact, approximate and simulated birthday probabilities (`code/ch01/03_birthday.py`)

```
def p_shared_exact(k, N):
    """1 - prod_{j=0}^{k-1} (N - j)/N, computed as a product of factors < 1."""
    j = np.arange(k)
    return 1.0 - np.prod((N - j) / N)

def p_shared_approx(k, N):
    return 1.0 - np.exp(-k * (k - 1) / (2.0 * N))

def p_shared_mc(k, N, trials, rng):
    """Draw k labels uniformly from N, many times; count draws with a repeat."""
    draws = rng.integers(0, N, size=(trials, k))
```

```
    draws.sort(axis=1)
    has_repeat = np.any(draws[:, 1:] == draws[:, :-1], axis=1)
    return has_repeat.mean()
```

The exact function (lines 20–23) evaluates the product in (1.15) as a product of numbers below one, which avoids the enormous factorials. The simulation (lines 30–35) draws a (trials $\times$ k) array of random labels in $\{0, \dots, N-1\}$, one row per group. Sorting each row puts equal labels next to each other, so a row contains a repeat exactly when two neighbours are equal. The mean of that boolean column is the frequency of D. With 200 000 simulated groups of 23 the frequency is 0.5070 ± 0.0011, and for 10^5 simulated pixel frames it is 0.3951 ± 0.0015. The error bars are the scatter $\sqrt{q(1-q)/N}$ of a frequency. The two simulated values lie 0.3 and 2.3 error bars from the exact ones.

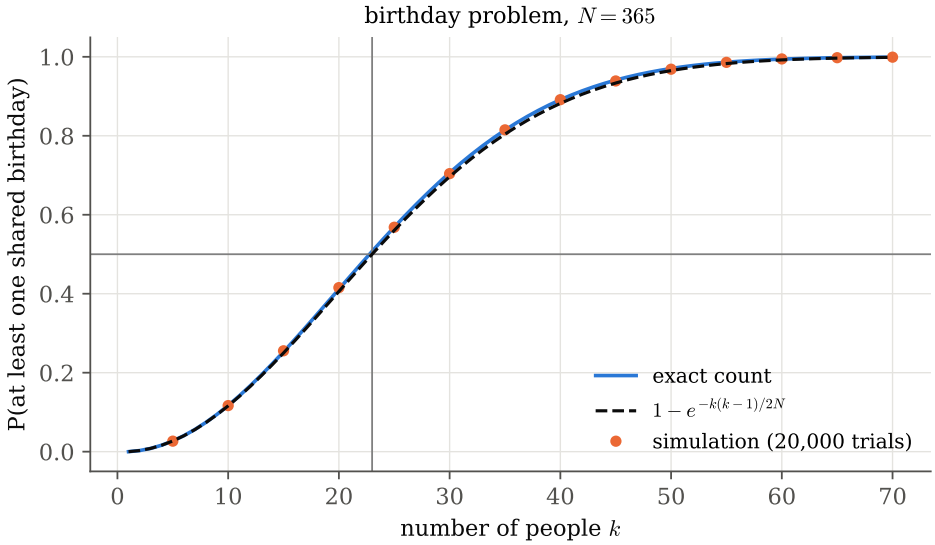

Figure 1.10: Probability that at least two of k people share a birthday. The exact count (solid) rises steeply and crosses one half between 22 and 23 people. The exponential approximation (dashed) lies just below it, and the simulated frequencies (dots) fall on the exact curve.

What this bought us. Coincidences are governed by the number of *pairs*, $\binom{k}{2} \approx k^2/2$, not by k. A collision among N equally likely labels becomes likely at $k \sim \sqrt{N}$ draws, far below N.

In research: where the $\sqrt{N}$ rule bites. Pixel and strip detectors are designed so that occupancy stays low enough for merged clusters to be rare, and the merging rate is estimated exactly as in Example 1.12, then refined with a full simulation that includes the real, non-uniform hit density near the beam. The same rule applies to random seeds. If each of many parallel Monte Carlo jobs picks a 32-bit seed at random, two jobs share a seed (and produce identical "independent" samples) with probability one half after only $1.18\sqrt{2^{32}} \approx 77\,000$ jobs. This is why `common.py` derives seeds deterministically through `SeedSequence` (Chapter 6).

1.4 Conditional probability: shrinking the sample space

At a collider, the trigger decides in microseconds which collisions are kept. Everything an analyst later measures, such as the fraction of events with two muons, the fraction whose muons have opposite charge or the fraction that fall in a mass window, is a fraction *among*

triggered events. The events that were not kept are gone. The analyst's world has shrunk from "all collisions" to "collisions that fired the trigger".

That is the whole idea: *information shrinks the sample space*. The question is this. Once we learn that an event B happened, what is the new probability of an event A? Conditional probability is the rule that answers it, by computing probabilities inside the shrunken space. It is how a probability changes when we learn something. Trees, the law of total probability, independence and Bayes' theorem are all built from it. In a simulation it is literally a selection: keep the rows in which B holds, and count among them.

In the area picture, conditioning changes only the unit of measurement. Before we learn anything, $\mathrm{P}(A)$ is the fraction of the whole box Ω covered by A. If we learn that the outcome lies in B, every point outside B is ruled out, and B becomes the new box. The probability of A is now the fraction of B covered by A: the area of the overlap AB, measured in units of the area of B (Figure 1.11). Nothing inside B is re-weighted relative to anything else inside B.

In Figure 1.11 the two regions are a hypothesis H and an observed event E. Their overlap HE (green) can be measured against either one. Measured against H, it is the share of the hypothesis region in which E also happens. Measured against E, it is the share of the observed region in which H was also true. One patch, two yardsticks. Bayes' theorem (Section 1.7) is the relation between those two readings of the same patch, so the picture already contains it.

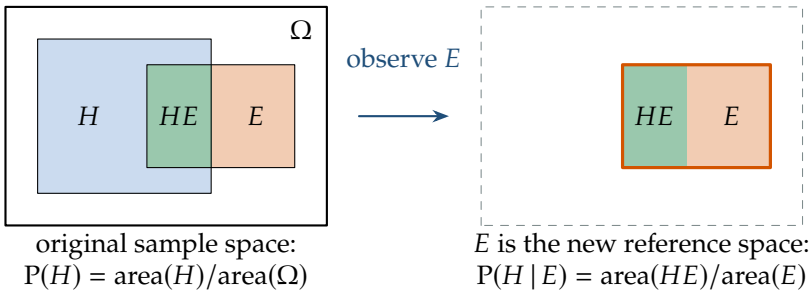

Figure 1.11: Conditioning as a change of reference space. Left: the hypothesis region H (blue) and the observed region E (orange) overlap in the green rectangle. Right: after we observe E, everything outside it is discarded and the green area is measured as a fraction of the orange one. Measured against H instead, the same green area gives $\mathrm{P}(E \mid H)$.

In words, computing a conditional probability takes four steps:

1. What do we know has happened? That event, B, is the new sample space.
2. Discard every outcome outside B.
3. Among the outcomes that remain, how much probability lies in A as well?
4. Rescale, so that the surviving outcomes carry total probability one.

These four steps determine the formula completely. Write $\mathrm{P}_B(A)$ for the new probability of A once B is known. We ask for three things: (i) P_B is a probability, (ii) $\mathrm{P}_B(B) = 1$, since B is now certain, and (iii) inside B nothing changes except the unit, $\mathrm{P}_B(C) = c\ \mathrm{P}(C)$ for every $C \subset B$, with one constant c. Then for any event A,

$$\mathrm{P}_B(A) \overset{(1)}{=} \mathrm{P}_B(AB) + \mathrm{P}_B(AB^c) \overset{(2)}{=} \mathrm{P}_B(AB) \overset{(3)}{=} c\ \mathrm{P}(AB), \qquad \text{and} \qquad 1 \overset{(4)}{=} \mathrm{P}_B(B) \overset{(5)}{=} c\ \mathrm{P}(B).$$

(1) A is the disjoint union of its parts inside and outside B, and P_B is additive by (i).
(2) $AB^c \subset B^c$, and $\mathrm{P}_B(B^c) = 1 - \mathrm{P}_B(B) = 0$ by (ii), so by monotonicity $\mathrm{P}_B(AB^c) = 0$.
(3) $AB \subset B$, so (iii) applies.

(4) Requirement (ii).
(5) Requirement (iii) with $C = B$.

The last equation fixes $c = 1/\mathrm{P}(B)$, and the first gives $\mathrm{P}_B(A) = \mathrm{P}(AB)/\mathrm{P}(B)$. There is no other choice.

Working definition 1.7 (conditional probability)

If $\mathrm{P}(B) > 0$, the **conditional probability of A given B** is

$$\mathrm{P}(A \mid B) = \frac{\mathrm{P}(AB)}{\mathrm{P}(B)}. \tag{1.17}$$

Read the bar as "given" [restricted to the outcomes in which B is true]. *Frequency reading:* among the runs in which B happened, the fraction in which A also happened, $\mathrm{P}(A \mid B) \approx n_{AB}/n_B$ [n_{AB} counts runs with both, n_B runs with B, whatever A did]. *Operational test in code:* `A[B].mean()`.

Three remarks. First, $\mathrm{P}(A) = \mathrm{P}(A \mid \Omega)$: every probability is conditional on the sample space we chose [Cowan p. 2]. Second, the bar carries no arrow of time.

$$\mathrm{P}(\text{rain last night} \mid \text{wet ground this morning})$$

is a perfectly good conditional probability: among mornings with wet ground, the fraction that followed a rainy night [Kruschke §4.4.1]. Third, if A and B are disjoint then $\mathrm{P}(A \mid B) = 0$: once B has happened, A cannot have.

The shrinking sample space, drawn to scale. Very often a problem does not hand us $\mathrm{P}(AB)$ directly. It tells us how probable a situation H is, and how often an observation E occurs *inside* each situation. Take $\mathrm{P}(H) = 0.25$, and suppose E happens in 60% of the H-world and in 10% of the H^c-world. This is the picture of Figure 1.11 drawn to scale (Figure 1.12). Draw Ω as a rectangle of area one and H as a vertical strip of width 0.25. Inside each strip, mark the part where E happens as a piece running the full height of the strip: it covers 0.6 of the H strip and 0.1 of the H^c strip. Set the two pieces against the line between the strips, so that together they make one box, the event E. The share of a strip that its piece covers is itself a conditional probability: it is E measured against the strip as its reference space, so the two shares are $\mathrm{P}(E \mid H)$ and $\mathrm{P}(E \mid H^c)$.

Before we observe anything, $\mathrm{P}(H)$ is the width 0.25 of the H strip, a fraction of the whole rectangle. Now learn that E happened. Every point outside the box is ruled out. The surviving region is the new sample space, and probabilities are re-measured against its area:

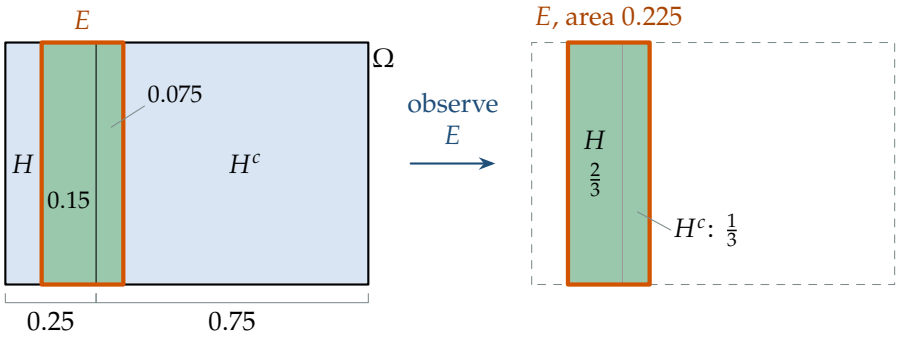
$$\begin{aligned}\mathrm{P}(H \mid E) &\overset{(1)}{=} \frac{\text{area}(HE)}{\text{area}(E)} \overset{(2)}{=} \frac{\text{area}(HE)}{\text{area}(HE) + \text{area}(H^cE)} \\ &\overset{(3)}{=} \frac{0.25 \times 0.6}{0.25 \times 0.6 + 0.75 \times 0.1} = \frac{0.15}{0.225} = \frac{2}{3}.\end{aligned}$$

(1) Definition of conditional probability as re-measured area. The areas are probabilities because Ω has area one.
(2) E is the union of its two pieces, which do not overlap because H and H^c are disjoint.
(3) Each piece is the strip's width times the share of the strip it covers, the width being the strip's probability and the share the conditional probability of E inside the strip.

Learning E moved the probability of H from $\frac{1}{4}$ to $\frac{2}{3}$. Why? The figure shows it. The H strip was only a third as wide as the H^c strip (0.25 against 0.75). But E is six times as common inside

H as outside it (0.6 against 0.1). So, of the area that survives, the H piece (0.15) is twice the H^c piece (0.075), and H holds two thirds of it.

Step (3) used the multiplication rule $\mathrm{P}(HE) = \mathrm{P}(E \mid H)\,\mathrm{P}(H)$, read off the picture here and derived as (1.18) below. With every term named, and the denominator written as a sum over all hypotheses, the same calculation is Bayes' theorem (Section 1.7 and Chapter 5). Here it is only the definition of conditional probability, drawn to scale.



before: H fills a quarter of Ω

after: E is the new sample space, H fills two thirds of it

Figure 1.12: Conditioning drawn to scale, in the picture of Figure 1.11. Left: the rectangle Ω has area 1, split into the strip H of width 0.25 and the strip H^c of width 0.75. The event E (orange outline) covers 0.6 of the H strip and 0.1 of the H^c strip, so its two green pieces have areas $0.25 \times 0.6 = 0.15$ and $0.75 \times 0.1 = 0.075$. Right: once E is observed, everything outside the orange box is discarded. H keeps the share of the box that its piece fills, $0.15/0.225 = \frac{2}{3}$, although its strip was only a quarter of Ω.

Example 1.13 (Two dice, by counting in the shrunken space). Roll two fair dice. Let A be "the sum is 8" and B "at least one die shows 6". By counting, B has 11 of the 36 outcomes (six with a first 6, six with a second 6, minus the double-counted $(6,6)$), $A = \{(2,6),(3,5),(4,4),(5,3),(6,2)\}$ has 5, and $AB = \{(2,6),(6,2)\}$ has 2. Then

$$\mathrm{P}(A \mid B) \overset{(1)}{=} \frac{\mathrm{P}(AB)}{\mathrm{P}(B)} \overset{(2)}{=} \frac{2/36}{11/36} = \frac{2}{11} \approx 0.182, \qquad \mathrm{P}(B \mid A) = \frac{2/36}{5/36} = \frac{2}{5} = 0.4.$$

(1) Definition (1.17).

(2) Uniform distribution on 36 outcomes. The 1/36 cancels, so the answer is a ratio of counts *inside* B: $|AB|/|B|$.

Learning B raises the probability of A from $5/36 \approx 0.139$ to 0.182. The two conditional probabilities use the same overlap and differ only in what it is divided by.

Example 1.14 (Hair and eye colour: reallocating credibility). A sample of people has the joint proportions of eye and hair colour below [Kruschke Table 4.1] (rows do not add exactly because of rounding in the original data):

eye \ hair	black	brunette	red	blond	marginal
brown	0.11	0.20	0.04	0.01	0.37
blue	0.03	0.14	0.03	0.16	0.36
hazel	0.03	0.09	0.02	0.02	0.16
green	0.01	0.05	0.02	0.03	0.11
marginal	0.18	0.48	0.12	0.21	1.0

Learning "blue eyes" keeps only the second row and divides it by its total:

$$\mathrm{P}(\text{black} \mid \text{blue}) = \tfrac{0.03}{0.36} = 0.08, \qquad \mathrm{P}(\text{brunette} \mid \text{blue}) = \tfrac{0.14}{0.36} = 0.39,$$
$$\mathrm{P}(\text{red} \mid \text{blue}) = \tfrac{0.03}{0.36} = 0.08, \qquad \mathrm{P}(\text{blond} \mid \text{blue}) = \tfrac{0.16}{0.36} = 0.45.$$

The probability of blond hair rises from 0.21 to 0.45. The four numbers still add up to one, because the row was divided by its own total. Learning "blue eyes" has moved probability from some hair colours to others. Kruschke calls this a reallocation of credibility. It is already Bayesian inference in miniature.

1.4.1 $\mathrm{P}(\cdot \mid B)$ is a probability, $\mathrm{P}(A \mid \cdot)$ is not

For fixed B with $\mathrm{P}(B) > 0$, the function $A \mapsto \mathrm{P}(A \mid B)$ satisfies the three axioms [Wasserman p. 14, Ex. 9]. Axiom 1 holds because a ratio of a nonnegative number and a positive number is nonnegative. Axiom 2 holds because $\mathrm{P}(\Omega \mid B) = \mathrm{P}(\Omega B)/\mathrm{P}(B) = \mathrm{P}(B)/\mathrm{P}(B) = 1$. For Axiom 3, let $A_1, A_2, \ldots$ be disjoint:

$$\mathrm{P}\Big(\bigcup_i A_i \,\Big|\, B\Big) \overset{(1)}{=} \frac{\mathrm{P}\big((\bigcup_i A_i) \cap B\big)}{\mathrm{P}(B)} \overset{(2)}{=} \frac{\mathrm{P}\big(\bigcup_i (A_i B)\big)}{\mathrm{P}(B)} \overset{(3)}{=} \frac{\sum_i \mathrm{P}(A_i B)}{\mathrm{P}(B)} \overset{(4)}{=} \sum_i \mathrm{P}(A_i \mid B).$$

(1) Definition (1.17).
(2) Distributive law (1.2), for a countable family.
(3) The sets $A_i B$ are disjoint, because $A_i B \subset A_i$ and the A_i are. Then Axiom 3 for P.
(4) Split the sum and use the definition for each term.

So every rule of Section 1.2 holds with "$\mid B$" appended everywhere: $\mathrm{P}(A^c \mid B) = 1 - \mathrm{P}(A \mid B)$, inclusion–exclusion, Boole. This matters later, when all the machinery of probability is applied to a posterior, which is a probability conditional on the data.

The same is *not* true in the other slot. For fixed A, the map $B \mapsto \mathrm{P}(A \mid B)$ is not a probability. In general $\mathrm{P}(A \mid B \cup C) \neq \mathrm{P}(A \mid B) + \mathrm{P}(A \mid C)$, even for disjoint B and C. The quickest check: take $A = \Omega$, and any disjoint B and C of positive probability. Every conditional probability of Ω is one, so the left side is 1 and the right side is $1 + 1 = 2$. The rules of probability act only on events to the left of the bar [Wasserman p. 10].

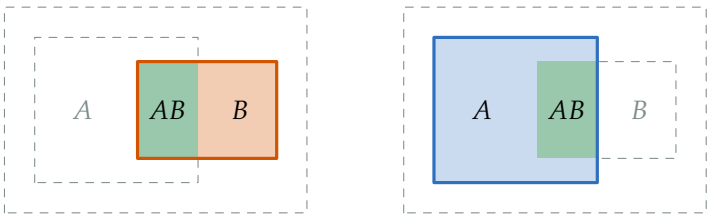
1.4.2 $\mathrm{P}(A \mid B)$ is not $\mathrm{P}(B \mid A)$

The probability of spots given measles is essentially one. The probability of measles given spots is small, since many things cause spots. The two conditional probabilities share the numerator $\mathrm{P}(AB)$ and differ in the denominator. Figure 1.13 draws it with the rectangles of Figure 1.11, now labelled A and B. Conditioning on B makes B the whole world, and we ask what fraction of it the overlap fills. Swapping the roles makes A the whole world, and the same overlap is now measured against a bigger region. In the picture the overlap has area 1.6, B has area 3.68 and A has area 6.48, so

$$\mathrm{P}(A \mid B) = \frac{\text{area}(AB)}{\text{area}(B)} = \frac{1.6}{3.68} = 0.43, \qquad \mathrm{P}(B \mid A) = \frac{\text{area}(AB)}{\text{area}(A)} = \frac{1.6}{6.48} = 0.25.$$

Same patch, different yardstick, different answer. The two are equal only when A and B have the same probability.

Mistaking one for the other is common enough in court to have a name, the **prosecutor's fallacy**: "the chance that an innocent person matches the DNA sample is one in a million, so the chance that the defendant is innocent is one in a million". In statistics the same mistake



condition on B: $\mathrm{P}(A \mid B) = \text{area}(AB)/\text{area}(B)$ — condition on A: $\mathrm{P}(B \mid A) = \text{area}(AB)/\text{area}(A)$

Figure 1.13: Swapping what we condition on. The rectangles are those of Figure 1.11. Left: we learn that B happened, so B (orange outline) is the new reference space and the green overlap is read as a fraction of B. Right: we learn that A happened instead, so A (blue outline) is the reference space and the same green overlap is read as a fraction of the larger region A. Same numerator, different denominator: $\mathrm{P}(A \mid B) = 0.43$ but $\mathrm{P}(B \mid A) = 0.25$.

reads "P(data this extreme $\mid H_0$) = 0.01, so P($H_0 \mid$ data) = 0.01", which confuses a p-value with a posterior probability (Chapters 4 and 5).

Example 1.15 (A medical test). A test for a disease D has outcomes + and −, and the joint probabilities are [Wasserman p. 10, Ex. 1.13]

	D	D^c
+	0.009	0.099
−	0.001	0.891

Condition on the column (the true state) to get the test's performance:

$$\mathrm{P}(+ \mid D) \overset{(1)}{=} \frac{\mathrm{P}(+ \cap D)}{\mathrm{P}(D)} \overset{(2)}{=} \frac{0.009}{0.009 + 0.001} = 0.9, \qquad \mathrm{P}(- \mid D^c) = \frac{0.891}{0.891 + 0.099} = 0.9.$$

(1) Definition (1.17).
(2) P(D) is the sum of its column, since $D = (+ \cap D) \cup (- \cap D)$ disjointly.

The test is right 90% of the time for the sick and for the healthy. Now condition on the row (the result) instead:

$$\mathrm{P}(D \mid +) \overset{(1)}{=} \frac{\mathrm{P}(+ \cap D)}{\mathrm{P}(+)} \overset{(2)}{=} \frac{0.009}{0.009 + 0.099} = \frac{9}{108} \approx 0.08.$$

(1) Definition (1.17), now with + as the conditioning event.
(2) P(+) is the sum of the first row.

A positive result means the disease with probability 8%, not 90%. Among positives, the healthy outnumber the sick eleven to one, because there are ninety-nine times more healthy people to produce false positives (Figure 1.14).

Example 1.16 (A radioactive nucleus does not age). A nucleus with decay constant λ survives to time t with probability $\mathrm{P}(S_t) = e^{-\lambda t}$, where S_t is "not yet decayed at time t". Given that it has survived to t, what is the probability that it survives a further time s? Surviving to $t + s$ implies surviving to t, so $S_{t+s} \subset S_t$ and $S_{t+s} S_t = S_{t+s}$. Then

$$\mathrm{P}(S_{t+s} \mid S_t) \overset{(1)}{=} \frac{\mathrm{P}(S_{t+s} S_t)}{\mathrm{P}(S_t)} \overset{(2)}{=} \frac{\mathrm{P}(S_{t+s})}{\mathrm{P}(S_t)} \overset{(3)}{=} \frac{e^{-\lambda(t+s)}}{e^{-\lambda t}} \overset{(4)}{=} e^{-\lambda s} = \mathrm{P}(S_s).$$

(1) Definition (1.17).

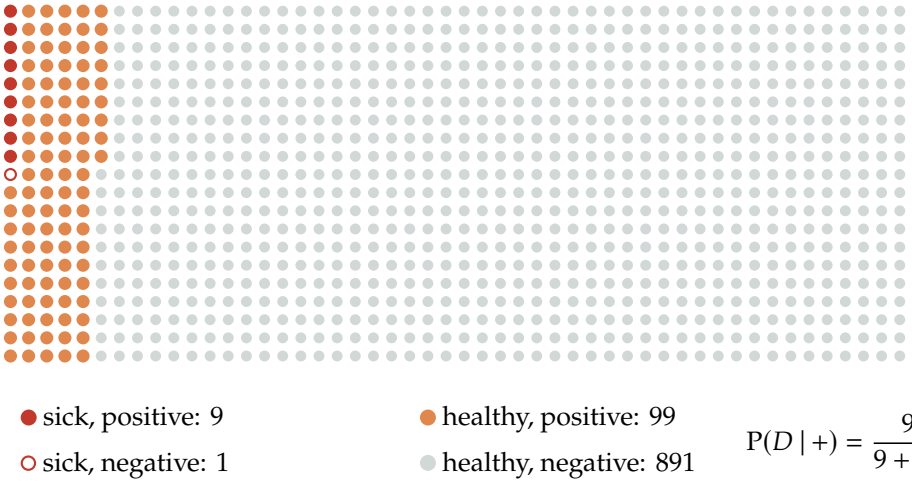


Figure 1.14: The medical test as a thousand people. The red dots at the top left are the ten who are sick, nine of whom test positive. The orange block is the ninety-nine healthy people who also test positive. Conditioning on a positive result keeps only the filled coloured dots, and the red ones are a small minority of them.

(2) $S_{t+s} \subset S_t$.
(3) The survival law.
(4) $e^{a+b} = e^a e^b$.

A nucleus that has already lived a thousand years is exactly as likely to survive the next second as a freshly made one. The exponential law is the only survival law with this **memoryless** property, and it is why the decay constant is meaningful at all. Taking $s = \mathrm{d}t$ small, $\mathrm{P}(\text{decay in } [t, t+\mathrm{d}t] \mid S_t) = 1 - e^{-\lambda\,\mathrm{d}t} \approx \lambda\,\mathrm{d}t$: the decay constant *is* a conditional probability per unit time, the same at every age. A human, or a photomultiplier tube, does age, and its survival law is not exponential.

1.4.3 The multiplication rule

Multiplying (1.17) by $\mathrm{P}(B)$, and doing the same with the roles of A and B exchanged, gives the **multiplication rule** [Wasserman p. 11, Lemma 1.14]:

$$\mathrm{P}(AB) = \mathrm{P}(A \mid B)\ \mathrm{P}(B) = \mathrm{P}(B \mid A)\ \mathrm{P}(A). \tag{1.18}$$

Read it as a two-step story: for A and B both to happen, first A must happen, and then, in the world where A has happened, B must happen [Lambert §3.6]. Applying it repeatedly gives the **chain rule** [Wasserman p. 15, Ex. 17]:

$$\mathrm{P}(ABC) \overset{(1)}{=} \mathrm{P}\big(A \mid BC\big)\ \mathrm{P}(BC) \overset{(2)}{=} \mathrm{P}(A \mid BC)\ \mathrm{P}(B \mid C)\ \mathrm{P}(C), \tag{1.19}$$

(1) Multiplication rule (1.18) with the two events A and BC.
(2) Multiplication rule again, for $\mathrm{P}(BC)$.

and in general $\mathrm{P}(A_1 A_2 \cdots A_n) = \mathrm{P}(A_1)\,\mathrm{P}(A_2 \mid A_1)\,\mathrm{P}(A_3 \mid A_1 A_2) \cdots \mathrm{P}(A_n \mid A_1 \cdots A_{n-1})$. The chain rule is the arithmetic of a path through a tree, which is the subject of the next section.

Example 1.17 (Cards drawn without replacement). Draw two cards from a deck without putting the first back. Let A be "first is the ace of clubs" and B "second is the queen of diamonds". Then $\mathrm{P}(A) = 1/52$, and once A has happened the second card is uniform over the

51 cards that remain, one of which is the queen of diamonds. So $\mathrm{P}(AB) = \mathrm{P}(A)\,\mathrm{P}(B \mid A) = \frac{1}{52} \cdot \frac{1}{51}$ [Wasserman p. 11, Ex. 1.15].

Four aces in a row: with E_j "the j-th card is an ace",

$$\mathrm{P}(E_1E_2E_3E_4) \overset{(1)}{=} \mathrm{P}(E_1)\,\mathrm{P}(E_2 \mid E_1)\,\mathrm{P}(E_3 \mid E_1E_2)\,\mathrm{P}(E_4 \mid E_1E_2E_3) \overset{(2)}{=} \frac{4}{52} \cdot \frac{3}{51} \cdot \frac{2}{50} \cdot \frac{1}{49} = \frac{1}{270\,725}.$$

(1) Chain rule.
(2) At each step the shrunken deck is uniform: after j aces, $52 - j$ cards remain, $4 - j$ of them aces.

This equals $1/\binom{52}{4}$, as it must. Now condition on having started well [CasellaBerger Ex. 1.3.3]. Given that the first i cards are aces, the deck has $52 - i$ cards with $4 - i$ aces, and the probability that the next $4 - i$ cards are exactly those aces is $1/\binom{52-i}{4-i}$. For $i = 1, 2, 3$ this is 0.00005, 0.00082 and 0.0204. Each piece of good news makes the event four aces far more probable, though still unlikely.

1.4.4 Conditioning is selection: a simulation

In code, conditioning on B means keeping only the rows where B is true. We repeat Example 1.13 with 200000 simulated rolls.

Listing 1.4: Conditioning by filtering (`code/ch01/04_conditioning_by_filtering.py`)

```
21 rng = rng_for("ch01", "1a_conditioning")
22 N = 200_000
23 d1 = rng.integers(1, 7, size=N)
24 d2 = rng.integers(1, 7, size=N)
25 A = (d1 + d2 == 8)
26 B = (d1 == 6) | (d2 == 6)
27
28 # --- conditioning = filtering: keep only the rows in B, then count A among them
29 A_given_B = A[B].mean()
30 B_given_A = B[A].mean()
31 # the same thing written as the ratio of frequencies, P(AB)/P(B)
32 ratio = (A & B).mean() / B.mean()
```

Lines 25–26 build the two masks. Line 29 is the whole of conditional probability: `A[B]` is the sub-array of A over the rows in which B happened, and its mean is the fraction of those rows in which A also happened, n_{AB}/n_B. Line 32 computes the same number as a ratio of two unconditional frequencies, $\hat{\mathrm{P}}(AB)/\hat{\mathrm{P}}(B)$, and the two agree exactly (0.1817 and 0.1817), because $n_{AB}/n_B = (n_{AB}/N)/(n_B/N)$.

Of the 200000 rolls, 61090 had at least one six, 27774 had sum eight, and 11100 had both. The estimates are $\hat{\mathrm{P}}(A \mid B) = 0.1817$ (exact $2/11 = 0.1818$) and $\hat{\mathrm{P}}(B \mid A) = 0.3997$ (exact $2/5 = 0.4000$).

The figure shows the price of conditioning. The estimate of $\mathrm{P}(A \mid B)$ uses only $n_B \approx N\,\mathrm{P}(B)$ rolls, so its scatter is about $\sqrt{\mathrm{P}(A \mid B)(1 - \mathrm{P}(A \mid B))/(N\,\mathrm{P}(B))}$, the running-frequency rule of Section 1.2 with n replaced by the number of survivors. Conditioning on a rare event leaves few survivors, and then the estimate is noisy however large N was.

So conditioning is selection followed by renormalisation. In a simulation it is one line, `A[B].mean()`, and its statistical error is set by how many events survive the selection, not by how many were generated.

Two traps are worth naming. First, $\mathrm{P}(A \mid B)$ and $\mathrm{P}(B \mid A)$ are different numbers, and they can be very different (Example 1.15), so always say in words which event is known. Second, (1.17) needs $\mathrm{P}(B) > 0$. Conditioning on an event of probability zero, such as "the measured energy is exactly 91.1876 GeV", is still meaningful but needs densities, which come in the next part.

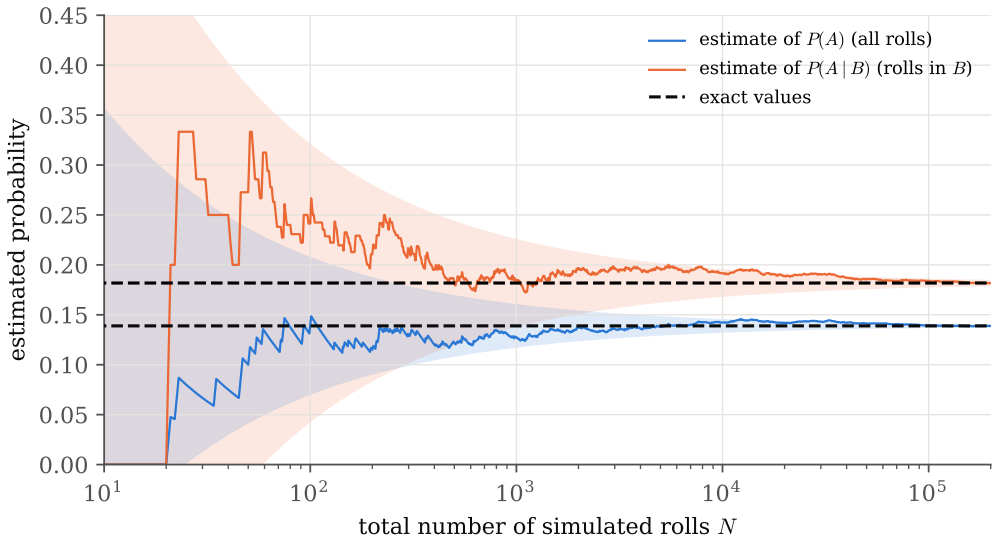

Figure 1.15: Running estimates of P(A) from all rolls (blue) and of P($A \mid B$) from the rolls in B only (orange), against the total number of simulated rolls, with the exact values dashed. Both converge, but the conditional estimate wanders more and its band is wider, because only about 30% of the rolls survive the selection.

How this is used in real research: Tag-and-probe

The efficiency of a muon identification algorithm is a conditional probability, P(identified | real muon). In data we do not know which tracks are real muons, so we make a subset in which we do. Select events with two tracks whose invariant mass is at the Z peak and in which one track (the "tag") passes a very tight identification. The other track (the "probe") is then almost certainly a muon, and the fraction of probes that pass the algorithm is the efficiency. The whole technique is the definition (1.17), implemented as a selection on real events. Here it is the research instrument: no formula gives this efficiency.

Everything in this section comes back to one picture: the conditioning event B becomes the new, shrunk sample space [Wasserman pp. 10–12, §1.6]. It is certain inside itself, $\mathrm{P}(B \mid B) = \mathrm{P}(B)/\mathrm{P}(B) = 1$ [CasellaBerger §1.3], and every other probability is re-measured as a share of it (Seeing Theory draws the same idea as "shelves", [SeeingTheory p. 27]). The medical test shows why we should not trust intuition here: the shrunk space can hold a very different mix of cases from the original one.

1.5 Probability trees and the law of total probability

One collision in a hundred contains a real high-momentum muon (S, for signal). The other 99% do not (B, background). The hardware level-1 trigger (L1) fires for 95% of the signal collisions and, because of fake muons from hadrons punching through the calorimeter, for 2% of the background. The collisions that pass L1 are examined by the software high-level trigger (HLT), which, *among those that passed L1*, keeps 90% of the signal and 10% of the background. What fraction of all collisions is written to disk, and how much of what is written is signal?

A situation built from successive stages is drawn as a tree. Two rules then answer both questions. The probability of each complete path is the product of the conditional probabilities along it. The probability of an observation is the sum over all the paths that lead to it. That sum is the law of total probability. Read the right way, it is also marginalisation: averaging out

the stage we do not observe.

Water flowing through pipes. Pour one litre of water in at the root. At every junction the water divides among the outgoing pipes in fixed proportions (the conditional probabilities), and no water is lost, so the proportions at each junction add up to one. The water reaching the end of a pipe is the product of the proportions along the way. The total water collected in a bucket that several pipes drain into is the sum of what each pipe delivers.

Building and reading a tree. The recipe, in words, is as follows.

1. What are the stages of the situation, in the order they are easiest to describe? (Nature picks S or B, then L1 decides, then HLT decides.)
2. At each node, what are the mutually exclusive possibilities for the next stage, and what is the probability of each *given the path so far*?
3. The probability of a complete path is the product along it.
4. The probability of an event is the sum over the leaves where the event is true.

Working definition 1.8 (probability tree)

A **probability tree** is a rooted tree whose branches leaving each node are the possible results of the next stage [mutually exclusive and exhaustive, given everything above the node]. Each branch carries the conditional probability of its result given the path from the root to its node, so the labels leaving a node sum to one. A **path** from the root to a leaf is one complete history, and the leaves partition Ω [every outcome follows exactly one path]. *Rules:* multiply along a path, add across paths.

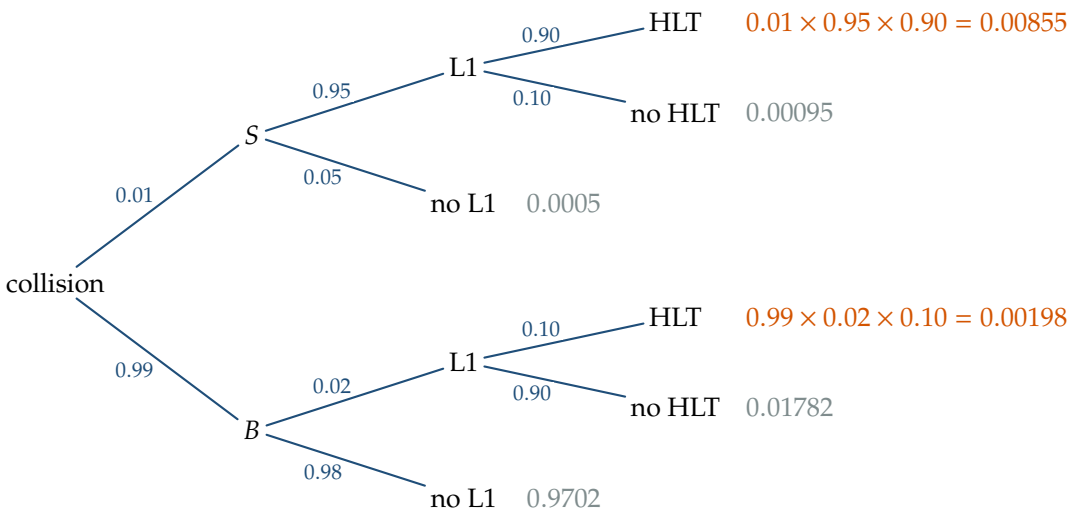

Figure 1.16: The two-level trigger as a tree. The first split is nature's choice between signal and background. Each later split is a trigger decision, and its numbers are conditional on everything to the left. The numbers at the right are the path probabilities, which add up to one. The two orange paths end in "written to disk".

1.5.1 Multiply along a path

A path is an intersection of events, one per stage, so its probability is the chain rule (1.19). For the top path of Figure 1.16,

$$\mathrm{P}(S \cap \mathrm{L1} \cap \mathrm{HLT}) \overset{(1)}{=} \mathrm{P}(S)\ \mathrm{P}(\mathrm{L1} \mid S)\ \mathrm{P}(\mathrm{HLT} \mid S \cap \mathrm{L1}) \overset{(2)}{=} 0.01 \times 0.95 \times 0.90 = 0.00855. \tag{1.20}$$

(1) Chain rule, with the events taken in the order of the stages.
(2) The branch labels. The last one is the HLT efficiency *for signal that passed L1*, which is exactly how the HLT number was specified.

The path probabilities at the right of Figure 1.16 sum to one. The reason is that the labels leaving each node sum to one. So the paths through the branches leaving a node add up to the probability of the path that reaches that node. Repeating this from the leaves back to the root leaves the root's probability, one. In the water picture, no water is lost at a junction.

1.5.2 Add across paths: the law of total probability

Let "accepted" be Acc = L1 ∩ HLT. Two paths end in it, one through S and one through B. They are disjoint (a collision cannot be both signal and background), so their probabilities add:

$$\mathrm{P}(\mathrm{Acc}) = 0.00855 + 0.99 \times 0.02 \times 0.10 = 0.00855 + 0.00198 = 0.01053.$$

About one collision in a hundred is kept. Nothing here was special to the trigger: whenever the first stage splits Ω into disjoint pieces, the probability of an event is the sum over the paths that end in it.

Key idea: Law of total probability

Let $A_1, \ldots, A_k$ be a partition of Ω. Then for any event B,

$$\mathrm{P}(B) = \sum_{i=1}^{k} \mathrm{P}(B \mid A_i)\ \mathrm{P}(A_i). \tag{1.21}$$

The first stage of the tree is the partition, the second stage is "does B happen", and (1.21) adds the paths that end in B.

To prove it, cut B along the partition as in Figure 1.3: $C_i = BA_i$. Every outcome of B lies in exactly one A_i, so the C_i are disjoint and $B = \bigcup_i C_i$ [Wasserman p. 12, Thm 1.16]. Then

$$\mathrm{P}(B) \overset{(1)}{=} \mathrm{P}\Big(\bigcup_i C_i\Big) \overset{(2)}{=} \sum_i \mathrm{P}(BA_i) \overset{(3)}{=} \sum_i \mathrm{P}(B \mid A_i)\ \mathrm{P}(A_i).$$

(1) B is the union of its pieces C_i.
(2) Finite additivity for the disjoint pieces $C_i = BA_i$.
(3) Multiplication rule (1.18) for each piece. If some $\mathrm{P}(A_i) = 0$, the term $\mathrm{P}(BA_i) = 0$ is simply dropped.

The law holds just as well for a countable partition $A_1, A_2, \ldots$, by Axiom 3 in place of finite additivity.

Total probability is an average. The weights $\mathrm{P}(A_i)$ in (1.21) are nonnegative and sum to one. So $\mathrm{P}(B)$ is a *weighted average* of the conditional probabilities $\mathrm{P}(B \mid A_i)$, and it lies between

the smallest and the largest of them. In the trigger, the acceptance 0.01053 lies between the background acceptance 0.002 (= 0.02 × 0.10) and the signal acceptance 0.855 (= 0.95 × 0.90). It sits very close to the background value, because background carries 99% of the weight.

This averaging is what it means to **marginalise**. We average out the stage we do not observe, here the true nature of the collision. That stage plays the role of a *nuisance* variable: it matters for the answer, but we do not ask about it. In Chapter 5 the same sum becomes an integral over parameters $\boldsymbol{\theta}$ given data $\boldsymbol{d}$, $p(\boldsymbol{d}) = \int p(\boldsymbol{d} \mid \boldsymbol{\theta})\, p(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}$, the evidence.

Example 1.18 (The 662 keV line of caesium-137). A ^{137}Cs nucleus β-decays either to the excited isomer ^{137m}Ba (probability about 0.944) or directly to the ground state of ^{137}Ba (about 0.056). The isomer de-excites by emitting a 662 keV photon with probability about 0.902. Otherwise the energy is carried off by an internal-conversion electron. The direct branch emits no 662 keV photon. The probability that one decay produces a 662 keV photon is

$$\begin{aligned} \mathrm{P}(\gamma_{662}) &\overset{(1)}{=} \mathrm{P}(\gamma_{662} \mid {}^{137m}\mathrm{Ba})\ \mathrm{P}({}^{137m}\mathrm{Ba}) + \mathrm{P}(\gamma_{662} \mid \text{ground})\ \mathrm{P}(\text{ground}) \\ &\overset{(2)}{=} 0.902 \times 0.944 + 0 \times 0.056 \approx 0.851, \end{aligned}$$

(1) Law of total probability over the two decay branches.
(2) Branch probabilities from the nuclear data tables.

which is the "85.1% gamma intensity" printed in the tables. A third stage, "the photon deposits its full energy in the detector" with probability ε, multiplies the useful path by ε. A source of activity $\mathcal{A}$ (decays per second) therefore gives a photopeak rate $0.851\, \varepsilon \mathcal{A}$. Every calibration with a radioactive source uses this tree.

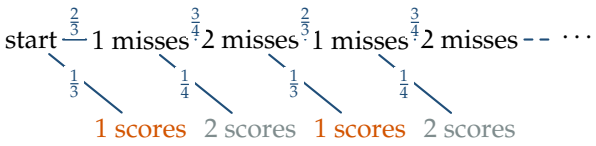
Example 1.19 (A coin from a bag). A bag holds a fair coin and a coin with P(heads) = 0.95. We pick one blindly and toss it three times [SeeingTheory p. 27]. Let F be "fair coin picked" and H_3 "three heads". Given the coin, the tosses are independent (Section 1.6), so $\mathrm{P}(H_3 \mid F^c) = 0.95^3 = 0.857$ and $\mathrm{P}(H_3 \mid F) = 0.5^3 = 0.125$. Then

$$\mathrm{P}(H_3) \overset{(1)}{=} \mathrm{P}(H_3 \mid F^c)\, \mathrm{P}(F^c) + \mathrm{P}(H_3 \mid F)\, \mathrm{P}(F) = 0.857 \times 0.5 + 0.125 \times 0.5 \approx 0.491.$$

(1) Law of total probability over the partition $\{F, F^c\}$.

We will reverse this tree in Section 1.7 to ask which coin we hold.

Example 1.20 (Taking turns: a tree with infinitely many paths). Two players take turns shooting at a basket, player 1 first. Player 1 scores with probability 1/3, player 2 with probability 1/4, independently each time. What is the probability that player 1 scores first [Wasserman p. 9, Ex. 1.11]?



Let A_j be "the first basket is by player 1, on her j-th attempt". Each A_j is one path: $j-1$ rounds of "both miss", then player 1 scores. The A_j are disjoint and their union is the event E we want. Each round of two misses has probability $\frac{2}{3} \cdot \frac{3}{4} = \frac{1}{2}$, so $\mathrm{P}(A_j) = (\frac{1}{2})^{j-1} \frac{1}{3}$, and

$$\mathrm{P}(E) \overset{(1)}{=} \sum_{j=1}^{\infty} \mathrm{P}(A_j) \overset{(2)}{=} \frac{1}{3} \sum_{j=1}^{\infty} \left(\frac{1}{2}\right)^{j-1} \overset{(3)}{=} \frac{1}{3} \cdot \frac{1}{1 - \frac{1}{2}} = \frac{2}{3}.$$

(1) Axiom 3, since the paths A_j are disjoint.
(2) Multiply along each path.
(3) Geometric series, $\sum_{m=0}^{\infty} r^m = 1/(1-r)$ for $0 \le r < 1$. It follows from $(1-r)(1+r+\cdots+r^M) = 1 - r^{M+1}$ and $r^{M+1} \to 0$. More generally $\sum_{j=k}^{\infty} r^j = r^k/(1-r)$.

A shortcut avoids the series. Look only at the first round. With probability $\frac{1}{3}$ player 1 scores at once. With probability $\frac{1}{2}$ both miss, and then the game starts afresh, so player 1 scores first with probability $\mathrm{P}(E)$ again. In the remaining case player 2 scored. So $\mathrm{P}(E) = \frac{1}{3} + \frac{1}{2}\mathrm{P}(E)$, which again gives $\mathrm{P}(E) = \frac{2}{3}$.

Try it: Until both faces have appeared. Toss a fair coin until both a head and a tail have appeared [Wasserman p. 15, Ex. 13]. The sample space is $\{HT, TH, HHT, TTH, HHHT, TTTH, \dots\}$. Show that exactly three tosses are needed with probability 1/4. *Answer:* two paths, HHT and TTH, each of probability $(1/2)^3$.

1.5.3 Following each collision down the tree

The trigger tree can be simulated literally: generate the nature of each collision, then each trigger decision with the probability appropriate to that branch.

Listing 1.5: The trigger tree, exactly and by simulation (`code/ch01/05_trigger_chain.py`)

```
24 # --- exact: multiply along each path, add the paths that end in "accepted"
25 path_S = s * e1S * e2S
26 path_B = (1 - s) * e1B * e2B
27 p_acc = path_S + path_B
28 purity = path_S / p_acc      # used again in the Bayes section
29
30 # --- simulation: follow every collision down the tree
31 rng = rng_for("ch01", "1a_trigger_chain")
32 N = 2_000_000
33 is_S = rng.random(N) < s
34 l1 = np.where(is_S, rng.random(N) < e1S, rng.random(N) < e1B)
35 hlt = l1 & np.where(is_S, rng.random(N) < e2S, rng.random(N) < e2B)
36 mc_acc = hlt.mean()
37 mc_path_S = (hlt & is_S).mean()
38 mc_path_B = (hlt & ~is_S).mean()
39 mc_purity = is_S[hlt].mean()        # conditioning = filtering on "accepted"
```

Lines 25–28 are the tree read as arithmetic: multiply along the two accepted paths and add them. Line 33 is nature's choice at the root. Line 34 is the L1 split: `np.where` uses the signal efficiency on signal rows and the background efficiency on background rows, which is precisely what "conditional on the branch" means. Line 35 applies the HLT only to rows that passed L1 (the `l1 &`), again with a branch-dependent efficiency. Lines 37–38 count the accepted collisions separately on each path. Line 39 is a preview of Section 1.7: among accepted collisions, the fraction that is signal.

With 2×10^6 simulated collisions, 21248 are accepted, a frequency of 0.01062 against the exact 0.01053. The signal path contributes 0.00865 (exact 0.00855) and the background path 0.00198 (exact 0.00198).

What this bought us. A tree turns a many-stage problem into bookkeeping: conditional probabilities on the branches, products along paths, sums across paths. The law of total probability is the sum across the paths that end in the observed event, and it is a weighted average of the branch-wise probabilities.

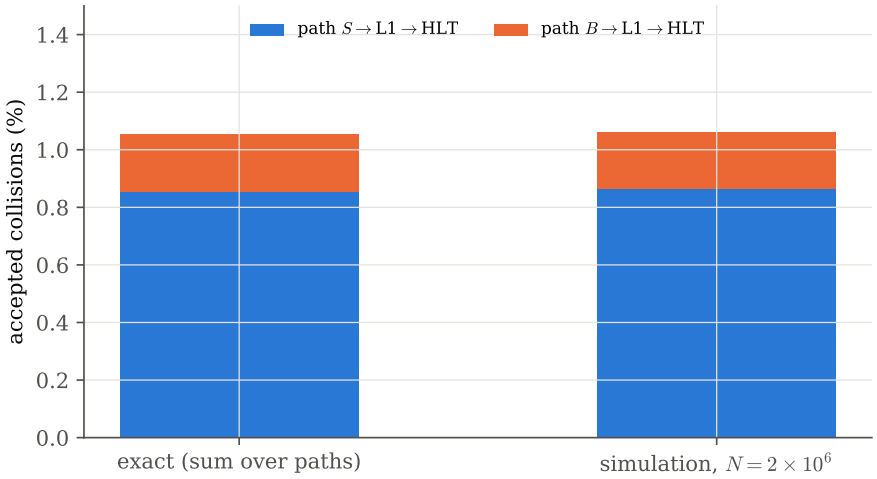


Figure 1.17: The fraction of collisions written to disk, split into the two paths of the tree that lead there. The left bar is the exact sum over paths, the right bar the simulation. Signal (blue) supplies most of the accepted collisions although only one collision in a hundred is signal.

In research: trigger rates and emulation. In a real experiment each trigger level has a rate budget (for example 100 kHz out of L1 and a few kHz out of the HLT), and the total rate is computed exactly as a sum over the physics processes that can fire it, each weighted by its cross section: the law of total probability with the processes as the partition. Here the simulation only verified the tree. In practice the branch efficiencies depend on the momentum, angle and pile-up of each collision, and no closed formula exists. One then runs the trigger emulation on millions of simulated events and counts, so the simulation is the instrument and the tree is the check that one understands the result.

Watch out: Branch labels are conditional on the path

Two traps. First, the HLT keeps 90% of signal *that passed L1*. That is P(HLT | $S \cap$ L1), not P(HLT | S) and certainly not P(HLT). Multiplying unconditional probabilities along a path is correct only when the stages are independent, which is the subject of the next section. Second, the paths that are added must be disjoint. The leaves of a tree always are, which is why drawing the tree is safer than adding probabilities by eye.

1.6 Independence: when learning B tells us nothing about A

In Example 1.6 we used a table in which the pattern 111 had probability $0.729 = 0.9^3$ and each pattern with one silent paddle had $0.081 = 0.9^2 \times 0.1$. Those numbers come from one assumption: each paddle fires with probability 0.9 *whatever the other paddles do*. The paddles are separate pieces of plastic with separate photomultipliers, so this is plausible. It fails if the three tubes share a high-voltage supply that sometimes sags, because then one silent paddle makes it more likely that the others are silent too.

Independence is the precise version of "whatever the others do". It is the one situation in which the probability of "A and B" is the product of the two probabilities. That product rule lets us write the probability of a data set as a product over data points, and every likelihood in this book is built that way. There are two things that independence is not. First, independence is not the same as disjointness. Second, when there are three or more events, independence does not mean merely that every pair of events is independent.

Crossed strips. Draw Ω as the unit square. Let A be a vertical strip of width $\mathrm{P}(A)$ and B a horizontal strip of height $\mathrm{P}(B)$. Their overlap is a rectangle of area $\mathrm{P}(A)\,\mathrm{P}(B)$. Inside A, the strip B covers the same fraction $\mathrm{P}(B)$ as it covers of the whole square, so learning "A happened" does not change the probability of B. Independence is this product structure. Two dice, two separate detectors or two separate nuclei behave like the two axes of the square.

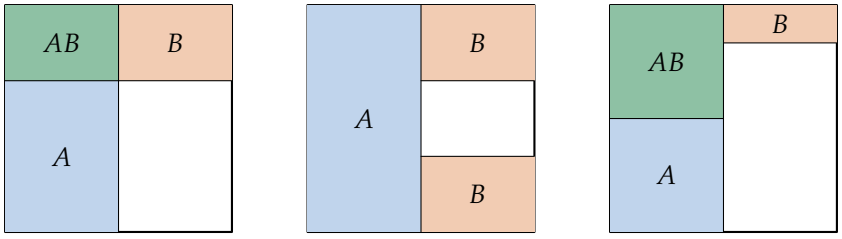

Figure 1.18: Three ways for two events to sit in the unit square, all drawn to scale and all with $\mathrm{P}(A) = \frac{1}{2}$ (the left half) and $\mathrm{P}(B) = \frac{1}{3}$. Left: B is the top third, so it fills a third of A and a third of the square, and $\mathrm{P}(AB) = \frac{1}{6}$, exactly the product: independent. Middle: A and B do not meet, so $\mathrm{P}(AB) = 0$ and knowing A rules B out. Right: B still has area $\frac{1}{3}$ but leans into A, so $\mathrm{P}(AB) = \frac{1}{4} \neq \frac{1}{6}$. The two overlaps have the same width, so compare their heights: B covers half of A on the right but only a third of A on the left. Covering more of A than its $\frac{1}{3}$ share of the square, B becomes more likely once we learn A.

Checking independence. Whenever a calculation seems to need independence, we ask four questions.

1. In words: does knowing that B happened change how likely A is?
2. In numbers: is $\mathrm{P}(AB)$ equal to $\mathrm{P}(A)\,\mathrm{P}(B)$?
3. Is independence being *assumed* (no physical mechanism links the two) or *derived* (computed from a known distribution)?
4. For more than two events, check every sub-collection, not just the pairs.

Working definition 1.9 (independence)

Two events A and B are **independent**, written $A \perp\!\!\!\perp B$, if

$$\mathrm{P}(AB) = \mathrm{P}(A)\ \mathrm{P}(B). \tag{1.22}$$

A collection $\{A_i : i \in I\}$ is **independent** (or **mutually independent**) if $\mathrm{P}\big(\bigcap_{i\in J} A_i\big) = \prod_{i\in J} \mathrm{P}(A_i)$ for *every* finite subset $J \subseteq I$ [for three events that means the three pairs and the triple, four equations in all]. Otherwise the events are dependent. *Operational test:* with $\mathrm{P}(B) > 0$, independence is $\mathrm{P}(A \mid B) = \mathrm{P}(A)$.

The conditional form is the meaning, and the product form is the convenient definition, because it is symmetric and also makes sense when $\mathrm{P}(B) = 0$. They agree whenever $\mathrm{P}(B) > 0$ [Wasserman p. 11, Lemma 1.14]:

$$\mathrm{P}(A \mid B) \overset{(1)}{=} \frac{\mathrm{P}(AB)}{\mathrm{P}(B)} \overset{(2)}{=} \frac{\mathrm{P}(A)\,\mathrm{P}(B)}{\mathrm{P}(B)} = \mathrm{P}(A),$$

(1) Definition of conditional probability.
(2) Independence (1.22).

and conversely, if $\mathrm{P}(A \mid B) = \mathrm{P}(A)$ then multiplying by $\mathrm{P}(B)$ gives (1.22). By the symmetry of (1.22), $\mathrm{P}(B \mid A) = \mathrm{P}(B)$ too when $\mathrm{P}(A) > 0$: if B tells us nothing about A, then A tells us nothing about B.

Assumed or derived. Often independence is an *assumption* that expresses physics: a coin has no memory of its last toss, two nuclei do not communicate, the noise in two separate amplifiers has separate sources. Sometimes it is a *result* [Wasserman p. 8]. Roll one fair die and let $A = \{2, 4, 6\}$ and $B = \{1, 2, 3, 4\}$. Then $AB = \{2, 4\}$ and

$$\mathrm{P}(AB) = \tfrac{2}{6} = \tfrac{1}{3} = \tfrac{1}{2} \times \tfrac{2}{3} = \mathrm{P}(A)\,\mathrm{P}(B),$$

so A and B are independent, although both are about the same single roll. Nobody assumed it. With $C = \{4, 5, 6\}$ instead, $AC = \{4, 6\}$ and $\mathrm{P}(AC) = \frac{1}{3} \neq \frac{1}{2} \times \frac{1}{2}$: knowing the roll is high makes it more likely to be even.

1.6.1 Consequences

Complements of independent events are independent. If $A \perp\!\!\!\perp B$,

$$\mathrm{P}(AB^c) \overset{(1)}{=} \mathrm{P}(A) - \mathrm{P}(AB) \overset{(2)}{=} \mathrm{P}(A) - \mathrm{P}(A)\,\mathrm{P}(B) \overset{(3)}{=} \mathrm{P}(A)\big(1 - \mathrm{P}(B)\big) \overset{(4)}{=} \mathrm{P}(A)\,\mathrm{P}(B^c).$$

(1) A is the disjoint union of AB and AB^c, so $\mathrm{P}(A) = \mathrm{P}(AB) + \mathrm{P}(AB^c)$.
(2) Independence of A and B.
(3) Factor out $\mathrm{P}(A)$.
(4) Complement rule.

So $A \perp\!\!\!\perp B^c$ [Wasserman p. 15, Ex. 11], [CasellaBerger Thm 1.3.9]. Applying the same argument with the roles of the events exchanged gives $A^c \perp\!\!\!\perp B^c$. If a paddle's firing tells us nothing about another's, neither does its silence.

Sure and impossible events are independent of everything [Wasserman p. 15, Ex. 14]. If $\mathrm{P}(A) = 0$, then $\mathrm{P}(AB) \leq \mathrm{P}(A) = 0$ by monotonicity, so $\mathrm{P}(AB) = 0 = \mathrm{P}(A)\,\mathrm{P}(B)$. If $\mathrm{P}(A) = 1$, then $\mathrm{P}(A^c) = 0$, so A^c is independent of every B, and by the complement result so is A. Finally, an event independent of itself satisfies $\mathrm{P}(A) = \mathrm{P}(AA) = \mathrm{P}(A)^2$, so $\mathrm{P}(A) \in \{0, 1\}$.

Key idea: Disjoint is not independent

If A and B are disjoint and both have positive probability, they are *dependent*: $\mathrm{P}(A)\,\mathrm{P}(B) > 0$, but $\mathrm{P}(AB) = \mathrm{P}(\varnothing) = 0$ [Wasserman p. 9]. Disjoint events are as dependent as events can be: learning that one happened tells us for certain that the other did not.

Apart from this case, a Venn diagram cannot show independence. Whether the overlap equals the product depends on the areas, not on the shapes. In Figure 1.18 the right panel looks as "overlapping" as the left one, yet only the left is independent.

Two more warnings [Lambert §3.4]. First, take a playing card. Its colour and its suit are dependent: "red" forces hearts or diamonds. Its suit and its value are independent: $\mathrm{P}(\heartsuit \mid \text{queen}) = \frac{1}{4} = \mathrm{P}(\heartsuit)$. Second, dependence is not causation. The colour does not *cause* the suit. Dependence only means that knowing one tells us something about the other.

1.6.2 Examples

Example 1.21 (At least one head in ten tosses). Let A be "at least one head" in ten tosses of a fair coin and T_j "tails on toss j" [Wasserman p. 9, Ex. 1.10]. Then

$$\mathrm{P}(A) \overset{(1)}{=} 1 - \mathrm{P}(A^c) \overset{(2)}{=} 1 - \mathrm{P}(T_1 T_2 \cdots T_{10}) \overset{(3)}{=} 1 - \mathrm{P}(T_1)\,\mathrm{P}(T_2)\cdots\mathrm{P}(T_{10}) \overset{(4)}{=} 1 - \left(\frac{1}{2}\right)^{10} \approx 0.999.$$

(1) Complement rule.
(2) "No head" means "tails on every toss".
(3) The tosses are independent (assumed: the coin has no memory).
(4) Each factor is $\frac{1}{2}$.

The Chevalier de Méré's bet "at least one six in four rolls of a die" is the same computation, $1 - (5/6)^4 \approx 0.518$ [CasellaBerger Ex. 1.3.8], a slightly favourable bet. His other bet, "at least one double six in 24 rolls of two dice", gives $1 - (35/36)^{24} \approx 0.491$, slightly unfavourable, which puzzled him enough to write to Pascal.

Example 1.22 (Telescope efficiency, and the first decay in a sample). *(a)* Each paddle fires with probability ε, independently. The trigger needs at least two paddles. The pattern 111 has probability ε^3, and each of the three patterns with exactly one silent paddle has probability $\varepsilon^2(1-\varepsilon)$, by the product rule for the three independent events "paddle j fired or not" (complements are independent too). So

$$\mathrm{P}(T) \overset{(1)}{=} 3\varepsilon^2(1-\varepsilon) + \varepsilon^3 = 3\varepsilon^2 - 2\varepsilon^3,$$

(1) Finite additivity over the four disjoint patterns in T.

which is 0.972 at $\varepsilon = 0.9$, reproducing the table of Example 1.6. A two-out-of-three majority turns 90% paddles into a 97% trigger.

(b) A sample holds N nuclei, each surviving to time t with probability $e^{-\lambda t}$ (Example 1.16), independently of the others. The probability that *none* has decayed by t is

$$\mathrm{P}\Big(\bigcap_{i=1}^{N} S_t^{(i)}\Big) \overset{(1)}{=} \prod_{i=1}^{N} \mathrm{P}\big(S_t^{(i)}\big) = \big(e^{-\lambda t}\big)^N = e^{-N\lambda t}.$$

(1) Mutual independence of the N survival events.

"None has decayed by t" is the same event as "the first decay comes after t". So the waiting time until the first click of a Geiger counter has the survival law $e^{-N\lambda t}$ of a single nucleus with rate $N\lambda$: it is itself exponential, with rate $N\lambda$, the activity of the sample. This is the seed of the Poisson process of Chapter 2.

Example 1.23 (Blue eyes). Each of three children has blue eyes with probability $\frac{1}{4}$, independently [Wasserman p. 15, Ex. 15]. Let K be the number of blue-eyed children. *(a)* Given that at least one has blue eyes, what is the probability that at least two do? The event $\{K \geq 2\}$ lies inside $\{K \geq 1\}$, so

$$\mathrm{P}(K \geq 2 \mid K \geq 1) \overset{(1)}{=} \frac{\mathrm{P}(K \geq 2)}{\mathrm{P}(K \geq 1)} \overset{(2)}{=} \frac{3 \cdot \frac{1}{16} \cdot \frac{3}{4} + \frac{1}{64}}{1 - \left(\frac{3}{4}\right)^3} = \frac{10/64}{37/64} = \frac{10}{37} \approx 0.27.$$

(1) Definition of conditional probability, with $\{K \geq 2\} \cap \{K \geq 1\} = \{K \geq 2\}$.
(2) Numerator: exactly two blue (three choices of the brown-eyed child) or all three. Denominator: complement of "none blue". Independence gives each pattern's probability as a product.

(b) Given that the *youngest* has blue eyes, at least two are blue-eyed exactly when at least one of the other two is. By independence the youngest tells us nothing about them, so the answer is $1-(\frac{3}{4})^2=\frac{7}{16}\approx 0.44$. The two conditions sound alike but carry different information, and (b) is the larger because it pins down *which* child is blue-eyed.

1.6.3 Pairwise is not mutual

For three events, one might hope that the triple product $\mathrm{P}(ABC)=\mathrm{P}(A)\,\mathrm{P}(B)\,\mathrm{P}(C)$ is enough, or that it is enough for each pair to be independent. Neither is [CasellaBerger Exs. 1.3.10–1.3.11].

Example 1.24 (The triple product without the pairs). Roll two dice. Let A be "doubles", B "the sum is between 7 and 10" and C "the sum is 2, 7 or 8". Counting among the 36 outcomes, $\mathrm{P}(A)=\frac{6}{36}=\frac{1}{6}$, $\mathrm{P}(B)=\frac{6+5+4+3}{36}=\frac{1}{2}$ and $\mathrm{P}(C)=\frac{1+6+5}{36}=\frac{1}{3}$. The only double with sum in $\{7,8\}$ is $(4,4)$, so $\mathrm{P}(ABC)=\frac{1}{36}=\frac{1}{6}\cdot\frac{1}{2}\cdot\frac{1}{3}$. But $\mathrm{P}(BC)=\mathrm{P}(\text{sum 7 or 8})=\frac{11}{36}\neq\frac{1}{6}=\mathrm{P}(B)\,\mathrm{P}(C)$, and $\mathrm{P}(AB)=\mathrm{P}(\{(4,4),(5,5)\})=\frac{1}{18}\neq\frac{1}{12}$. The triple product holds by coincidence, while the pairs are dependent.

Example 1.25 (The pairs without the triple). Let Ω consist of the nine strings aaa, bbb, ccc, abc, bca, cab, acb, bac, cba, each with probability $\frac{1}{9}$, and let A_i be "the i-th letter is a". Each A_i contains three strings (for A_1: aaa, abc, acb), so $\mathrm{P}(A_i)=\frac{1}{3}$. Any two positions are both a only in aaa, so $\mathrm{P}(A_iA_j)=\frac{1}{9}=\mathrm{P}(A_i)\,\mathrm{P}(A_j)$: every pair is independent. But all three are a also only in aaa, so $\mathrm{P}(A_1A_2A_3)=\frac{1}{9}\neq\frac{1}{27}$. Knowing that the first two letters are a makes the third certain to be a.

Try it: Conditionally independent, marginally dependent. Suppose that on 95% of days the telescope's shared high-voltage supply is fine and each paddle fires with probability 0.92, independently, while on 5% of days the voltage sags and each fires with probability 0.5, independently. Show, with the law of total probability, that $\mathrm{P}(\text{top})=\mathrm{P}(\text{middle})\approx 0.899$ but $\mathrm{P}(\text{top and middle})\approx 0.817\neq 0.899^2\approx 0.808$. The paddles are independent *given* the state of the supply, but not independent overall. The unobserved common cause creates the dependence. This is the structure of the hierarchical models of Chapter 5.

1.6.4 Testing independence on simulated data

Take the die events $A=\{2,4,6\}$, $B=\{1,2,3,4\}$ (independent) and $C=\{4,5,6\}$ (dependent), simulate rolls, and compare $\hat{\mathrm{P}}(AB)$ with $\hat{\mathrm{P}}(A)\hat{\mathrm{P}}(B)$ [Wasserman p. 17, Ex. 23].

Listing 1.6: Independence checked by simulation (`code/ch01/06_independence_dice.py`)

```
rng = rng_for("ch01", "1a_independence")
N = 10_000
roll = rng.integers(1, 7, size=N)
A = np.isin(roll, [2, 4, 6])
B = np.isin(roll, [1, 2, 3, 4])
C = np.isin(roll, [4, 5, 6])

fA, fB, fC = A.mean(), B.mean(), C.mean()
fAB, fAC = (A & B).mean(), (A & C).mean()

# repeat the whole N-roll experiment many times to see the scatter of the test
reps = 4000
rolls = rng.integers(1, 7, size=(reps, N), dtype=np.int8)
Ar, Br, Cr = np.isin(rolls, [2, 4, 6]), np.isin(rolls, [1, 2, 3, 4]), np.isin(rolls, [4, 5,
    6])
diff_AB = (Ar & Br).mean(1) - Ar.mean(1) * Br.mean(1)
```

```
34 diff_AC = (Ar & Cr).mean(1) - Ar.mean(1) * Cr.mean(1)
```

Lines 21–24 roll one die N times and build the three masks with `np.isin`. Lines 26–27 are the frequencies. Lines 30–34 repeat the whole N-roll experiment 4000 times, as rows of a two-dimensional array, and compute for each repeat the difference $\hat{\mathrm{P}}(\text{both}) - \hat{\mathrm{P}}(\text{first})\hat{\mathrm{P}}(\text{second})$.

In a single run of $N = 10000$ rolls, $\hat{\mathrm{P}}(A) = 0.4964$, $\hat{\mathrm{P}}(B) = 0.6706$, $\hat{\mathrm{P}}(C) = 0.4927$. For the independent pair, $\hat{\mathrm{P}}(AB) = 0.3317$ against $\hat{\mathrm{P}}(A)\hat{\mathrm{P}}(B) = 0.3329$. For the dependent pair, $\hat{\mathrm{P}}(AC) = 0.3280$ against $\hat{\mathrm{P}}(A)\hat{\mathrm{P}}(C) = 0.2446$. Even the independent pair does not satisfy the product rule *exactly*, and no finite simulation would, because frequencies scatter. So the real question is whether the difference is larger than that random scatter. The repeats answer it, by showing how large the difference typically is.

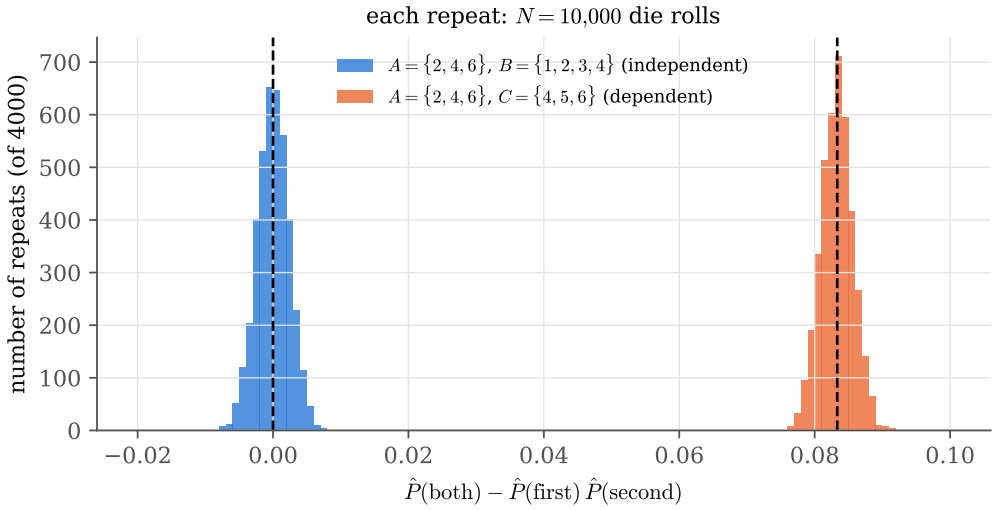

Figure 1.19: The difference between the frequency of "both" and the product of the two frequencies, over many repeats of a 10^4-roll experiment. For the independent pair (blue) the differences scatter symmetrically around zero. For the dependent pair (orange) they scatter around $\frac{1}{3} - \frac{1}{4} = \frac{1}{12}$, far from zero compared with the width of either histogram.

For the independent pair the differences have mean near zero and standard deviation 0.0024. For the dependent pair their mean is 0.0833, the exact $\frac{1}{12}$, some thirty-five standard deviations away. A difference of $0.3317 - 0.3329$ in the single run is typical of independence. A difference of 0.08 is not.

What this bought us. With data, "is $\mathrm{P}(AB) = \mathrm{P}(A)\,\mathrm{P}(B)$?" becomes "is the observed difference large compared with its scatter under independence?". That is a hypothesis test with independence as the null hypothesis, and Chapter 4 makes it precise.

In research: independence is what lets us multiply. Every likelihood in this book is a product, and every product is an assumption of independence. Poisson counts in different bins of a histogram are independent if the events arrive independently (colliders, photon counting). The spherical-harmonic coefficients $a_{\ell m}$ of a statistically isotropic Gaussian sky are independent for different (ℓ, m) (Chapter 7), which is why the full-sky CMB likelihood factorises over ℓ. For stationary detector noise, the Fourier amplitudes at different frequencies are independent, which is why the gravitational-wave log-likelihood is a sum over frequency bins weighted by the power spectral density (Chapter 10). A mask breaks the $a_{\ell m}$ independence and correlated noise breaks the frequency independence. Handling that loss is much of the work of Chapter 8.

Watch out: Three ways to get independence wrong

(1) Treating disjoint events as independent. (2) Checking only pairs, or only the full product, for three or more events. (3) Assuming independence where a hidden common cause exists (a shared power supply, a common calibration constant, a shared beam condition). Common-mode effects are the usual reason why a redundant system fails more often than the product of the individual failure rates predicts.

1.7 Bayes' theorem: reading the tree backwards

A tree can be read in two directions, and the analyst at a collider needs the direction it was not drawn in. Recall the two-level trigger of Section 1.5: a fast hardware trigger (L1) followed by a software high-level trigger (HLT), which together write about one collision in a hundred to disk. Its tree runs in the order in which things happen. First nature makes the collision signal (S) or background (B). Then L1 decides. Then the HLT decides. Read in that order, the tree answers *prediction* questions: if a collision is signal, how likely is it to be kept?

The analyst who opens the files on disk never sees nature's first choice. She sees only the collisions that were kept. So she asks the opposite question: of the collisions written to disk, what fraction is signal? That is an *inference* question. It starts from an observation and asks which branch of the tree produced it. These are the two directions of probability of Chapter 0. For a hypothesis H and an observed event E, $\mathrm{P}(E \mid H)$ runs forward, from H to what it produces. $\mathrm{P}(H \mid E)$ runs backward, from what we saw to what produced it.

Bayes' theorem turns the first kind of number into the second. We need it because the two kinds come from different places. The forward numbers are what physics and calibration give us: efficiencies, misidentification rates, branching fractions, the probability of the data under a model. The backward numbers are what we want: the purity of a sample, the probability that a track is a kaon, the credibility of a cosmological model. So the question is: given a tree built in the forward direction, how do we read it backwards?

The analyst's question can be said in words, in four steps, before any formula.

1. What did she see? A collision on disk, one that the trigger kept.
2. What could have put it there? It was either a signal collision or a background collision.
3. If it was signal, how probable was it to be kept? And if it was background?
4. Given those two answers, how must the shares of signal and background that nature started with be revised?

Step 3 is ordinary prediction, done once for each hypothesis. Only step 4 is new, and it needs nothing more than the definition of conditional probability, used once.

1.7.1 Two routes to the same leaf

The whole theorem rests on one fact: a leaf of a tree is the same event whichever order the tree was drawn in. Take a hypothesis H and an observed event E. The leaf "H and E", written HE for $H \cap E$, can be reached in two orders. In the forward tree we pass first through H and then through E. In a tree drawn the other way round we pass first through E and then through H [Lambert §3.6.1]. Both routes end at the same event HE, so they give it the same probability. The multiplication rule (1.18), $\mathrm{P}(HE) = \mathrm{P}(E \mid H)\,\mathrm{P}(H)$, computes it along the forward route.

Dividing by $\mathrm{P}(E)$, which we assume is positive, gives the backward number:

$$\mathrm{P}(H \mid E) \overset{(1)}{=} \frac{\mathrm{P}(HE)}{\mathrm{P}(E)} \overset{(2)}{=} \frac{\mathrm{P}(E \mid H)\ \mathrm{P}(H)}{\mathrm{P}(E)}. \tag{1.23}$$

(1) Definition (1.17) of conditional probability, with E as the conditioning event: E is the new, shrunk sample space.
(2) Multiplication rule along the forward route, $\mathrm{P}(HE) = \mathrm{P}(E \mid H)\,\mathrm{P}(H)$.

The numerator is one leaf of the forward tree. The denominator $\mathrm{P}(E)$ is the total probability of the observation, and it too comes from the forward tree. Suppose the possible hypotheses $H_1, \ldots, H_k$ form a partition of the sample space Ω [exactly one of them is true]. Then the law of total probability (1.21) gives $\mathrm{P}(E)$ as the sum of all the forward leaves that end in E. Putting that sum in the denominator gives the general form [Wasserman p. 12, Thm 1.17].

Key idea: Bayes' theorem

Let $H_1, \ldots, H_k$ be a partition of Ω with every $\mathrm{P}(H_i) > 0$, and let $\mathrm{P}(E) > 0$. Then for each i,

$$\mathrm{P}(H_i \mid E) = \frac{\mathrm{P}(E \mid H_i)\ \mathrm{P}(H_i)}{\sum_{j=1}^{k} \mathrm{P}(E \mid H_j)\ \mathrm{P}(H_j)}. \tag{1.24}$$

In the tree: the posterior of H_i is the leaf "H_i then E" divided by the sum of all leaves that end in E.

Each ingredient has a name [Wasserman p. 12, Remark 1.18].

- $\mathrm{P}(H_i)$ is the **prior** probability of H_i: how probable H_i was before the observation.
- $\mathrm{P}(H_i \mid E)$ is its **posterior** probability: how probable it is after.
- $\mathrm{P}(E \mid H_i)$ is the **likelihood** of H_i: the probability of the observation we actually made, computed as if H_i were true.
- $\mathrm{P}(E)$ is the **evidence**. It is the same number for every H_i, and its only job is to make the posteriors add up to one.

Nothing here goes beyond the definition of conditional probability and the law of total probability. The only new thing is the direction in which we read the tree.

Inverting a tree means: compute the leaves forward, then regroup them by the observation instead of by the hypothesis. Figure 1.20 shows this for the trigger. The forward tree and the inverted tree have the same four leaves with the same probabilities, because the leaves are the same events. What changes is the order of the two splits, and with it the conditional probabilities written on the branches.

Example: inverting the trigger tree. *What she saw.* A collision on disk: it passed both L1 and the HLT. Call this one merged decision "accepted", Acc = L1 ∩ HLT.

What could have produced it? The collision was either signal, S, or background, B. These are the two hypotheses.

How probable was acceptance under each? Multiply along the paths of Figure 1.16. A signal collision passes L1 with probability 0.95 and then the HLT with probability 0.90, so $\mathrm{P}(\mathrm{Acc} \mid S) = 0.95 \times 0.90 = 0.855$. A background collision passes L1 with probability 0.02 and then the HLT with probability 0.10, so $\mathrm{P}(\mathrm{Acc} \mid B) = 0.02 \times 0.10 = 0.002$.

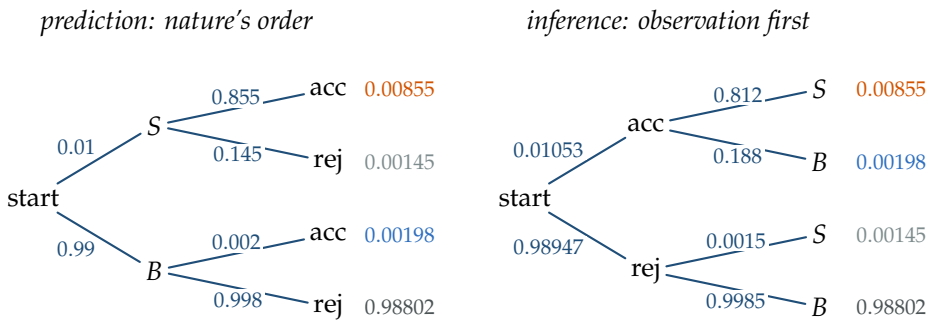

Figure 1.20: The trigger of Figure 1.16 with the two trigger levels merged into one decision, accepted (acc) or rejected (rej), drawn in both orders. Left: nature chooses signal or background, then the trigger decides. Right: the same four leaves, same colours, same probabilities, regrouped by the trigger decision first. The branches on the right are the inference numbers: among accepted collisions, 81% are signal.

Then the priors, and normalise. Before the trigger, one collision in a hundred is signal: $\mathrm{P}(S) = 0.01$, $\mathrm{P}(B) = 0.99$. The signal fraction of the recorded sample, called its **purity**, is

$$\mathrm{P}(S \mid \mathrm{Acc}) \overset{(1)}{=} \frac{\mathrm{P}(\mathrm{Acc} \mid S)\ \mathrm{P}(S)}{\mathrm{P}(\mathrm{Acc} \mid S)\ \mathrm{P}(S) + \mathrm{P}(\mathrm{Acc} \mid B)\ \mathrm{P}(B)} \overset{(2)}{=} \frac{0.855 \times 0.01}{0.855 \times 0.01 + 0.002 \times 0.99}$$
$$= \frac{0.00855}{0.00855 + 0.00198} = \frac{0.00855}{0.01053} \approx 0.812.$$

(1) Bayes' theorem (1.24) with the partition $\{S, B\}$.
(2) The branch probabilities of the merged tree.

Only one collision in a hundred is signal, yet four out of five recorded collisions are. The trigger has raised the probability of "signal" from a prior of 0.01 to a posterior of 0.81. The reason is the ratio of the two likelihoods: a signal collision is $0.855/0.002 \approx 430$ times more likely to be accepted than a background one. The simulation of Section 1.5 (the last line of its listing) counted the signal fraction among the accepted collisions directly and found 0.8138, against the exact 0.8120.

Example: dots and dashes. Morse code sends dots and dashes in the proportion 3 : 4, so $\mathrm{P}(\text{dot sent}) = \frac{3}{7}$ [CasellaBerger Ex. 1.3.6]. Noise on the line turns a dot into a dash, or a dash into a dot, with probability $\frac{1}{8}$. We receive a dot. How sure can we be that a dot was sent?

What we saw is "dot received". Two things could have produced it: a dot was sent and arrived intact, or a dash was sent and noise flipped it. Under the first, a received dot has probability $\frac{7}{8}$; under the second, $\frac{1}{8}$. The priors are $\frac{3}{7}$ for a dot and $\frac{4}{7}$ for a dash. Then

$$\mathrm{P}(\text{dot sent} \mid \text{dot rec.}) \overset{(1)}{=} \frac{\frac{7}{8} \cdot \frac{3}{7}}{\frac{7}{8} \cdot \frac{3}{7} + \frac{1}{8} \cdot \frac{4}{7}} \overset{(2)}{=} \frac{21/56}{21/56 + 4/56} = \frac{21}{25} = 0.84.$$

(1) Bayes' theorem: the likelihood of "dot received" is $\frac{7}{8}$ if a dot was sent and $\frac{1}{8}$ if a dash was sent.
(2) Put both products over the common denominator 56.

So a received dot is wrong 4 times in 25, about one time in six, even though each symbol is flipped only one time in eight. The extra errors come from the dashes. Dashes are sent more often than dots, so the flipped dashes make up a larger share of the received dots than the flip rate alone suggests.

1.7.2 The recipe: prior times likelihood, then normalise

The evidence $\mathrm{P}(E)$ is the same for every hypothesis. So we can leave it out, compute prior times likelihood for each hypothesis, and divide by the total at the end:

$$\mathrm{P}(H_i \mid E) \;\propto\; \mathrm{P}(E \mid H_i)\,\mathrm{P}(H_i), \qquad \text{then divide by the sum over } i. \tag{1.25}$$

This is the most useful form in practice. It turns every discrete Bayes problem into a table with one row per hypothesis and four columns: the prior; the likelihood; their product, which is the forward leaf that ends in E; and the product divided by the sum of its column, which is the posterior. The sum of the product column is $\mathrm{P}(E)$.

Example: spam. An email is spam (A_1), low priority (A_2) or high priority (A_3), with prior probabilities 0.7, 0.2 and 0.1 [Wasserman pp. 12–13, Ex. 1.19]. The word "free" (E) appears in 90% of spam and in 1% of each of the other two kinds.[1] An email arrives containing "free". That is what we saw, and the three kinds of email are the hypotheses that could have produced it. The table is

hypothesis	prior $\mathrm{P}(A_i)$	likelihood $\mathrm{P}(E \mid A_i)$	product	posterior $\mathrm{P}(A_i \mid E)$
spam	0.7	0.90	0.630	0.9953
low priority	0.2	0.01	0.002	0.0032
high priority	0.1	0.01	0.001	0.0016
sum	1	0.92	0.633	1

so $\mathrm{P}(A_1 \mid E) = 0.630/0.633 \approx 0.995$.

The column sums carry a lesson: the likelihoods are not a probability distribution over the hypotheses. The priors add up to one, and so do the posteriors, because both are probabilities *over the hypotheses*. The likelihoods add up to 0.92, and nothing forces them to add up to one. Each likelihood is a probability over *outcomes* (does "free" appear or not?), computed in a different world: one where the email is spam, one where it is low priority, one where it is high priority. Read across those worlds, as a function of the hypothesis, the list of likelihoods is not a probability distribution. This is the statement "$\mathrm{P}(A \mid \cdot)$ is not a probability" of Section 1.4. It is also why, in Chapter 3, the likelihood of a parameter is called a function and not a density.

Example: which operating system? Among computer owners 30% use a Mac, 50% Windows and 20% Linux, and the fractions infected by a virus are 0.65, 0.82 and 0.50 [Wasserman p. 16, Ex. 19]. A randomly chosen owner turns out to be infected. The products are $0.3 \times 0.65 = 0.195$, $0.5 \times 0.82 = 0.410$ and $0.2 \times 0.50 = 0.100$, with sum $\mathrm{P}(\text{infected}) = 0.705$, so

$$\mathrm{P}(\text{Windows} \mid \text{infected}) = \frac{0.410}{0.705} \approx 0.582, \qquad \mathrm{P}(\text{Mac} \mid \cdot) \approx 0.277, \qquad \mathrm{P}(\text{Linux} \mid \cdot) \approx 0.142.$$

Windows rises from 0.50 to 0.58. Mac falls from 0.30 to 0.28, and Linux from 0.20 to 0.14. The rule is visible in the numbers. The average infection rate is $\mathrm{P}(\text{infected}) = 0.705$. Windows owners are infected more often than that (0.82), so Windows gains. Mac (0.65) and Linux (0.50) owners are infected less often, so they lose.

That rule is general: probability can only move between the hypotheses, never be created or destroyed [Wasserman p. 16, Ex. 18]. The reason is that the priors and the posteriors both add up

[1] Wasserman prints $\mathrm{P}(B \mid A_1) = .01$ for the third likelihood. The subscript should be A_3, as the computation that follows it shows.

to one. So if one hypothesis loses, another must gain. To see it in symbols, suppose A_1 loses, $\mathrm{P}(A_1 \mid E) < \mathrm{P}(A_1)$. Then

$$\sum_{i=2}^{k} \mathrm{P}(A_i \mid E) \overset{(1)}{=} 1 - \mathrm{P}(A_1 \mid E) \overset{(2)}{>} 1 - \mathrm{P}(A_1) \overset{(3)}{=} \sum_{i=2}^{k} \mathrm{P}(A_i),$$

(1) $\mathrm{P}(\cdot \mid E)$ is a probability (Section 1.4), and the A_i partition Ω, so the posteriors add up to one.
(2) The assumption $\mathrm{P}(A_1 \mid E) < \mathrm{P}(A_1)$.
(3) The priors add up to one.

A sum of $k-1$ terms can be larger than another sum of $k-1$ terms only if at least one of its terms is larger. So some other hypothesis gains: $\mathrm{P}(A_i \mid E) > \mathrm{P}(A_i)$ for at least one $i \geq 2$. For exactly this reason Kruschke calls Bayesian inference a *reallocation of credibility* across the possibilities [Kruschke §2.1].

The extreme case is a hypothesis whose likelihood is zero. The observation is impossible under it, so its posterior is zero. Its prior weight goes to the hypotheses that survive, shared in proportion to each one's prior times likelihood. Repeat this with more observations until only one hypothesis is left, and you get Sherlock Holmes's rule: once every other cause has been ruled out, the one that remains carries all the probability.

1.7.3 Base rates and the odds form

Bayes' theorem is least intuitive when the prior is small. A test for a rare disease detects it with probability $\mathrm{P}(+ \mid D) = 0.98$, and gives a false positive with probability $\mathrm{P}(+ \mid D^c) = 0.03$. The prevalence is $\mathrm{P}(D) = 0.001$ [Cowan p. 4]. You test positive.

What happened. The test came back positive, written $+$. *What could have produced it?* Two situations: you have the disease, D, or you do not, D^c. A positive result can come out of either. *How probable was a positive under each?* With the disease it is the detection probability, 0.98; without it, the false-positive rate, 0.03. *Then the base rates.* Before the test, D had probability 0.001 and D^c had 0.999. The two forward leaves that end in "+" give

$$\mathrm{P}(D \mid +) \overset{(1)}{=} \frac{0.98 \times 0.001}{0.98 \times 0.001 + 0.03 \times 0.999} \overset{(2)}{=} \frac{0.00098}{0.00098 + 0.02997} \approx 0.032.$$

(1) Bayes' theorem (1.24) with the partition $\{D, D^c\}$.
(2) The two forward leaves that end in "+".

The test is wrong only 2% or 3% of the time, yet after a positive result the probability of disease is only about 3%. The two leaves show why. The false-positive leaf, 0.02997, is thirty times larger than the true-positive leaf, 0.00098. Healthy people rarely test positive, but there are a thousand times more of them, so they produce most of the positives. The medical test of Example 1.15 ($\mathrm{P}(D \mid +) \approx 0.08$) and the screening example of [Lambert §3.6.2] (also 0.08) have the same structure. Ignoring the prior in such a problem is called the **base-rate fallacy**. It is the prosecutor's fallacy of Section 1.4 in another guise: it confuses $\mathrm{P}(+ \mid D)$ with $\mathrm{P}(D \mid +)$.

With two hypotheses, the effect of an observation is a single multiplication. To see it, write Bayes' theorem (1.23) for H_1 and for H_2, and divide one by the other. The evidence $\mathrm{P}(E)$ cancels:

$$\frac{\mathrm{P}(H_1 \mid E)}{\mathrm{P}(H_2 \mid E)} \overset{(1)}{=} \frac{\mathrm{P}(E \mid H_1)\,\mathrm{P}(H_1)/\mathrm{P}(E)}{\mathrm{P}(E \mid H_2)\,\mathrm{P}(H_2)/\mathrm{P}(E)} \overset{(2)}{=} \underbrace{\frac{\mathrm{P}(E \mid H_1)}{\mathrm{P}(E \mid H_2)}}_{\text{likelihood ratio}} \times \underbrace{\frac{\mathrm{P}(H_1)}{\mathrm{P}(H_2)}}_{\text{prior odds}}. \tag{1.26}$$

(1) Bayes' theorem (1.23) in the numerator and in the denominator.
(2) Cancel P(E) and regroup.

The ratio on the left is the **posterior odds**. The observation multiplies the prior odds by the **likelihood ratio**, and it does nothing else. For the rare disease, take $H_1 = D$ and $H_2 = D^c$. The likelihood ratio is $0.98/0.03 \approx 32.7$ and the prior odds are $0.001/0.999 \approx 0.0010$, so the posterior odds are 0.0327. Turning odds back into a probability, $\mathrm{P}(D \mid +) = 0.0327/(1 + 0.0327) \approx 0.032$, as before. The test is good evidence (it multiplies the odds by about thirty), but it starts from odds of one to a thousand.

The odds form makes repeated observations easy: each new observation multiplies the odds again. Suppose a second test is also positive, and the two results are independent *given the disease status* (Section 1.6). Then yesterday's posterior is today's prior, and the odds are multiplied by 32.7 again, to 1.07, so $\mathrm{P}(D \mid ++) \approx 0.52$. A third positive test gives odds 34.9 and $\mathrm{P}(D \mid +++) \approx 0.97$. In logarithms the multiplications become additions: each independent observation *adds* its log likelihood ratio to the log odds. This is why analyses add up log likelihoods rather than multiply likelihoods. The condition "independent given the disease status" matters. A test that fails for a reason specific to the patient will fail again, and then repeating it adds much less [Lambert Problem 3.8.5].

Watch out: Efficiency is not purity

A detector's efficiency P(tag | true) is a forward number, measured once on a calibration sample, and it does not depend on what else is in the beam. The purity P(true | tag) is an inverse number, and it depends strongly on the prior, the composition of the sample. A selection with 90% efficiency and a 5% fake rate can give a sample that is mostly fakes, if the true particles are rare. Quote both, and never call one by the other's name.

Example: particle identification with misidentification. A hadron beam contains pions, kaons and protons in the proportions 0.80 : 0.15 : 0.05. A Cherenkov detector tags a track as "kaon" with probability 0.90 for a real kaon, 0.05 for a pion and 0.10 for a proton. A track is tagged as a kaon. Which particle is it?

What we saw is the tag "kaon". Any of the three species could have produced it, so they are the three hypotheses. Their priors are the beam proportions, and their likelihoods are the three tagging probabilities. The table:

species	prior	P(tag K | species)	product	posterior
π	0.80	0.05	0.040	0.2222
K	0.15	0.90	0.135	0.7500
p	0.05	0.10	0.005	0.0278
sum	1		0.1800	1

One tagged track in four is not a kaon, and almost all of the impostors are pions. Pions are misidentified only 5% of the time, but there are more than five times as many pions as kaons in the beam. So the purity depends on the beam, not only on the detector. As the kaon fraction falls, the purity collapses (Figure 1.21). At a kaon fraction of 1% it is only 0.148, with the same detector and the same 90% efficiency.

1.7.4 When the observation carries information in how it was produced

When the observation comes out of a person's choice, intuition tends to ignore how it was produced, and goes wrong. In the trigger, the detector and the medical test, the observation

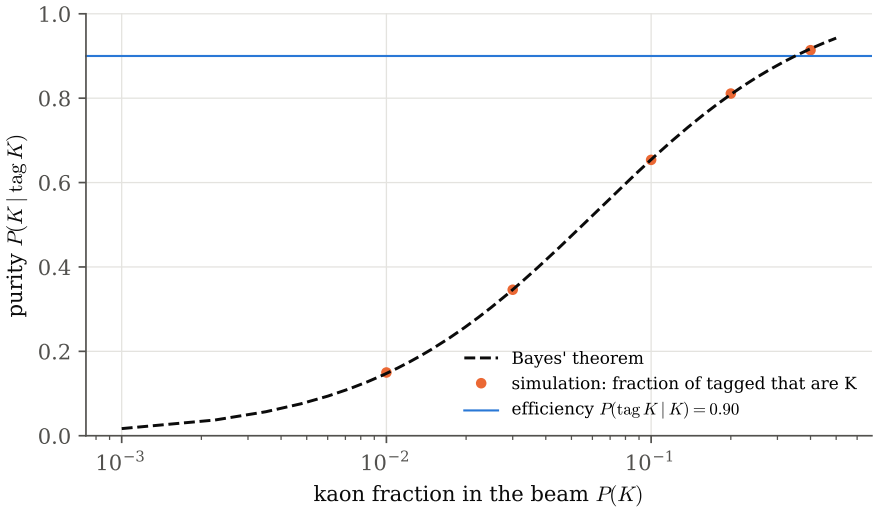

Figure 1.21: Purity of the kaon-tagged sample against the kaon fraction of the beam, on a logarithmic axis. The dashed curve is Bayes' theorem, the dots are simulated beams in which we tag tracks and count the true kaons among the tagged ones. The horizontal line is the efficiency, which stays at 0.90 whatever the beam. The two agree only when kaons dominate.

came from a fixed mechanism that was easy to see. In three famous puzzles, Monty Hall, the three prisoners and the three cards, the mechanism is hidden inside someone's decision. The four steps of the reasoning handle them without any new idea. Everything turns on the third step: under each hypothesis, how probable was *exactly the observation we made*?

Example: Monty Hall. A car is behind one of three doors, each with probability $\frac{1}{3}$, and goats are behind the other two. We pick door 1. The host, Monty, knows where the car is. He always opens one of the two doors we did not pick, never the car door, and if he has a choice he picks at random. He opens door 3 [Wasserman p. 14, Ex. 10]. Should we switch to door 2?

What we saw. Monty opened door 3. Call this event M_3.

What could have made him open it? Monty's choice depends on one thing we do not know, where the car is. So the candidate explanations are the three places the car can be: H_1, H_2 and H_3, the car behind door 1, 2 or 3. We want to know which of these places could have led Monty to open door 3, and how strongly.

How likely was door 3 under each location? Take the three in turn. Monty knows where the car is, he never reveals it, and he never opens our door.

- H_1, the car is behind our door 1: both other doors hide goats, so Monty can open door 2 or door 3 and chooses at random, $\mathrm{P}(M_3 \mid H_1) = \frac{1}{2}$.
- H_2, the car is behind door 2: he may not open our door 1 and may not reveal the car behind door 2, so he is forced to open door 3, $\mathrm{P}(M_3 \mid H_2) = 1$.
- H_3, the car is behind door 3: opening door 3 would reveal the car, so he cannot open it, $\mathrm{P}(M_3 \mid H_3) = 0$.

These are the second-stage branches of the tree in Figure 1.23. *Then the priors, and normalise.* Each location had prior $\mathrm{P}(H_d) = \frac{1}{3}$, so the three leaves that end in M_3 weigh $\frac{1}{3} \cdot \frac{1}{2} = \frac{1}{6}$, $\frac{1}{3} \cdot 1 = \frac{1}{3}$

and $\frac{1}{3} \cdot 0 = 0$. Normalising by their sum,

$$\mathrm{P}(H_2 \mid M_3) \overset{(1)}{=} \frac{\mathrm{P}(M_3 \mid H_2)\,\mathrm{P}(H_2)}{\sum_{d=1}^{3} \mathrm{P}(M_3 \mid H_d)\,\mathrm{P}(H_d)} \overset{(2)}{=} \frac{1 \cdot \frac{1}{3}}{\frac{1}{2} \cdot \frac{1}{3} + 1 \cdot \frac{1}{3} + 0 \cdot \frac{1}{3}} = \frac{1/3}{1/2} = \frac{2}{3},$$

(1) Bayes' theorem with the partition $\{H_1, H_2, H_3\}$.

(2) The three likelihoods above and the uniform prior. The evidence is $\mathrm{P}(M_3) = \frac{1}{6} + \frac{1}{3} = \frac{1}{2}$.

and in the same way $\mathrm{P}(H_1 \mid M_3) = \frac{1}{6}/\frac{1}{2} = \frac{1}{3}$ and $\mathrm{P}(H_3 \mid M_3) = 0$. Switching wins with probability $\frac{2}{3}$.

The whole calculation is one look at the picture of Figure 1.11, drawn to scale in Figure 1.22. The three places the car can be fill the sample space in three equal strips. The event M_3 is a box that takes half of the H_1 strip, all of the H_2 strip and none of the H_3 strip, exactly the three likelihoods above. Once we see M_3, that box is the whole world, and the H_2 piece of it is twice the H_1 piece.

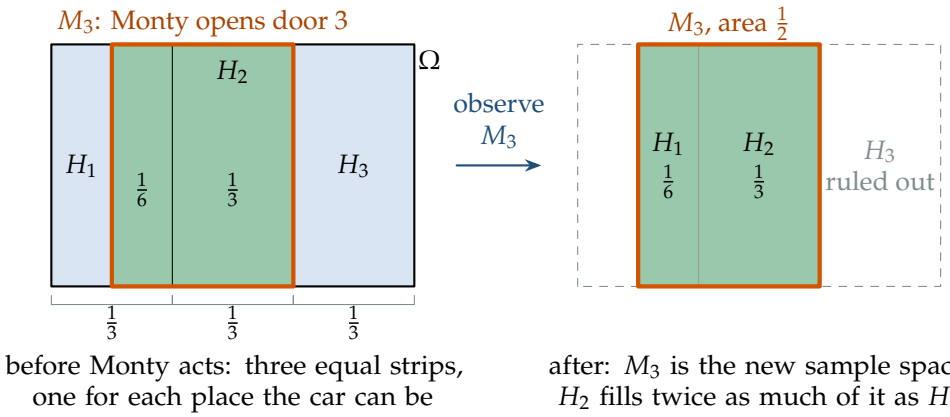

Figure 1.22: Monty Hall drawn to scale in the picture of Figure 1.11. Left: the rectangle Ω has area 1, and since the car is behind exactly one door, the three hypotheses H_1, H_2, H_3 fill it in three strips of area $\frac{1}{3}$. The event M_3, "Monty opens door 3" (orange outline), covers half of H_1 (with the car behind our door he picks door 2 or 3 at random), all of H_2 (he is forced to open door 3) and none of H_3 (he never reveals the car), so its area is $\frac{1}{6} + \frac{1}{3} = \frac{1}{2}$. Right: seeing M_3 discards everything outside the orange box, and each hypothesis keeps the share of the box that its piece fills: $\frac{1}{3}$ for H_1, $\frac{2}{3}$ for H_2.

Most people's first answer is that, with one door gone, the two doors left must be even. That answer throws away what Monty's choice told us. Door 3 was not equally likely to be opened under the two locations still possible: with the car behind door 2, Monty had no other move, while with the car behind our door 1 he would have opened door 3 only half the time. What we saw is therefore twice as probable under H_2 as under H_1, and the posteriors inherit that factor of two, $\frac{2}{3}$ against $\frac{1}{3}$.

The fifty–fifty answer gets one step right and skips another. It shrinks the sample space correctly: door 3 is out. But it forgets the likelihoods. A counterexample shows that they decide the answer. Suppose Monty did *not* know where the car is, opened door 2 or door 3 at random, and happened to show a goat behind door 3. Under H_1 he opens door 3 with probability $\frac{1}{2}$ and it hides a goat. Under H_2 he also opens door 3 with probability $\frac{1}{2}$, and it again hides a goat. So $\mathrm{P}(M_3, \text{goat} \mid H_1) = \mathrm{P}(M_3, \text{goat} \mid H_2) = \frac{1}{2}$, and the answer really would be fifty–fifty. Same doors, same observation, different mechanism, different posterior.

Example: the three prisoners. The same tree appears as an older puzzle [CasellaBerger Ex. 1.3.4]. One of three prisoners A, B, C is to be pardoned, each with probability $\frac{1}{3}$. Prisoner A asks the warden to name one of the *other two* who will be executed.

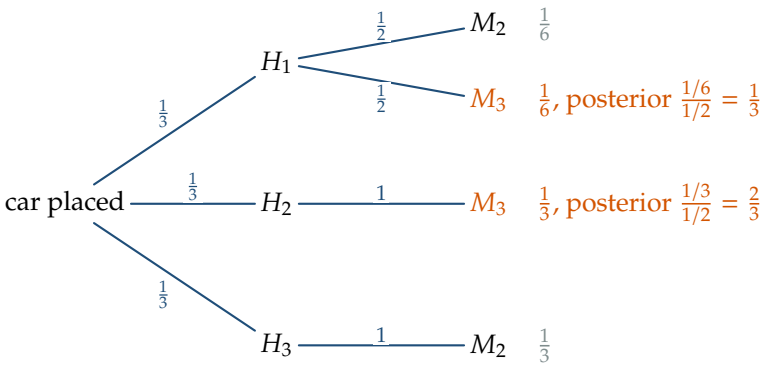

Figure 1.23: Monty Hall as a tree. We always pick door 1. The first split is where the car is. The second is which door Monty opens, which is random only when the car is behind our door. The two orange leaves are the ways of producing the observation "Monty opened door 3". They have probabilities $\frac{1}{6}$ and $\frac{1}{3}$, and dividing each by their total $\frac{1}{2}$ gives the posterior. The car cannot be behind door 3, so that hypothesis has no leaf in the observation.

What happened. The warden names B. Call this event W.

What could have made him name B? The one thing A does not know is who is pardoned, so the hypotheses are "A pardoned", "B pardoned" and "C pardoned", written simply A, B, C. Take them in turn.

- If A is pardoned, both B and C will be executed. The warden can name either and picks at random, so $\mathrm{P}(W \mid A) = \frac{1}{2}$.
- If B is pardoned, the warden cannot name B as one to be executed, so $\mathrm{P}(W \mid B) = 0$.
- If C is pardoned, then of B and C only B will be executed, so the warden must name B: $\mathrm{P}(W \mid C) = 1$.

Then the priors, and normalise. These are the Monty Hall likelihoods, with prisoner A in the place of door 1, and the priors are again $\frac{1}{3}$ each. So $\mathrm{P}(A \mid W) = \frac{1}{3}$ and $\mathrm{P}(C \mid W) = \frac{2}{3}$.

Prisoner A reasons "now it is A or C, so my chance has risen to $\frac{1}{2}$". He is wrong. The warden is right that he told A nothing about A's own fate. But he told A a great deal about C's.

Example: three cards. One card is green on both sides, one red on both sides, one green on one side and red on the other. We draw a card at random, look at one side at random, and see green [Wasserman p. 15, Ex. 12]. What is the probability that the other side is green too?

What we saw is a green face. It could have come from any card that has a green side, so the hypotheses are the three cards: GG, RR and GR, with prior $\frac{1}{3}$ each. Take them in turn. The GG card shows green whichever side we look at, so the likelihood is 1. The RR card never shows green: 0. The GR card shows green only if we happen to look at its green side: $\frac{1}{2}$. The posterior of GG is

$$\mathrm{P}(GG \mid \text{see } G) \overset{(1)}{=} \frac{1 \cdot \frac{1}{3}}{1 \cdot \frac{1}{3} + 0 \cdot \frac{1}{3} + \frac{1}{2} \cdot \frac{1}{3}} \overset{(2)}{=} \frac{1/3}{1/2} = \frac{2}{3},$$

(1) Bayes' theorem with the partition $\{GG, RR, GR\}$.
(2) The evidence is $\mathrm{P}(\text{see } G) = \frac{1}{2}$, as it must be by symmetry between the colours.

and the hidden side is green exactly when the card is GG. The popular answer, $\frac{1}{2}$, counts cards: two cards have a green side, so it treats them as equally likely. But what we saw was a face, not

a card. The correct answer counts green *faces*. There are three, and two of them are on the GG card.

1.7.5 A posterior over a parameter: coins in a box

The hypotheses can be the possible values of a number, not just named situations. Then the posterior is a probability distribution over that number. That is the step from the puzzles to parameter estimation.

Example: which coin? A bag holds a fair coin and a biased coin with P(heads) = 0.95. We pick one at random and toss it three times, getting three heads, H_3 [SeeingTheory pp. 28–29]. Which coin did we pick? The hypotheses are "biased" and "fair", each with prior $\frac{1}{2}$. Given the coin, the tosses are independent, so the likelihoods of three heads are $0.95^3 = 0.857$ for the biased coin and $0.5^3 = 0.125$ for the fair one. In Example 1.19 we computed the two forward leaves, $\mathrm{P}(H_3 \mid \text{biased})\,\mathrm{P}(\text{biased}) = 0.857 \times 0.5$ and $\mathrm{P}(H_3 \mid \text{fair})\,\mathrm{P}(\text{fair}) = 0.125 \times 0.5$, and their sum $\mathrm{P}(H_3) \approx 0.491$. Reading that tree backwards,

$$\mathrm{P}(\text{biased} \mid H_3) = \frac{0.857 \times 0.5}{0.491} \approx 0.873.$$

Three heads move the biased coin from $\frac{1}{2}$ to 0.87. In the odds form (1.26): the prior odds were 1, the likelihood ratio is $0.857/0.125 \approx 6.9$, so the posterior odds are 6.9.

Example: five coins, and a prediction from a posterior. A box holds five coins whose probabilities of heads are $p_1 = 0$, $p_2 = \frac{1}{4}$, $p_3 = \frac{1}{2}$, $p_4 = \frac{3}{4}$ and $p_5 = 1$ [Wasserman p. 16, Ex. 20]. We pick coin C_i at random, prior $\frac{1}{5}$ each, toss it once and get heads (H_1). The likelihood of coin i is p_i, so

$$\mathrm{P}(C_i \mid H_1) \overset{(1)}{=} \frac{p_i \cdot \frac{1}{5}}{\sum_j p_j \cdot \frac{1}{5}} \overset{(2)}{=} \frac{p_i}{5/2} = \big(0,\ 0.1,\ 0.2,\ 0.3,\ 0.4\big) \quad \text{for } i = 1, \dots, 5.$$

(1) Bayes' theorem. The uniform prior cancels between numerator and denominator.
(2) $\sum_j p_j = 0 + \frac{1}{4} + \frac{1}{2} + \frac{3}{4} + 1 = \frac{5}{2}$.

With a flat prior, the posterior is just the likelihood, rescaled to add up to one. The two-headed coin ($p_5 = 1$) is now the most probable, and the two-tailed coin ($p_1 = 0$) is ruled out.

Now toss the same coin again. What is the probability of another head, $\mathrm{P}(H_2 \mid H_1)$, where H_2 is "heads on the second toss"? We do not know which coin we hold, so we average over the coins. Given the coin C_i, the tosses are independent, so $\mathrm{P}(H_2 \mid C_i H_1) = p_i$. The conditional probability $\mathrm{P}(\cdot \mid H_1)$ is itself a probability (Section 1.4), so every rule holds for it, including the law of total probability. Hence

$$\mathrm{P}(H_2 \mid H_1) \overset{(1)}{=} \sum_{i=1}^{5} \mathrm{P}(H_2 \mid C_i H_1)\ \mathrm{P}(C_i \mid H_1) \overset{(2)}{=} \sum_{i=1}^{5} p_i\ \mathrm{P}(C_i \mid H_1)$$
$$\overset{(3)}{=} \frac{\sum_i p_i^2}{\sum_i p_i} = \frac{0 + \frac{1}{16} + \frac{1}{4} + \frac{9}{16} + 1}{5/2} = \frac{15/8}{5/2} = \frac{3}{4}.$$

(1) Law of total probability (1.21) for the probability $\mathrm{P}(\cdot \mid H_1)$, over the partition $\{C_i\}$. Each term is $\mathrm{P}(H_2 C_i \mid H_1) = \mathrm{P}(H_2 \mid C_i H_1)\,\mathrm{P}(C_i \mid H_1)$ by the multiplication rule applied inside $\mathrm{P}(\cdot \mid H_1)$.

(2) Given the coin, the second toss does not care about the first.
(3) The posterior from the previous chain.

The chance of heads has gone from $\frac{1}{2}$ to $\frac{3}{4}$. Before any toss, it was the prior average of p_i, which is $\frac{1}{2}$. After one head it is the *posterior* average of p_i, which is $\frac{3}{4}$. This is a **posterior predictive** probability: a prediction made by averaging over what we still do not know, weighted by what we now believe. So the two tosses are *not* independent: $\mathrm{P}(H_2 \mid H_1) = \frac{3}{4} \neq \mathrm{P}(H_2) = \frac{1}{2}$. They are independent only given the coin. The first head changes the forecast for the second because it tells us something about the coin.

Finally, suppose instead that we toss the chosen coin until the first head, and it arrives on toss 4 (B_4). The likelihood of coin i is three tails and then a head, $(1-p_i)^3 p_i$:

$$\big((1-p_i)^3 p_i\big)_{i=1}^{5} = \Big(0,\ \tfrac{27}{256},\ \tfrac{16}{256},\ \tfrac{3}{256},\ 0\Big),$$
$$\mathrm{P}(C_i \mid B_4) = \Big(0,\ \tfrac{27}{46},\ \tfrac{16}{46},\ \tfrac{3}{46},\ 0\Big) \approx (0,\ 0.59,\ 0.35,\ 0.07,\ 0),$$

where the second list is the first divided by its sum $\frac{46}{256}$ (the flat prior again cancels). A late first head favours a coin with a small p. Both extreme coins are eliminated: $p_1 = 0$ never gives a head, and $p_5 = 1$ gives one on the first toss.

The five values p_i are a coarse grid over a continuous parameter, the probability of heads $p \in [0,1]$. With a finer and finer grid, the posterior becomes a density $p(p \mid \boldsymbol{d})$, where $\boldsymbol{d}$ stands for the observed tosses, and the sum in the evidence becomes an integral. That is the subject of Chapter 5.

1.7.6 Bayes' theorem in a simulation: selecting on the observation

Bayes' theorem can be simulated in one line, because conditioning is selection (Section 1.4). The recipe has three steps.

1. Generate many trials in the forward order, exactly as the tree says: first the hypothesis, then the observation.
2. Keep only the trials in which the observation came out as it actually did.
3. Among those, count how often each hypothesis was the true one.

That fraction estimates the posterior, and no formula is involved. Here it is for the particle-identification beam of the kaon-tagging example.

Listing 1.7: Bayes' theorem by selecting tagged tracks (`code/ch01/07_particle_id_bayes.py`)

```
30 # --- simulation: conditioning = selecting the tagged tracks
31 rng = rng_for("ch01", "1a_particle_id")
32 N = 1_000_000
33 true = rng.choice(3, size=N, p=prior)
34 tagged = rng.random(N) < p_tag[true]
35 mc_post = np.bincount(true[tagged], minlength=3) / tagged.sum()
```

Line 33 is the first split of the tree, the true species of each of a million tracks, drawn from the beam composition (the prior). Line 34 is the second split, the detector's decision. `p_tag[true]` looks up, for each track, the tagging probability of its own species, so this line uses exactly the likelihoods of the table. Line 35 is the inversion: `true[tagged]` keeps the true species of the tagged tracks only, and `np.bincount` counts how many are pions, kaons and protons. Of the 180515 tagged tracks, the fractions are 0.2228, 0.7492 and 0.0280, against the exact posteriors

0.2222, 0.7500 and 0.0278. The same selection, repeated for five beam compositions, gives the dots in Figure 1.21.

For Monty Hall the forward simulation must also contain Monty's rule, because his rule is the likelihood.

Listing 1.8: Monty Hall by selecting the games in which door 3 was opened (code/ch01/08_monty_hall.py)

```
26 prize = rng.integers(1, 4, size=N)            # door hiding the prize, uniform on {1,2,3}
27 coin = rng.random(N) < 0.5                    # Monty's tie-break when prize is behind
       door 1
28 # we always pick door 1. Monty opens a door that is neither ours nor the prize door.
29 opened = np.where(prize == 1, np.where(coin, 2, 3),   # free choice between 2 and 3
30                   np.where(prize == 2, 3, 2))         # forced choice
31 sel = opened == 3                              # the observation "Monty opened door 3"
32 post = np.array([np.mean(prize[sel] == d) for d in (1, 2, 3)])
```

Line 26 places the prize (the prior). Lines 29–30 are Monty's behaviour, which is the likelihood: with the prize behind door 1 he opens door 2 or 3 according to a fair coin, otherwise he opens the one empty door we did not pick. Line 31 selects the observation, "Monty opened door 3", which happened in 150332 of the 300000 games, a fraction 0.5011 (exact $\frac{1}{2}$, the evidence). Line 32 counts where the prize was in those games: door 1 in a fraction 0.3326, door 2 in 0.6674, door 3 in 0.0000. Over all games, switching won 0.6652 of the time and staying 0.3348 (Figure 1.24). The three-card problem is simulated the same way in the same script: of the 150117 draws that showed a green face, the hidden face was green in a fraction 0.6647 (exact $\frac{2}{3}$).

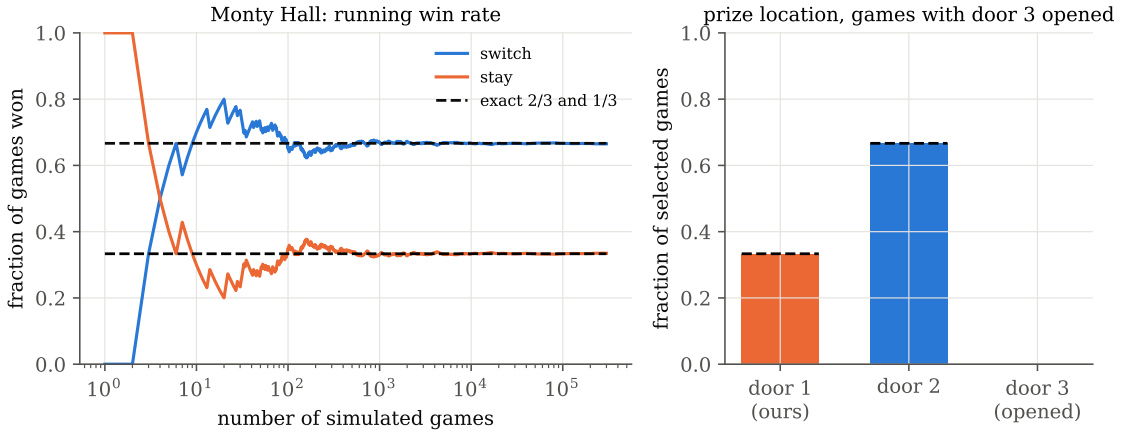

Figure 1.24: Monty Hall by simulation. Left: the running fraction of games won by always switching and by always staying, settling on $\frac{2}{3}$ and $\frac{1}{3}$. Right: among the games in which Monty opened door 3, where the prize was. The bars are the posterior, estimated by counting, and the dashed ticks are the exact values $\frac{1}{3}$ and $\frac{2}{3}$.

How this is used in real research: Selecting on the observation is how analyses estimate purity

Here the simulation only verified a posterior that Bayes' theorem gives in one line. In a real analysis the "hypotheses" are the physics processes (signal and every background), the "observation" is a long list of selection cuts, and the likelihood of passing them depends on the kinematics of each event, for which no formula exists. The expected composition of the selected sample is then computed exactly as above: simulate each process with its cross section as the prior weight, apply the selection, and count what survives. The numbers that come out are the prior-times-likelihood column of the table, event by event, and the fractions among the survivors are the posterior. Bayes' theorem in its tabular form is also

how particle-ID systems combine the responses of several detectors: the likelihood ratios of independent subdetectors multiply, as in (1.26), and the prior is the expected particle mix.

1.7.7 Where this goes

Every later chapter uses one of the two directions, prediction or inference, and many use both. Side by side:

prediction	inference
start from a hypothesis H	start from an observed event E
ask what outcomes it can produce	ask which hypotheses could have produced it
uses $\mathrm{P}(E \mid H)$, the forward tree	wants $\mathrm{P}(H \mid E)$, the tree read backwards
efficiency, sampling distribution, p-value	purity, posterior, credible interval

They are not rival interpretations of probability. They are two questions about one joint probability structure, the leaves of a single tree.

From the trigger to the five coins, every example was settled by two sentences said before any symbol. First: which hypotheses could have given what we saw? They are the rows of the table, and the posterior is spread over them. Second: how probable was the observation under each one? That is the likelihood column. Chapter 5 turns this into a standing habit.

The arithmetic is always the same, but the meaning of the posterior depends on the hypotheses. When they are outcomes of a repeatable process (signal or background, which coin, which door), a posterior is a long-run frequency among the selected trials, as the simulations showed. When the hypothesis is a value of a physical constant, which nature chose once, there are no repeated trials to count. Then the posterior can only be read as a degree of belief, the second interpretation of Section 1.2.

In the pipeline that runs from a physical model, through the data and a summary of them, to physics inferred, the forward tree is the sampling distribution $P(S \mid \theta)$ of a summary S computed from the data, given the model parameters θ. Reading that tree backwards is the last arrow, inference. Chapter 5 replaces the list of hypotheses by a continuous parameter $\boldsymbol{\theta}$, the likelihood by $\mathcal{L}(\boldsymbol{\theta}) = p(\boldsymbol{d} \mid \boldsymbol{\theta})$ (the probability density of the data $\boldsymbol{d}$ given $\boldsymbol{\theta}$), and the sum in the evidence by the integral $Z = p(\boldsymbol{d}) = \int p(\boldsymbol{d} \mid \boldsymbol{\theta})\, p(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}$, which runs over every possible parameter value and is usually the hard part. Chapter 9 avoids computing it at all: in the proportional form (1.25) only ratios of posteriors appear, and Z cancels in every ratio, just as $\mathrm{P}(E)$ cancelled in the odds (1.26). In Chapter 4 we meet the forward direction on its own, in the p-value, which is a statement about $\mathrm{P}(\text{data} \mid H_0)$, the probability of the data if the null hypothesis H_0 ("nothing but chance") were true. It must never be read as $\mathrm{P}(H_0 \mid \text{data})$.

Reading the literature

Events. [Wasserman pp. 3–5, §1.2] Wasserman defines Ω, outcomes and events in three lines and gives the three examples of Example 1.2, the table of terminology (our dictionary, where $\varnothing$ is the "null event" that is always false and Ω the "true event"), disjointness, partitions, indicators and the limits of monotone sequences with the example $[0, 1/i)$. He writes $A \cap B$ as AB or (A, B), the convention used from here on. The proofs of De Morgan's laws and the distributive law are exercises there ([Wasserman p. 14, Ex. 4]) and worked in [SeeingTheory pp. 20–21]. Kruschke adds the point that the sample space is set by the measurement operation [Kruschke §4.1].

Axioms. [Wasserman pp. 5–7, 13, §1.3, §1.9] Wasserman states the axioms (Definition 1.5, footnote on σ-fields), the two interpretations in one paragraph, the properties (1.1) without proof, inclusion–exclusion (Lemma 1.6) with the proof we expanded, the two-toss example (Example 1.7) and continuity (Theorem 1.8, increasing case only, the decreasing case being his Exercise 1). The appendix §1.9 defines σ-fields, probability spaces and the Borel σ-field. Cowan [Cowan §1.1] lists finite additivity instead of countable additivity as the third axiom, noting that this is a simplification. Countable additivity is what makes continuity and Example 1.9 work. The Bonferroni inequality and the disjointification in Boole's inequality are from [CasellaBerger §1.2]; the electron-mass argument is [Cowan §1.2.2]; calibration by gambles is [Kruschke §4.2.2].

Counting. [Wasserman pp. 7–8, §1.4] Wasserman treats finite sample spaces in a page: the 36 outcomes of two dice, $\mathrm{P}(\text{sum} = 11) = 2/36$, the uniform distribution $\mathrm{P}(A) = |A|/|\Omega|$, $n!$ with $0! = 1$, the binomial coefficient (1.2), the committee of 3 from 20 (1140), and $\binom{n}{0} = \binom{n}{n} = 1$, $\binom{n}{k} = \binom{n}{n-k}$. He writes that "we needn't delve into these in any great detail", which is why we supplied the derivations. The two-by-two table of counting rules, stars and bars, the lottery and poker counts, and the warning that unordered outcomes with replacement are not equally likely come from [CasellaBerger §1.2.3–1.2.4]. The recursion $P_n = nP_{n-1}$ and counting by overcounting are from [SeeingTheory pp. 22–24]. The birthday problem is not treated in these sources.

Trees. [Wasserman p. 12, Thm 1.16] Wasserman states the law of total probability for a finite partition and proves it in one line, as in our chain. He draws no trees. The tree picture, with the first stage as the hypotheses and the second as the outcomes they produce, organises the librarian–farmer, Monty Hall and medical-test problems above, and Lambert's "two routes to the joint probability" [Lambert §3.6.1] is a two-stage tree read in both orders. Cowan derives the same law as (1.7) [Cowan p. 3], and Seeing Theory's coins in a bag is Example 1.19 [SeeingTheory pp. 28–29].

Independence. [Wasserman pp. 8–10, §1.5] Wasserman defines independence by the product rule (Definition 1.9, with $A \perp\!\!\!\perp B$ for independence), distinguishes assumed from derived independence with the die events $\{2, 4, 6\}$ and $\{1, 2, 3, 4\}$, shows that disjoint events with positive probability are dependent and that a Venn diagram cannot display independence, and gives Examples 1.10 and 1.11 and a summary box. His Exercises 11, 14, 15 and 23 are solved above. The pairwise and mutual examples and de Méré's bet are from [CasellaBerger §1.3], the card-colour and causation remarks from [Lambert §3.4], and suit versus value from [Kruschke §4.4.2]. Seeing Theory lists $B = \{\text{second flip heads}\}$ as $\{HT, TT\}$ [SeeingTheory p. 12]. It should be $\{HH, TH\}$.

Conditioning and Bayes. Conditional probability and Bayes' theorem are [Wasserman pp. 11–13, §1.6–1.7], [Cowan §1.2], [CasellaBerger §1.3], [Kruschke §4.4] and [SeeingTheory pp. 26–30]. Wasserman gives the law of total probability and Bayes' theorem as Theorems 1.16 and 1.17 [Wasserman pp. 12–17], the names prior and posterior in Remark 1.18, the spam example as Example 1.19, and Monty Hall, the three cards, the rule that a losing hypothesis forces another to gain, the operating systems and the five coins as Exercises 10, 12, 18, 19 and 20. The two routes to the joint probability are [Lambert §3.6]. The disease example and the combined form of the theorem are [Cowan pp. 3–4, (1.6)–(1.8)]. The Morse-code and prisoners examples are [CasellaBerger §1.3], and the coins in a bag are [SeeingTheory pp. 28–29].

Recap: Events, conditional probability and trees

- An experiment has a sample space Ω of outcomes. Events are subsets, combined by $\cup$, $\cap$ and complement. In code an event is a Boolean mask over simulated outcomes.

- Probability obeys three axioms. Complement rule, monotonicity, inclusion–exclusion, Boole's inequality and continuity all follow. It can be read as a long-run frequency or as a degree of belief.
- With equally likely outcomes, probability is counting: $\mathrm{P}(A) = |A|/|\Omega|$, with $n!$ and $\binom{n}{k}$ as the tools (birthday problem).
- Information shrinks the sample space: $\mathrm{P}(A \mid B) = \mathrm{P}(AB)/\mathrm{P}(B)$, the overlap re-measured against the surviving region B. In code, `A[B].mean()`.
- Trees: multiply along a path (chain rule), add across paths (law of total probability, a weighted average over the unobserved stage).
- Independence, $\mathrm{P}(AB) = \mathrm{P}(A)\,\mathrm{P}(B)$, is not disjointness. Mutual independence needs every sub-collection.
- Bayes' theorem reads the tree backwards: $\mathrm{P}(H_i \mid E) \propto \mathrm{P}(E \mid H_i)\,\mathrm{P}(H_i)$, normalised by $\mathrm{P}(E) = \sum_j \mathrm{P}(E \mid H_j)\,\mathrm{P}(H_j)$. Posterior odds are the likelihood ratio times the prior odds.
- Efficiency is a forward number, purity an inverse one. Small priors make even good evidence weak (base rates).

1.8 Random variables: turning outcomes into numbers

A charged track crosses ten layers of a silicon tracker. Each layer either records a hit or misses it. The raw outcome of one track is therefore a 10-letter pattern such as `HHTHHTHHTT` (H for hit, T for miss). Nobody analyses patterns directly. The track-quality cut asks for a *number*: "how many hits?" A pattern-recognition algorithm asks for a different number: "what is the longest run of consecutive hits?" Both numbers are computed from the same pattern, and both are uncertain before the track arrives.

A **random variable** is exactly this: a rule that reads a number off each outcome. We want numbers because a pattern of letters cannot be put in a histogram, averaged or added, and a number can. Every data point, every estimator and every summary statistic in the rest of the book is a random variable.

Recall the box Ω of all possible outcomes from the first part of Chapter 1, where the probability of an event was its share of the area of the box. A random variable is a measuring device clipped onto that box. Nature picks the point ω, and the device prints the number $X(\omega)$. Nothing random happens inside the device. It is an ordinary function, and all the randomness is in which ω nature picked. Several devices can be clipped onto the same box, and each reads its own number off the *same* outcome. This is why two random variables can be related to each other (correlated, dependent): both are functions of one common ω.

Building a random variable takes four questions, asked in this order.

1. What is one outcome ω? (One full hit pattern, one collision event record, one sky map.)
2. What number do we want to read off it? Write it as a rule $\omega \mapsto X(\omega)$.
3. For each set A of numbers we might ask about, which outcomes give a value in A? That set of outcomes is an event, and its probability is the probability that X lands in A.
4. Collect those probabilities for all A. That list is the *distribution* of X, and from then on we can mostly forget Ω.

1.8.1 The definition, and the event hiding behind every statement about X

The four questions give one definition. They also give a rule we will use constantly: every statement about the number X is a statement about a set of outcomes.

Working definition 1.10 (random variable, distribution)

A **random variable** is a map

$$X : \Omega \to \mathbb{R}$$

that assigns a real number $X(\omega)$ to each outcome ω [a fixed rule, such as "count the H's", applied to whichever outcome occurs]. For a set $A \subseteq \mathbb{R}$ the **inverse image** is $X^{-1}(A) = \{\omega \in \Omega : X(\omega) \in A\}$ [all outcomes whose reading lands in A. It is a set of outcomes, not an inverse function], and

$$\mathrm{P}(X \in A) := \mathrm{P}\big(X^{-1}(A)\big), \qquad \mathrm{P}(X = x) := \mathrm{P}\big(\{\omega : X(\omega) = x\}\big).$$

The collection of all the numbers $\mathrm{P}(X \in A)$ is the **distribution** of X [how the probability of Ω is spread along the real line by the map X]. *Operational test:* you have a random variable when, given any outcome, you can compute a single real number from it without further information.

Capital X is the random variable (the rule). Lower-case x is a particular value it can take. "$X = x$" is therefore an event: the set of outcomes whose reading is x. (Strictly, X must be **measurable**: every set $\{\omega : X(\omega) \le x\}$ must be an event we are allowed to assign a probability to. Every function met in practice is, and we will not mention it again [Wasserman p. 43].)

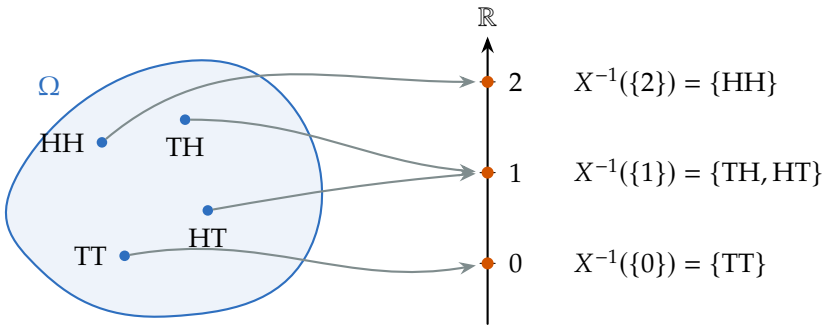

Figure 1.25: A random variable is a function from outcomes to numbers. For two coin flips, X = number of heads sends the four outcomes to three numbers. Two outcomes land on the value 1, so the probability that $X = 1$ collects the probability of both. The inverse images on the right are the events that statements about X secretly refer to.

Example 1.26 (Two flips: from the outcome table to the distribution). Flip a fair coin twice, $\Omega = \{\mathrm{TT}, \mathrm{TH}, \mathrm{HT}, \mathrm{HH}\}$, each outcome with probability $1/4$, and let X be the number of heads. Then

$$\begin{aligned} \mathrm{P}(X = 1) &\overset{(1)}{=} \mathrm{P}\big(\{\omega : X(\omega) = 1\}\big) \\ &\overset{(2)}{=} \mathrm{P}\big(\{\mathrm{TH}, \mathrm{HT}\}\big) \\ &\overset{(3)}{=} \mathrm{P}(\{\mathrm{TH}\}) + \mathrm{P}(\{\mathrm{HT}\}) = \tfrac{1}{4} + \tfrac{1}{4} = \tfrac{1}{2}. \end{aligned}$$

(1) Definition of $\mathrm{P}(X = x)$ as the probability of the inverse image.
(2) Read off which outcomes contain exactly one H.
(3) The two outcomes are disjoint events, so the axiom of additivity (first part of Chapter 1) adds their probabilities.

In the same way $\mathrm{P}(X=0)=\mathrm{P}(\{\mathrm{TT}\})=1/4$ and $\mathrm{P}(X=2)=\mathrm{P}(\{\mathrm{HH}\})=1/4$. Two tables summarise the situation:

ω	$\mathrm{P}(\{\omega\})$	$X(\omega)$
TT	1/4	0
TH	1/4	1
HT	1/4	1
HH	1/4	2

x	$\mathrm{P}(X=x)$
0	1/4
1	1/2
2	1/4

The left table describes the outcomes themselves. The right table is the distribution of X, and it answers every question about X alone. What the right table has lost, *which* flip was the head, is exactly what X does not measure.

Example 1.27 (Several random variables on one disk). Pick a point uniformly at random in the unit disk $\Omega=\{(x,y):\ x^2+y^2\le 1\}$, so that the probability of a region is its area divided by π. The outcome is the point $\omega=(x,y)$. Four random variables on the same Ω are $X(\omega)=x$, $Y(\omega)=y$, $Z(\omega)=x+y$ and $W(\omega)=\sqrt{x^2+y^2}$ [Wasserman p. 20]. Let us find the distribution of the distance W from the centre. For $0\le r\le 1$,

$$\mathrm{P}(W\le r)\overset{(1)}{=}\mathrm{P}\big(\{(x,y):\ x^2+y^2\le r^2\}\big)\overset{(2)}{=}\frac{\pi r^2}{\pi}=r^2.$$

(1) $W\le r$ happens exactly for the points inside the circle of radius r.
(2) Uniform on the disk means probability = area/π, and the small disk has area πr^2.

So $\mathrm{P}(W\le\frac{1}{2})=\frac{1}{4}$: a "uniformly random point" is *not* uniformly distributed in its distance from the centre. Three quarters of the area lies in the outer ring $\frac{1}{2}<W\le 1$. A detector that is uniformly illuminated sees most hits near its rim, simply because the rim has more area.

1.8.2 Bernoulli and binomial: one trial and many trials

The simplest random variables take only two values. Many of the most useful ones in the book are sums of them.

Working definition 1.11 (Bernoulli and binomial)

X is **Bernoulli**(p) if $\mathrm{P}(X=1)=p$ and $\mathrm{P}(X=0)=1-p$ [a single yes-or-no trial, 1 for success]. Compactly $\mathrm{P}(X=x)=p^x(1-p)^{1-x}$ for $x\in\{0,1\}$. X is **binomial**(n,p) if it counts the successes in n successive, independent Bernoulli(p) trials [the same trial repeated n times, with outcomes that do not influence each other]. *Operational test:* a single detector layer that fires or not is Bernoulli. The number of the ten layers that fired is binomial, provided the layers have the same efficiency and fire independently.

Bernoulli is for a single trial; binomial is for multiple successive trials. That is the whole difference between the two. A binomial variable is a sum of Bernoulli variables, $X=X_1+\cdots+X_n$ with X_i the indicator of success on trial i.

Example 1.28 (The binomial distribution, by counting paths). Generalise Example 1.26 to n trials with success probability p [Wasserman p. 20 ("try generalizing this to n flips")]. An outcome is a sequence of n letters. Consider one particular sequence with exactly k successes, say $\mathrm{S}^k\mathrm{F}^{n-k}$

(all successes first). Then

$$\mathrm{P}(\mathrm{S}\cdots\mathrm{S}\,\mathrm{F}\cdots\mathrm{F}) \overset{(1)}{=} \underbrace{p\cdots p}_{k}\ \underbrace{(1-p)\cdots(1-p)}_{n-k} = p^k(1-p)^{n-k},$$

$$\mathrm{P}(X=k) \overset{(2)}{=} \sum_{\text{sequences with } k \text{ S}} p^k(1-p)^{n-k} \overset{(3)}{=} \binom{n}{k} p^k(1-p)^{n-k}, \qquad k = 0, 1, \ldots, n.$$

(1) The trials are independent, so the probability of a sequence is the product of the probabilities of its letters.
(2) $\{X = k\}$ is the disjoint union of all sequences with exactly k successes, and every one of them has the same probability (only the number of S's matters, not their positions).
(3) The number of such sequences is the number of ways to choose which k of the n positions carry an S, $\binom{n}{k} = n!/(k!(n-k)!)$ (the counting rule of the first part of Chapter 1).

For $n = 10$, $p = \frac{1}{2}$: $\mathrm{P}(X = 5) = \binom{10}{5}/2^{10} = 252/1024 = 0.2461$. Simulated coin tosses give 0.2467, against the exact 0.2461. The binomial and its relatives (geometric, Poisson, multinomial) are derived from first principles in Chapter 2.

Example 1.29 (The sample space that "disappears"). The named distributions are usually stated with no Ω in sight. Is there still a set of outcomes behind them? Yes: one can always be built [Wasserman p. 27]. Take $\Omega = [0, 1]$ with $\mathrm{P}([a, b]) = b - a$ (uniform), fix p, and define

$$X(\omega) = \begin{cases} 1, & \omega \le p, \\ 0, & \omega > p. \end{cases}$$

Then

$$\mathrm{P}(X = 1) \overset{(1)}{=} \mathrm{P}(\{\omega : \ \omega \le p\}) \overset{(2)}{=} \mathrm{P}([0, p]) \overset{(3)}{=} p,$$

(1) Inverse image of the value 1 under the rule above.
(2) The outcomes with $\omega \le p$ form the interval $[0, p]$.
(3) Uniform probability of an interval is its length.

and $\mathrm{P}(X = 0) = 1 - p$, so $X \sim \text{Bernoulli}(p)$. This is not a curiosity: it is exactly how a computer makes a Bernoulli variable, `x = (u <= p)` with `u` a uniform random number (Chapter 6 makes this the general recipe). In practice we think of a random variable as "a random number". Formally it is still a function on some Ω.

Watch out: Three notational traps

- $X \sim F$ means "X *has* distribution F", not "X is approximately F" [Wasserman p. 25].
- In Binomial(n, p), X is random and x is a value it can take, but n and p are **parameters**: fixed numbers of the model. The parameter is usually unknown and has to be learned from data. That is what statistical inference is about. Do not confuse the random variable with the parameter [Wasserman p. 26].
- X and Y are **equal in distribution**, $X \overset{d}{=} Y$, if $\mathrm{P}(X \le x) = \mathrm{P}(Y \le x)$ for every x. This does not mean $X = Y$. If $\mathrm{P}(X = 1) = \mathrm{P}(X = -1) = \frac{1}{2}$ and $Y = -X$, then X and Y have the same distribution but $\mathrm{P}(X = Y) = 0$ [Wasserman p. 25].

1.8.3 Seeing it: two random variables on the same outcomes

A simulation shows two random variables read off the same outcomes. The script first builds a Bernoulli variable from a uniform ω, as in Example 1.29. It then generates 2×10^5 outcomes of ten fair flips (each row of an array is one ω) and applies two different maps to every row: X = number of heads and Y = longest run of heads.

Listing 1.9: Two random variables read off the same simulated outcomes (code/ch01/10_rv_as_map.py)

```
25 # --- 1. Bernoulli from a uniform outcome omega in [0,1] ------------------------------
26 p = 0.3
27 omega = rng.uniform(0.0, 1.0, size=100_000)       # the outcomes
28 X_bern = (omega <= p).astype(int)                  # the map omega -> {0,1}
29 bern_frac = X_bern.mean()
30
31 # --- 2. Ten fair coin flips: one outcome = one sequence of 10 H/T -------------------
32 n_exp, n_flip = 200_000, 10
33 flips = rng.integers(0, 2, size=(n_exp, n_flip))  # 1 = heads; each row is an omega
34
35
36 def longest_run(row):
37     best = cur = 0
38     for b in row:
39         cur = cur + 1 if b else 0
40         best = max(best, cur)
41     return best
42
43
44 X = flips.sum(axis=1)                              # map 1: number of heads
45 Y = np.array([longest_run(r) for r in flips])      # map 2: longest run of heads
46
47 k = np.arange(n_flip + 1)
48 pmf_X = np.array([(X == j).mean() for j in k])
49 pmf_Y = np.array([(Y == j).mean() for j in k])
50 pmf_binom = stats.binom.pmf(k, n_flip, 0.5)
```

Lines 26–29 are Example 1.29 verbatim: `omega` is an array of 10^5 uniform outcomes and `X_bern` is the boolean test $\omega \le p$ turned into 0/1. Its average is the fraction of ones, 0.3016 for $p = 0.3$. Line 33 draws the outcomes of the second experiment: an array with one row per outcome and one column per flip. The two maps on lines 44–45 are ordinary Python functions of a row, which is the definition of a random variable made executable. Lines 47–50 estimate each distribution by the fraction of outcomes that land on each value.

The numbers the script produced: the simulated $P(X = 5)$ is 0.2467 (exact 0.2461), the average number of heads is 4.997 (we will show in Section 1.12 that the exact value is $np = 5$), the average longest run is 2.796, and the most likely longest run is 2, with $P(Y = 3) = 0.2606$. No simple formula gives the distribution of Y. The simulation gets it with the same effort as the binomial one, because once we can generate outcomes, *any* random variable is just a function applied to them.

What this bought us. A random variable is a function, so a histogram of a random variable is a histogram of a function evaluated on simulated outcomes. That single sentence is the whole of Monte Carlo simulation (Chapter 6).

How research uses it. A collider Monte Carlo generator produces outcomes ω: complete event records with every particle's four-momentum. An analysis then defines random variables on them: the missing transverse momentum, the invariant mass of the two leading jets, the

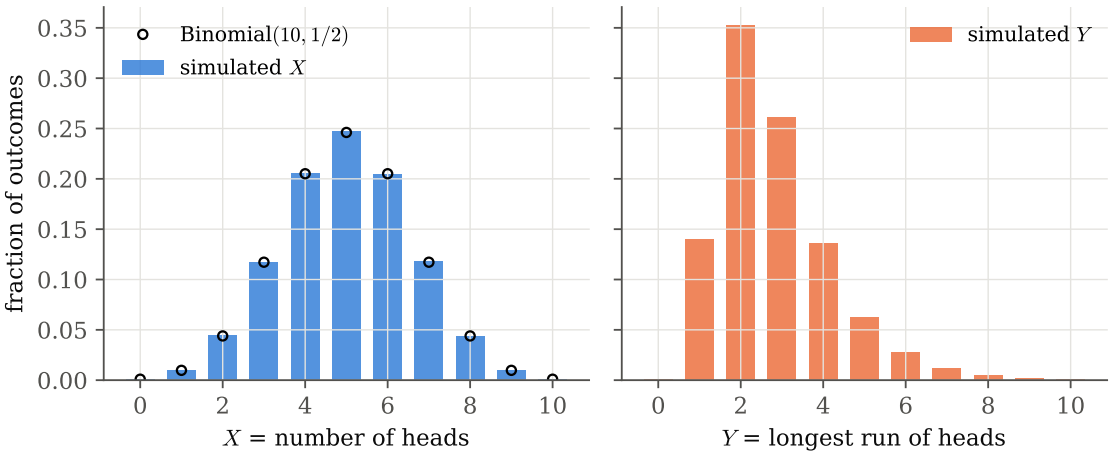

Figure 1.26: The same 2×10^5 simulated ten-flip outcomes, read by two different random variables. Left: the number of heads, whose fractions sit on the binomial probabilities (open circles). Right: the longest run of heads, which has a completely different, skewed distribution although it is computed from exactly the same outcomes.

number of b-tagged jets. The same ω's feed every observable, which is why one simulated sample serves a whole collaboration, and why two observables computed from the same events are in general correlated (Section 1.13). In cosmology the outcome is a whole simulated sky map, and the random variables are its summaries: a power spectrum $\widehat{C}_\ell$ at each ℓ, the number of hot spots above a threshold, the Euler characteristic of an excursion set (Chapters 7 and 12).

Later chapters use many named random variables. The table lists the named distributions of [Wasserman pp. 26–30], each with the mechanism that produces it. Chapter 2 derives every one of them from its mechanism.

Taxonomy: Named random variables and the story that produces each

distribution	generating story
point mass δ_a	no randomness at all, $\mathrm{P}(X = a) = 1$
discrete uniform	k equally likely labels (a fair die)
Bernoulli(p)	one yes/no trial
Binomial(n, p)	successes in n independent identical trials
Geometric(p)	number of trials up to and including the first success, $p(1-p)^{k-1}$
Poisson(λ)	counts of rare events in a fixed window (decays, events in a bin), $e^{-\lambda}\lambda^k/k!$
Uniform(a, b)	"a point at random" in an interval, density $1/(b-a)$
Normal $\mathcal{N}(\mu, \sigma^2)$	sums of many small independent effects (noise)
Exponential(β)	waiting time to the next rare event, density $e^{-x/\beta}/\beta$
Gamma, χ^2_p, t_ν, Beta, Cauchy	sums of waiting times, sums of squared Gaussians, ratios, probabilities of probabilities, resonance line shapes

1.9 Mass, density and the cumulative distribution

A test beam fires electrons of exactly 50 GeV into an electromagnetic calorimeter. The calorimeter does not report 50 every time: the shower fluctuates and the readout is noisy, so the measured energy E scatters around 50 with a spread of about 0.25 GeV. We want to answer questions

such as "what fraction of electrons are measured below 49.5?", "which energy is exceeded by only 5% of them?" and "how does the histogram of measured energies look if we take more data?"

Three objects describe how a random variable is spread out: the probability mass function for counts, the density for continuous readings, and the cumulative distribution for both. We need more than one because counts and continuous readings differ in kind. For a count (hits, heads) we can list the probability of each value. For a continuous reading like E we cannot, because the probability of measuring *exactly* $50.000\ldots$ is zero. Each of the three objects can be read off a histogram. The idea people get wrong most often is that a density is probability *per unit* x, so it carries units.

Mass and density are familiar from mechanics. A string of beads has point masses. A metal rod has a mass density $\lambda(x)$ in kg/m, and the mass of a piece is $\int \lambda \, dx$. Nobody asks "what is the mass at the point $x = 0.3\,\text{m}$?". The answer is zero, and yet $\lambda(0.3)$ is a perfectly good number. Probability works the same way. Discrete random variables are beads: the probability sits on isolated values. Continuous random variables are rods: the probability of a single point is zero, and $f(x)$ is probability per unit length. The cumulative distribution $F(x)$ is "the mass to the left of x", which makes sense for beads, rods and anything in between.

To describe how a random number is spread out, we ask four questions in turn.

1. Does X take isolated values (counts) or a continuum (energies, angles, positions)?
2. Isolated values: list $\mathrm{P}(X = x)$ for each value.
3. Continuum: ask instead for the probability of a small interval, divided by its width. That ratio is the density.
4. Either way: the probability of landing at or below x is a single function $F(x)$ that answers every interval question by subtraction, and whose inverse gives the quantiles.

1.9.1 The cumulative distribution function

Beads and rods need different bookkeeping, but one function works for both: the total probability collected up to a point.

Working definition 1.12 (cumulative distribution function)

The **cumulative distribution function** (CDF) of X is

$$F_X(x) = \mathrm{P}(X \le x), \qquad x \in \mathbb{R},$$

[the probability that the reading is at most x, defined for every real x, including values X never takes]. We write F when the variable is clear. *Operational test:* sort a sample of N readings. The fraction of readings $\le x$ is the **empirical CDF**, and it tends to $F(x)$ as $N \to \infty$.

Example 1.30 (The CDF of two flips). With X = number of heads in two fair flips (Example 1.26),

$$F_X(x) = \begin{cases} 0, & x < 0, \\ 1/4, & 0 \le x < 1, \\ 3/4, & 1 \le x < 2, \\ 1, & x \ge 2. \end{cases}$$

For instance

$$F_X(1.4) \overset{(1)}{=} \mathrm{P}(X \le 1.4) \overset{(2)}{=} \mathrm{P}(X=0) + \mathrm{P}(X=1) = \tfrac{1}{4} + \tfrac{1}{2} = \tfrac{3}{4}.$$

(1) Definition of the CDF at the point $x = 1.4$.
(2) X only takes the values 0, 1, 2, and the ones ≤ 1.4 are 0 and 1. The events $\{X=0\}$ and $\{X=1\}$ are disjoint, so their probabilities add.

The CDF is a staircase. It is flat between the values, jumps by $\mathrm{P}(X=x)$ at each value, and at a jump takes the *upper* value (the filled dots in Figure 1.27): $F(1) = 3/4$, not $1/4$, because $X \le 1$ includes $X = 1$.

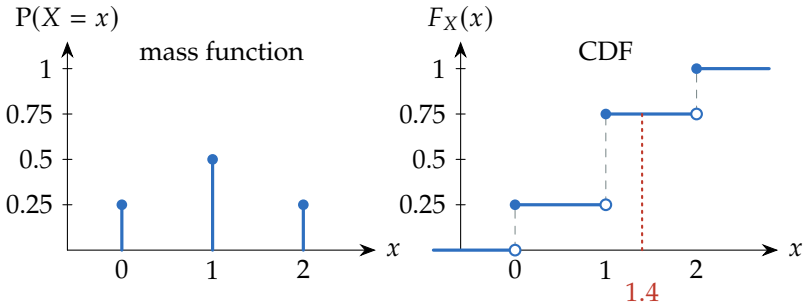

Figure 1.27: Two fair flips. Left: the mass function puts probability 1/4, 1/2, 1/4 on the values 0, 1, 2. Right: the CDF accumulates it into a staircase that jumps by those amounts. Filled dots mark the value the CDF takes at each jump, open dots the value it approaches from the left. The dotted line reads off $F(1.4) = 3/4$.

Every CDF has three properties, and conversely any function with these properties is the CDF of some random variable [Wasserman Thm 2.8, p. 21]:

(i) *non-decreasing*: $x_1 < x_2 \Rightarrow F(x_1) \le F(x_2)$, because $\{X \le x_1\} \subseteq \{X \le x_2\}$;
(ii) *normalised*: $F(x) \to 0$ as $x \to -\infty$ and $F(x) \to 1$ as $x \to +\infty$;
(iii) *right-continuous*: $F(x) = \lim_{y \downarrow x} F(y)$.

Property (iii) is why the CDF takes the upper value at each jump (the filled dots). Why does it hold? The tool is the *continuity of probability* from the first part of Chapter 1: if $A_1 \supseteq A_2 \supseteq \cdots$ shrink to $A = \bigcap_i A_i$, then $\mathrm{P}(A) = \lim_i \mathrm{P}(A_i)$. Take any sequence $y_1 > y_2 > \cdots$ decreasing to x, and $A_i = \{X \le y_i\}$. Then

$$F(x) \overset{(1)}{=} \mathrm{P}(X \le x) \overset{(2)}{=} \mathrm{P}\Big(\bigcap_i \{X \le y_i\}\Big) \overset{(3)}{=} \lim_i \mathrm{P}(X \le y_i) = \lim_i F(y_i).$$

(1) Definition of F.
(2) $X \le x$ holds exactly when $X \le y_i$ for every i, because the y_i come arbitrarily close to x from above.
(3) The events $\{X \le y_i\}$ shrink, so continuity of probability applies.

From the left the argument fails. The events $\{X \le y_i\}$ with $y_i \uparrow x$ grow to $\{X < x\}$, and that event misses the point $X = x$. This asymmetry gives the handy rules of [Wasserman Lemma 2.15, pp. 24–25]. Write $F(x^-) = \lim_{y \uparrow x} F(y)$. Then

$$\mathrm{P}(X = x) = F(x) - F(x^-), \qquad \mathrm{P}(x < X \le y) = F(y) - F(x), \qquad \mathrm{P}(X > x) = 1 - F(x). \tag{1.27}$$

The first says that the size of the jump at x is the probability of the value x. The second is additivity: $\{X \le y\}$ is the disjoint union of $\{X \le x\}$ and $\{x < X \le y\}$. The third is the complement rule.

1.9.2 Discrete variables: the probability mass function

For counts the bookkeeping is the simplest one, a list of probabilities, one per allowed value.

Working definition 1.13 (probability mass function)

X is **discrete** if it takes countably many values $x_1, x_2, \ldots$ [values that can be listed one after another, like $0, 1, 2, \ldots$]. Its **probability mass function** (pmf) is $f_X(x) = \mathrm{P}(X = x)$. It satisfies $f_X(x) \geq 0$, $\sum_i f_X(x_i) = 1$, and $F_X(x) = \sum_{x_i \leq x} f_X(x_i)$. *Operational test:* from N simulated or measured values, the fraction equal to x_i estimates $f_X(x_i)$. The fractions are pure numbers and none can exceed 1.

A set is countable if its elements can be listed so that each one is reached after finitely many steps. The integers are countable: list them as $0, 1, -1, 2, -2, \ldots$. The real numbers in $[0, 1]$ are not. Cantor's diagonal argument builds, from any proposed list, a number that differs from the n-th entry in its n-th decimal, so it is missing from the list [SeeingTheory pp. 33–34]. A Poisson count can take infinitely many values and is still discrete.

1.9.3 Continuous variables: density is probability per unit x

Return to the calorimeter of the opening, which measures 50 GeV electrons with a spread of about 0.25 GeV. Divide the energy axis into bins of width Δ, record N electrons and let n_i be the number in bin i. The fraction n_i/N estimates the probability of the bin. It depends on the bin width: halve Δ and every fraction roughly halves. Dividing by the width removes this dependence. The ratio

$$\frac{n_i}{N\,\Delta} \approx \frac{\mathrm{P}(\text{bin } i)}{\Delta}$$

does *not* depend on the bin width once the bins are narrow, and as $N \to \infty$ and $\Delta \to 0$ it becomes a smooth function of E, the probability density [Cowan §1.3, Fig. 1.2] [Kruschke §4.3.2].

Working definition 1.14 (probability density function)

X is **continuous** if there is a function $f_X \geq 0$ with $\int_{-\infty}^{\infty} f_X(x)\,\mathrm{d}x = 1$ such that for every $a \leq b$

$$\mathrm{P}(a < X < b) = \int_a^b f_X(x)\,\mathrm{d}x.$$

f_X is the **probability density function** (pdf) [probability per unit of x, so $f_X(x)\,\mathrm{d}x$ is the probability of the small interval $[x, x + \mathrm{d}x]$]. Then $F_X(x) = \int_{-\infty}^{x} f_X(t)\,\mathrm{d}t$, and $f_X = F_X'$ wherever F_X is differentiable. *Operational test:* histogram N values in bins of width Δ and divide each count by $N\Delta$. The result has units of $1/[x]$ and converges to f_X.

Example 1.31 (A density has units, and its peak can exceed 1). Let $E \sim \mathcal{N}(\mu, \sigma^2)$ with $\mu = 50\,\mathrm{GeV}$ and $\sigma = 0.25\,\mathrm{GeV}$. The Gaussian density is

$$f(E) = \frac{1}{\sigma\sqrt{2\pi}} \exp\!\left[-\frac{(E-\mu)^2}{2\sigma^2}\right],$$

so its peak value is

$$f(\mu) \overset{(1)}{=} \frac{1}{\sigma\sqrt{2\pi}} = \frac{1}{0.25\,\mathrm{GeV} \times 2.5066} \overset{(2)}{=} 1.596\,\mathrm{GeV}^{-1} \overset{(3)}{=} 1.596 \times 10^{-3}\,\mathrm{MeV}^{-1}.$$

(1) At $E = \mu$ the exponent vanishes and $e^0 = 1$.
(2) $\sqrt{2\pi} = 2.5066$. The unit is inverse GeV because σ has units of GeV.
(3) $1\,\text{GeV} = 10^3\,\text{MeV}$, so $1\,\text{GeV}^{-1} = 10^{-3}\,\text{MeV}^{-1}$.

A density of 1.6 is not a probability of 1.6. The probability of a 10 MeV window at the peak is about $1.596\,\text{GeV}^{-1} \times 0.010\,\text{GeV} = 0.016$. The same physical statement written in MeV gives $1.596 \times 10^{-3}\,\text{MeV}^{-1} \times 10\,\text{MeV} = 0.016$. The density changed by a factor 1000 when we changed units, and the probability did not change at all. This is the first instance of the Jacobian rule of Section 1.11: densities transform, probabilities do not.

Example 1.32 (Valid and invalid densities). Checking a candidate density means checking $f \geq 0$ and $\int f = 1$ [Wasserman pp. 23–24].

- $f(x) = 1$ on $[0, 1]$ (Uniform$(0, 1)$). The CDF is $F(x) = x$ on $[0, 1]$, 0 to the left, 1 to the right.
- $f(x) = 5$ on $[0, \frac{1}{5}]$. Here $\int f = 5 \times \frac{1}{5} = 1$: a valid density whose value is 5 everywhere on its support.
- $f(x) = \frac{2}{3}x^{-1/3}$ on $(0, 1)$. It is unbounded at 0, yet

$$\int_0^1 \tfrac{2}{3}x^{-1/3}\mathrm{d}x \overset{(1)}{=} \tfrac{2}{3}\left[\tfrac{3}{2}x^{2/3}\right]_0^1 = 1.$$

  (1) The antiderivative of $x^{-1/3}$ is $x^{2/3}/(2/3)$, and it vanishes at $x = 0$, so the singularity is integrable.

- $f(x) = 1/(1+x)^2$ for $x \geq 0$: $\int_0^\infty (1+x)^{-2}\mathrm{d}x = \left[-(1+x)^{-1}\right]_0^\infty = 1$. Valid.
- $f(x) = 1/(1+x)$ for $x \geq 0$ is *not* a density: $\int_0^\infty \mathrm{d}x/(1+x) = \int_1^\infty \mathrm{d}u/u = \ln\infty = \infty$. It falls off too slowly to be normalised.

Watch out: A density is not a probability

If X is continuous then $\mathrm{P}(X = x) = 0$ for every x. Do not read $f(x)$ as $\mathrm{P}(X = x)$. Probabilities come from integrating f over an interval. A pdf can exceed 1 and can even be infinite at a point. A pmf can do neither. For a continuous X it does not matter whether interval ends are included: $\mathrm{P}(a < X < b) = \mathrm{P}(a \leq X < b) = \mathrm{P}(a < X \leq b) = \mathrm{P}(a \leq X \leq b) = F(b) - F(a)$.

Neither mass nor density. Some measured quantities are mixed. A zero-suppressed calorimeter cell reads exactly 0 with a finite probability (no signal above threshold) and a continuous energy otherwise. Such a variable has neither a pmf nor a pdf. Its CDF has a jump at 0 and rises smoothly afterwards. The CDF still exists and still determines everything: if two variables have the same CDF then $\mathrm{P}(X \in A) = \mathrm{P}(Y \in A)$ for every A [Wasserman Thm 2.7, p. 21]. That is why the CDF, not the density, is the fundamental object.[2]

1.9.4 Quantiles: reading the CDF backwards

The CDF answers "what fraction lies below x?". The reverse question, "below which x lies a fraction q?", is answered by the quantile function.

[2] Loosely, one hears that a variable is continuous "if it takes uncountably many values" [SeeingTheory p. 35]. The mixed variable above takes uncountably many values and has no density, so the definition through $\int f$ is the correct one.

Working definition 1.15 (quantile function, median, quartiles)

The **quantile function** or inverse CDF is

$$F^{-1}(q) = \inf\{x : F(x) \geq q\}, \qquad 0 < q < 1,$$

[the smallest x at which the CDF has reached height q]. If F is continuous and strictly increasing, $F^{-1}(q)$ is simply the unique x with $F(x) = q$. $F^{-1}(\frac{1}{2})$ is the **median**, $F^{-1}(\frac{1}{4})$ and $F^{-1}(\frac{3}{4})$ are the first and third **quartiles**. The **mode** is the value where the density (or pmf) is largest. *Operational test:* sort N values. The value at position $\lceil qN \rceil$ is the sample q-quantile.

The definition above uses $\geq$, and other books use a strict inequality.[3] Nothing below depends on the choice.

Example 1.33 (Gaussian probabilities and quantiles by standardising). Let $X \sim \mathcal{N}(3, 5)$, so $\mu = 3$ and $\sigma^2 = 5$ (the second argument is the variance). Write $Z = (X - \mu)/\sigma$, which is standard normal $\mathcal{N}(0, 1)$ (we prove this in Section 1.11), with CDF Φ. Then [Wasserman Ex. 2.17, p. 29]

$$\mathrm{P}(X > 1) \overset{(1)}{=} 1 - \mathrm{P}(X \leq 1) \overset{(2)}{=} 1 - \mathrm{P}\Big(Z \leq \frac{1-3}{\sqrt{5}}\Big) \overset{(3)}{=} 1 - \Phi(-0.8944) \overset{(4)}{=} 1 - 0.1855 = 0.81.$$

(1) Complement rule (1.27).
(2) $X \leq 1$ is the same event as $(X - 3)/\sqrt{5} \leq (1 - 3)/\sqrt{5}$, because subtracting and dividing by a positive number preserve the inequality.
(3) Definition of Φ, with $-2/2.2361 = -0.8944$.
(4) A table or `scipy.stats.norm.cdf(-0.8944)`.

For the 20% quantile q we need $\mathrm{P}(X < q) = 0.2$:

$$0.2 \overset{(1)}{=} \Phi\Big(\frac{q-3}{\sqrt{5}}\Big) \quad \Longrightarrow \quad \frac{q-3}{\sqrt{5}} \overset{(2)}{=} \Phi^{-1}(0.2) = -0.8416 \quad \Longrightarrow \quad q = 3 - 0.8416\sqrt{5} = 1.1181.$$

(1) Same standardisation as above.
(2) Apply the inverse of the strictly increasing function Φ to both sides. $\Phi^{-1}(0.2) = -0.8416$ from a table or `norm.ppf(0.2)`.

Example 1.34 (Exponential lifetimes: quantiles and a random-number recipe). A detector component has lifetime $X \sim \mathrm{Exp}(\beta)$, density $f(x) = e^{-x/\beta}/\beta$ for $x > 0$. Its CDF and quantile function are

$$F(x) \overset{(1)}{=} \int_0^x \frac{e^{-t/\beta}}{\beta}\,\mathrm{d}t = \big[-e^{-t/\beta}\big]_0^x = 1 - e^{-x/\beta},$$
$$F^{-1}(q) \overset{(2)}{=} -\beta \ln(1 - q).$$

(1) $f = 0$ for $t < 0$, so the integral starts at 0. The antiderivative of $e^{-t/\beta}/\beta$ is $-e^{-t/\beta}$.
(2) Solve $q = 1 - e^{-x/\beta}$ for x: $e^{-x/\beta} = 1 - q$, take logs.

The median lifetime is $\beta \ln 2 = 0.693\beta$, shorter than the mean β (Section 1.12): a few very long-lived components pull the mean up.

The quantile function is also a random-number generator. If $U \sim \mathrm{Uniform}(0, 1)$ and F is continuous and strictly increasing, then $X = F^{-1}(U)$ has CDF F:

$$\mathrm{P}\big(F^{-1}(U) \leq x\big) \overset{(1)}{=} \mathrm{P}\big(U \leq F(x)\big) \overset{(2)}{=} F(x).$$

[3] [Wasserman Def. 2.16] writes $\inf\{x : F(x) > q\}$. We use $\geq$, as in [CasellaBerger §2.1]. The two agree whenever F is strictly increasing and differ only on flat stretches of F. For two flips and $q = \frac{1}{4}$ the strict version gives 1, the $\geq$ version gives 0.

(1) F is strictly increasing, so applying it to both sides of $F^{-1}(U) \le x$ gives the equivalent inequality $U \le F(x)$.
(2) For a uniform U, $\mathrm{P}(U \le u) = u$ for $u \in [0, 1]$.

So `x = -beta*np.log(1-u)` turns uniform numbers into exponential lifetimes. Running the argument backwards, $Y = F(X)$ is Uniform$(0, 1)$ whenever X has the continuous CDF F (the **probability integral transform**) [Wasserman Exercise 2.15, p. 45] [CasellaBerger Thm 2.1.10]. Both facts become the inverse-transform method of Chapter 6 and the idea behind calibrated p-values in Chapter 4.

Example 1.35 (Which interval holds 95%?). A q-quantile pins one point. To summarise a spread we need an interval that holds, say, 95% of the probability. Many intervals do, so we must say which one we mean. Two choices are common. The **equal-tailed interval** $[F^{-1}(0.025), F^{-1}(0.975)]$ leaves 2.5% in each tail. The **highest density interval** (HDI) contains the values whose density exceeds a level W, with W chosen so that the enclosed probability is 95%. Every point inside it is more probable (per unit x) than every point outside [Kruschke §4.3.4]. For a Gaussian both are $\mu \pm 1.96\sigma$. For the exponential lifetime they differ:

$$\text{equal-tailed: } \left[-\beta \ln 0.975,\ -\beta \ln 0.025\right] = [0.025\beta,\ 3.689\beta], \quad \text{width } 3.66\beta,$$
$$\text{HDI: } \left[0,\ -\beta \ln 0.05\right] = [0,\ 2.996\beta], \quad \text{width } 3.00\beta.$$

The density is largest at $x = 0$ and decreases, so the highest-density region must start at 0 and extend until $F(x) = 0.95$. It is the narrowest interval with 95% probability. Both appear later: equal-tailed intervals in frequentist confidence constructions (Chapter 3), HDIs for Bayesian posteriors (Chapter 5).

1.9.5 Seeing it: from counts to density, and the empirical CDF

Listing 1.10: Histogram counts, divided by $N\Delta$, become a density (`code/ch01/11_density_histogram.py`)

```
mu, sigma = 50.0, 0.25                      # GeV
E_all = rng.normal(mu, sigma, size=100_000)
grid = np.linspace(mu - 4 * sigma, mu + 4 * sigma, 400)
pdf = stats.norm.pdf(grid, mu, sigma)       # per GeV

# --- figure 1: counts (left) and counts/(N*width) (right) ---------------------------
fig, axes = plt.subplots(1, 2)
cases = [(100, 0.2), (1_000, 0.1), (100_000, 0.025)]
for (N, w), c in zip(cases, SERIES):
    E = E_all[:N]
    bins = np.arange(mu - 4 * sigma, mu + 4 * sigma + w / 2, w)
    counts, edges = np.histogram(E, bins=bins)
    centres = 0.5 * (edges[1:] + edges[:-1])
    axes[0].step(centres, counts, where="mid", color=c, label=f"$N={N}$, $\\Delta={w}$")
    dens = counts / (N * w)
    axes[1].step(centres, dens, where="mid", color=c, label=f"$N={N}$")
theory_line(axes[1], grid, pdf, label="pdf")
axes[0].set_yscale("log")
axes[0].set_xlabel("$E$ [GeV]")
axes[0].set_ylabel("counts per bin")
axes[0].set_ylim(0.7, 2e5)
axes[0].legend(fontsize=7, loc="upper left")
axes[1].set_xlabel("$E$ [GeV]")
axes[1].set_ylabel("counts / ($N\\Delta$)  [GeV$^{-1}$]")
axes[1].legend(fontsize=7, loc="upper right")
fig.tight_layout()
```

The script draws 10^5 Gaussian energies with $\mu = 50$, $\sigma = 0.25$ (line 26). The loop over `cases` makes three histograms with different numbers of events and bin widths. The left panel plots raw counts per bin (line 38): they differ by orders of magnitude between the three cases, because counts scale with both N and Δ. Line 39 divides by $N\Delta$, and the right panel shows that all three collapse onto the same curve, the pdf drawn by `theory_line`.

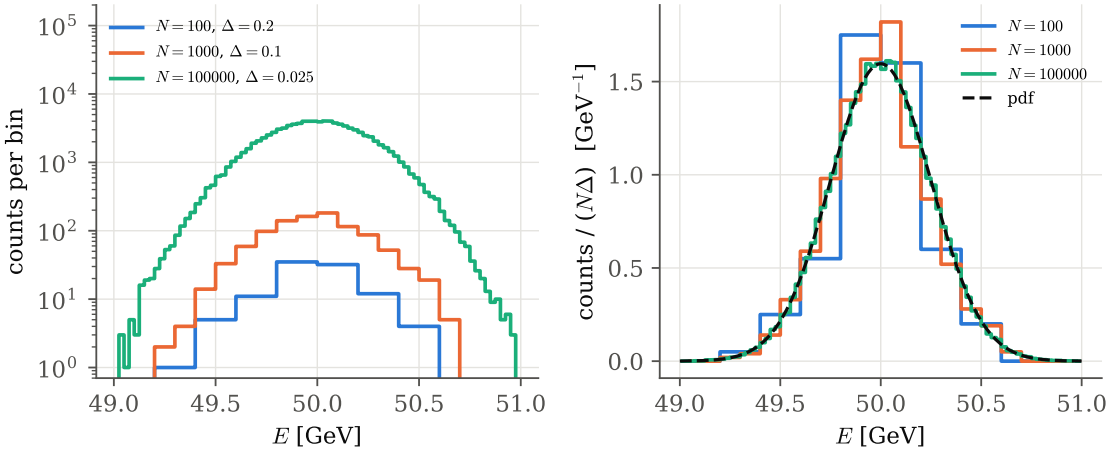

Figure 1.28: Left: counts per bin for three data sets ($N = 100$, 10^3, 10^5 with bins of 0.2, 0.1, 0.025 GeV). The heights are not comparable. Right: the same histograms divided by $N\Delta$. They now fluctuate around one curve, the Gaussian density, whose peak is above 1 per GeV.

With the finest bins the estimated peak density is $1.612\,\text{GeV}^{-1}$ against the exact $1.596\,\text{GeV}^{-1}$, and the fraction of electrons within $\pm\sigma$ of 50 GeV is 0.683 (the Gaussian value is 0.6827).

Listing 1.11: The empirical CDF is a sorted sample (`code/ch01/11_density_histogram.py`)

```
58
59 # --- figure 2: empirical CDF and quantiles ----------------------------------------
60 N = 1_000
61 E = np.sort(E_all[:N])
62 ecdf = np.arange(1, N + 1) / N
63 fig, axes = plt.subplots(1, 2)
64 ax = axes[0]
65 ax.step(E, ecdf, where="post", color=SERIES[0], label=f"empirical CDF, $N={N}$")
66 theory_line(ax, grid, stats.norm.cdf(grid, mu, sigma), label="$F(E)$")
67 for q, c in zip([0.25, 0.5, 0.75], SERIES[1:]):
68     xq = stats.norm.ppf(q, mu, sigma)
69     ax.plot([grid[0], xq], [q, q], color=c, lw=0.9)
```

Lines 60–61 are the whole empirical CDF: sort the sample, and assign to the i-th smallest value the height i/N. Lines 66–69 draw the quartiles as the construction "go across at height q, then down to the axis". With $N = 1000$ the sample quartiles are 49.826, 49.996, 50.146 GeV, against the exact 49.831, 50.000, 50.169 GeV.

What this bought us. Counts depend on how you bin. Densities do not, but they carry units of $1/[x]$. The CDF needs no binning at all, which is why tests that compare a sample to a model, such as Kolmogorov–Smirnov in Chapter 4, are built on the empirical CDF.

How research uses it. Here the histogram *verifies* a density we already know. In research the direction is often reversed: nobody knows the density of, say, the estimated tensor-to-scalar ratio after a realistic foreground cleaning pipeline, so we simulate the whole pipeline many

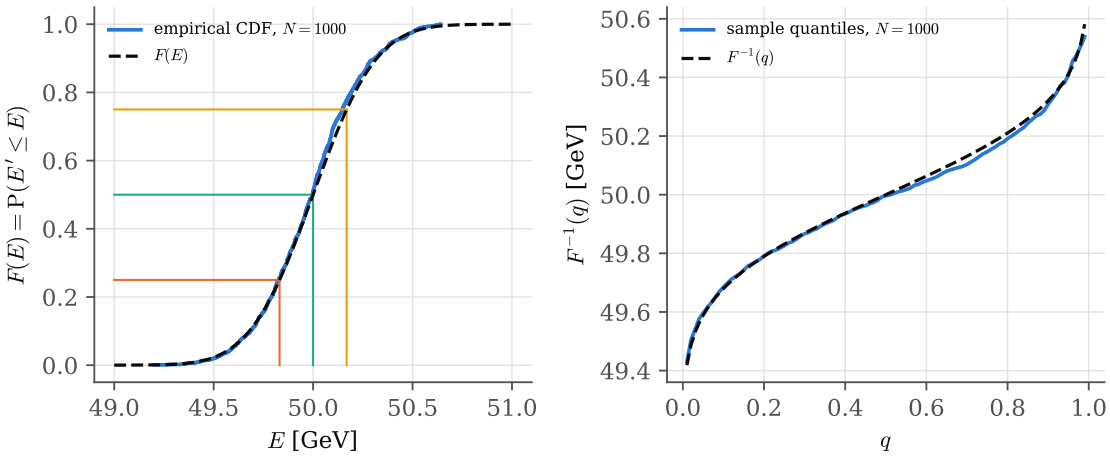

Figure 1.29: Left: the empirical CDF of 1000 simulated energies (a staircase with 1000 tiny steps) on top of the exact CDF. The coloured lines read off the quartiles: across at $q = 0.25, 0.5, 0.75$ and down to the energy axis. Right: the same information turned sideways, sample quantiles against q, compared with the exact quantile function.

times and the normalised histogram (or the empirical CDF) of the output *is* our best knowledge of its sampling distribution. Its quantiles become the error bars. Chapters 6 and 8 do exactly this.

1.10 Several variables at once: joint, marginal and conditional distributions

A calorimeter measures a photon. Two numbers describe the event: the true energy E that nature gave the photon, and the measured energy $E_{\text{meas}} = E +$ noise that the readout reports. The physics (a falling spectrum from a decay or a background process) tells us how E is distributed. The detector response tells us how E_{meas} is spread for a given E. But the histogram we actually fill contains only E_{meas}. The true energy is a **nuisance variable**: it is essential to the physics of the measurement, and we never observe it.

The same situation appears in every cosmological analysis. A fit returns a joint constraint on (Ω_m, σ_8), and a talk quotes "$\Omega_m = 0.31 \pm 0.01$" with σ_8 "marginalised over". In both cases we hold the joint distribution of several random variables and need one of two operations. *Marginalising* isolates one variable by averaging out the others. *Conditioning* fixes one variable and asks how the rest are distributed. Neither is new. Both are rules from the first part of Chapter 1 (the law of total probability and conditional probability), applied to densities.

Two pictures make both operations concrete. Draw a scatter plot of many simulated pairs (x, y). The density of points in the plane is the joint density. Squash all the points onto the x axis, ignoring y, and histogram them: that is the marginal of x. Instead, keep only the points in a thin vertical band at $x = x_0$, histogram their y values and normalise: that is the conditional density of y given x_0 [Cowan Figs. 1.4–1.6]. Projecting adds up all the ways a value of x could have arisen. Slicing throws away everything that disagrees with what we know. This is the "shrinking of the sample space" of the first part of this chapter.

So with two random variables there are four questions to ask.

1. How are the two variables distributed *together*? (Joint.)
2. How is one of them distributed if we do not care about, or cannot see, the other? (Marginal:

average out the nuisance.)

3. How is one distributed if we *know* the value of the other? (Conditional: slice and renormalise.)
4. Does knowing one change what we expect for the other? (If not, they are independent, and the joint is the product of the marginals.)

1.10.1 Joint distributions

The other three questions are all answered from the distribution of the pair taken together, so we define it first.

Working definition 1.16 (joint mass function, joint density)

For discrete X, Y the **joint mass function** is $f(x,y) = \mathrm{P}(X = x, Y = y)$ [the probability that both statements hold at once, $\mathrm{P}(X = x \text{ and } Y = y)$]. For continuous variables a **joint density** is a function $f(x,y) \geq 0$ with $\iint f \,\mathrm{d}x\,\mathrm{d}y = 1$ such that for every region A of the plane

$$\mathrm{P}\big((X,Y) \in A\big) = \iint_A f(x,y)\,\mathrm{d}x\,\mathrm{d}y,$$

[probability per unit area, so $f(x,y)\,\mathrm{d}x\,\mathrm{d}y$ is the probability of the small rectangle at (x,y)]. The joint CDF is $F(x,y) = \mathrm{P}(X \leq x, Y \leq y)$. *Operational test:* a 2-D histogram of N simulated pairs with cells $\Delta x \times \Delta y$, divided by $N\Delta x\Delta y$, estimates $f(x,y)$. Its units are $1/([x][y])$.

Example 1.36 (A joint table and a uniform square). Two binary variables with the joint table [Wasserman Ex. 2.18, p. 31]

	$Y=0$	$Y=1$	
$X=0$	$1/9$	$2/9$	$1/3$
$X=1$	$2/9$	$4/9$	$2/3$
	$1/3$	$2/3$	1

have $f(1,1) = \mathrm{P}(X=1, Y=1) = 4/9$. The row and column sums written in the margins of the table are the marginals of the next subsection. For a continuous example, let (X,Y) be uniform on the unit square, $f = 1$ there. Then $\mathrm{P}(X < \tfrac{1}{2}, Y < \tfrac{1}{2})$ is the integral of 1 over the lower-left quarter, which is its area, $\tfrac{1}{4}$.

Example 1.37 (A density on a curved region). Let $f(x,y) = c\,x^2 y$ on the region $x^2 \leq y \leq 1$ (and 0 elsewhere) [Wasserman Ex. 2.22, p. 32]. The region forces $-1 \leq x \leq 1$. Fix c by normalisation, integrating y first at fixed x:

$$1 \overset{(1)}{=} c\int_{-1}^{1}\!\!\int_{x^2}^{1} x^2 y\,\mathrm{d}y\,\mathrm{d}x \overset{(2)}{=} c\int_{-1}^{1} x^2\,\frac{1-x^4}{2}\,\mathrm{d}x \overset{(3)}{=} \frac{c}{2}\Big(\frac{2}{3}-\frac{2}{7}\Big) = \frac{4c}{21} \quad\Longrightarrow\quad c = \frac{21}{4}.$$

(1) For each $x \in [-1,1]$, y runs over $[x^2, 1]$: this is the only delicate step, and Figure 1.30 is there to make it visible.

(2) $\int_{x^2}^{1} y\,\mathrm{d}y = \tfrac{1}{2}(1-x^4)$.

(3) $\int_{-1}^{1} x^2\mathrm{d}x = \tfrac{2}{3}$ and $\int_{-1}^{1} x^6\mathrm{d}x = \tfrac{2}{7}$.

Now the probability that $X \geq Y$. Inside the support this needs $x \geq y \geq x^2$, possible only for $0 \leq x \leq 1$ (the hatched sliver in the figure):

$$\mathrm{P}(X \geq Y) \overset{(1)}{=} \frac{21}{4}\int_0^1\!\!\int_{x^2}^{x} x^2 y\,\mathrm{d}y\,\mathrm{d}x \overset{(2)}{=} \frac{21}{4}\int_0^1 x^2\,\frac{x^2-x^4}{2}\,\mathrm{d}x \overset{(3)}{=} \frac{21}{8}\Big(\frac{1}{5}-\frac{1}{7}\Big) = \frac{3}{20}.$$

(1) The event $\{X \geq Y\}$ intersected with the support is $\{0 \leq x \leq 1,\ x^2 \leq y \leq x\}$.
(2) $\int_{x^2}^{x} y\,\mathrm{d}y = \frac{1}{2}(x^2 - x^4)$.
(3) $\int_0^1 x^4 = \frac{1}{5}$, $\int_0^1 x^6 = \frac{1}{7}$, and $\frac{21}{8} \cdot \frac{2}{35} = \frac{3}{20}$.

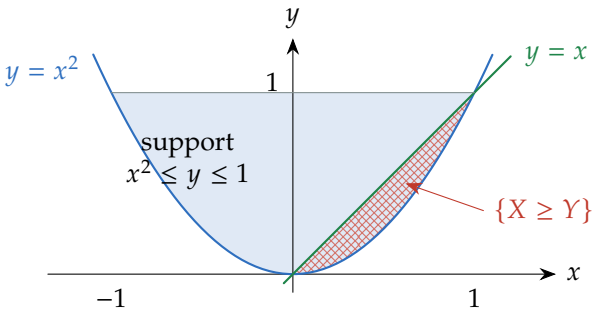

Figure 1.30: The density $\frac{21}{4}x^2 y$ lives on the shaded region between the parabola $y = x^2$ and the line $y = 1$. The event $X \geq Y$ is the hatched sliver between the parabola and the diagonal $y = x$. To integrate, fix x and let y run up the vertical segment inside the region.

1.10.2 Marginal distributions: averaging out the nuisance

If we only care about X, the event "$X = x$" is the disjoint union of the events "$X = x$ and $Y = y$" over all values y. The law of total probability (first part of Chapter 1) adds them up.

Working definition 1.17 (marginal distribution)

The **marginal** mass function or density of X is

$$f_X(x) = \sum_y f(x,y) \quad \text{(discrete)}, \qquad f_X(x) = \int_{-\infty}^{\infty} f(x,y)\,\mathrm{d}y \quad \text{(continuous)},$$

and similarly $f_Y(y) = \sum_x f(x,y)$ or $\int f(x,y)\,\mathrm{d}x$ [sum or integrate the joint over every value of the variable we want to get rid of]. The variable summed over is *marginalised* or *integrated out*. *Operational test:* simulate pairs (x,y), throw away the y's, and histogram the x's.

We need a marginal distribution to isolate and understand the probability of a single variable by averaging out or removing "nuisance" variables from a complex joint distribution. The word "averaging" is meant literally. Write the joint as $f(x,y) = f(x \mid y) f_Y(y)$ (the product rule, derived below). Then the marginal $f_X(x) = \int f(x \mid y) f_Y(y) \mathrm{d}y$ is the average of the conditional densities $f(x \mid y)$, each weighted by how probable its nuisance value y is.

Why is the continuous marginal an integral over y [Cowan (1.20)–(1.21)]? Cut the vertical strip $[x, x + \mathrm{d}x]$ into small cells of height Δy at heights y_i:

$$\mathrm{P}\big(x \leq X \leq x + \mathrm{d}x\big) \overset{(1)}{=} \sum_i \mathrm{P}\big(x \leq X \leq x + \mathrm{d}x,\ y_i \leq Y \leq y_i + \Delta y\big)$$
$$\overset{(2)}{=} \sum_i f(x, y_i)\,\Delta y\,\mathrm{d}x \xrightarrow{\Delta y \to 0} \left[\int f(x,y)\,\mathrm{d}y\right]\mathrm{d}x.$$

(1) The cells are disjoint and together make up the strip (the law of total probability).
(2) The probability of a small cell is the joint density times its area.

The bracket is probability per unit x: the marginal density.

Example 1.38 (Margins of a table, and what they cannot tell you). For the table [Wasserman Ex. 2.24, p. 33]

	$Y=0$	$Y=1$	
$X=0$	1/10	2/10	3/10
$X=1$	3/10	4/10	7/10
	4/10	6/10	1

the marginal of X is the column of row sums, $f_X(0)=3/10$, $f_X(1)=7/10$, and the marginal of Y is the row of column sums. The name "marginal" literally means "written in the margin of the table".

Marginals lose information. The joint table $f(0,0)=\frac{1}{12}$, $f(1,0)=\frac{5}{12}$, $f(0,1)=f(1,1)=\frac{3}{12}$ has marginals $f_X=(\frac{1}{3},\frac{2}{3})$ and $f_Y=(\frac{1}{2},\frac{1}{2})$. So does the different table $f(0,0)=\frac{1}{6}$, $f(1,0)=\frac{1}{3}$, $f(0,1)=\frac{1}{6}$, $f(1,1)=\frac{1}{3}$ [CasellaBerger Ex. 4.1.9]. Knowing both marginals does not determine the joint. This is a small instance of a big theme: summarising discards information. A CMB power spectrum C_ℓ is a "marginal" summary that keeps the variance at each scale and throws away the phases, and Chapter 12 is about recovering some of what was thrown away.

Example 1.39 (Marginal densities by integration).

- $f(x,y)=e^{-(x+y)}$ for $x,y\ge 0$: $f_X(x)=e^{-x}\int_0^\infty e^{-y}\mathrm{d}y=e^{-x}$ [Wasserman Ex. 2.26].
- $f(x,y)=x+y$ on the unit square: $f_Y(y)=\int_0^1(x+y)\mathrm{d}x=\frac{1}{2}+y$ [Wasserman Ex. 2.27].
- $f(x,y)=\frac{21}{4}x^2y$ on $x^2\le y\le 1$ (Example 1.37):

$$f_X(x)\overset{(1)}{=}\frac{21}{4}x^2\int_{x^2}^1 y\,\mathrm{d}y=\frac{21}{8}x^2(1-x^4),\qquad -1\le x\le 1.$$

(1) At fixed x the density is nonzero only for $x^2\le y\le 1$, so those are the limits of the y integral [Wasserman Ex. 2.28, p. 34].

In the last case the limits of integration depend on x. Forgetting that is the commonest error in marginalisation.

1.10.3 The Gaussian case: marginalising by completing the square

The single most important joint density is the bivariate Gaussian. With zero means, standard deviations σ_x,σ_y and a correlation parameter $\rho\in(-1,1)$ (Section 1.13 shows that ρ is the correlation coefficient),

$$f(x,y)=\frac{1}{2\pi\sigma_x\sigma_y\sqrt{1-\rho^2}}\exp\left\{-\frac{1}{2(1-\rho^2)}\left[\frac{x^2}{\sigma_x^2}-\frac{2\rho xy}{\sigma_x\sigma_y}+\frac{y^2}{\sigma_y^2}\right]\right\}. \tag{1.28}$$

The contours of f are ellipses, tilted when $\rho\neq 0$. We need one integral, the Gaussian integral $\int_{-\infty}^{\infty}e^{-(y-m)^2/(2s^2)}\mathrm{d}y=\sqrt{2\pi}\,s$ (for any shift m and width $s>0$).

Example 1.40 (The marginal and the conditional of a bivariate Gaussian). The question: how is X distributed on its own, and how is Y distributed once $X=x$ is known? The plan is to rewrite the exponent so that y appears in a single square. Then the y integral becomes the Gaussian integral just recalled. First rearrange the bracket in (1.28):

$$\frac{x^2}{\sigma_x^2}-\frac{2\rho xy}{\sigma_x\sigma_y}+\frac{y^2}{\sigma_y^2}\overset{(1)}{=}\left(\frac{y}{\sigma_y}-\frac{\rho x}{\sigma_x}\right)^2+\frac{x^2}{\sigma_x^2}-\frac{\rho^2x^2}{\sigma_x^2}=\frac{\left(y-\rho\sigma_y x/\sigma_x\right)^2}{\sigma_y^2}+(1-\rho^2)\frac{x^2}{\sigma_x^2}.$$

(1) Expanding $(y/\sigma_y - \rho x/\sigma_x)^2$ gives $y^2/\sigma_y^2 - 2\rho xy/(\sigma_x\sigma_y) + \rho^2x^2/\sigma_x^2$, so we must add back $(1-\rho^2)x^2/\sigma_x^2$ to restore the original expression.

Dividing by $2(1-\rho^2)$ and writing $m(x) = \rho\sigma_y x/\sigma_x$ and $s = \sigma_y\sqrt{1-\rho^2}$, the joint density factorises as

$$f(x,y) = \frac{1}{2\pi\sigma_x s}\exp\!\left[-\frac{(y-m(x))^2}{2s^2}\right]\exp\!\left[-\frac{x^2}{2\sigma_x^2}\right].$$

The marginal of X follows:

$$f_X(x) \overset{(1)}{=} \frac{e^{-x^2/2\sigma_x^2}}{2\pi\sigma_x s}\int_{-\infty}^{\infty} e^{-(y-m(x))^2/2s^2}\,\mathrm{d}y \overset{(2)}{=} \frac{e^{-x^2/2\sigma_x^2}}{2\pi\sigma_x s}\sqrt{2\pi}\,s = \frac{1}{\sqrt{2\pi}\,\sigma_x}e^{-x^2/2\sigma_x^2}.$$

(1) Definition of the marginal. The factor depending only on x comes out of the y integral.
(2) Gaussian integral with shift $m(x)$ and width s. The shift does not change the area, which is why the answer is so simple.

So $X \sim \mathcal{N}(0,\sigma_x^2)$ whatever ρ is, and by the symmetry of (1.28), $Y \sim \mathcal{N}(0,\sigma_y^2)$. The conditional density of Y at fixed $X = x$ is the joint divided by the marginal (defined in the next subsection):

$$f(y\mid x) = \frac{f(x,y)}{f_X(x)} = \frac{1}{\sqrt{2\pi}\,s}\exp\!\left[-\frac{(y-\rho\sigma_y x/\sigma_x)^2}{2s^2}\right], \qquad Y\mid X=x \;\sim\; \mathcal{N}\!\left(\rho\frac{\sigma_y}{\sigma_x}x,\; \sigma_y^2(1-\rho^2)\right).$$

Knowing X does two things to Y: it shifts the centre along the line $y = \rho\sigma_y x/\sigma_x$ (the "regression line"), and it shrinks the width by the factor $\sqrt{1-\rho^2}$. For $\rho = 0.7$ that factor is 0.71.

Watch out: Marginal width is not conditional width

In a two-parameter fit, the error bar on one parameter with the other held fixed at its best value is the *conditional* width $\sigma_y\sqrt{1-\rho^2}$. The error bar with the other parameter marginalised is σ_y. For strongly correlated parameters these differ a lot: $\rho = 0.95$ gives a factor 3.2. Quoting the conditional error as if it were the marginal one is a classic way to overstate a result. Chapter 10 meets the same distinction as $1/\sqrt{\mathbf{F}_{ii}}$ versus $\sqrt{(\mathbf{F}^{-1})_{ii}}$.

1.10.4 Conditional distributions: slicing and renormalising

Slicing the scatter plot at $Y = y$ and renormalising the slice gives the definition.

Working definition 1.18 (conditional mass function and density)

For discrete variables, the **conditional mass function** of X given $Y = y$ is

$$f_{X|Y}(x\mid y) = \mathrm{P}(X = x \mid Y = y) = \frac{f(x,y)}{f_Y(y)}, \qquad f_Y(y) > 0,$$

the ordinary conditional probability of the first part of Chapter 1. For continuous variables the **conditional density** is defined by the same formula [the joint along the line $Y = y$, divided by its total, so that it integrates to 1 over x], and $\mathrm{P}(X \in A \mid Y = y) = \int_A f_{X|Y}(x\mid y)\,\mathrm{d}x$. *Operational test:* keep only simulated pairs with y in a thin band around y_0, histogram their x values and normalise.

In the continuous case the event $\{Y = y\}$ has probability zero. So conditioning on it cannot literally mean $\mathrm{P}(A\cap B)/\mathrm{P}(B)$, which would be $0/0$. Why is the definition still right? Think of a thin band of width $\mathrm{d}y$ around y. Both numerator and denominator carry the same factor

$\mathrm{d}y$, which cancels and leaves the ratio of densities [Cowan (1.23)]. (Wasserman [Wasserman p. 36, footnote 6] calls conditioning on a probability-zero event "treading in deep water" and simply adopts the formula as the definition.) Rearranging the definition gives the product rule

$$f(x,y) = f_{X|Y}(x \mid y)\, f_Y(y) = f_{Y|X}(y \mid x)\, f_X(x), \tag{1.29}$$

and from it the continuous law of total probability and Bayes' theorem [Cowan (1.26)–(1.28)]:

$$f_X(x) = \int f_{X|Y}(x \mid y) f_Y(y)\, \mathrm{d}y, \qquad f_{Y|X}(y \mid x) = \frac{f_{X|Y}(x \mid y)\, f_Y(y)}{\int f_{X|Y}(x \mid y') f_Y(y')\, \mathrm{d}y'}. \tag{1.30}$$

The first is "sum over the branches of a tree", with a continuum of branches. The second reads the tree backwards. With y a parameter and x the data, $f_{X|Y}$ is the prediction and $f_{Y|X}$ the inference: this is the equation Chapter 5 is built on.

Example 1.41 (Conditional probabilities from a density).

(a) $f(x,y) = x + y$ on the unit square, with $f_Y(y) = y + \frac{1}{2}$ (Example 1.39). Then $f(x \mid y) = (x+y)/(y+\frac{1}{2})$ and [Wasserman Ex. 2.38, p. 37]

$$\mathrm{P}\big(X < \tfrac{1}{4} \mid Y = \tfrac{1}{3}\big) \overset{(1)}{=} \int_0^{1/4} \frac{x + \frac{1}{3}}{\frac{1}{3} + \frac{1}{2}}\, \mathrm{d}x \overset{(2)}{=} \frac{6}{5}\Big[\frac{x^2}{2} + \frac{x}{3}\Big]_0^{1/4} = \frac{6}{5}\Big(\frac{1}{32} + \frac{1}{12}\Big) = \frac{11}{80}.$$

(1) Integrate the conditional density over the event, at $y = \frac{1}{3}$.
(2) $1/(\frac{1}{3} + \frac{1}{2}) = \frac{6}{5}$, and the antiderivative is elementary. Then $\frac{1}{32} + \frac{1}{12} = \frac{11}{96}$.

(b) Build a joint from a marginal and a conditional: $X \sim \mathrm{Uniform}(0,1)$ and then $Y \mid X = x \sim \mathrm{Uniform}(x,1)$ [Wasserman Ex. 2.39]. Then $f(y \mid x) = 1/(1-x)$ for $x < y < 1$, and by (1.29) $f(x,y) = 1/(1-x)$ on $0 < x < y < 1$. The marginal of Y is

$$f_Y(y) \overset{(1)}{=} \int_0^y \frac{\mathrm{d}x}{1-x} \overset{(2)}{=} -\int_1^{1-y} \frac{\mathrm{d}u}{u} = -\ln(1-y), \qquad 0 < y < 1.$$

(1) At fixed y, the joint is nonzero for $0 < x < y$.
(2) Substitute $u = 1 - x$, $\mathrm{d}u = -\mathrm{d}x$; the limits $x = 0, y$ become $u = 1, 1-y$.

The density of Y rises towards $y = 1$: each stage pushes Y upward.

(c) For $f = \frac{21}{4}x^2 y$ on $x^2 \le y \le 1$, dividing by the marginal of Example 1.39 gives $f(y \mid x) = 2y/(1-x^4)$ on $x^2 \le y \le 1$. At $x = \frac{1}{2}$ this is $32y/15$, and [Wasserman Ex. 2.40, p. 38]

$$\mathrm{P}\big(Y \ge \tfrac{3}{4} \mid X = \tfrac{1}{2}\big) \overset{(1)}{=} \int_{3/4}^1 \frac{32y}{15}\, \mathrm{d}y = \frac{16}{15}\Big(1 - \frac{9}{16}\Big) = \frac{7}{15}.$$

(1) The conditional density at $x = \frac{1}{2}$ lives on $\frac{1}{4} \le y \le 1$, and the event asks for the top part.

1.10.5 Independence

The last question is whether slicing changes anything at all. If every slice looks the same, learning one variable teaches us nothing about the other.

Working definition 1.19 (independent random variables)

X and Y are **independent**, written $X \perp Y$, if for every pair of sets A, B

$$\mathrm{P}(X \in A,\ Y \in B) = \mathrm{P}(X \in A)\ \mathrm{P}(Y \in B)$$

[every event about X is independent of every event about Y]. Equivalently the joint factorises into the marginals, $f(x,y) = f_X(x) f_Y(y)$ for all x, y [Wasserman Thm 2.30, p. 35], and then $f(y \mid x) = f_Y(y)$: learning x does not change the distribution of Y. *Operational test:* slice the scatter plot at several x values. If the normalised y-histograms in the slices all look the same, and the same as the marginal, the variables are independent.

Example 1.42 (Checking independence).

(a) The table with all four entries $\frac{1}{4}$ is independent: $f_X = f_Y = (\frac{1}{2}, \frac{1}{2})$ and every cell equals $\frac{1}{2} \cdot \frac{1}{2}$. The table $f(0,0) = f(1,1) = \frac{1}{2}$, $f(0,1) = f(1,0) = 0$ has the *same* marginals but is not independent: $f_X(0) f_Y(1) = \frac{1}{4} \neq 0 = f(0,1)$ [Wasserman Ex. 2.31].

(b) X, Y independent with the same density $f(x) = 2x$ on $[0,1]$. The joint is $4xy$ on the unit square, and [Wasserman Ex. 2.32]

$$\mathrm{P}(X+Y \le 1) \overset{(1)}{=} 4 \int_0^1 x \Big[\int_0^{1-x} y \,\mathrm{d}y \Big] \mathrm{d}x \overset{(2)}{=} 2 \int_0^1 x(1-x)^2 \,\mathrm{d}x \overset{(3)}{=} 2\Big(\frac{1}{2} - \frac{2}{3} + \frac{1}{4}\Big) = \frac{1}{6}.$$

(1) The event is the triangle below the line $y = 1 - x$; for each x, y runs from 0 to $1 - x$.
(2) $\int_0^{1-x} y \,\mathrm{d}y = \frac{1}{2}(1-x)^2$.
(3) Expand $x(1-x)^2 = x - 2x^2 + x^3$ and integrate term by term.

(c) Shortcut [Wasserman Thm 2.33, p. 36]: if the joint is nonzero on a rectangle (possibly infinite) and has the form $g(x)h(y)$, the variables are independent. $f = 2e^{-(x+2y)}$ on $x, y > 0$ is $g(x)h(y)$ with $g = 2e^{-x}$, $h = e^{-2y}$, so $X \perp Y$.

(d) The rectangle condition matters. $\frac{21}{4} x^2 y$ on $x^2 \le y \le 1$ looks like $g(x)h(y)$, but the region is not a rectangle, and $f(y \mid x) = 2y/(1-x^4)$ depends on x: learning x tells us $y \ge x^2$. X and Y are dependent.

For more than two variables the definitions carry over. A **random vector** $\boldsymbol{X} = (X_1, \ldots, X_n)$ has a joint density $f(x_1, \ldots, x_n)$; marginals integrate out any subset of components; $X_1, \ldots, X_n$ are independent if $f = \prod_i f_{X_i}(x_i)$. If they are independent *and* all have the same marginal F they are **iid** (independent and identically distributed), written $X_1, \ldots, X_n \overset{\text{iid}}{\sim} F$, and form a **random sample** of size n from F [Wasserman Def. 2.41, p. 39]. Repeated measurements, Monte Carlo draws and the pixels of a white-noise map are the standard iid examples.

Two multivariate models recur throughout the book [Wasserman §2.10]. The **multinomial** counts how n independent draws fall into k categories (histogram bins) with probabilities $p_1, \ldots, p_k$. The marginal of one count X_j is Binomial(n, p_j): lump all the other categories into "not j" and each draw becomes a Bernoulli(p_j) trial. The **multivariate normal** $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$ has density

$$f(\boldsymbol{x}) = \frac{1}{(2\pi)^{k/2}\,|\Sigma|^{1/2}} \exp\Big\{ -\tfrac{1}{2} (\boldsymbol{x} - \boldsymbol{\mu})^{\mathsf{T}} \Sigma^{-1} (\boldsymbol{x} - \boldsymbol{\mu}) \Big\}, \tag{1.31}$$

with Σ a symmetric positive-definite $k \times k$ matrix. For $k = 2$ and $\Sigma = \left(\begin{smallmatrix} \sigma_x^2 & \rho\sigma_x\sigma_y \\ \rho\sigma_x\sigma_y & \sigma_y^2 \end{smallmatrix}\right)$ it reduces to

(1.28):

$$|\Sigma| \overset{(1)}{=} \sigma_x^2\sigma_y^2(1-\rho^2), \qquad \Sigma^{-1} \overset{(2)}{=} \frac{1}{\sigma_x^2\sigma_y^2(1-\rho^2)}\begin{pmatrix}\sigma_y^2 & -\rho\sigma_x\sigma_y\\ -\rho\sigma_x\sigma_y & \sigma_x^2\end{pmatrix},$$

$$\boldsymbol{x}^{\mathsf{T}}\Sigma^{-1}\boldsymbol{x} \overset{(3)}{=} \frac{\sigma_y^2x^2 - 2\rho\sigma_x\sigma_y xy + \sigma_x^2y^2}{\sigma_x^2\sigma_y^2(1-\rho^2)} = \frac{1}{1-\rho^2}\left[\frac{x^2}{\sigma_x^2} - \frac{2\rho xy}{\sigma_x\sigma_y} + \frac{y^2}{\sigma_y^2}\right].$$

(1) Determinant of a 2×2 matrix, $ad - bc$.
(2) Inverse of a 2×2 matrix: swap the diagonal, negate the off-diagonal, divide by the determinant.
(3) Multiply out $(x,y)\,\Sigma^{-1}(x,y)^{\mathsf{T}}$, then divide numerator and denominator by $\sigma_x^2\sigma_y^2$.

The general marginal and conditional rules [Wasserman Thm 2.44, p. 40], $X_b \mid X_a = x_a \sim \mathcal{N}\big(\mu_b + \Sigma_{ba}\Sigma_{aa}^{-1}(x_a-\mu_a),\ \Sigma_{bb} - \Sigma_{ba}\Sigma_{aa}^{-1}\Sigma_{ab}\big)$, reduce for $k=2$ to exactly what we derived in Example 1.40: $\Sigma_{ba}\Sigma_{aa}^{-1} = \rho\sigma_x\sigma_y/\sigma_x^2 = \rho\sigma_y/\sigma_x$ and $\Sigma_{bb} - \Sigma_{ba}^2/\Sigma_{aa} = \sigma_y^2(1-\rho^2)$. The general proofs are in Chapter 2.

1.10.6 Seeing it: projections, slices, and the smeared spectrum

The first script samples the bivariate Gaussian with $\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.7$, projects, and slices at $x_0 = 1$.

Listing 1.12: Marginal by projection, conditional by slicing (code/ch01/12_marginal_gaussian.py)

```
23 sx, sy, rho = 1.0, 2.0, 0.7
24 C = np.array([[sx**2, rho * sx * sy], [rho * sx * sy, sy**2]])
25 N = 200_000
26 XY = rng.multivariate_normal([0.0, 0.0], C, size=N)
27 X, Y = XY[:, 0], XY[:, 1]
28
29 # thin band at x0
30 x0, half = 1.0, 0.05
31 band = np.abs(X - x0) < half
32 Yb = Y[band]
33 cond_mean = rho * sy / sx * x0
34 cond_sd = sy * np.sqrt(1 - rho**2)
```

Line 26 draws 2×10^5 pairs from $\mathcal{N}(\mathbf{0}, \mathbf{C})$. The marginal needs no code at all: `Y` on its own *is* a sample from f_Y (line 27 just splits the columns). The conditional is a boolean mask, the band $|x-1| < 0.05$ (line 31), exactly the "conditioning is selecting a subset" of the first part of Chapter 1.

The simulated marginal widths are 1.001 and 2.006 (exact 1 and 2). The band holds 4855 points, whose y values have mean 1.404 and standard deviation 1.426, against the exact conditional $\rho\sigma_y x_0/\sigma_x = 1.400$ and $\sigma_y\sqrt{1-\rho^2} = 1.428$ (the band has finite width, which adds a tiny extra spread).

Example 1.43 (The measured spectrum: marginalising the true energy). Return to the photon in the calorimeter from the start of this section. Its true energy E is never observed. Only the measured energy $E_{\text{meas}} = E + \text{noise}$ is recorded, and we want the spectrum of E_{meas}. Let the true energy be exponential, $f(E) = e^{-E/\beta}/\beta$ for $E > 0$ with $\beta = 20\,\text{GeV}$ (a falling spectrum), and the detector Gaussian, $f(x \mid E) = \exp[-(x-E)^2/2\sigma^2]/(\sqrt{2\pi}\sigma)$ with $\sigma = 5\,\text{GeV}$, where $x = E_{\text{meas}}$. The joint is the product (1.29), and the spectrum we histogram is the marginal

$$f(x) = \int_0^\infty \frac{e^{-E/\beta}}{\beta}\,\frac{e^{-(x-E)^2/2\sigma^2}}{\sqrt{2\pi}\,\sigma}\,\mathrm{d}E. \tag{1.32}$$

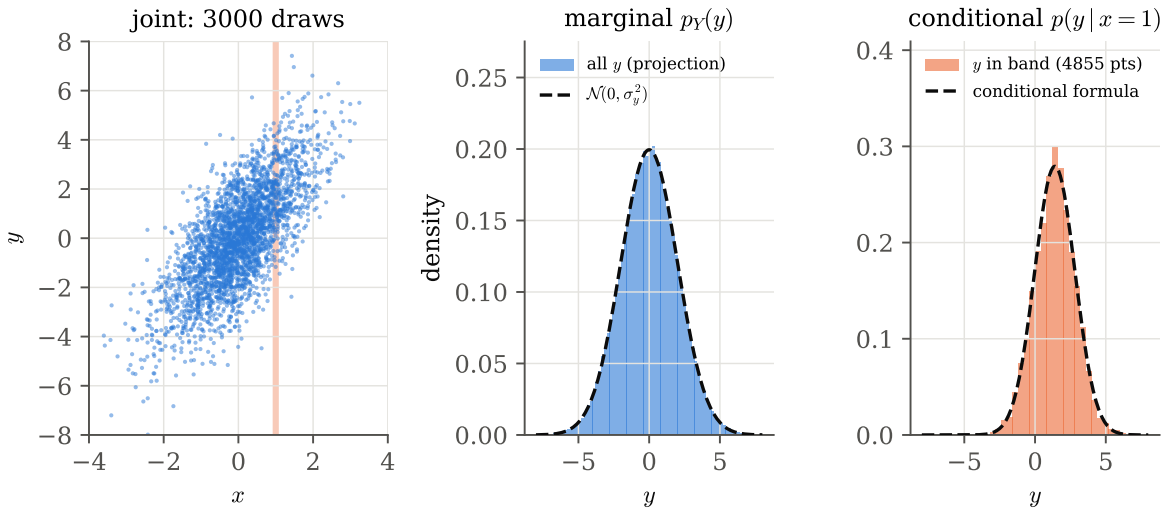

Figure 1.31: Left: 3000 draws from the correlated Gaussian, with the thin band at $x = 1$ shaded. Middle: all y values, projected onto the y axis, follow the marginal $\mathcal{N}(0, 4)$. Right: only the y values from inside the band, renormalised, follow the narrower and shifted conditional density.

To do the integral, collect the E-dependence of the exponent into one square, so that what is left is a Gaussian integral:

$$-\frac{E}{\beta} - \frac{(x-E)^2}{2\sigma^2} \overset{(1)}{=} -\frac{E^2 - 2E\left(x - \sigma^2/\beta\right) + x^2}{2\sigma^2} \overset{(2)}{=} -\frac{\left(E-m\right)^2}{2\sigma^2} + \frac{m^2 - x^2}{2\sigma^2}$$
$$\overset{(3)}{=} -\frac{\left(E-m\right)^2}{2\sigma^2} - \frac{x}{\beta} + \frac{\sigma^2}{2\beta^2},$$

with $m = x - \sigma^2/\beta$.

(1) Put both terms over $2\sigma^2$: $E/\beta = 2\sigma^2 E/(2\sigma^2\beta)$, and expand $(x-E)^2$.
(2) Complete the square, $E^2 - 2Em = (E-m)^2 - m^2$.
(3) $m^2 - x^2 = -2x\sigma^2/\beta + \sigma^4/\beta^2$; divide by $2\sigma^2$.

The last two terms do not involve E and leave the integral. What remains is a Gaussian in E centred at m, integrated over $E > 0$ only:

$$f(x) \overset{(1)}{=} \frac{1}{\beta}\, e^{\sigma^2/2\beta^2 - x/\beta} \int_0^\infty \frac{e^{-(E-m)^2/2\sigma^2}}{\sqrt{2\pi}\,\sigma}\,\mathrm{d}E \overset{(2)}{=} \frac{1}{\beta}\, e^{\sigma^2/2\beta^2 - x/\beta}\, \Phi\Big(\frac{x - \sigma^2/\beta}{\sigma}\Big).$$

(1) Insert the rearranged exponent into (1.32).
(2) The remaining integral is $\mathrm{P}(W > 0)$ for $W \sim \mathcal{N}(m, \sigma^2)$, which is $\mathrm{P}\big((W-m)/\sigma > -m/\sigma\big) = 1 - \Phi(-m/\sigma) = \Phi(m/\sigma)$ by the symmetry of the standard Gaussian.

The formula shows two things. First, far above the resolution scale, $x \gg \sigma^2/\beta + \sigma$, we have $\Phi \to 1$. There the measured spectrum is the true exponential with the same slope, multiplied by the constant $e^{\sigma^2/2\beta^2} > 1$. Smearing "feeds" events from low to high energy, and so raises the tail. Second, near and below zero the Φ factor cuts in. There is a finite probability of measuring a *negative* energy, which no true photon has.

Listing 1.13: Simulating the nuisance, then forgetting it (`code/ch01/13_detector_smearing.py`)

```
beta, sigma = 20.0, 5.0
N = 500_000
```

```
26 E_true = rng.exponential(beta, size=N)                    # the nuisance: never observed
27 E_meas = E_true + rng.normal(0.0, sigma, size=N)          # what the detector reports
28
29
30 def p_meas(x):
31     """Marginal density of the measured energy (true energy integrated out)."""
32     return (1 / beta) * np.exp(sigma**2 / (2 * beta**2) - x / beta) * \
33         stats.norm.cdf((x - sigma**2 / beta) / sigma)
```

Lines 26–27 are the whole physics: draw the true energy, add the noise. Marginalising over the nuisance then costs nothing: we simply never look at `E_true` again. The function `p_meas` (lines 30–33) is the closed form just derived.

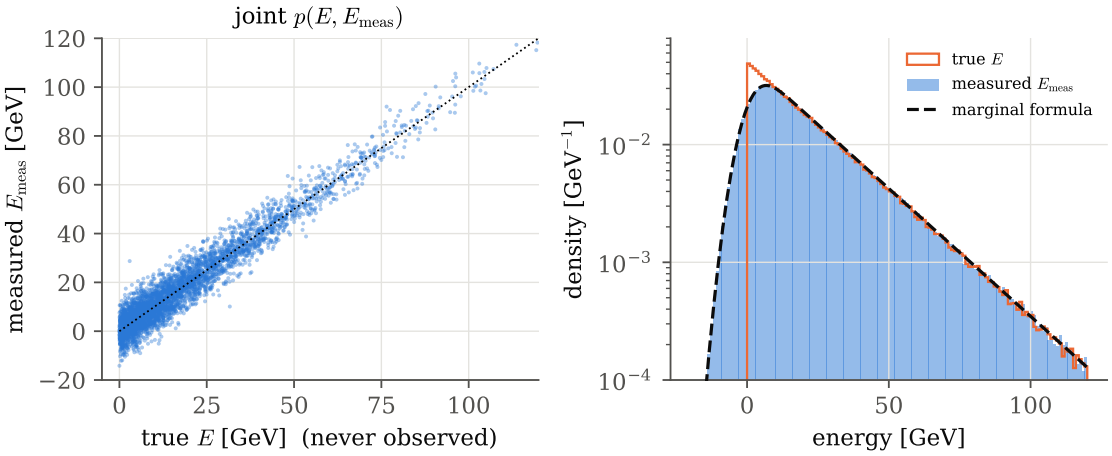

Figure 1.32: Left: the joint distribution of (true, measured) energy, scattered around the diagonal. Only the vertical coordinate is ever recorded. Right, on a log scale: the true spectrum (orange outline) is a straight line starting at zero. The measured spectrum (blue) is its marginal with the true energy integrated out. It leaks below zero and runs parallel to, and slightly above, the true line in the tail. The dashed curve is the closed form.

With 5×10^5 photons the simulation gives a mean measured energy of 19.99 GeV (exact $\beta = 20$), a variance of 425.0 GeV^2 (exact $\beta^2 + \sigma^2 = 425.0$, derived in Section 1.12), and a fraction 0.0866 of negative measured energies (exact $\int_{-\infty}^{0} f = 0.0860$). A χ^2 comparison of the histogram with the bin-integrated formula gives 125 for 136 bins, which is what agreement looks like (Chapter 4 makes this precise).

What this bought us. Marginalising a nuisance variable is, in simulation, the act of not looking at it. Analytically it is an integral over the joint, $f(x) = \int f(x \mid E) f(E)\, \mathrm{d}E$. The same integral with E a parameter is the Bayesian evidence of Chapter 5, and with E the true sky it is the forward model of Chapter 8.

How this is used in real research: Verification here, forward modelling in research

The closed form above *verifies* the simulation. In a real calorimeter the response $f(x \mid E)$ has non-Gaussian tails, depends on position and is known only through test-beam data and detector simulation. Then the marginal $\int f(x \mid E) f(E \mid \theta)\, \mathrm{d}E$ has no closed form and is computed by exactly the two lines of code above, repeated for each theory parameter θ. That forward-folded spectrum is what a fit compares with data. Going the other way, from x back to E, is *unfolding*, a conditional distribution $f(E \mid x)$ computed with (1.30).

1.11 Functions of random variables: change of variables and Jacobians

A classical harmonic oscillator swings as $x(t) = A\cos\omega t$. We take a photograph at a random moment, with no idea of the phase. Where is the bob most likely to be caught? The motion is completely deterministic; the only randomness is *when* we look, and the time t is uniform over a period. The position is a function of that uniform time, $X = A\cos\omega T$, so its distribution is fixed by the distribution of T and the function. We will find that the bob is most likely near the turning points, where it moves slowly, and least likely at the centre, where it is fastest.

The same question appears whenever an observable is a function of something whose distribution we know: the angle of a decay product, the transverse momentum computed from that angle, a flux from a magnitude, the logarithm of a likelihood. In each case we know the density of X and want the density of $Y = r(X)$. The tool is the Jacobian, and it works for several variables at once. The oscillator has a second use: histogramming $x(t)$ at random times is the same act as histogramming samples from a posterior (Chapter 5).

The key idea is that probability is conserved when we relabel. Think of probability as a fluid of total mass 1 spread along the x axis. The map $y = r(x)$ moves each drop of fluid to a new place but creates and destroys nothing. Whatever mass sat in $[x, x + \mathrm{d}x]$ now sits in the image interval $[y, y + \mathrm{d}y]$. If the map stretches that interval ($|\mathrm{d}y| > |\mathrm{d}x|$), the same mass is spread thinner and the density drops. If it compresses it, the density rises. For the oscillator the "map" is from time to position: near the turning points a long stretch of time maps onto a short stretch of position, so the density of position is high there. This is the same bookkeeping as a number density $n(\boldsymbol{x})$ under a change of coordinates, or a phase-space density under a canonical transformation.

In practice we find the distribution of $Y = r(X)$ in three steps.

1. For a value y, which values of x produce $Y \le y$? Draw it.
2. The probability of $Y \le y$ is the probability of that set of x's. That is the CDF of Y.
3. Differentiate to get the density. If r is one-to-one, this collapses to "old density times $|\mathrm{d}x/\mathrm{d}y|$". If several x's give the same y, add their contributions.

1.11.1 Discrete variables: collect the preimages

For a discrete X, $Y = r(X)$ is discrete and $\mathrm{P}(Y = y) = \mathrm{P}\big(X \in r^{-1}(y)\big)$, where $r^{-1}(y)$ is the set of all x with $r(x) = y$. If $\mathrm{P}(X = -1) = \mathrm{P}(X = 1) = \frac{1}{4}$, $\mathrm{P}(X = 0) = \frac{1}{2}$ and $Y = X^2$, then $\mathrm{P}(Y = 0) = \mathrm{P}(X = 0) = \frac{1}{2}$ and $\mathrm{P}(Y = 1) = \mathrm{P}(X = 1) + \mathrm{P}(X = -1) = \frac{1}{2}$ [Wasserman Ex. 2.45, p. 41]. Y takes fewer values than X because r is not one-to-one.

1.11.2 Continuous variables: the CDF method and the Jacobian

For a continuous variable the same three steps work with integrals instead of sums, and when r is one-to-one they collapse into a single formula.

Working definition 1.20 (change of variables for one variable)

Let X have density f_X and $Y = r(X)$. The **CDF method** computes

$$F_Y(y) = \mathrm{P}\big(r(X) \le y\big) = \int_{A_y} f_X(x)\,\mathrm{d}x, \qquad A_y = \{x : r(x) \le y\}, \qquad f_Y = F_Y'.$$

If r is strictly monotone with inverse $x = s(y)$, this gives

$$f_Y(y) = f_X\big(s(y)\big)\left|\frac{\mathrm{d}s}{\mathrm{d}y}\right|, \tag{1.33}$$

[the old density evaluated at the x that maps to y, times the factor by which the map squeezes lengths near that point]. If several x_k map to the same y (with r monotone near each), the contributions add: $f_Y(y) = \sum_k f_X(x_k)\,|\mathrm{d}x_k/\mathrm{d}y|$. *Operational test:* simulate X, apply r, histogram Y. The histogram must follow the formula.

Why does (1.33) hold [CasellaBerger Thm 2.1.5]? Take r increasing first. Then s is increasing too, and $r(X) \le y \iff X \le s(y)$:

$$f_Y(y) \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}y}\,\mathrm{P}\big(X \le s(y)\big) = \frac{\mathrm{d}}{\mathrm{d}y}F_X\big(s(y)\big) \overset{(2)}{=} f_X\big(s(y)\big)\,\frac{\mathrm{d}s}{\mathrm{d}y}.$$

(1) $F_Y(y) = \mathrm{P}(r(X) \le y)$, and for increasing r the event is $\{X \le s(y)\}$.
(2) Chain rule, with $F_X' = f_X$.

If r is decreasing, $r(X) \le y \iff X \ge s(y)$, so $F_Y(y) = 1 - F_X(s(y))$ and $f_Y = -f_X(s)\,s'$. Now $s' < 0$, so $-s' = |s'|$. Both cases are (1.33). The absolute value is there because densities are positive whichever way the map runs [Cowan (1.30)–(1.32)]. In the fluid picture: $f_Y\,|\mathrm{d}y| = f_X\,|\mathrm{d}x|$, "mass in = mass out".

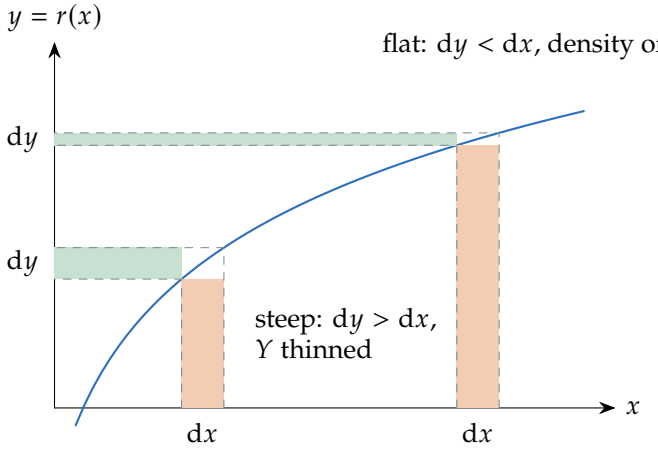

Figure 1.33: The Jacobian rule. Two strips of equal width $\mathrm{d}x$ carry probability $f_X\mathrm{d}x$ up to the curve and across to the y axis. Where the curve is steep (left) the strip lands on a wide interval $\mathrm{d}y$ and the density of Y is diluted. Where it is flat (right) the same width lands on a narrow interval and the density is concentrated. The factor is $|\mathrm{d}x/\mathrm{d}y| = 1/|r'(x)|$.

Example 1.44 (Standardising a Gaussian, and changing units). Let $X \sim \mathcal{N}(\mu, \sigma^2)$ and $Z = (X - \mu)/\sigma$. The inverse is $x = s(z) = \mu + \sigma z$ with $\mathrm{d}s/\mathrm{d}z = \sigma > 0$, so

$$f_Z(z) \overset{(1)}{=} f_X(\mu + \sigma z)\,\sigma \overset{(2)}{=} \frac{\sigma}{\sigma\sqrt{2\pi}}\exp\left[-\frac{(\sigma z)^2}{2\sigma^2}\right] = \frac{1}{\sqrt{2\pi}}e^{-z^2/2}.$$

(1) (1.33) with $|s'| = \sigma$.
(2) Substitute $x - \mu = \sigma z$ in the Gaussian density.

So $Z \sim \mathcal{N}(0,1)$, the fact used in Example 1.33. Reversed, $X = \mu + \sigma Z$ is $\mathcal{N}(\mu, \sigma^2)$ [Wasserman p. 28]. A change of units is the same calculation: $E_{\mathrm{MeV}} = 1000\,E_{\mathrm{GeV}}$ has $|\mathrm{d}E_{\mathrm{GeV}}/\mathrm{d}E_{\mathrm{MeV}}| = 10^{-3}$, so every density value is divided by 1000, which is what we found by hand in Example 1.31.

Example 1.45 (The logarithm of an exponential, and what does not transform). Let $X \sim \text{Exp}(1)$, $F_X(x) = 1 - e^{-x}$, and $Y = \ln X$ [Wasserman Ex. 2.46, p. 41]. By the CDF method,

$$F_Y(y) \overset{(1)}{=} \mathrm{P}(\ln X \le y) \overset{(2)}{=} \mathrm{P}(X \le e^y) = 1 - e^{-e^y}, \qquad f_Y(y) \overset{(3)}{=} e^y e^{-e^y}, \quad y \in \mathbb{R}.$$

(1) Definition of the CDF of Y.
(2) ln is increasing, so $\ln X \le y \iff X \le e^y$. Then use F_X.
(3) Differentiate: $\frac{\mathrm{d}}{\mathrm{d}y}(-e^{-e^y}) = e^{-e^y} \cdot e^y$.

The monotone formula gives the same thing directly: $s(y) = e^y$, $s' = e^y$, $f_X(e^y) = e^{-e^y}$.

Now compare summaries. The point: a change of variables carries the quantiles along, but it moves the mode. The *median* of X is $\ln 2$. The median of Y solves $1 - e^{-e^y} = \frac{1}{2}$, that is $e^y = \ln 2$, so it is $\ln(\ln 2)$, the log of the median of X. This holds for every quantile and any increasing map, because $\mathrm{P}(Y \le r(x)) = \mathrm{P}(X \le x)$. The *mode* behaves differently. The mode of X is 0 (the density e^{-x} is largest there), whose log is $-\infty$. The mode of Y is where $\frac{\mathrm{d}}{\mathrm{d}y}(y - e^y) = 0$, at $y = 0$, that is $x = 1$. The peak moves because the Jacobian reshapes the curve. Maximum a posteriori estimates therefore depend on the parametrisation, and quantile-based intervals do not (Chapter 5).

Example 1.46 (A square: two branches and two regimes). Let $X \sim \text{Uniform}(-1, 3)$, density $\frac{1}{4}$, and $Y = X^2$, with values in $(0, 9)$ [Wasserman Ex. 2.47, p. 42]. The set $A_y = \{x : x^2 \le y\}$ is $[-\sqrt{y}, \sqrt{y}]$, intersected with $(-1, 3)$.

- $0 < y < 1$: $A_y = [-\sqrt{y}, \sqrt{y}]$ lies inside $(-1, 3)$, so $F_Y(y) = 2\sqrt{y}/4 = \frac{1}{2}\sqrt{y}$ and $f_Y = \frac{1}{4\sqrt{y}}$.
- $1 \le y < 9$: $-\sqrt{y} \le -1$, so $A_y \cap (-1, 3) = (-1, \sqrt{y}]$ and $F_Y(y) = (\sqrt{y} + 1)/4$, $f_Y = \frac{1}{8\sqrt{y}}$.

The density halves at $y = 1$ because below 1 two values of x (one negative, one positive) feed each y, and above 1 only the positive one does. The general version is the sum over branches [CasellaBerger Thm 2.1.8]: for $Y = X^2$ with any density, $f_Y(y) = \frac{1}{2\sqrt{y}}\left[f_X(\sqrt{y}) + f_X(-\sqrt{y})\right]$. For $X \sim \mathcal{N}(0, 1)$,

$$f_Y(y) \overset{(1)}{=} \frac{1}{2\sqrt{y}} \cdot 2 \cdot \frac{e^{-y/2}}{\sqrt{2\pi}} = \frac{1}{\sqrt{2\pi y}}\, e^{-y/2}, \qquad y > 0,$$

(1) Both branches $x = \pm\sqrt{y}$ have $|\mathrm{d}x/\mathrm{d}y| = 1/(2\sqrt{y})$ and, by symmetry, the same density $e^{-y/2}/\sqrt{2\pi}$.

which is the χ^2 density with one degree of freedom. It diverges at $y = 0$ (but integrably), and the sum of ν such squares gives the χ^2_ν of Chapter 2.

1.11.3 The oscillator: histogramming a deterministic motion

A mass m on a spring moves as $x(t) = A\cos\omega t$, $p(t) = -m\omega A \sin\omega t$, with period $T = 2\pi/\omega$. Nothing about this motion is random: once A is fixed, $x(t)$ is known at every instant. Yet there is an everyday question about it whose answer is a probability density:

If I look at the oscillator at a randomly chosen instant, where will I find it?

The probability cannot come from the equation of motion, which has none in it. It comes from four words of the question, "a randomly chosen instant". They sound innocent, but they carry

an assumption: the act of looking is equally likely to happen at every instant of the period, no part of the swing preferred,

$$P(t)\,\mathrm{d}t = \frac{\mathrm{d}t}{T}, \qquad 0 \le t < T.$$

This rule, which says *what* is chosen at random and how, is the **sampling prescription**. The rule is uniform; the motion is not. Why does the question make the instant uniform, and not something else? Because choosing the instant is what picks the state. At fixed energy the possible states of the oscillator are the points (x, p) on its phase-space orbit, so here the orbit is the sample space. The motion passes through each point of the orbit at exactly one instant of the period, so a random instant picks a random point of the orbit (Figure 1.35b). Once the instant is chosen, the dynamics carry it to its point, and that step has nothing random in it. The only probabilistic input is therefore the uniform t. Everything else (Method 2 below) is a change of variables from t to x. This is also why sampling is easy here. We never have to build the distribution on phase space: the motion walks us over it, and we only choose the time. To find the distribution of position, we histogram x for a large set of random values of t. We now find the density of x in three ways.

Method 1: the CDF. For $-A < x < A$, $\cos\omega t \le x/A$ holds for ωt in $[\arccos(x/A),\, 2\pi - \arccos(x/A)]$, an interval of length $2\pi - 2\arccos(x/A)$ out of 2π. So

$$F_X(x) \overset{(1)}{=} 1 - \frac{1}{\pi}\arccos\frac{x}{A} \overset{(2)}{=} \frac{1}{2} + \frac{1}{\pi}\arcsin\frac{x}{A}, \qquad f_X(x) \overset{(3)}{=} \frac{1}{\pi}\,\frac{1/A}{\sqrt{1 - x^2/A^2}} = \frac{1}{\pi\sqrt{A^2 - x^2}}.$$

(1) ωt is uniform on $[0, 2\pi)$, so the probability is the fraction of the circle: $(2\pi - 2\arccos(x/A))/2\pi$.
(2) $\arccos u = \frac{\pi}{2} - \arcsin u$.
(3) $\frac{\mathrm{d}}{\mathrm{d}u}\arcsin u = 1/\sqrt{1-u^2}$ and the chain rule with $u = x/A$.

Method 2: uniform time, then change variable from t to x. The sampling prescription of the question says that the time is uniformly distributed over one period,

$$P(t)\,\mathrm{d}t = \frac{\mathrm{d}t}{T}, \qquad 0 \le t < T. \tag{1.34}$$

Everything else is a change of variable. The map $t \mapsto x = A\cos\omega t$ is two-to-one: every $x \in (-A, A)$ is passed twice per period, once on the way out ($p < 0$) and once on the way back ($p > 0$). The probability of landing in $[x, x + \mathrm{d}x]$ is the probability of the two time intervals that map onto it, each of length $\mathrm{d}t = \mathrm{d}x/|v|$:

$$P(x)\,\mathrm{d}x \overset{(1)}{=} 2 \times \frac{1}{T}\left|\frac{\mathrm{d}t}{\mathrm{d}x}\right|\mathrm{d}x \overset{(2)}{=} \frac{2}{T}\,\frac{\mathrm{d}x}{\omega\sqrt{A^2 - x^2}} \overset{(3)}{=} \frac{\mathrm{d}x}{\pi\sqrt{A^2 - x^2}}.$$

(1) (1.34) applied to the two branches, which contribute equally; this is the Jacobian rule of Eq. (1.33) summed over preimages.
(2) $|\mathrm{d}x/\mathrm{d}t| = |v| = A\omega\,|\sin\omega t| = \omega\sqrt{A^2 - x^2}$, using $\sin^2 + \cos^2 = 1$ (equivalently energy conservation, $\frac{1}{2}mv^2 + \frac{1}{2}m\omega^2x^2 = \frac{1}{2}m\omega^2A^2$).
(3) $T = 2\pi/\omega$.

In words: the probability of finding the mass in $\mathrm{d}x$ is the fraction of the period it spends there, $\propto \mathrm{d}x/|v|$. It is slow near the turning points, so it is found there most often.

Change the rule, change the answer. The arcsine law is the answer to the question about a random *instant*. Ask a different question about the same oscillator: pick a *position* at random, uniformly on $(-A, A)$, so that $P(x) = 1/(2A)$, and ask at which instant of the period the oscillator is there. Each x is passed twice per period, once moving left ($p < 0$, $0 < t < T/2$) and once moving right ($p > 0$, $T/2 < t < T$), so the rule must also say which passage we mean; we let a fair coin decide. Now the map runs the other way, from x to t, and the pair (position, branch) fixes the instant uniquely. The instant t in $(0, T/2)$ comes only from the position $x(t)$ on the left-moving branch, and an instant in $(T/2, T)$ only from $x(t)$ on the right-moving one, so

$$P(t) \overset{(1)}{=} \frac{1}{2}\, P\big(x(t)\big) \left|\frac{\mathrm{d}x}{\mathrm{d}t}\right| \overset{(2)}{=} \frac{1}{2} \cdot \frac{1}{2A} \cdot A\omega\, |\sin \omega t| = \frac{\omega}{4}\, |\sin \omega t|\,, \qquad 0 \le t < T. \tag{1.35}$$

(1) The Jacobian rule (1.33) for the map $x \mapsto t$ on the branch that contains t, times the probability $\frac{1}{2}$ that the coin chose that branch. Each instant has exactly one preimage, so there is one term.

(2) $P(x) = 1/(2A)$ is the new sampling prescription, and $|\mathrm{d}x/\mathrm{d}t| = A\omega\, |\sin \omega t|$ from $x = A \cos \omega t$.

It is normalised: $\int_0^T \frac{\omega}{4}\, |\sin \omega t|\, \mathrm{d}t = \frac{\omega}{4} \cdot 2 \cdot \frac{2}{\omega} = 1$. The time is no longer uniform. The sampled instants crowd around $t = T/4$ and $3T/4$, where the mass crosses the centre at full speed, and they avoid the turning points. This is the reverse of the arcsine picture. Why? Every $\mathrm{d}x$ now carries the same probability, and a fast stretch of the swing covers many $\mathrm{d}x$ per unit time, so it collects many of the sampled instants. The fraction of instants in the first tenth of the period is $(1 - \cos \frac{\pi}{5})/4 = 0.0477$, not 0.1. The script `14b_sampling_rule.py` finds 0.0478, and its histogram of t matches (1.35) with $\chi^2 = 54.7$ over 50 bins (Figure 1.34). The equation of motion is the same in both questions. Only the sampling rule changed, and the distributions of both x and t changed with it.

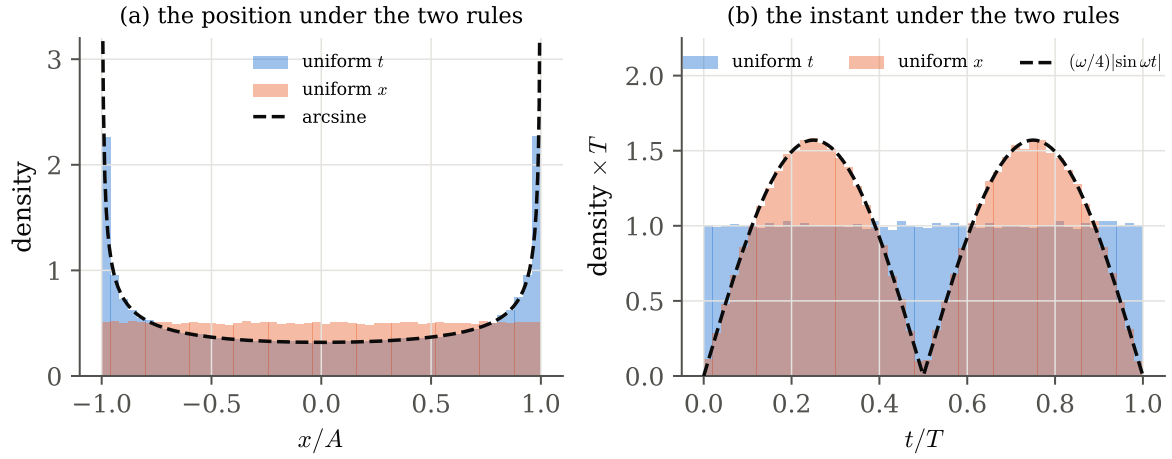

Figure 1.34: One oscillator, two sampling rules, 2×10^5 samples each. (a) Choosing the instant uniformly gives the arcsine law for the position (blue); choosing the position uniformly gives, by construction, a flat histogram (orange). (b) The instants behind the same samples: flat under the first rule, and under the second rule the two humps of $(\omega/4)\, |\sin \omega t|$, highest where the mass passes the centre and zero at the turning points $t = 0$, $T/2$, T.

Key idea: Equations of motion + sampling prescription → probability distribution

A deterministic motion has no distribution until we say what is chosen at random. The same orbit gives the arcsine law for x if the instant is uniform, and $(\omega/4)\, |\sin \omega t|$ for t if the position is uniform. Conservation laws tell us which states are *accessible* (energy

conservation confines the oscillator to its ellipse), not that they are equally probable. Being canonically conjugate does not make a variable uniform either: the phase $\theta = \omega t$, conjugate to the action E/ω, is uniform under the first rule only because that rule chose the instant uniformly, and under the second rule it has density $\frac{1}{4}|\sin\theta|$.

Method 3: from first principles, if we did not know that t is uniform. Method 2 assumed (1.34). Suppose we did not know that the instant is uniformly distributed, and asked instead what statistical mechanics says: in the **microcanonical ensemble** all phase-space points with energy between E and $E + \Delta E$ are equally probable. We then only have to measure areas in phase space. The energy is

$$H(x,p) = \frac{p^2}{2m} + \frac{1}{2}m\omega^2 x^2 = E, \qquad E = \frac{1}{2}m\omega^2 A^2,$$

so the orbit is the ellipse $x^2/A^2 + p^2/(m\omega A)^2 = 1$, with the two branches $p_\pm(x) = \pm m\omega\sqrt{A^2 - x^2}$. Thicken it into a shell $E \to E + \Delta E$. At fixed x the shell has thickness in the p direction

$$\Delta p \overset{(1)}{=} \sqrt{2m(E+\Delta E) - m^2\omega^2x^2} - \sqrt{2mE - m^2\omega^2x^2} \overset{(2)}{=} \frac{m\,\Delta E}{\sqrt{2mE - m^2\omega^2x^2}} \overset{(3)}{=} \frac{\Delta E}{\omega\sqrt{A^2 - x^2}}.$$

(1) Solve $H = E$ for $|p|$: $|p| = \sqrt{2mE - m^2\omega^2x^2}$, at the outer and inner energies.
(2) First order in ΔE: $\sqrt{a+\epsilon} - \sqrt{a} \simeq \epsilon/(2\sqrt{a})$ with $\epsilon = 2m\Delta E$.
(3) $2mE = m^2\omega^2A^2$, so the square root is $m\omega\sqrt{A^2 - x^2}$.

The vertical strip between x and $x + \mathrm{d}x$ meets the shell twice, at p_+ and at p_- (the two dark patches in Figure 1.35b), so the shell area inside the strip and the total shell area are

$$\mathrm{d}\mathcal{A} \overset{(1)}{=} 2\,\Delta p\,\mathrm{d}x = \frac{2\Delta E}{\omega\sqrt{A^2 - x^2}}\,\mathrm{d}x,$$
$$\mathcal{A}_{\text{shell}} \overset{(2)}{=} \mathcal{A}(E+\Delta E) - \mathcal{A}(E) \overset{(3)}{=} \frac{2\pi}{\omega}\,\Delta E.$$

(1) Two patches, each of height Δp and width $\mathrm{d}x$.
(2) The shell is the region between the two ellipses.
(3) The ellipse of energy E has semi-axes $\sqrt{2E/m\omega^2}$ and $\sqrt{2mE}$, so it encloses $\mathcal{A}(E) = \pi\sqrt{2E/m\omega^2}\sqrt{2mE} = 2\pi E/\omega$, which is linear in E.

Equal probability for equal phase-space area then gives

$$P(x)\,\mathrm{d}x \overset{(1)}{=} \frac{\mathrm{d}\mathcal{A}}{\mathcal{A}_{\text{shell}}} \overset{(2)}{=} \frac{2\Delta E\,\mathrm{d}x/\left(\omega\sqrt{A^2 - x^2}\right)}{2\pi\Delta E/\omega} = \frac{\mathrm{d}x}{\pi\sqrt{A^2 - x^2}}, \qquad |x| < A,$$

(1) Microcanonical ensemble: probability is proportional to phase-space area within the shell.
(2) The two results above; ΔE and ω cancel.

and it is normalised, $\frac{1}{\pi}\int_{-A}^{A}\mathrm{d}x/\sqrt{A^2 - x^2} = \frac{1}{\pi}[\arcsin(x/A)]_{-A}^{A} = 1$.

All three methods agree, and the agreement is not a coincidence. Methods 2 and 3 say the same thing from two ends: the *time* average over one orbit equals the *ensemble* average over the energy shell. Why? The time spent in a patch of the shell is its width over the speed, $\mathrm{d}x/|v|$. The patch area is $2\Delta p\,\mathrm{d}x$, and $\Delta p \propto 1/|v|$, so the area is proportional to the same thing. A uniformly random instant therefore lands in each patch in proportion to its area. This equality

of time and ensemble averages is **ergodicity**, and it is the property that makes Markov-chain sampling work in Chapter 9.

The density diverges at the turning points, where $v = 0$, but integrably. For example

$$\mathrm{P}\big(|X| > 0.9A\big) \overset{(1)}{=} 1 - \big[F_X(0.9A) - F_X(-0.9A)\big] \overset{(2)}{=} 1 - \frac{2}{\pi}\arcsin 0.9 = 0.2871,$$

(1) Complement of $-0.9A < X \le 0.9A$, and (1.27).
(2) arcsin is odd, so $F(0.9A) - F(-0.9A) = \frac{2}{\pi}\arcsin 0.9$.

so more than a quarter of the time is spent in the outer 10% of the range, both sides combined. Averaging x^2 over this density gives $\langle x^2\rangle = A^2/2$ (Section 1.12), the statement that the time-averaged potential energy is half the total.

Listing 1.14: The oscillator: random instants, deterministic map onto the phase-space orbit (`code/ch01/14_oscillator_arcsine.py`)

```
23 omega = 2 * np.pi / T
24 N = 200_000
25 t = rng.uniform(0.0, T, size=N)      # the random ingredient: WHEN we look
26 x = A * np.cos(omega * t)            # the deterministic map t -> (x, p): a point on the
       orbit
27 p = -m * omega * A * np.sin(omega * t)
```

Line 26 is the only random line: *when* we look. Lines 27–28 apply the deterministic map to a point (x, p) of the orbit, which is the sampled element of the sample space. Everything else is comparison. The script also computes the quantum probability density $|\psi_{30}(x)|^2$ of the oscillator eigenstate with $n = 30$, using the stable recursion for Hermite functions (lines 39–46), at the same energy $E = (n + \frac{1}{2})\hbar\omega = \frac{1}{2}m\omega^2A^2$, i.e. $A = \sqrt{2n+1}$ in units $\hbar = m = \omega = 1$.

The script finds $\mathrm{P}(|X| > 0.9A) = 0.2872$ (exact 0.2871), $\langle x^2\rangle = 0.4995\,A^2$ (exact 0.5), and a χ^2 of 65.4 over 60 bins against the bin-integrated arcsine law, computed from CDF differences (lines 105–109 of the script).

How research uses it. The oscillator experiment is: pick random t, compute $x(t)$, histogram. The histogram converges to the density of x without our ever writing that density down. Chapters 5 and 9 do exactly this with a posterior: an MCMC sampler produces points $\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \ldots$ and the histogram of any function $g(\boldsymbol{\theta})$ of them (a derived parameter such as H_0 computed from $\Omega_m h^2$ and Ω_m) is its posterior density, Jacobian included automatically. Here the Monte Carlo *verifies* a known arcsine law. There it *is* the answer, because the posterior density of a derived parameter has no closed form.

1.11.4 Why every point of the energy shell is equally likely: maximum entropy

Method 3 for the oscillator (Section 1.11.3) found the arcsine law without ever mentioning time. It used one sentence instead: all points of the energy shell are equally probable. Where does that sentence come from? Not from energy conservation, which only confines the oscillator to its ellipse and says nothing about how probable each point of it is (the key idea of Section 1.11.3). It is an extra assumption, and it can be derived from a cleaner one. Three assumptions are needed.

1. *A probabilistic description.* Cut phase space into small cells $i = 1, 2, \ldots$ of equal area $\mathrm{d}x\,\mathrm{d}p$. The state of the system is described by probabilities $p_i \ge 0$ with $\sum_i p_i = 1$. Equal area is the natural cell size because phase-space area is what the Hamiltonian motion preserves (Liouville's theorem).

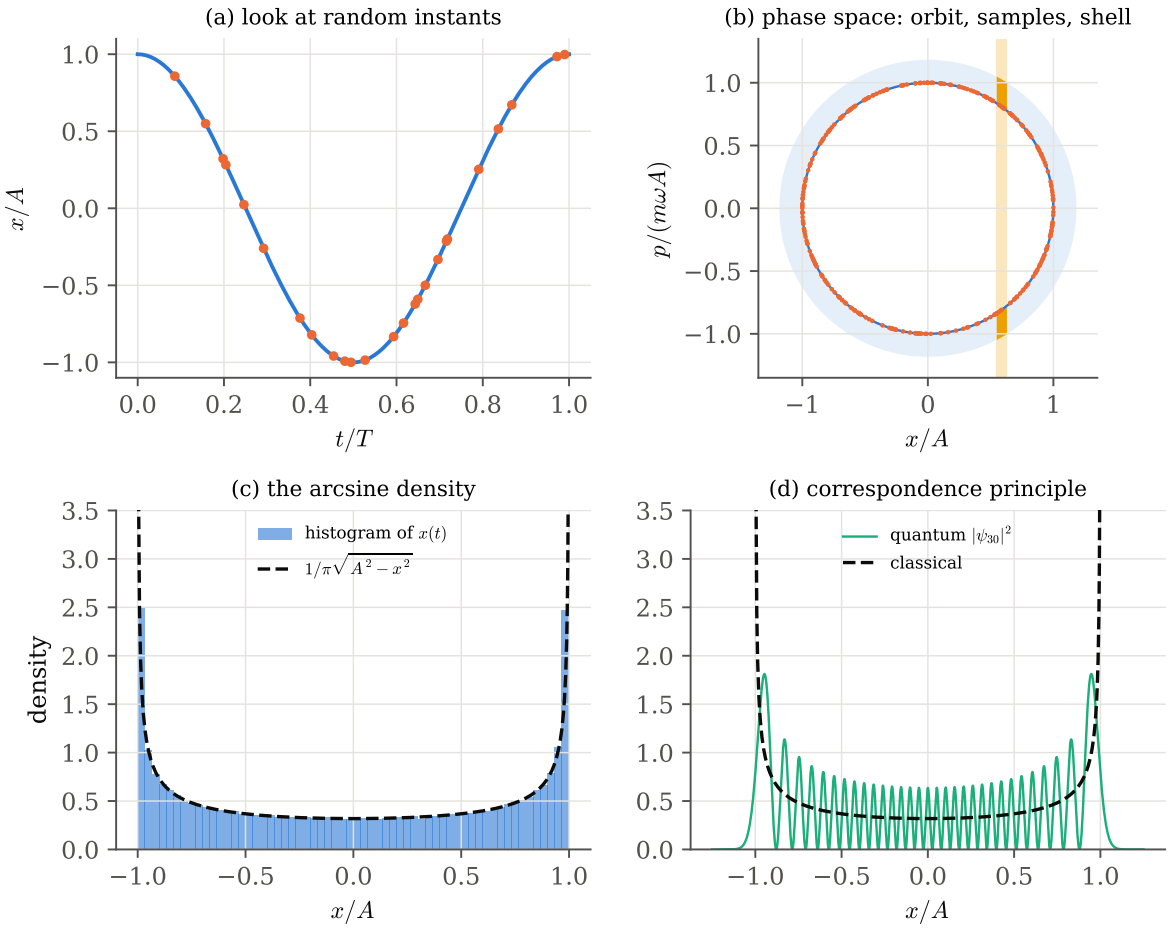

Figure 1.35: (a) The trajectory, looked at in random instants (dots). (b) The same instants as points (x, p) of phase space: they all lie on the energy ellipse (a circle in the scaled units), the sample space of this problem. The pale ring is a thickened energy shell; the vertical strip between x and $x + \mathrm{d}x$ meets it in two dark patches, at p_+ and p_-, whose area is what Method 3 computes. (c) The histogram of x at 2×10^5 random instants follows the arcsine density, lowest at the centre and rising steeply towards the turning points. (d) The quantum density for $n = 30$ oscillates rapidly, but its local average follows the same classical curve: the correspondence principle seen as a statement about probability densities.

2. *Constraints.* What we know about the system is written as equations the p_i must obey.
3. *Equilibrium.* Among all distributions that obey the constraints, the equilibrium one maximises the Gibbs–Shannon entropy

$$S[p] = -k_B \sum_i p_i \ln p_i. \tag{1.36}$$

Only normalisation: the microcanonical distribution. Keep only the M cells of the shell between E and $E + \Delta E$, the accessible states, and impose nothing but normalisation. With a Lagrange multiplier $k_B\alpha$ for $\sum_i p_i = 1$, the maximum has

$$0 \overset{(1)}{=} \frac{\partial}{\partial p_j}\Big[-k_B \sum_i p_i \ln p_i - k_B\alpha\Big(\sum_i p_i - 1\Big)\Big] \overset{(2)}{=} -k_B\big(\ln p_j + 1 + \alpha\big),$$

$$p_j \overset{(3)}{=} e^{-1-\alpha} \overset{(4)}{=} \frac{1}{M} \qquad \text{for every cell } j \text{ of the shell.}$$

(1) The stationary point of the entropy with the constraint added through its multiplier.
(2) Only the term $i = j$ depends on p_j, and $\frac{\mathrm{d}}{\mathrm{d}p}(p \ln p) = \ln p + 1$.
(3) Solve for p_j.
(4) The right side of (3) is the same number for every j; normalisation over the M cells fixes it to $1/M$.

It is a maximum, because $\partial^2 S/\partial p_j^2 = -k_B/p_j < 0$, and its value is $S = k_B \ln M$, Boltzmann's entropy of Section 1.3. Equal probability per cell of equal area means probability proportional to phase-space area: Method 3's "equal probability for equal phase-space area" was this assumption.

Normalisation and a fixed mean energy: the canonical distribution. Now let the system exchange energy with its surroundings, so that cells of every energy E_i are accessible, and suppose all we know is the mean energy, $\sum_i p_i E_i = U$. A second multiplier λ enters:

$$0 \overset{(1)}{=} \frac{\partial}{\partial p_j}\Big[S[p] - k_B\alpha\Big(\sum_i p_i - 1\Big) - \lambda\Big(\sum_i p_i E_i - U\Big)\Big] \overset{(2)}{=} -k_B\big(\ln p_j + 1 + \alpha\big) - \lambda E_j,$$

$$p_j \overset{(3)}{=} e^{-1-\alpha}\, e^{-\beta E_j} \overset{(4)}{=} \frac{e^{-\beta E_j}}{Z}, \qquad \beta \equiv \frac{\lambda}{k_B}, \quad Z = \sum_i e^{-\beta E_i}.$$

(1) The stationary point with both constraints.
(2) As before, plus $\partial(\sum_i p_i E_i)/\partial p_j = E_j$.
(3) Solve for $\ln p_j$ and exponentiate.
(4) Normalisation fixes $e^{-1-\alpha} = 1/Z$; Z, the **partition function**, is simply the normaliser.

What is β? Put the solution back into the entropy and ask how the maximum entropy changes with U:

$$S \overset{(1)}{=} -k_B \sum_i p_i\big(-\beta E_i - \ln Z\big) \overset{(2)}{=} k_B\big(\beta U + \ln Z\big),$$

$$\frac{\mathrm{d}S}{\mathrm{d}U} \overset{(3)}{=} k_B\Big(\beta + U\frac{\mathrm{d}\beta}{\mathrm{d}U} + \frac{\partial \ln Z}{\partial \beta}\frac{\mathrm{d}\beta}{\mathrm{d}U}\Big) \overset{(4)}{=} k_B\beta.$$

(1) $\ln p_i = -\beta E_i - \ln Z$.
(2) $\sum_i p_i E_i = U$ and $\sum_i p_i = 1$.
(3) β depends on U through the constraint; differentiate both terms.
(4) $\partial_\beta \ln Z = -\sum_i E_i e^{-\beta E_i}/Z = -U$, so the last two terms cancel.

Thermodynamics defines the temperature by $1/T = \mathrm{d}S/\mathrm{d}U$. So $\lambda = k_B\beta = 1/T$, that is $\beta = 1/k_B T$, and the maximum-entropy distribution at fixed mean energy is the Boltzmann distribution $p_i = e^{-E_i/k_B T}/Z$.

No sampling rule, and a definition that closes on itself. In Section 1.11.3 a probability needed a sampling prescription: choose the instant, or choose the position, and the answers differed. Here we never said what is chosen at random, and we did not need to. Why not? The entropy (1.36) is a function of the probabilities themselves, so maximising it is a statement about the p_i directly. The third assumption takes the place of the sampling rule. That assumption is also a definition: equilibrium *is* the maximum-entropy state compatible with the constraints. So the argument closes on itself. The microcanonical and canonical distributions apply exactly when the system is in that state, and the derivation says nothing about whether, or how fast, a given system gets there. For the one-dimensional oscillator the dynamics answer that question at

once: a uniform instant lands on the shell in proportion to area (the ergodicity paragraph of Section 1.11.3). The same variational argument with a fixed variance gives the Gaussian as the maximum-entropy density, in Chapter 2.

1.11.5 Time averages of a bounded motion: the virial theorem

The oscillator's $\langle x^2\rangle = A^2/2$ of Section 1.11.3 is a time average: under the uniform-instant rule, averaging over the arcsine density is averaging over one period. It says that the mean potential energy is $\langle V\rangle = \frac{1}{2}m\omega^2\langle x^2\rangle = \frac{1}{4}m\omega^2A^2 = E/2$, so the mean kinetic energy is $\langle K\rangle = E - \langle V\rangle = E/2$ as well: $2\langle K\rangle = 2\langle V\rangle$. This is the virial theorem for a potential $V \propto x^2$, and the general version takes three lines.

Take particles with positions $\boldsymbol{r}_a$ and momenta $\boldsymbol{p}_a$, potential $V(\boldsymbol{r}_1, \boldsymbol{r}_2, \dots)$, and kinetic energy $K = \sum_a \boldsymbol{p}_a^2/2m_a$. Let $G = \sum_a \boldsymbol{r}_a \cdot \boldsymbol{p}_a$ (for one particle in one dimension, $G = xp$). Then

$$\frac{\mathrm{d}G}{\mathrm{d}t} \overset{(1)}{=} \sum_a \dot{\boldsymbol{r}}_a \cdot \boldsymbol{p}_a + \sum_a \boldsymbol{r}_a \cdot \dot{\boldsymbol{p}}_a \overset{(2)}{=} 2K - \sum_a \boldsymbol{r}_a \cdot \nabla_a V,$$

$$\frac{G(\tau) - G(0)}{\tau} \overset{(3)}{=} 2\langle K\rangle_\tau - \Big\langle \sum_a \boldsymbol{r}_a \cdot \nabla_a V \Big\rangle_\tau \overset{(4)}{=} 0 \quad \text{in the limit } \tau \to \infty.$$

(1) Product rule.
(2) $\dot{\boldsymbol{r}}_a = \boldsymbol{p}_a/m_a$, so the first sum is $\sum_a \boldsymbol{p}_a^2/m_a = 2K$; Newton's law $\dot{\boldsymbol{p}}_a = -\nabla_a V$ in the second.
(3) Average both sides over a time τ, $\langle f\rangle_\tau = \frac{1}{\tau}\int_0^\tau f\,\mathrm{d}t$.
(4) For a bounded motion G stays bounded, so the left side goes to zero as $\tau \to \infty$ (for a periodic motion it is exactly zero over one period).

Hence the time-averaged **virial theorem**

$$2\langle K\rangle = \Big\langle \sum_a \boldsymbol{r}_a \cdot \nabla_a V \Big\rangle \qquad \Longrightarrow \qquad 2\langle K\rangle = n\,\langle V\rangle \quad \text{for } V \propto r^n, \tag{1.37}$$

the second form because a potential homogeneous of degree n, $V(\lambda\boldsymbol{r}_1, \lambda\boldsymbol{r}_2, \dots) = \lambda^n V$, obeys Euler's relation $\sum_a \boldsymbol{r}_a \cdot \nabla_a V = nV$ (differentiate in λ at $\lambda = 1$). For the oscillator $n = 2$ and $\langle K\rangle = \langle V\rangle$, as found above.

Gravity: negative heat capacity. For self-gravitating masses, $V = -\sum_{a<b} Gm_a m_b/|\boldsymbol{r}_a - \boldsymbol{r}_b|$ is homogeneous of degree $n = -1$. Then

$$E \overset{(1)}{=} \langle K\rangle + \langle V\rangle \overset{(2)}{=} \langle K\rangle - 2\langle K\rangle = -\langle K\rangle \overset{(3)}{=} -\tfrac{3}{2}Nk_BT, \qquad \frac{\mathrm{d}E}{\mathrm{d}T} = -\tfrac{3}{2}Nk_B < 0.$$

(1) E is conserved, so it equals its own time average.
(2) The virial theorem (1.37) with $n = -1$: $\langle V\rangle = -2\langle K\rangle$.
(3) The kinetic-gas definition of temperature for N particles, $\langle K\rangle = \frac{3}{2}Nk_BT$.

A self-gravitating system has a negative heat capacity: when it loses energy it heats up. A star radiates, contracts, its potential energy falls by twice the energy lost, and half of that goes into faster thermal motion. Star clusters behave the same way: the core loses energy to the halo and gets hotter.

The canonical distribution cannot have $C < 0$. The canonical distribution of Section 1.11.4 fixes the sign of the heat capacity, so it cannot describe such a system. With $Z(\beta) = \sum_i e^{-\beta E_i}$,

$$\frac{\partial \ln Z}{\partial \beta} \overset{(1)}{=} -\frac{\sum_i E_i e^{-\beta E_i}}{Z} = -\langle E \rangle, \qquad \frac{\partial^2 \ln Z}{\partial \beta^2} \overset{(2)}{=} \frac{\sum_i E_i^2 e^{-\beta E_i}}{Z} - \left(\frac{\sum_i E_i e^{-\beta E_i}}{Z}\right)^2 = \mathrm{Var}(E),$$

$$C \overset{(3)}{=} \frac{\mathrm{d}\langle E \rangle}{\mathrm{d}T} \overset{(4)}{=} \frac{\mathrm{d}\beta}{\mathrm{d}T}\,\frac{\mathrm{d}\langle E \rangle}{\mathrm{d}\beta} \overset{(5)}{=} \left(-\frac{1}{k_B T^2}\right)\left(-\frac{\partial^2 \ln Z}{\partial \beta^2}\right) = \frac{\mathrm{Var}(E)}{k_B T^2} \;\geq\; 0.$$

(1) Differentiate $\ln Z$; the ratio is the canonical average of E.
(2) Differentiate once more (quotient rule): $\partial_\beta (Z'/Z) = Z''/Z - (Z'/Z)^2$, which is $\langle E^2 \rangle - \langle E \rangle^2$ (the generating-function view of $\ln Z$ is in Section 1.14).
(3) The heat capacity is the change of mean energy with temperature.
(4) Chain rule through $\beta = 1/k_B T$.
(5) $\mathrm{d}\beta/\mathrm{d}T = -1/k_B T^2$ and the two results of the first line.

A variance is never negative, so a system described by the canonical distribution has $C \geq 0$. A self-gravitating system, with $C < 0$, cannot be described by the canonical distribution, and physically it cannot sit in equilibrium with a heat bath: if it is a little hotter than the bath it loses energy, gets hotter still, and runs away. Only the microcanonical description, an isolated system at fixed E with maximum entropy on its shell, can apply to it. The assumptions of Section 1.11.4 say exactly when each distribution is legitimate: fixed energy gives the microcanonical, a fixed mean energy (which in practice means contact with a bath) gives the canonical, and the second needs $C \geq 0$ to be consistent.

1.11.6 Isotropic decays: flat in $\cos\theta$, peaked in p_T

Example 1.47 (Angles and transverse momentum of an isotropic decay). A particle at rest decays into two daughters, each of momentum p^* in opposite directions. "Isotropic" means the daughter direction is uniform on the unit sphere: the probability of a patch is its solid angle over 4π, $\mathrm{d}\,\mathrm{P} = \mathrm{d}\Omega/4\pi = \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi/4\pi$ with $\theta \in [0, \pi]$ the polar angle to the beam axis z. Then:

$$f(\theta) \overset{(1)}{=} \int_0^{2\pi} \frac{\sin\theta}{4\pi}\,\mathrm{d}\phi = \frac{\sin\theta}{2}, \qquad f_{\cos\theta}(u) \overset{(2)}{=} \frac{\sin\theta}{2} \cdot \frac{1}{\sin\theta} = \frac{1}{2}, \quad u \in [-1, 1].$$

(1) The joint density of (θ, ϕ) is $\sin\theta/4\pi$. Marginalise the azimuth ϕ.
(2) $u = \cos\theta$ is decreasing on $[0, \pi]$ with $|\mathrm{d}\theta/\mathrm{d}u| = 1/\sin\theta$. Apply (1.33).

So $\cos\theta$ is flat, θ is not (few decays go along the beam, because the poles have little solid angle), and $p_z = p^* \cos\theta$ is uniform on $[-p^*, p^*]$. The transverse momentum $p_T = p^* \sin\theta$ is different: two angles, θ and $\pi - \theta$, give the same p_T. With $\sin\theta = p_T/p^*$ and $|\cos\theta| = \sqrt{1 - p_T^2/p^{*2}}$,

$$\left|\frac{\mathrm{d}\theta}{\mathrm{d}p_T}\right| \overset{(1)}{=} \frac{1}{p^*\,|\cos\theta|} = \frac{1}{\sqrt{p^{*2} - p_T^2}},$$

$$f(p_T) \overset{(2)}{=} 2 \times \frac{\sin\theta}{2} \times \frac{1}{\sqrt{p^{*2} - p_T^2}} = \frac{p_T}{p^*\sqrt{p^{*2} - p_T^2}}, \qquad 0 < p_T < p^*.$$

(1) $\mathrm{d}p_T/\mathrm{d}\theta = p^* \cos\theta$.
(2) Two branches ($\theta < \pi/2$ and $\theta > \pi/2$) with the same density $\sin\theta/2$ and the same Jacobian.

The density diverges at $p_T = p^*$, the **Jacobian peak**: decays near $\theta = \pi/2$ all pile up at the maximum p_T, because p_T is stationary there. For $W \to e\nu$ with the W at rest, $p^* = m_W/2 \approx 40\,\text{GeV}$, and the sharp edge of the electron p_T spectrum near 40 GeV is what makes the p_T distribution sensitive to m_W. As a check, $\mathrm{P}(p_T > 0.9p^*) = \mathrm{P}(|\cos\theta| < \sqrt{1-0.81}) = \sqrt{0.19} = 0.4359$, because $\cos\theta$ is uniform.

Listing 1.15: Isotropic directions and the transverse momentum (`code/ch01/15_decay_angles.py`)

```
22 m_W = 80.4                       # GeV
23 pstar = m_W / 2
24 N = 400_000
25 # uniform direction on the sphere: normalise a 3-D standard Gaussian vector
26 v = rng.normal(size=(N, 3))
27 v /= np.linalg.norm(v, axis=1, keepdims=True)
28 cos_t = v[:, 2]
29 theta = np.arccos(cos_t)
30 pT = pstar * np.sqrt(v[:, 0]**2 + v[:, 1]**2)
```

Lines 26–27 generate isotropic directions by normalising a vector of three independent standard Gaussians. This works because the joint density of the three Gaussians, $(2\pi)^{-3/2}e^{-|v|^2/2}$, depends only on the length $|v|$, so it is unchanged by rotations and the direction must be uniform. Lines 28–30 compute the three random variables of the example from the same simulated directions.

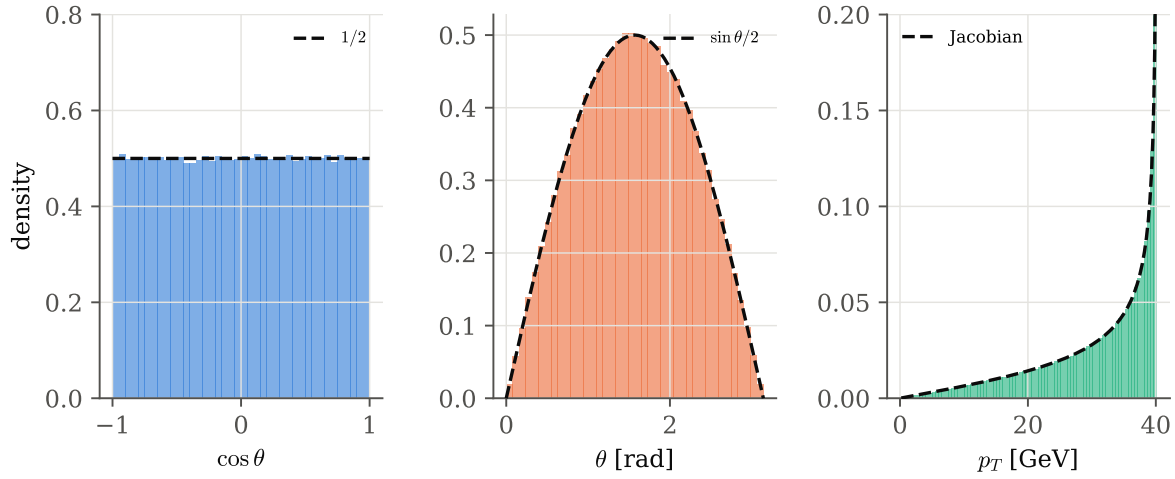

Figure 1.36: 4×10^5 isotropic decays of a particle at rest with $p^* = m_W/2$. Left: $\cos\theta$ is flat at $\frac{1}{2}$. Middle: θ itself follows $\sin\theta/2$, vanishing along the beam. Right: the transverse momentum rises towards the kinematic endpoint p^* and piles up there (the Jacobian peak).

The simulation gives $\langle\cos\theta\rangle = 0.0006$ (exact 0), $\langle p_T\rangle = 31.566\,\text{GeV}$ against the exact $p^*\langle\sin\theta\rangle = \pi p^*/4 = 31.573\,\text{GeV}$, and $\mathrm{P}(p_T > 0.9p^*) = 0.4353$ against 0.4359.

1.11.7 Several variables: the Jacobian determinant

Everything above extends to several variables at once, with lengths replaced by areas or volumes.

Working definition 1.21 (change of variables in several dimensions)

Let (X, Y) have joint density $f_{X,Y}$ and let $(U, V) = g(X, Y)$ be one-to-one on the region where $f_{X,Y} > 0$, with inverse $x = h_1(u, v)$, $y = h_2(u, v)$. Then

$$f_{U,V}(u, v) = f_{X,Y}\big(h_1(u, v), h_2(u, v)\big)\ |J|\,, \qquad J = \det \begin{pmatrix} \partial x/\partial u & \partial x/\partial v \\ \partial y/\partial u & \partial y/\partial v \end{pmatrix}, \tag{1.38}$$

[the old density at the preimage point, times the factor by which the inverse map scales areas near it]. The same holds in n dimensions with the $n \times n$ Jacobian determinant [Cowan (1.37)–(1.38)]. *Operational test:* a small rectangle $\mathrm{d}u\,\mathrm{d}v$ is the image of a parallelogram of area $|J|\,\mathrm{d}u\,\mathrm{d}v$, and both must carry the same probability.

The multidimensional formula is (1.33) with "length" replaced by "area": the inverse map sends the rectangle with sides $\mathrm{d}u, \mathrm{d}v$ to a parallelogram spanned by the vectors $(\partial_u x, \partial_u y)\mathrm{d}u$ and $(\partial_v x, \partial_v y)\mathrm{d}v$, whose area is $|J|\,\mathrm{d}u\,\mathrm{d}v$, the familiar volume element of a coordinate change.

Example 1.48 (Sum and difference of two Gaussians; polar coordinates). Let $X, Y \overset{\text{iid}}{\sim} \mathcal{N}(0, 1)$ and $U = X + Y$, $V = X - Y$ [CasellaBerger Ex. 4.3.4]. The inverse is $x = (u + v)/2$, $y = (u - v)/2$, so

$$J \overset{(1)}{=} \det \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} \end{pmatrix} = -\tfrac{1}{2}, \qquad x^2 + y^2 \overset{(2)}{=} \frac{(u+v)^2 + (u-v)^2}{4} = \frac{u^2 + v^2}{2},$$

$$f_{U,V}(u, v) \overset{(3)}{=} \frac{1}{2\pi} e^{-(u^2+v^2)/4} \cdot \frac{1}{2} = \left[\frac{e^{-u^2/4}}{\sqrt{2\pi \cdot 2}}\right]\left[\frac{e^{-v^2/4}}{\sqrt{2\pi \cdot 2}}\right].$$

(1) Partial derivatives of x and y with respect to u, v.
(2) The cross terms $\pm 2uv$ cancel.
(3) (1.38) with $f_{X,Y} = \frac{1}{2\pi} e^{-(x^2+y^2)/2}$ and $|J| = \frac{1}{2}$.

The joint factorises: U and V are independent, each $\mathcal{N}(0, 2)$. The sum and difference of two equally noisy channels are statistically independent, a fact Section 1.13 will explain through their covariance.

In polar coordinates, $x = r\cos\varphi$, $y = r\sin\varphi$, $J = r$, and the same density becomes $f(r, \varphi) = \frac{1}{2\pi} \cdot r e^{-r^2/2}$: the angle is uniform on $[0, 2\pi)$, independent of the radius, and R has density $r e^{-r^2/2}$ (the Rayleigh distribution). Read backwards this is the Box–Muller recipe for making Gaussians from uniforms (Chapter 6).

For a single function $Z = r(X, Y)$ the three-step CDF method still works [Wasserman p. 42]: find $A_z = \{(x, y) : r(x, y) \le z\}$, integrate the joint over it, differentiate. Alternatively, invent a second variable to make the map one-to-one, use (1.38), and marginalise the invented variable [CasellaBerger §4.3]. For $Z = X + Y$ take $(x, y) \to (x, z)$ with $z = x + y$, so $y = z - x$ and $|J| = 1$. For independent X, Y with densities g, h:

$$f_Z(z) \overset{(1)}{=} \int f_{X,Z}(x, z)\,\mathrm{d}x \overset{(2)}{=} \int g(x)\,h(z - x)\,\mathrm{d}x, \tag{1.39}$$

(1) Marginalise the auxiliary variable x.
(2) (1.38) with $|J| = 1$ and independence, $f_{X,Y}(x, z - x) = g(x)h(z - x)$.

the **convolution** $g * h$: the density of a sum is the convolution of the densities [Cowan (1.36)]. For a product $Z = XY$ take $y = z/x$, $|J| = 1/|x|$, and get $f_Z(z) = \int g(x)h(z/x)\,\mathrm{d}x/|x|$, the Mellin convolution [Cowan (1.35)].

Example 1.49 (The sum of two uniforms is a triangle). Let $X_1, X_2 \overset{\text{iid}}{\sim} \mathrm{Uniform}(0, 1)$ and $Y = X_1 + X_2$ [Wasserman Ex. 2.48, p. 43]. *By geometry*: $A_y = \{x_1 + x_2 \le y\}$ within the unit square

is a triangle of area $y^2/2$ for $0 \le y < 1$, and the square minus a corner triangle of area $(2-y)^2/2$ for $1 \le y < 2$ (Figure 1.37). So $F_Y = y^2/2$ and then $1-(2-y)^2/2$, and $f_Y(y) = y$ on $[0,1]$, $2-y$ on $[1,2]$. *By convolution* (1.39), with $g = h = \mathbb{1}_{[0,1]}$ (the indicator of $[0,1]$),

$$f_Y(y) \overset{(1)}{=} \int_0^1 \mathbb{1}\left[0 \le y - x \le 1\right] dx \overset{(2)}{=} \min(y,1) - \max(0, y-1) = \begin{cases} y, & 0 \le y \le 1, \\ 2-y, & 1 \le y \le 2. \end{cases}$$

(1) $g(x) = 1$ restricts x to $[0,1]$, and $h(y-x) = 1$ needs $0 \le y - x \le 1$.
(2) Both conditions together: $\max(0, y-1) \le x \le \min(1, y)$. The integral is the length of that interval.

Adding two flat distributions gives a peaked one. Adding more gives something ever closer to a Gaussian, the central limit theorem of Chapter 2; Section 1.14 shows why the convolution becomes simple after a Fourier transform.

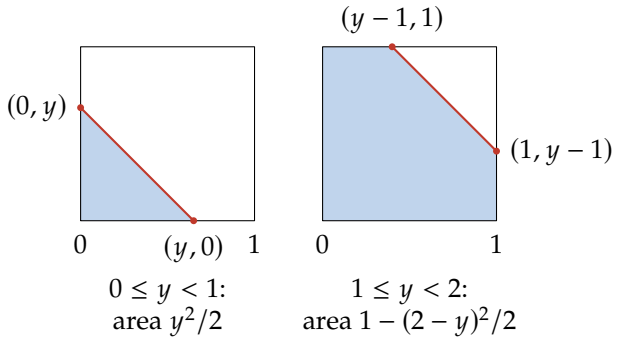

Figure 1.37: The event $X_1 + X_2 \le y$ inside the unit square is everything below the red line $x_2 = y - x_1$. For $y < 1$ it is a small triangle. For $y > 1$ it is the whole square minus the unshaded corner. The shaded area is the CDF of the sum.

The worked cases used every method in turn. The table says which one to reach for in each situation.

Taxonomy: Which method for which transformation

situation	method
X discrete	add probabilities of all preimages
r monotone	$f_Y = f_X(s(y))\,\lvert s'(y)\rvert$
r many-to-one (e.g. x^2, cos, sin)	sum the monotone formula over branches, or use the CDF
awkward region, piecewise	CDF method: draw A_y, integrate, differentiate
n variables to n variables	Jacobian determinant (1.38)
one function of n variables	add auxiliary variables, Jacobian, marginalise; sums $\to$ convolution
sums of many independent variables	characteristic functions (Section 1.14)
anything else	simulate and histogram (Monte Carlo, Chapter 6)

Three mistakes recur in all of these methods.

Watch out: Transforming the density's value instead of its argument

Writing $f_Y(y) = f_X(s(y))$ and forgetting the Jacobian is the commonest error. The result is not normalised, so a quick check $\int f_Y = 1$ catches it. A second error is forgetting branches

(θ and $\pi - \theta$ both give the same p_T). A third is expecting the peak to transform like a point: modes move under reparametrisation, quantiles do not (Example 1.45).

1.12 Expectation and variance: the long-run average and the spread

A slot machine pays \$100 with probability 0.001, pays \$5 with probability 0.14, and otherwise takes our \$1. Should we play? No single pull answers that, because a single pull is random. What we can predict is the average over many pulls. In N pulls we expect about $0.001N$ big wins, $0.14N$ small wins and $0.859N$ losses, so the average payoff per pull is

$$0.001 \times 100 + 0.14 \times 5 + 0.859 \times (-1) = -0.059$$

dollars. In the long run we lose about six cents per pull [Kruschke §4.3.3]. Each possible value was weighted by how often it occurs. That weighted average is the expectation.

Physicists use this object all the time under other names. The ensemble average $\langle A \rangle = \sum_i p_i A_i$ of statistical mechanics, with $p_i = e^{-\beta E_i}/Z$, is an expectation. So is the quantum expectation value $\langle \psi | \hat{A} | \psi \rangle = \sum_a a \, |\langle a | \psi \rangle|^2$, where the Born probabilities $|\langle a | \psi \rangle|^2$ weight the eigenvalues a. Two numbers summarise a whole distribution: a location (the mean) and a spread (the variance). There are rules for computing both for sums, for functions and for conditional situations, without ever writing down the density of the quantity being averaged. Three questions organise the topic.

1. What is the average value of X, and of any function $r(X)$?
2. How far from that average does X typically fall?
3. If we learn the value of another variable, how do the average and the spread change, and how do the conditional pieces reassemble into the whole?

1.12.1 The expectation

Start from data. Draw X independently N times and let n_x be the number of draws that gave the value x. The average of the draws is

$$\frac{1}{N} \sum_{j=1}^{N} X_j = \sum_x x \, \frac{n_x}{N}.$$

The frequencies n_x/N approach the probabilities $f(x) = \mathrm{P}(X = x)$ as N grows (the frequency interpretation of Section 1.2; the law of large numbers in Chapter 2 makes this precise). So the long-run average is $\sum_x x \, f(x)$. For a continuous variable, sort the draws into bins of width Δx. The fraction in the bin at x is about $f(x)\,\Delta x$, where f is the density, and the sum over bins becomes an integral as $\Delta x \to 0$.

Working definition 1.22 (expectation, mean)

The **expectation** (or **mean**, or first moment) of X is

$$\mathbb{E}(X) = \begin{cases} \sum_x x \, f(x) & X \text{ discrete}, \\ \int_{-\infty}^{\infty} x \, f(x) \, \mathrm{d}x & X \text{ continuous}, \end{cases} \tag{1.40}$$

the values weighted by the pmf [$f(x) = \mathrm{P}(X = x)$, the mass at x] or by the density [probability per unit x]. It is written μ, μ_X, $\mathbb{E}\,X$ or $\langle X \rangle$ and has the units of X. It **exists** only

if $\sum_x |x|\, f(x)$ (or $\int |x|\, f(x)\,\mathrm{d}x$) is finite. *Operational test:* the average of many independent draws of X settles down to $\mathbb{E}(X)$.

[Wasserman Def. 3.1, p. 47] writes both cases as $\int x\,\mathrm{d}F(x)$, a single notation for "sum against the masses or integrate against the density". We will use the two explicit forms.

Example: simple means. For a Bernoulli trial, $\mathbb{E}(X) = 0\cdot(1-p) + 1\cdot p = p$: the mean of an indicator is the probability of the event it indicates. For the number of heads in two fair flips, $\mathbb{E}(X) = 0\cdot\frac{1}{4} + 1\cdot\frac{1}{2} + 2\cdot\frac{1}{4} = 1$ [Wasserman Exs. 3.2–3.3, p. 48]. For a fair die, $\mathbb{E}(X) = \frac{1}{6}(1+2+\cdots+6) = \frac{21}{6} = 3.5$ [SeeingTheory p. 10], a value the die can never show. The mean is a long-run average, not a typical outcome. For $X \sim \mathrm{Uniform}(-1,3)$ the density is $\frac{1}{4}$ on $(-1,3)$ and

$$\mathbb{E}(X) \overset{(1)}{=} \int_{-1}^{3} x\cdot\tfrac{1}{4}\,\mathrm{d}x \overset{(2)}{=} \tfrac{1}{4}\Big[\tfrac{x^2}{2}\Big]_{-1}^{3} = \tfrac{1}{4}\cdot\tfrac{9-1}{2} = 1.$$

(1) (1.40) with $f = \frac{1}{4}$ inside the interval and 0 outside.
(2) Antiderivative of x.

The mean is the midpoint, as symmetry demands. The same happens for the parabola $f(x) = 6x(1-x)$ on $[0,1]$ [Kruschke (4.7)]: $\mathbb{E}(X) = 6\int_0^1 (x^2 - x^3)\,\mathrm{d}x = 6\big(\frac{1}{3} - \frac{1}{4}\big) = \frac{1}{2}$.

Example: the mean lifetime. A lifetime with density $f(x) = e^{-x/\beta}/\beta$ for $x > 0$ (exponential with mean β, Section 1.9) has

$$\mathbb{E}(X) \overset{(1)}{=} \int_0^\infty x\,\frac{e^{-x/\beta}}{\beta}\,\mathrm{d}x \overset{(2)}{=} \beta\int_0^\infty u\,e^{-u}\,\mathrm{d}u$$
$$\overset{(3)}{=} \beta\Big(\big[-u\,e^{-u}\big]_0^\infty + \int_0^\infty e^{-u}\,\mathrm{d}u\Big) \overset{(4)}{=} \beta\,(0+1) = \beta.$$

(1) Definition (1.40); the density vanishes for $x < 0$.
(2) Substitute $u = x/\beta$, so $x = \beta u$ and $\mathrm{d}x = \beta\,\mathrm{d}u$.
(3) Integrate by parts with u differentiated and e^{-u} integrated.
(4) $ue^{-u} \to 0$ at both ends, and $\int_0^\infty e^{-u}\mathrm{d}u = 1$.

So β really is the mean lifetime, and the median $\beta\ln 2$ found in Example 1.34 sits below it.

The balance point. If we read $f(x)$ as a mass density along a rod (or as point masses $f(x_i)$ at positions x_i), then $\mathbb{E}(X) = \sum_i x_i f(x_i)$ with $\sum_i f(x_i) = 1$ is the centre of mass: the rod balances on a fulcrum placed at the mean (Figure 1.38). A small mass far out in a tail pulls the balance point a long way. This is why the mean of a skewed distribution is dragged towards its long tail, and why a single outlier can move a sample mean a lot.

Example: a density with no mean. The Cauchy density $f(x) = 1/[\pi(1+x^2)]$ is the Breit–Wigner (Lorentzian) line shape of a resonance with unit half-width, centred at 0. It is symmetric, so one is tempted to say its mean is 0. But the mean exists only if $\int |x|\, f(x)\,\mathrm{d}x$ is finite, and

$$\int_{-\infty}^{\infty} \frac{|x|}{\pi(1+x^2)}\,\mathrm{d}x \overset{(1)}{=} \frac{2}{\pi}\int_0^\infty \frac{x}{1+x^2}\,\mathrm{d}x \overset{(2)}{=} \frac{1}{\pi}\Big[\ln(1+x^2)\Big]_0^\infty = \infty.$$

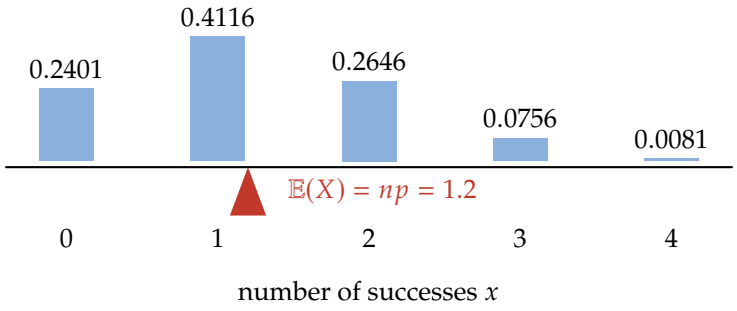

Figure 1.38: The pmf of a binomial with $n = 4$, $p = 0.3$, drawn as masses on a rod. The rod balances on the red fulcrum at $x = 1.2$, which is the mean. The mean is not one of the possible values, and it lies to the right of the most probable value $x = 1$ because the tail extends to the right.

(1) The integrand is even, so the integral is twice the integral over $x > 0$.
(2) $\frac{\mathrm{d}}{\mathrm{d}x}\ln(1+x^2) = \frac{2x}{1+x^2}$, and the logarithm grows without bound.

([Wasserman Ex. 3.5, p. 48] reaches the same conclusion by parts.) The tails fall only like $1/x^2$, so $xf(x) \sim 1/(\pi x)$ and the integral diverges logarithmically. The positive and negative halves are each infinite, and "$\infty - \infty$" has no value. This is not a mathematical curiosity. In a simulation the running average never settles down: every so often a draw from far out in a tail arrives and moves the average by a finite amount, however many draws came before (Figure 1.39, the computer experiment of [Wasserman Exercise 3.9, p. 59]). After 10^4 draws the four Gaussian averages are all within 0.022 of zero, while the four Cauchy averages lie between 0.28 and 1.21 in absolute value and are still jumping. Section 1.14 will show the reason: the average of n Cauchy draws has exactly the same Cauchy distribution as a single draw.

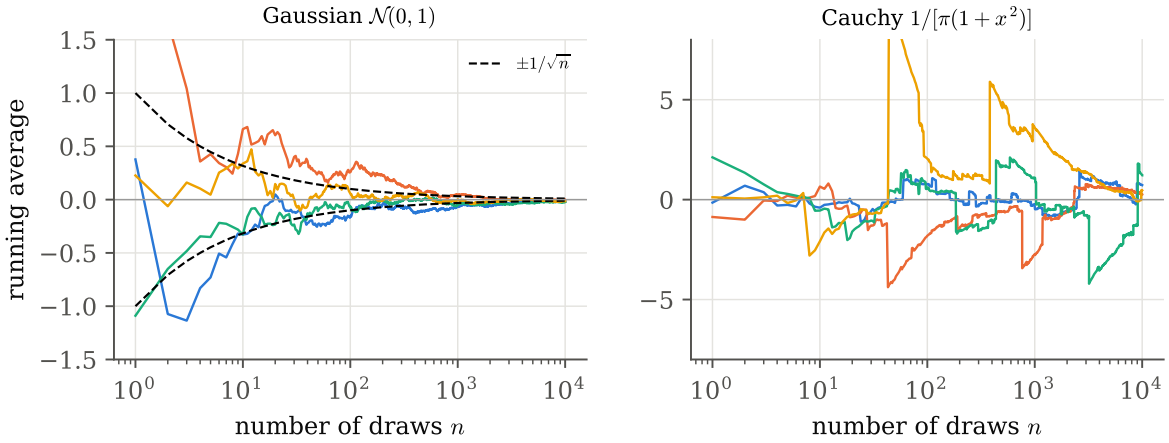

Figure 1.39: Running averages of four independent sequences of draws, on a logarithmic axis in n. Left: Gaussian draws; the averages close in on zero inside the dashed $\pm 1/\sqrt{n}$ envelope. Right: Cauchy draws; the averages wander and jump whenever a very large draw arrives, and do not converge.

From here on, whenever we write an expectation we assume it exists.

1.12.2 The average of a function: the lazy statistician

Often we want the mean of $Y = r(X)$: the kinetic energy $\frac{1}{2}mv^2$ of a molecule with random velocity, the flux $10^{-0.4m}$ of a star of random magnitude, the p_T of a decay product at a random angle. One route is to find f_Y by the change-of-variables rules of Section 1.11 and average y

against it. There is a much easier way [Wasserman Thm. 3.6, p. 48]:

$$\mathbb{E}\big(r(X)\big) = \sum_x r(x)\, f_X(x) \quad \text{or} \quad \mathbb{E}\big(r(X)\big) = \int r(x)\, f_X(x)\, \mathrm{d}x. \tag{1.41}$$

It is called the rule of the lazy statistician because it looks like what a lazy person would write without thinking, and it is right. Think of a game in which X is drawn and we are paid $r(X)$: our average income is each payment $r(x)$ times the chance of that x, summed.

Why does it hold? For discrete X [Wasserman Exercise 3.6, p. 59], group the values of x according to the value $y = r(x)$ they produce:

$$\mathbb{E}(Y) \overset{(1)}{=} \sum_y y\ \mathrm{P}(Y = y) \overset{(2)}{=} \sum_y y \sum_{x:\, r(x)=y} f_X(x) \overset{(3)}{=} \sum_y \sum_{x:\, r(x)=y} r(x)\, f_X(x) \overset{(4)}{=} \sum_x r(x)\, f_X(x).$$

(1) Definition (1.40) applied to Y.
(2) $\mathrm{P}(Y = y)$ is the total mass of all preimages of y (Section 1.11).
(3) Inside the inner sum $r(x) = y$, so y may be replaced by $r(x)$.
(4) Every x lies in exactly one set $\{x : r(x) = y\}$, so the double sum visits each x once.

For continuous X and increasing r with inverse s, the same thing happens with a Jacobian:

$$\mathbb{E}(Y) \overset{(1)}{=} \int y\, f_X\big(s(y)\big)\, s'(y)\, \mathrm{d}y \overset{(2)}{=} \int r(x)\, f_X(x)\, \mathrm{d}x.$$

(1) Definition of $\mathbb{E}(Y)$ with f_Y from (1.33).
(2) Substitute $x = s(y)$, so $y = r(x)$ and $\mathrm{d}x = s'(y)\, \mathrm{d}y$.

The Jacobian in the density is exactly cancelled by the Jacobian of the measure. In the fluid picture: $f_Y(y)\, \mathrm{d}y = f_X(x)\, \mathrm{d}x$ is the same drop of probability, and we multiply it by the same number $y = r(x)$ whichever coordinate we use [Cowan (1.40)]. A decreasing r or several branches give the same result branch by branch.

The most important special case is an indicator. Let $r = I_A$, the indicator of a set A ($I_A(x) = 1$ if $x \in A$ and 0 otherwise). Then

$$\mathbb{E}\big(I_A(X)\big) = \int I_A(x) f_X(x)\, \mathrm{d}x = \int_A f_X(x)\, \mathrm{d}x = \mathrm{P}(X \in A). \tag{1.42}$$

Probability is a special case of expectation. This is how every Monte Carlo estimate of a probability works (Chapter 6): the fraction of simulated draws that land in A is the sample mean of an indicator.

Example: $\mathbb{E}(e^X)$ two ways. Let $X \sim \mathrm{Uniform}(0, 1)$ and $Y = e^X$ [Wasserman Ex. 3.7, p. 49]. By (1.41), $\mathbb{E}(Y) = \int_0^1 e^x\, \mathrm{d}x = e - 1$. The long way first finds f_Y: the inverse is $s(y) = \ln y$ with $s'(y) = 1/y$, so (1.33) gives $f_Y(y) = 1/y$ on $(1, e)$, and $\mathbb{E}(Y) = \int_1^e y \cdot \frac{1}{y}\, \mathrm{d}y = e - 1$. Same answer, more work. A simulation with 10^6 draws gives 1.7189 (exact 1.7183). Note that $e^{\mathbb{E}(X)} = e^{1/2} = 1.649$ is *not* the answer.

Example: the broken stick. Break a stick of unit length at a uniformly random point X and keep the longer piece, $Y = \max\{X, 1 - X\}$ [Wasserman Ex. 3.8, p. 49]. On $x < \frac{1}{2}$ the longer piece is $1 - x$, on $x \geq \frac{1}{2}$ it is x:

$$\mathbb{E}(Y) \overset{(1)}{=} \int_0^{1/2} (1 - x)\, \mathrm{d}x + \int_{1/2}^1 x\, \mathrm{d}x \overset{(2)}{=} \left(\tfrac{1}{2} - \tfrac{1}{8}\right) + \left(\tfrac{1}{2} - \tfrac{1}{8}\right) = \tfrac{3}{4}.$$

(1) (1.41) with the density 1 on $(0,1)$, split where r changes formula.
(2) $\int_0^{1/2}(1-x)\mathrm{d}x = \frac{1}{2} - \frac{1}{8}$, and $\int_{1/2}^1 x\,\mathrm{d}x = \frac{1}{2} - \frac{1}{8}$.

The simulation gives 0.7498.

Example: time average and ensemble average for the oscillator. For the oscillator $x(t) = A\cos\omega t$ of Section 1.11.3 we can compute $\langle x^2\rangle$ in two ways. As an average over the position density $f(x) = 1/(\pi\sqrt{A^2-x^2})$:

$$\mathbb{E}(X^2) \overset{(1)}{=} \int_{-A}^{A} \frac{x^2}{\pi\sqrt{A^2-x^2}}\,\mathrm{d}x \overset{(2)}{=} \frac{1}{\pi}\int_{-\pi/2}^{\pi/2} \frac{A^2\sin^2\varphi}{A\cos\varphi}\,A\cos\varphi\,\mathrm{d}\varphi \overset{(3)}{=} \frac{A^2}{\pi}\cdot\frac{\pi}{2} = \frac{A^2}{2}.$$

(1) (1.41) with $r(x) = x^2$.
(2) Substitute $x = A\sin\varphi$: $\mathrm{d}x = A\cos\varphi\,\mathrm{d}\varphi$ and $\sqrt{A^2-x^2} = A\cos\varphi \geq 0$ on $[-\frac{\pi}{2}, \frac{\pi}{2}]$.
(3) $\int_{-\pi/2}^{\pi/2}\sin^2\varphi\,\mathrm{d}\varphi = \frac{\pi}{2}$ (the average of $\sin^2$ over a half period is $\frac{1}{2}$).

As an average over the uniform time T on one period $P = 2\pi/\omega$, again by (1.41) but now with $X = r(T)$: $\mathbb{E}(X^2) = \frac{1}{P}\int_0^P A^2\cos^2\omega t\,\mathrm{d}t = \frac{A^2}{2}$. The ensemble average over positions equals the time average over one period, a small instance of the ergodic idea that returns with Markov chains in Chapter 9. Multiplied by $\frac{1}{2}m\omega^2$ it says that the mean potential energy is half the total energy. The simulation with $A = 1$ gives 0.4995.

The rule extends to several variables [Wasserman (3.4), p. 49],

$$\mathbb{E}\big(r(X,Y)\big) = \iint r(x,y)\,f(x,y)\,\mathrm{d}x\,\mathrm{d}y.$$

For (X,Y) uniform on the unit square, $\mathbb{E}(X^2+Y^2) = \int_0^1\int_0^1 (x^2+y^2)\,\mathrm{d}x\,\mathrm{d}y = \frac{1}{3}+\frac{1}{3} = \frac{2}{3}$ [Wasserman Ex. 3.9, p. 49].

Watch out: The average of a function is not the function of the average

In general $\mathbb{E}\big(r(X)\big) \neq r\big(\mathbb{E}\,X\big)$: above, $\mathbb{E}(e^X) = 1.718$ but $e^{\mathbb{E}\,X} = 1.649$. Equality holds for linear r only. For a convex r (curving upwards, like x^2 or e^x) the inequality always runs one way, $\mathbb{E}\,r(X) \geq r(\mathbb{E}\,X)$ (Jensen's inequality, [CasellaBerger Thm. 4.7.7]), which is why $\langle v^2\rangle \geq \langle v\rangle^2$. Averaging magnitudes and then converting to flux, or averaging $\ln\mathcal{L}$ and exponentiating, gives biased answers for the same reason.

1.12.3 Linearity, and products of independent variables

The single most useful property of the expectation is that it is linear, whether or not the variables are independent [Wasserman Thm. 3.11, p. 50]. For two continuous variables with joint density $f(x,y)$:

$$\begin{aligned}\mathbb{E}(aX+bY) &\overset{(1)}{=} \iint (ax+by)\,f(x,y)\,\mathrm{d}x\,\mathrm{d}y\\ &\overset{(2)}{=} a\int x\Big[\int f(x,y)\,\mathrm{d}y\Big]\mathrm{d}x + b\int y\Big[\int f(x,y)\,\mathrm{d}x\Big]\mathrm{d}y\\ &\overset{(3)}{=} a\int x\,f_X(x)\,\mathrm{d}x + b\int y\,f_Y(y)\,\mathrm{d}y \overset{(4)}{=} a\,\mathbb{E}(X) + b\,\mathbb{E}(Y).\end{aligned}$$

(1) The lazy statistician for two variables, with $r(x,y) = ax+by$.

(2) Split the integral into two and do the inner integral over the variable that does not appear in front.
(3) The inner integrals are the marginal densities (Section 1.10).
(4) Definition (1.40).

No independence was used: marginalisation did all the work. By induction, $\mathbb{E}\big(\sum_i a_i X_i\big) = \sum_i a_i \,\mathbb{E}(X_i)$ for any number of variables, and $\mathbb{E}(aX + b) = a\,\mathbb{E}(X) + b$ because a constant is a variable with all its mass at one point.

Example: the binomial mean by indicators. The definition gives $\mathbb{E}(X) = \sum_{x=0}^{n} x \binom{n}{x} p^x (1-p)^{n-x}$, which is not an inviting sum. Instead write the number of successes as a sum of indicators, $X = \sum_{i=1}^{n} X_i$ with $X_i = 1$ if trial i succeeds [Wasserman Ex. 3.12, p. 50]. Each $\mathbb{E}(X_i) = p$, so linearity gives

$$\mathbb{E}(X) = \sum_{i=1}^{n} \mathbb{E}(X_i) = np.$$

This is the exact value 5 that the simulation of Section 1.8 found as 4.997 for ten fair flips. Linearity turned a combinatorial sum into one line. The same trick gives the mean count of any multinomial bin, $\mathbb{E}(X_j) = np_j$.

Example: the mean of the smeared energy. In the detector example of Example 1.43 the measured energy is $E_{\text{meas}} = E + \varepsilon$, the true energy plus a Gaussian error with mean 0. Linearity gives $\mathbb{E}(E_{\text{meas}}) = \mathbb{E}(E) + \mathbb{E}(\varepsilon) = \beta + 0 = 20\,\text{GeV}$ without touching the convolution integral (1.32). The simulation found 19.99 GeV.

For products the situation is different. If X and Y are independent then $f(x, y) = f_X(x) f_Y(y)$ and [Wasserman Thm. 3.13, p. 50]

$$\mathbb{E}(XY) \overset{(1)}{=} \iint xy\, f_X(x) f_Y(y)\,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} \Big(\int x\, f_X(x)\,\mathrm{d}x\Big)\Big(\int y\, f_Y(y)\,\mathrm{d}y\Big) = \mathbb{E}(X)\;\mathbb{E}(Y). \tag{1.43}$$

(1) Lazy statistician with $r = xy$, and the factorised joint density.
(2) The integrand is a function of x times a function of y, so the double integral is a product of single integrals.

The same argument gives, for any functions g and h [CasellaBerger Thm. 4.2.10],

$$\mathbb{E}\big(g(X)h(Y)\big) = \mathbb{E}\big(g(X)\big)\;\mathbb{E}\big(h(Y)\big)$$

([SeeingTheory p. 32] gives the discrete version). Without independence it fails: if $X = Y$ is a fair coin indicator then $\mathbb{E}(XY) = \mathbb{E}(X^2) = \frac{1}{2}$, while $\mathbb{E}(X)\,\mathbb{E}(Y) = \frac{1}{4}$.

Key idea: What expectation respects

$\mathbb{E}\big(\sum_i a_i X_i + b\big) = \sum_i a_i\,\mathbb{E}(X_i) + b$ always. The mean of a product is the product of the means when the variables are independent, and not in general.

1.12.4 The mean as the best single guess

Suppose we must summarise X by one number b and we are penalised by the squared miss $(X - b)^2$. Which b minimises the expected penalty? Adding and subtracting $\mu = \mathbb{E}\,X$ answers it

without calculus [CasellaBerger Ex. 2.2.6]:

$$\begin{aligned}\mathbb{E}(X-b)^2 &\overset{(1)}{=} \mathbb{E}\big[(X-\mu)+(\mu-b)\big]^2 \\ &\overset{(2)}{=} \mathbb{E}(X-\mu)^2 + 2(\mu-b)\,\mathbb{E}(X-\mu) + (\mu-b)^2 \\ &\overset{(3)}{=} \mathbb{E}(X-\mu)^2 + (\mu-b)^2. \end{aligned} \tag{1.44}$$

(1) Add and subtract μ inside the bracket.
(2) Expand the square and use linearity; $\mu - b$ is a constant and comes out of the expectation.
(3) $\mathbb{E}(X-\mu) = \mathbb{E}\,X - \mu = 0$.

The first term does not depend on b and the second is smallest, zero, at $b = \mu$. So the mean is the best guess under squared loss, and the smallest achievable expected squared miss is $\mathbb{E}(X-\mu)^2$, which is the variance we define next [Kruschke §4.3.3.1]. Equation (1.44) is a Pythagoras theorem: total squared miss = spread about the mean + squared offset of the guess. It returns in Chapter 3 as "mean squared error = variance + bias^2".

If the penalty is the absolute miss $|X - M|$, the best guess is the median instead. Write $\mathbb{E}\,|X-M| = \int_{-\infty}^{M}(M-x)f(x)\,\mathrm{d}x + \int_{M}^{\infty}(x-M)f(x)\,\mathrm{d}x$ and differentiate in M:

$$\frac{\mathrm{d}}{\mathrm{d}M}\,\mathbb{E}\,|X-M| \overset{(1)}{=} \int_{-\infty}^{M} f(x)\,\mathrm{d}x - \int_{M}^{\infty} f(x)\,\mathrm{d}x \overset{(2)}{=} F(M) - \big(1-F(M)\big) = 2F(M) - 1.$$

(1) Leibniz rule. The boundary terms vanish because each integrand is zero at $x = M$, leaving the derivatives $+1$ and -1 of the integrands.
(2) Definition of the CDF F (Section 1.9).

The derivative is negative for $F(M) < \frac{1}{2}$ and positive after, so the minimum is at $F(M) = \frac{1}{2}$, the median. With a penalty of 0 for an exact hit and 1 for any miss, the best guess is the mode. These three loss functions reappear in Chapter 5, where they turn a posterior into the posterior mean, median and mode. Figure 1.40 checks the first two for an exponential with $\beta = 1$: the simulated squared loss is smallest at $M = 1.00$ (exact 1), where it equals 0.996 (the variance, exact 1), and the absolute loss is smallest at $M = 0.69$ (exact $\ln 2 = 0.693$).

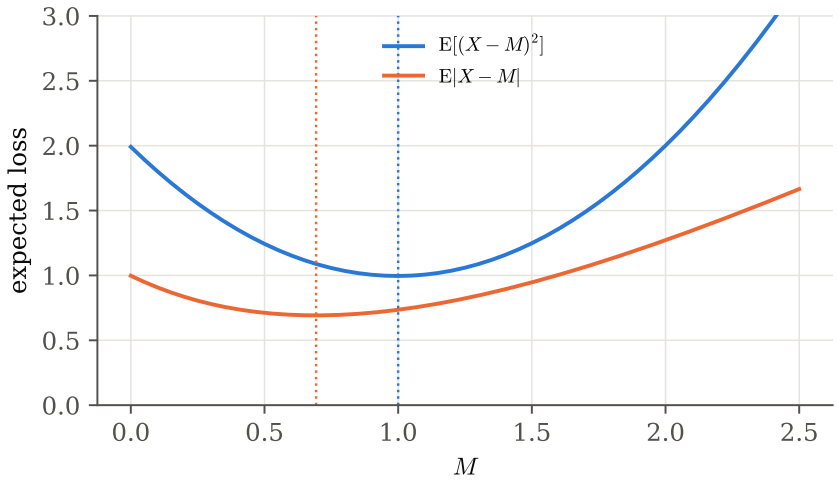

Figure 1.40: Expected squared miss and expected absolute miss of a guess M for exponential lifetimes with mean 1, computed by averaging over simulated draws. The squared miss bottoms out at the mean (blue dotted line), the absolute miss at the median $\ln 2$ (orange dotted line). The height of the blue minimum is the variance.

1.12.5 Variance and standard deviation

The mean says where a distribution sits. We also need how wide it is. The obvious candidate, the average deviation $\mathbb{E}(X-\mu)$, is useless: it is always $\mathbb{E}\,X-\mu=0$, because positive and negative deviations cancel by the definition of μ [Wasserman p. 50, footnote]. The average absolute deviation $\mathbb{E}\,|X-\mu|$ works but is awkward algebraically. The average *squared* deviation is the standard choice, and (1.44) has already shown why it is natural.

Working definition 1.23 (variance, standard deviation)

The **variance** of X is the mean squared deviation from the mean,

$$\operatorname{Var}(X)=\sigma^2=\mathbb{E}\big[(X-\mu)^2\big]=\int (x-\mu)^2 f(x)\,\mathrm{d}x, \tag{1.45}$$

[units of X squared]. The **standard deviation** is $\sigma=\sqrt{\operatorname{Var}(X)}$ [same units as X, a typical size of $X-\mu$]. *Operational test:* the average of $(X_j-\bar X)^2$ over many draws.

Three properties do most of the work [Wasserman Thm. 3.15, p. 51]. First, the shortcut formula:

$$\operatorname{Var}(X)\overset{(1)}{=}\mathbb{E}\big[X^2-2\mu X+\mu^2\big]\overset{(2)}{=}\mathbb{E}(X^2)-2\mu\,\mathbb{E}(X)+\mu^2\overset{(3)}{=}\mathbb{E}(X^2)-\mu^2. \tag{1.46}$$

(1) Expand the square in (1.45).
(2) Linearity; μ is a constant.
(3) $\mathbb{E}(X)=\mu$, so $-2\mu^2+\mu^2=-\mu^2$.

Second, shifting does nothing and scaling scales: $\operatorname{Var}(aX+b)=\mathbb{E}\big[(aX+b-a\mu-b)^2\big]=a^2\,\mathbb{E}(X-\mu)^2=a^2\operatorname{Var}(X)$. Third, $\operatorname{Var}(X)\ge 0$, with equality only when X equals a constant with probability one, since a non-negative quantity $(X-\mu)^2$ can have zero mean only if it is zero with probability one [Wasserman Exercise 3.2, p. 59].

Example: Bernoulli, die, uniform, exponential. For a Bernoulli trial $X^2=X$, so $\mathbb{E}(X^2)=p$ and $\operatorname{Var}(X)=p-p^2=p(1-p)$, largest for a fair coin and zero when the outcome is certain. For a fair die

$$\operatorname{Var}(X)=\mathbb{E}(X^2)-\mu^2=\tfrac{1}{6}(1+4+9+16+25+36)-3.5^2=\tfrac{91}{6}-\tfrac{49}{4}=\tfrac{35}{12}\approx 2.92$$

[SeeingTheory p. 14].[4] For $X\sim\text{Uniform}(a,b)$:

$$\operatorname{Var}(X)\overset{(1)}{=}\frac{1}{b-a}\int_a^b x^2\,\mathrm{d}x-\left(\frac{a+b}{2}\right)^2\overset{(2)}{=}\frac{a^2+ab+b^2}{3}-\frac{a^2+2ab+b^2}{4}\overset{(3)}{=}\frac{(b-a)^2}{12}.$$

(1) Shortcut (1.46), with density $1/(b-a)$ and mean $(a+b)/2$.
(2) $\int_a^b x^2\mathrm{d}x=(b^3-a^3)/3=(b-a)(a^2+ab+b^2)/3$.
(3) Common denominator 12: $4a^2+4ab+4b^2-3a^2-6ab-3b^2=(b-a)^2$.

A physicist meets this constantly: a silicon strip detector of pitch w that records only which strip fired localises a track uniformly within the strip, so its position resolution is $w/\sqrt{12}$. For the exponential, $\mathbb{E}(X^2)=\beta^2\int_0^\infty u^2e^{-u}\mathrm{d}u=2\beta^2$ (parts twice), so $\operatorname{Var}(X)=2\beta^2-\beta^2=\beta^2$: the standard deviation of a lifetime equals its mean.

[4] Seeing Theory writes the variance as "$E[(X-EX)]^2$" in this exercise and as "$E(X^2)-E(X)$" in Proposition 0.0.1(c) on p. 12; both should read $E[(X-EX)^2]=E(X^2)-(EX)^2$, as in its own proof.

For a sum, expand the square. With $\mu_X = \mathbb{E}\,X$, $\mu_Y = \mathbb{E}\,Y$:

$$\begin{aligned}\operatorname{Var}(X+Y) &\overset{(1)}{=} \mathbb{E}\big[(X-\mu_X)+(Y-\mu_Y)\big]^2 \\ &\overset{(2)}{=} \operatorname{Var}(X)+\operatorname{Var}(Y)+2\,\mathbb{E}\big[(X-\mu_X)(Y-\mu_Y)\big] \\ &\overset{(3)}{=} \operatorname{Var}(X)+\operatorname{Var}(Y) \qquad (X, Y \text{ independent}).\end{aligned} \tag{1.47}$$

(1) The mean of $X+Y$ is $\mu_X+\mu_Y$ by linearity.
(2) Expand and use linearity.
(3) For independent variables (1.43) with $g(X) = X-\mu_X$, $h(Y) = Y-\mu_Y$ gives $\mathbb{E}(X-\mu_X)\,\mathbb{E}(Y-\mu_Y) = 0\cdot 0$.

The cross term is the covariance, the subject of Section 1.13. For independent variables it vanishes and variances add, so that $\operatorname{Var}\big(\sum_i a_i X_i\big) = \sum_i a_i^2 \operatorname{Var}(X_i)$ [Wasserman (3.8), p. 51]. Standard deviations do not add; they add *in quadrature*. Every "add the errors in quadrature" in a laboratory is this line, valid when the error sources are independent.

Example: the binomial variance, and the smeared spectrum. With $X = \sum_i X_i$ a sum of n independent indicators, each with variance $p(1-p)$, we get $\operatorname{Var}(X) = np(1-p)$ [Wasserman Ex. 3.16, p. 51]. It vanishes for $p = 0$ or $p = 1$, where every trial has a certain outcome. For the smeared energy $E_{\text{meas}} = E + \varepsilon$ the detector error does not depend on the true energy, so $\operatorname{Var}(E_{\text{meas}}) = \operatorname{Var}(E) + \operatorname{Var}(\varepsilon) = \beta^2 + \sigma^2 = 400 + 25 = 425\,\text{GeV}^2$, as the simulation of Example 1.43 found (425.0). The detector resolution adds in quadrature to the intrinsic width of the spectrum.

1.12.6 The sample mean and the sample variance

In practice we do not know μ and σ^2. We have n independent draws $X_1, \dots, X_n$ from the same distribution (an iid sample, Section 1.10) and form the **sample mean** and the **sample variance** [Wasserman (3.9)–(3.10), p. 51],

$$\bar{X}_n = \frac{1}{n}\sum_{i=1}^{n} X_i, \qquad S_n^2 = \frac{1}{n-1}\sum_{i=1}^{n}\big(X_i - \bar{X}_n\big)^2. \tag{1.48}$$

They are functions of the data, so they are random variables with their own distributions. A function of the data is called a **statistic**, and its distribution over repeated experiments is its **sampling distribution** [Wasserman Exercise 3.19, p. 61]. In the chain from a physical model to inferred physics, this is the step "construct a summary S, then derive its sampling distribution $P(S \mid \theta)$", in its simplest form. The rules above already give the first two moments [Wasserman Thm. 3.17, p. 52]:

$$\begin{aligned}\mathbb{E}(\bar{X}_n) &\overset{(1)}{=} \frac{1}{n}\sum_{i=1}^{n}\mathbb{E}(X_i) = \mu, \\ \operatorname{Var}(\bar{X}_n) &\overset{(2)}{=} \frac{1}{n^2}\sum_{i=1}^{n}\operatorname{Var}(X_i) = \frac{\sigma^2}{n}.\end{aligned} \tag{1.49}$$

(1) Linearity.
(2) The draws are independent, so variances add, and each carries the factor $(1/n)^2$ from scaling.

The spread of the sample mean shrinks like $\sigma/\sqrt{n}$, the **standard error of the mean**: four times the data halves the error bar. For the sample variance we need $\mathbb{E}\big[\sum_i (X_i - \bar{X})^2\big]$:

$$\mathbb{E}\Big[\sum_{i=1}^{n}(X_i-\bar{X})^2\Big] \overset{(1)}{=} \mathbb{E}\Big[\sum_{i=1}^{n} X_i^2 - n\bar{X}^2\Big] \overset{(2)}{=} n\,\mathbb{E}(X_1^2) - n\,\mathbb{E}(\bar{X}^2)$$
$$\overset{(3)}{=} n(\sigma^2+\mu^2) - n\Big(\frac{\sigma^2}{n}+\mu^2\Big) = (n-1)\,\sigma^2.$$

(1) Expand: $\sum_i (X_i - \bar{X})^2 = \sum_i X_i^2 - 2\bar{X}\sum_i X_i + n\bar{X}^2$, and $\sum_i X_i = n\bar{X}$.
(2) Linearity; all X_i have the same distribution.
(3) The shortcut (1.46) read backwards, $\mathbb{E}(Z^2) = \mathrm{Var}(Z) + (\mathbb{E}\,Z)^2$, for $Z = X_1$ and for $Z = \bar{X}$ using (1.49).

Dividing by $n-1$ therefore gives $\mathbb{E}(S_n^2) = \sigma^2$. Why $n-1$ and not n? The deviations are measured from $\bar{X}$, which is computed from the same data. By (1.44) applied to the n data points, the sample mean is the point that makes $\sum_i (X_i - b)^2$ as small as possible. So deviations from $\bar{X}$ are systematically smaller than deviations from the true μ, by exactly one draw's worth of variance. In Python, `np.var(x)` divides by n unless one passes `ddof=1`, while `np.cov` divides by $n-1$ by default.

1.12.7 Conditional expectation and the law of total variance

What is the mean of Y among those experiments in which $X = x$? Compute the mean as before, but with the conditional density $f(y \mid x)$ of Section 1.10 in place of $f_Y(y)$ [Wasserman Def. 3.22, p. 54]:[5]

$$\mathbb{E}(Y \mid X = x) = \int y\, f(y \mid x)\,\mathrm{d}y \quad \Big(\text{or } \sum_y y\, f(y \mid x)\Big). \tag{1.50}$$

Similarly $\mathbb{E}\big(r(X,Y) \mid X = x\big) = \int r(x,y) f(y \mid x)\,\mathrm{d}y$. The result is a number for each x, that is, a function of x. Before X is observed we do not know which number it will be, so $\mathbb{E}(Y \mid X)$, the function evaluated at the random X, is itself a random variable. This is the subtle point of the definition [Wasserman p. 54, Warning]. $\mathbb{E}(Y)$ is a number, $\mathbb{E}(Y \mid X = x)$ is a function, and $\mathbb{E}(Y \mid X)$ is a random variable. Physically, $\mathbb{E}(Y \mid X = x)$ is the curve through the middle of the scatter plot of Y against X, the regression curve. Figure 1.44 traces it by binning.

Example: a two-stage draw. Draw $X \sim \mathrm{Uniform}(0,1)$ and then $Y \mid X = x \sim \mathrm{Uniform}(x,1)$ [Wasserman Ex. 3.23, p. 54]. The conditional density is $1/(1-x)$ on $(x,1)$, so

$$\mathbb{E}(Y \mid X = x) \overset{(1)}{=} \int_x^1 \frac{y}{1-x}\,\mathrm{d}y \overset{(2)}{=} \frac{1}{1-x}\cdot\frac{1-x^2}{2} \overset{(3)}{=} \frac{1+x}{2},$$

(1) (1.50) with the uniform conditional density.
(2) $\int_x^1 y\,\mathrm{d}y = (1-x^2)/2$.
(3) $1 - x^2 = (1-x)(1+x)$.

the midpoint of $(x,1)$, as it must be. So $\mathbb{E}(Y \mid X) = (1+X)/2$, a random variable.

Averaging the conditional mean over X gives back the unconditional mean. This is the **law of iterated expectations** [Wasserman Thm. 3.24, p. 55]:

$$\mathbb{E}\big[\mathbb{E}(Y \mid X)\big] \overset{(1)}{=} \int \Big[\int y\, f(y \mid x)\,\mathrm{d}y\Big] f_X(x)\,\mathrm{d}x \overset{(2)}{=} \iint y\, f(x,y)\,\mathrm{d}y\,\mathrm{d}x \overset{(3)}{=} \mathbb{E}(Y). \tag{1.51}$$

[5] [Wasserman (3.13)–(3.14), p. 54] has a stray "dx" after the two discrete sums; there is no integral in the discrete case.

(1) The outer expectation of the function $x \mapsto \mathbb{E}(Y \mid X = x)$, by the lazy statistician.
(2) Product rule $f(y \mid x) f_X(x) = f(x, y)$ (1.29).
(3) Lazy statistician with $r(x, y) = y$.

It is the law of total probability of Section 1.5 for averages: the overall mean is the mean in each branch weighted by the probability of the branch. For the two-stage draw, $\mathbb{E}(Y) = \mathbb{E}\big[(1 + X)/2\big] = (1 + \frac{1}{2})/2 = \frac{3}{4}$ [Wasserman Ex. 3.25, p. 55], with no joint density needed. A useful companion rule: anything already known given X comes out of the conditional expectation, $\mathbb{E}\big(r(X)s(Y) \mid X\big) = r(X)\, \mathbb{E}\big(s(Y) \mid X\big)$ [Wasserman Exercise 3.16, p. 60].

The spread splits in the same way. The **conditional variance** is [Wasserman Def. 3.26, p. 55]

$$\operatorname{Var}(Y \mid X = x) = \int \big(y - \mu(x)\big)^2 f(y \mid x)\, \mathrm{d}y, \qquad \mu(x) = \mathbb{E}(Y \mid X = x).$$

Then [CasellaBerger Thm. 4.4.7]

$$\begin{aligned} \operatorname{Var}(Y) &\overset{(1)}{=} \mathbb{E}\big[(Y - \mu(X)) + (\mu(X) - \mathbb{E}\,Y)\big]^2 \\ &\overset{(2)}{=} \mathbb{E}\big[(Y - \mu(X))^2\big] + \mathbb{E}\big[(\mu(X) - \mathbb{E}\,Y)^2\big] + 2\,\mathbb{E}\big[(Y - \mu(X))(\mu(X) - \mathbb{E}\,Y)\big] \\ &\overset{(3)}{=} \mathbb{E}\big[\operatorname{Var}(Y \mid X)\big] + \operatorname{Var}\big[\mathbb{E}(Y \mid X)\big] + 0. \end{aligned} \tag{1.52}$$

(1) Add and subtract $\mu(X) = \mathbb{E}(Y \mid X)$.
(2) Expand the square; linearity.
(3) First term: iterate, $\mathbb{E}[(Y - \mu(X))^2] = \mathbb{E}\big[\mathbb{E}\big((Y - \mu(X))^2 \mid X\big)\big] = \mathbb{E}[\operatorname{Var}(Y \mid X)]$. Second term: $\mu(X)$ has mean $\mathbb{E}\,Y$ by (1.51), so this is its variance. Third term: iterate again; given X the factor $\mu(X) - \mathbb{E}\,Y$ is known and comes out, leaving $\mathbb{E}\big(Y - \mu(X) \mid X\big) = \mu(X) - \mu(X) = 0$.

This is the **law of total variance** [Wasserman Thm. 3.27, p. 55]: the total spread is the average spread within each group plus the spread of the group means. A detector with a stable resolution but a calibration that drifts from run to run shows exactly this: within-run scatter plus run-to-run scatter of the mean response.

Example: counts with a random efficiency. A pixel counts how many of $n = 20$ photons it detects. Its efficiency Q is not known and varies from pixel to pixel, uniformly on $(0, 1)$ for the sake of the example; given $Q = q$ the count is $K \mid Q = q \sim \text{Binomial}(n, q)$. ([Wasserman Ex. 3.28, p. 56] tells the same story with counties and a disease rate.) A model built in stages like this is a **hierarchical model**. Then $\mathbb{E}(K \mid Q) = nQ$ and $\operatorname{Var}(K \mid Q) = nQ(1 - Q)$, so

$$\begin{aligned} \mathbb{E}(K) &\overset{(1)}{=} \mathbb{E}(nQ) = \frac{n}{2}, \\ \operatorname{Var}(K) &\overset{(2)}{=} \mathbb{E}\big[nQ(1 - Q)\big] + \operatorname{Var}(nQ) \overset{(3)}{=} n\Big(\frac{1}{2} - \frac{1}{3}\Big) + \frac{n^2}{12} = \frac{n}{6} + \frac{n^2}{12}. \end{aligned}$$

(1) Iterated expectations (1.51); $\mathbb{E}\,Q = \frac{1}{2}$.
(2) Law of total variance (1.52).
(3) $\mathbb{E}(Q) - \mathbb{E}(Q^2) = \frac{1}{2} - \frac{1}{3}$, and $\operatorname{Var}(nQ) = n^2 \operatorname{Var}(Q) = n^2/12$ from the uniform variance with $b - a = 1$.

For $n = 20$ this is 36.67, far larger than the variance $np(1 - p) = 5$ of a binomial with the same mean and a fixed efficiency of $\frac{1}{2}$. Most of the spread is the spread of the efficiencies, the $n^2/12$ term. The whole experiment takes three lines of Python:

Listing 1.16: A two-stage (hierarchical) draw (`code/ch01/16_expectation_checks.py`)

```
n = 20
Q = rng.uniform(size=N)
K = rng.binomial(n, Q)
K_plain = rng.binomial(n, 0.5, size=N)
var_exact = n / 6 + n**2 / 12
```

Line 31 draws one efficiency per pixel. Line 32 draws a binomial count *with that pixel's efficiency*: numpy broadcasts the array `Q`, so each count gets its own q. Line 33 is the comparison with a fixed efficiency. With 10^6 pixels the simulated mean is 9.997 (exact 10), the simulated variance is 36.67 (exact 36.67), and the fixed-efficiency variance is 4.998 (exact 5).

Figure 1.41 shows something more striking: the distribution of K is flat. To see why, marginalise the nuisance efficiency, exactly as in Section 1.10:

$$\mathrm{P}(K=k) \overset{(1)}{=} \int_0^1 \binom{n}{k} q^k (1-q)^{n-k}\,\mathrm{d}q \overset{(2)}{=} \binom{n}{k}\frac{k!\,(n-k)!}{(n+1)!} = \frac{1}{n+1}.$$

(1) Joint $= f(q)\ \mathrm{P}(K=k \mid q)$ with $f(q)=1$; integrate out q.

(2) The beta integral $I(a,b)=\int_0^1 q^a(1-q)^b\,\mathrm{d}q = \frac{a!\,b!}{(a+b+1)!}$. Integration by parts gives $I(a,b) = \frac{b}{a+1}I(a+1,b-1)$; repeating b times gives $I(a,b) = \frac{b!}{(a+1)\cdots(a+b)}\,I(a+b,0)$, and $I(a+b,0)=\frac{1}{a+b+1}$.

Every count from 0 to 20 has probability 1/21. The ignorance about Q has been passed on to K. In Chapter 5 the same calculation reappears as the *prior predictive* distribution of a binomial experiment with a flat prior on its success probability.

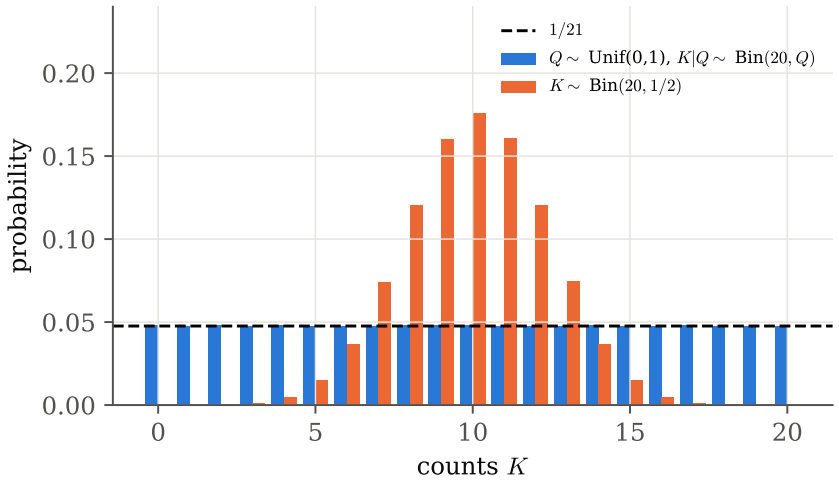

Figure 1.41: Counts out of 20 photons. Blue: each pixel has its own efficiency, drawn uniformly; the counts are spread evenly over $0,\ldots,20$ at the height 1/21 of the dashed line. Orange: every pixel has efficiency $\frac{1}{2}$; the counts crowd around 10. Both have mean 10, but the variances are 36.7 and 5.

The cross term $\mathbb{E}[(X-\mu_X)(Y-\mu_Y)]$ that appeared in the variance of a sum measures how two variables move together. Together with the averages and spreads above, it describes the *relation* between two variables at the level of second moments.

1.13 Covariance and correlation: how two variables move together

Two readout channels of a calorimeter sit on the same electronics board. Each channel records its own signal plus a common pedestal noise that the board adds to both: $X_1 = S_1 + N$ and $X_2 = S_2 + N$, with S_1, S_2 and N independent. Looked at one at a time, each channel is just a

noisy number. Looked at together, they tend to go up and down together, because whenever the pedestal N fluctuates high, both readings are pulled up. Nothing about the individual distributions reveals this. It is a property of the joint distribution, and the variance of a sum, (1.47), has already shown us the number that measures it: the cross term $\mathbb{E}\big[(X-\mu_X)(Y-\mu_Y)\big]$.

That number is the covariance. Its dimensionless version is the correlation coefficient. Both detect linear co-movement and miss everything else. For many variables the second moments collect into a covariance matrix, and a linear change of variables moves it by the rule $\mathbf{C}' = A\mathbf{C}A^{\mathsf{T}}$. Every error bar on a derived quantity, every Fisher forecast of Chapter 10 and every χ^2 of correlated band powers in Chapters 7 and 8 is built from this matrix. Three questions organise the topic.

1. How do we measure whether "X above its mean" goes with "Y above its mean"?
2. What does a zero value of that measure tell us, and what does it not?
3. For a vector of variables, how do the second moments change when we form linear combinations, and can we always find combinations that are uncorrelated?

1.13.1 Covariance and the correlation coefficient

Working definition 1.24 (covariance, correlation coefficient)

For X, Y with means μ_X, μ_Y and standard deviations σ_X, σ_Y, the **covariance** and the **correlation coefficient** are

$$\mathrm{Cov}(X,Y) = \mathbb{E}\big[(X-\mu_X)(Y-\mu_Y)\big], \qquad \rho_{XY} = \frac{\mathrm{Cov}(X,Y)}{\sigma_X\,\sigma_Y}. \tag{1.53}$$

Cov has the units of X times those of Y [positive if the two tend to be on the same side of their means]. ρ is a pure number between -1 and 1. *Operational test:* the average of $(x_j-\bar{x})(y_j-\bar{y})$ over many simulated pairs, `np.cov` and `np.corrcoef` in Python.

The definition is read off a scatter plot [Cowan pp. 18–19]. Put the origin at (μ_X, μ_Y) (Figure 1.42). A point in the upper-right or lower-left quadrant has deviations of the same sign, so its product $(x-\mu_X)(y-\mu_Y)$ is positive. A point in the other two quadrants contributes a negative product. The covariance is the probability-weighted balance of the two. A cloud tilted up to the right puts more mass in the positive quadrants and has Cov > 0. A cloud tilted down has Cov < 0. A cloud with as much mass in the negative quadrants as in the positive ones has Cov $= 0$, whatever its shape.

Expanding the product gives the form used in computation [Wasserman Thm. 3.19, p. 52]:

$$\begin{aligned}\mathrm{Cov}(X,Y) &\overset{(1)}{=} \mathbb{E}\big[XY - \mu_Y X - \mu_X Y + \mu_X\mu_Y\big] \\ &\overset{(2)}{=} \mathbb{E}(XY) - \mu_Y\mu_X - \mu_X\mu_Y + \mu_X\mu_Y = \mathbb{E}(XY) - \mathbb{E}(X)\,\mathbb{E}(Y).\end{aligned} \tag{1.54}$$

(1) Multiply out $(X-\mu_X)(Y-\mu_Y)$.
(2) Linearity; μ_X, μ_Y are constants.

With $Y = X$ this is the variance shortcut (1.46): $\mathrm{Cov}(X,X) = \mathrm{Var}(X)$. Constants shifted onto either variable drop out, and the covariance is linear in each argument separately:

$$\mathrm{Cov}\Big(\sum_i a_i X_i,\ \sum_j b_j Y_j\Big) = \sum_i \sum_j a_i b_j\ \mathrm{Cov}(X_i, Y_j) \tag{1.55}$$

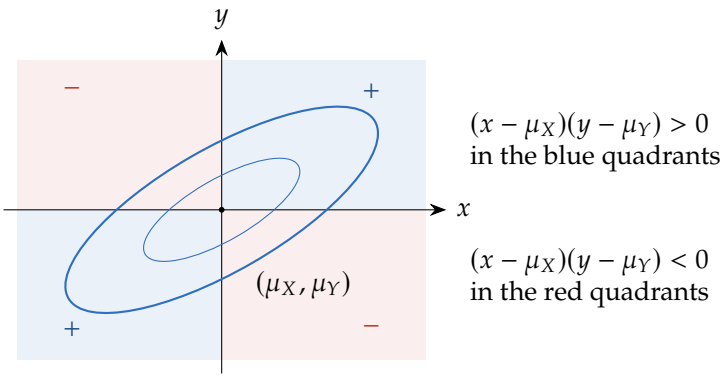

Figure 1.42: Reading the sign of a covariance. The ellipses are contours of a density tilted up to the right. Most of its probability sits in the blue quadrants, where the two deviations have the same sign, so the average of their product, the covariance, is positive.

[Wasserman Exercise 3.14, p. 60]. To see it, note that the deviation of $\sum_i a_i X_i$ from its mean is $\sum_i a_i (X_i - \mu_{X_i})$, do the same for the Y's, multiply the two sums term by term and take the expectation of each term. Setting both sums equal gives the variance of any linear combination [Wasserman Thm. 3.20, p. 52],

$$\operatorname{Var}\Big(\sum_i a_i X_i\Big) = \sum_i a_i^2 \operatorname{Var}(X_i) + 2 \sum_{i<j} a_i a_j \operatorname{Cov}(X_i, X_j), \tag{1.56}$$

and in particular $\operatorname{Var}(X \pm Y) = \operatorname{Var}(X) + \operatorname{Var}(Y) \pm 2\operatorname{Cov}(X, Y)$.

Example: the shared pedestal. Return to the two calorimeter channels of the opening, $X_1 = S_1 + N$ and $X_2 = S_2 + N$, which share the pedestal noise N. Take $\operatorname{Var}(S_1) = \operatorname{Var}(S_2) = \sigma_S^2$ and $\operatorname{Var}(N) = \sigma_N^2$. By (1.55),

$$\operatorname{Cov}(X_1, X_2) \overset{(1)}{=} \operatorname{Cov}(S_1, S_2) + \operatorname{Cov}(S_1, N) + \operatorname{Cov}(N, S_2) + \operatorname{Cov}(N, N) \overset{(2)}{=} \sigma_N^2,$$

(1) Bilinearity with $X_1 = S_1 + N$, $X_2 = S_2 + N$.
(2) Independent variables have zero covariance (shown below); $\operatorname{Cov}(N, N) = \operatorname{Var}(N)$.

so $\rho = \sigma_N^2/(\sigma_S^2 + \sigma_N^2)$, which is $\frac{1}{2}$ when the signal and the pedestal fluctuate equally. Now form the difference. By (1.56), $\operatorname{Var}(X_1 - X_2) = 2(\sigma_S^2 + \sigma_N^2) - 2\sigma_N^2 = 2\sigma_S^2$: the common noise has cancelled completely. The sum has $\operatorname{Var}(X_1 + X_2) = 2\sigma_S^2 + 4\sigma_N^2$: it is doubled. This is common-mode rejection, and it is why differential measurements are powerful. A gravitational-wave interferometer reads the *difference* of its two arm lengths, so the laser noise common to both arms cancels to first order.

1.13.2 Why $|\rho| \le 1$, and what $\rho = \pm 1$ means

The correlation coefficient removes the units by dividing by both standard deviations. That it then lies in $[-1, 1]$ follows from one observation [CasellaBerger Thm. 4.5.7]: the mean of a square is never negative. For every real t let

$$h(t) \overset{(1)}{=} \mathbb{E}\Big[\big(t(X - \mu_X) + (Y - \mu_Y)\big)^2\Big] \overset{(2)}{=} t^2\sigma_X^2 + 2t\ \operatorname{Cov}(X, Y) + \sigma_Y^2 \overset{(3)}{\ge} 0.$$

(1) Definition of h, the mean square of a combination of the two deviations.
(2) Expand the square and use linearity.

(3) The expectation of a non-negative quantity is non-negative.

A quadratic in t that is never negative has at most one real root, so its discriminant is not positive: $4\,\mathrm{Cov}(X,Y)^2 - 4\sigma_X^2\sigma_Y^2 \le 0$, that is, $|\mathrm{Cov}(X,Y)| \le \sigma_X\sigma_Y$, or $-1 \le \rho \le 1$. Equality, $|\rho| = 1$, means the discriminant is zero, so $h(t_0) = 0$ for one t_0, namely $t_0 = -\mathrm{Cov}(X,Y)/\sigma_X^2$. A non-negative variable with zero mean is zero with probability one, so $Y - \mu_Y = -t_0(X - \mu_X)$: the points lie exactly on a straight line with slope $a = -t_0 = \mathrm{Cov}/\sigma_X^2$, which has the sign of ρ. Conversely if $Y = aX + b$ then $\mathrm{Cov}(X,Y) = a\sigma_X^2$ and $\sigma_Y = |a|\,\sigma_X$, so $\rho = a/|a| = \pm 1$ [Wasserman Thm. 3.19, p. 52].

In the language of vectors this is the Cauchy–Schwarz inequality. Centred random variables form a vector space with the inner product $\langle U, V\rangle = \mathbb{E}(UV)$, the length of U is its standard deviation, and ρ is the cosine of the angle between $X - \mu_X$ and $Y - \mu_Y$. It is ± 1 when the two "vectors" are parallel, 0 when they are orthogonal. A quantum physicist will recognise the normalised overlap $\left|\langle\psi|\phi\rangle\right| / (\|\psi\|\,\|\phi\|) \le 1$. Because it is a cosine, ρ is unchanged by shifting or by rescaling either variable with a positive factor: it does not care whether energies are in GeV or TeV.

Figure 1.43 calibrates the eye. With 1500 points from bivariate Gaussians of unit variances and $\rho = -0.8,\ 0,\ 0.5,\ 0.95$, the sample correlations are -0.795, 0.040, 0.486 and 0.949. A correlation of 0.5 is a visibly tilted but still fat cloud; it takes ρ close to 1 to make a thin line.

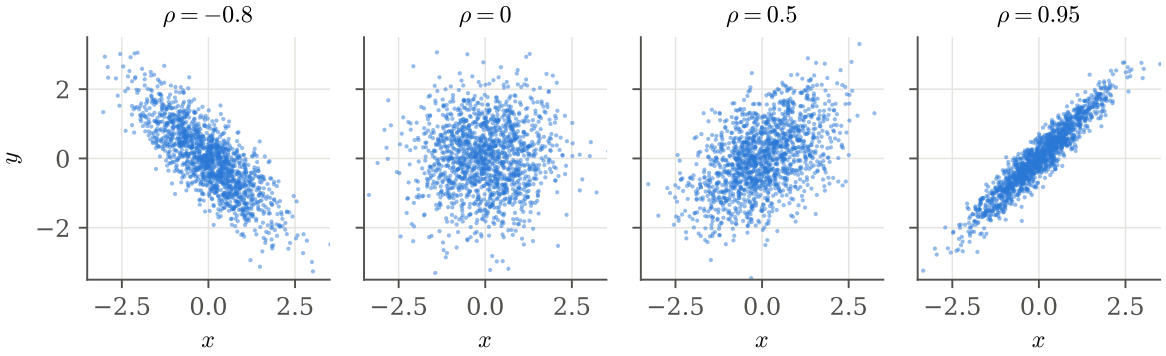

Figure 1.43: Clouds of 1500 draws from bivariate Gaussians with unit variances and four values of the correlation coefficient. The sign of ρ gives the direction of the tilt; its size says how tightly the points hug a straight line.

1.13.3 Zero correlation is not independence

If X and Y are independent, $\mathbb{E}(XY) = \mathbb{E}(X)\,\mathbb{E}(Y)$ by (1.43), and (1.54) gives $\mathrm{Cov}(X,Y) = 0$. The converse is false [Wasserman Thm. 3.19, p. 52]. The standard counterexample shows why. Let $X \sim \mathcal{N}(0,1)$ and $Y = X^2$. Then Y is completely determined by X, the strongest dependence there is. Yet

$$\mathrm{Cov}(X,Y) \overset{(1)}{=} \mathbb{E}(X\cdot X^2) - \mathbb{E}(X)\;\mathbb{E}(X^2) \overset{(2)}{=} \mathbb{E}(X^3) - 0\cdot 1 \overset{(3)}{=} 0.$$

(1) Shortcut (1.54) with $Y = X^2$.
(2) $\mathbb{E}(X) = 0$ and $\mathbb{E}(X^2) = \mathrm{Var}(X) = 1$.
(3) $\mathbb{E}(X^3) = \int x^3\varphi(x)\,\mathrm{d}x = 0$: the integrand is odd because the Gaussian density φ is even.

The covariance vanishes because the relation is symmetric: for every point (x, x^2) on the right branch of the parabola there is an equally likely point $(-x, x^2)$ on the left, and their products of

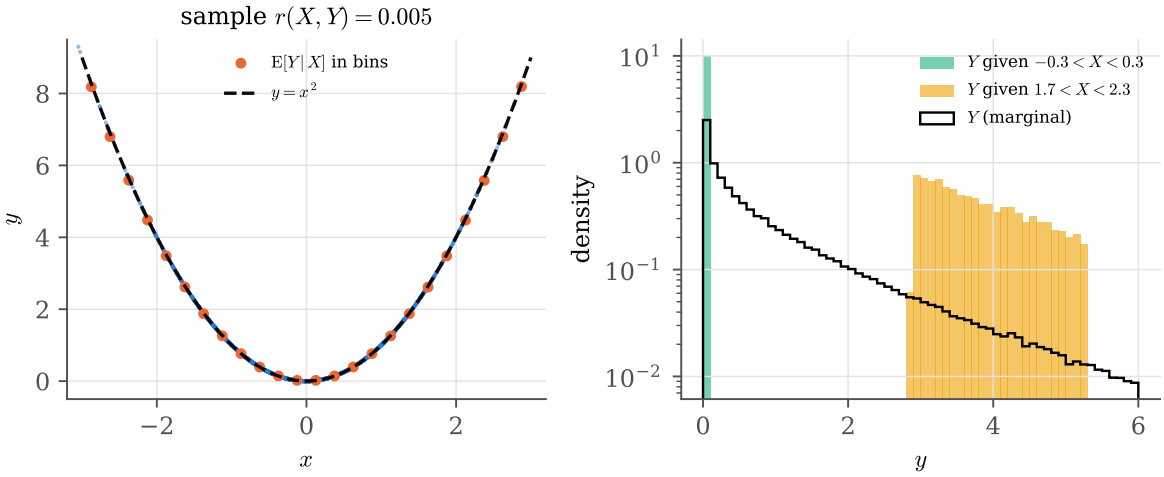

Figure 1.44: Left: draws of (X, X^2) with X Gaussian. The points lie exactly on the parabola, the binned conditional mean $\mathbb{E}(Y \mid X)$ (orange) follows it, and yet the sample correlation is essentially zero. Right: the distribution of Y for X near 0 and for X near 2 (logarithmic density axis). The two conditional distributions do not even overlap, so knowing X changes everything we know about Y, which is the opposite of independence.

deviations cancel [Cowan Fig. 1.10]. The correlation coefficient measures how well a *straight line* fits, and the best straight line through a symmetric parabola is flat.

Figure 1.44 shows it numerically. With 2×10^5 draws the sample correlation of X and Y is 0.0046. The dependence is all there: the correlation of Y with $|X|$ (a monotone function of X on each branch) is 0.9359, and the conditional distributions of Y in two slices of X are completely different. [CasellaBerger Ex. 4.5.9] gives a version with noise, $Y = X^2 + Z$, with the same conclusion. Operationally: before concluding that two quantities are unrelated because their correlation is small, plot them.

There is a ladder of conditions between independence and zero correlation. If the conditional mean of X does not depend on Y, $\mathbb{E}(X \mid Y = y) = c$ for all y, then X and Y are uncorrelated [Wasserman Exercise 3.18, p. 61]:

$$\mathbb{E}(XY) \overset{(1)}{=} \mathbb{E}\big[\mathbb{E}(XY \mid Y)\big] \overset{(2)}{=} \mathbb{E}\big[Y\ \mathbb{E}(X \mid Y)\big] \overset{(3)}{=} c\ \mathbb{E}(Y) \overset{(4)}{=} \mathbb{E}(X)\ \mathbb{E}(Y).$$

(1) Iterated expectations (1.51).
(2) Given Y, the factor Y is known and comes out.
(3) $\mathbb{E}(X \mid Y) = c$.
(4) $\mathbb{E}(X) = \mathbb{E}[\mathbb{E}(X \mid Y)] = c$.

The same two steps show that if $\mathbb{E}(Y \mid X) = X$ then $\mathbb{E}(XY) = \mathbb{E}(X^2)$ and $\mathbb{E}(Y) = \mathbb{E}(X)$, so $\mathrm{Cov}(X, Y) = \mathrm{Var}(X)$ [Wasserman Exercise 3.21, p. 61]. So independence implies a constant conditional mean, which implies zero correlation, and neither implication reverses (in the parabola example $\mathbb{E}(Y \mid X) = X^2$ is far from constant).

For one family the ladder collapses. If (X, Y) is bivariate Gaussian (1.28) with $\rho = 0$, the cross term $-2\rho xy/(\sigma_x\sigma_y)$ in the exponent vanishes, the exponent splits into an x part plus a y part, and the density factorises into $f_X(x)f_Y(y)$. For jointly Gaussian variables, uncorrelated means independent. This is why the sum and the difference of two equally noisy Gaussian channels in Example 1.48 came out independent. They are jointly Gaussian, and the sum-and-difference example of the next subsection shows that they are uncorrelated.

Watch out: Gaussian marginals do not make a Gaussian pair

The shortcut "uncorrelated ⇒ independent" needs the variables to be *jointly* Gaussian, not just each Gaussian. Let $X \sim \mathcal{N}(0,1)$ and let $S = \pm 1$ be an independent fair sign. Then $Y = SX$ is also $\mathcal{N}(0,1)$ (flipping the sign of a symmetric variable changes nothing), and $\operatorname{Cov}(X,Y) = \mathbb{E}(S)\,\mathbb{E}(X^2) = 0$. But $|Y| = |X|$ always, so the two are strongly dependent. The pair lives on the two diagonals $y = \pm x$, which no bivariate Gaussian does.

1.13.4 The covariance matrix and how linear maps move it

With many variables we collect them into a column vector $\boldsymbol{X} = (X_1, \dots, X_k)^{\mathsf{T}}$ with mean vector $\boldsymbol{\mu} = (\mathbb{E}\,X_1, \dots, \mathbb{E}\,X_k)^{\mathsf{T}}$. All the variances and covariances go into one matrix, the **covariance matrix** ("variance–covariance matrix" in [Wasserman p. 53], "error matrix" in [Cowan p. 18]):

$$\mathbf{C}_{ij} = \operatorname{Cov}(X_i, X_j), \qquad \mathbf{C} = \mathbb{E}\big[(\boldsymbol{X} - \boldsymbol{\mu})(\boldsymbol{X} - \boldsymbol{\mu})^{\mathsf{T}}\big] = \begin{pmatrix} \operatorname{Var}(X_1) & \operatorname{Cov}(X_1, X_2) & \cdots \\ \operatorname{Cov}(X_2, X_1) & \operatorname{Var}(X_2) & \cdots \\ \vdots & & \ddots \end{pmatrix}. \tag{1.57}$$

The outer product $(\boldsymbol{X} - \boldsymbol{\mu})(\boldsymbol{X} - \boldsymbol{\mu})^{\mathsf{T}}$ is a $k \times k$ matrix whose (i,j) entry is $(X_i - \mu_i)(X_j - \mu_j)$, and the expectation is taken entry by entry. The matrix is symmetric, its diagonal holds the variances, and it is positive semi-definite: for any fixed vector $\boldsymbol{a}$,

$$\boldsymbol{a}^{\mathsf{T}}\mathbf{C}\,\boldsymbol{a} \overset{(1)}{=} \sum_{i,j} a_i a_j \operatorname{Cov}(X_i, X_j) \overset{(2)}{=} \operatorname{Var}\big(\boldsymbol{a}^{\mathsf{T}}\boldsymbol{X}\big) \overset{(3)}{\geq} 0.$$

(1) Write out the quadratic form.
(2) Bilinearity (1.55) with $b_j = a_j$ and $Y_j = X_j$.
(3) A variance is never negative.

So all eigenvalues of $\mathbf{C}$ are ≥ 0. A zero eigenvalue means some combination $\boldsymbol{a}^{\mathsf{T}}\boldsymbol{X}$ has zero variance, i.e. is a constant: the variables obey an exact linear constraint (as the multinomial counts below do). Dividing entry (i,j) by $\sigma_i \sigma_j$ gives the correlation matrix, with ones on the diagonal.

Now let $\boldsymbol{Y} = A\boldsymbol{X} + \boldsymbol{b}$ for a fixed $m \times k$ matrix A and vector $\boldsymbol{b}$. Linearity gives $\mathbb{E}\,\boldsymbol{Y} = A\boldsymbol{\mu} + \boldsymbol{b}$, and [Wasserman Lemma 3.21, p. 54]

$$\mathbf{C}_{\boldsymbol{Y}} \overset{(1)}{=} \mathbb{E}\big[(A\boldsymbol{X} - A\boldsymbol{\mu})(A\boldsymbol{X} - A\boldsymbol{\mu})^{\mathsf{T}}\big] \overset{(2)}{=} \mathbb{E}\big[A(\boldsymbol{X} - \boldsymbol{\mu})(\boldsymbol{X} - \boldsymbol{\mu})^{\mathsf{T}}A^{\mathsf{T}}\big] \overset{(3)}{=} A\,\mathbf{C}\,A^{\mathsf{T}}. \tag{1.58}$$

(1) Definition (1.57) for $\boldsymbol{Y}$; the shift $\boldsymbol{b}$ cancels in $\boldsymbol{Y} - \mathbb{E}\,\boldsymbol{Y}$.
(2) $(A\boldsymbol{v})^{\mathsf{T}} = \boldsymbol{v}^{\mathsf{T}}A^{\mathsf{T}}$.
(3) A is constant and comes out of the entry-by-entry expectation on both sides (linearity).

In components, $(\mathbf{C}_{\boldsymbol{Y}})_{ij} = \sum_{k,l} A_{ik}A_{jl} \operatorname{Cov}(X_k, X_l)$ [Cowan (1.62)], which is just (1.55). For a single combination, $A = \boldsymbol{a}^{\mathsf{T}}$ is one row and $\operatorname{Var}(\boldsymbol{a}^{\mathsf{T}}\boldsymbol{X}) = \boldsymbol{a}^{\mathsf{T}}\mathbf{C}\boldsymbol{a}$, the quadratic form above. The covariance matrix transforms like a rank-2 tensor, $C'_{ij} = A_{ik}A_{jl}C_{kl}$; the inertia tensor and the stress tensor transform the same way.

Key idea: Linear maps move covariance by sandwiching

If $\boldsymbol{Y} = A\boldsymbol{X} + \boldsymbol{b}$ then $\mathbb{E}\,\boldsymbol{Y} = A\ \mathbb{E}\,\boldsymbol{X} + \boldsymbol{b}$ and $\mathbf{C}_{\boldsymbol{Y}} = A\,\mathbf{C}_{\boldsymbol{X}}A^{\mathsf{T}}$, exactly, for any distribution.

Example: sum and difference of two channels. Take $\mathbf{C} = \left(\begin{smallmatrix} \sigma_1^2 & c \\ c & \sigma_2^2 \end{smallmatrix}\right)$ and $A = \left(\begin{smallmatrix} 1 & 1 \\ 1 & -1 \end{smallmatrix}\right)$, so $Y_1 = X_1 + X_2$ and $Y_2 = X_1 - X_2$. Then

$$A\,\mathbf{C}\,A^{\mathsf{T}} \overset{(1)}{=} \begin{pmatrix} \sigma_1^2 + c & c + \sigma_2^2 \\ \sigma_1^2 - c & c - \sigma_2^2 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \overset{(2)}{=} \begin{pmatrix} \sigma_1^2 + \sigma_2^2 + 2c & \sigma_1^2 - \sigma_2^2 \\ \sigma_1^2 - \sigma_2^2 & \sigma_1^2 + \sigma_2^2 - 2c \end{pmatrix}.$$

(1) First product $A\mathbf{C}$, row by column; $A^{\mathsf{T}} = A$ here.
(2) Second product; e.g. the $(1,2)$ entry is $(\sigma_1^2 + c) - (c + \sigma_2^2)$.

The diagonal reproduces $\mathrm{Var}(X_1 \pm X_2) = \sigma_1^2 + \sigma_2^2 \pm 2c$. The new off-diagonal entry, $\mathrm{Cov}(X_1 + X_2, X_1 - X_2) = \sigma_1^2 - \sigma_2^2$, is zero whenever the two channels are equally noisy, whatever their correlation c. With $\mathbf{C} = \sigma^2 \mathbb{1}$ we get $A\mathbf{C}A^{\mathsf{T}} = 2\sigma^2\mathbb{1}$, and since the pair is jointly Gaussian that is the independence of Example 1.48. For the numerical case $\sigma_1^2 = 4$, $\sigma_2^2 = 1$, $c = 1.8$ the prediction is $\left(\begin{smallmatrix} 8.6 & 3 \\ 3 & 1.4 \end{smallmatrix}\right)$, and the sample covariance of 2×10^5 simulated pairs is $\left(\begin{smallmatrix} 8.595 & 2.999 \\ 2.999 & 1.401 \end{smallmatrix}\right)$.

Example: the multinomial covariance. Throw n events into k histogram bins with probabilities $p_1, \ldots, p_k$ (Section 1.10), and let X_i be the count in bin i. Each X_i is binomial, $\mathrm{Var}(X_i) = np_i(1-p_i)$. To get the covariance of two bins, merge them: $X_i + X_j$ counts the events that fell in either, so it is Binomial$(n, p_i + p_j)$ [Wasserman p. 54]. Then

$$\begin{aligned} 2\,\mathrm{Cov}(X_i, X_j) &\overset{(1)}{=} \mathrm{Var}(X_i + X_j) - \mathrm{Var}(X_i) - \mathrm{Var}(X_j) \\ &\overset{(2)}{=} n(p_i + p_j)(1 - p_i - p_j) - np_i(1 - p_i) - np_j(1 - p_j) \overset{(3)}{=} -2np_ip_j, \end{aligned}$$

(1) (1.56) for $X_i + X_j$, solved for the covariance.
(2) Binomial variances of the merged bin and of each bin.
(3) Expand: the linear terms cancel, and $-(p_i + p_j)^2 + p_i^2 + p_j^2 = -2p_ip_j$.

so $\mathrm{Cov}(X_i, X_j) = -np_ip_j$ for $i \neq j$. Histogram bins with a fixed total are anticorrelated: an extra event in one bin is an event missing from the others. The covariance matrix has a zero eigenvalue along $\boldsymbol{a} = (1, \ldots, 1)$, because $\sum_i X_i = n$ is exactly constant. (If the total itself is a Poisson count, as for a collider run of fixed luminosity, the bins become independent Poisson variables; see Chapter 2.)

1.13.5 Diagonalising: the principal axes of the error ellipse

Correlated variables are awkward: we cannot read off the uncertainty of one without the other. Can a linear change of variables always make them uncorrelated? Yes, and it is a rotation [Cowan §1.7]. Because $\mathbf{C}$ is real and symmetric, it has k orthonormal eigenvectors $\boldsymbol{r}_1, \ldots, \boldsymbol{r}_k$, $\mathbf{C}\boldsymbol{r}_j = \lambda_j \boldsymbol{r}_j$, with $\lambda_j \geq 0$ by positive semi-definiteness. Put them as the columns of an orthogonal matrix R and take $\boldsymbol{W} = R^{\mathsf{T}}\boldsymbol{X}$, so $W_i = \boldsymbol{r}_i^{\mathsf{T}}\boldsymbol{X}$ is the component of $\boldsymbol{X}$ along $\boldsymbol{r}_i$. By (1.58) with $A = R^{\mathsf{T}}$,

$$(\mathbf{C}_{\boldsymbol{W}})_{ij} \overset{(1)}{=} \left(R^{\mathsf{T}}\mathbf{C}R\right)_{ij} \overset{(2)}{=} \boldsymbol{r}_i^{\mathsf{T}}\mathbf{C}\,\boldsymbol{r}_j \overset{(3)}{=} \lambda_j\,\boldsymbol{r}_i^{\mathsf{T}}\boldsymbol{r}_j \overset{(4)}{=} \lambda_j\,\delta_{ij}.$$

(1) The sandwich rule with $A = R^{\mathsf{T}}$.
(2) Row i of R^{T} is $\boldsymbol{r}_i^{\mathsf{T}}$ and column j of R is $\boldsymbol{r}_j$.
(3) Eigenvalue equation.
(4) Orthonormality of the eigenvectors.

The new variables are uncorrelated and their variances are the eigenvalues [Cowan (1.65)]. Geometrically, the contours of a Gaussian density with covariance $\mathbf{C}$ are ellipses (ellipsoids)

whose axes point along the eigenvectors, with semi-axes $\sqrt{\lambda_j}$ at "1σ". The rotation simply turns the coordinate axes onto the principal axes of this **error ellipse**, exactly like rotating onto the principal axes of an inertia tensor or onto the normal modes of coupled oscillators.

In two dimensions everything is explicit. Write $\mathbf{C} = \begin{pmatrix} \sigma_1^2 & c \\ c & \sigma_2^2 \end{pmatrix}$ with $c = \rho\sigma_1\sigma_2$. The eigenvalues solve $\det(\mathbf{C} - \lambda\mathbb{1}) = \lambda^2 - (\sigma_1^2 + \sigma_2^2)\lambda + \sigma_1^2\sigma_2^2 - c^2 = 0$, so

$$\lambda_\pm = \tfrac{1}{2}\left[\sigma_1^2 + \sigma_2^2 \pm \sqrt{(\sigma_1^2 + \sigma_2^2)^2 - 4(1-\rho^2)\sigma_1^2\sigma_2^2}\right] \tag{1.59}$$

[Cowan (1.69)]. For the rotation angle, rotate by θ, $W_1 = \cos\theta\, X_1 + \sin\theta\, X_2$ and $W_2 = -\sin\theta\, X_1 + \cos\theta\, X_2$, and demand zero covariance:

$$\begin{aligned} \operatorname{Cov}(W_1, W_2) &\overset{(1)}{=} -\sin\theta\cos\theta\,\sigma_1^2 + (\cos^2\theta - \sin^2\theta)\,c + \sin\theta\cos\theta\,\sigma_2^2 \\ &\overset{(2)}{=} \tfrac{1}{2}\sin 2\theta\,(\sigma_2^2 - \sigma_1^2) + c\cos 2\theta, \end{aligned}$$

(1) Bilinearity (1.55).
(2) Double-angle formulas.

which vanishes for $\tan 2\theta = 2c/(\sigma_1^2 - \sigma_2^2)$ [Cowan (1.71)]. For $\sigma_1^2 = 4$, $\sigma_2^2 = 1$, $c = 1.8$ (so $\rho = 0.9$): $\tan 2\theta = 1.2$, $\theta = 25.1°$, and (1.59) gives $\lambda = (5 \pm \sqrt{21.96})/2 = 4.843$ and 0.157. The simulated rotated variables have variances 4.840 and 0.157 and covariance -0.001 (Figure 1.45, right). The long axis carries almost all the variance: nearly all the scatter of the two channels is in one combination.

The same algebra run backwards generates correlated variables. If $\boldsymbol{Z}$ has independent standard normal components, $\mathbf{C}_Z = \mathbb{1}$, and $\boldsymbol{X} = L\boldsymbol{Z}$ has covariance $L\mathbb{1}L^{\mathsf{T}} = LL^{\mathsf{T}}$. So any factorisation $\mathbf{C} = LL^{\mathsf{T}}$ gives a recipe. The standard one is the Cholesky factor, a lower triangular L; for 2×2, $L = \begin{pmatrix} \sigma_1 & 0 \\ \rho\sigma_2 & \sigma_2\sqrt{1-\rho^2} \end{pmatrix}$, which one checks by multiplying out. Here $L = \left(\begin{smallmatrix} 2.000 & 0 \\ 0.900 & 0.436 \end{smallmatrix}\right)$, and the script uses exactly this:

Listing 1.17: Correlated Gaussians, the sandwich rule and the eigenbasis (`code/ch01/18_covariance_transform.py`)

```
21 C = np.array([[4.0, 1.8], [1.8, 1.0]])
22 L = np.linalg.cholesky(C)
23 N = 200_000
24 Z = rng.normal(size=(2, N))
25 X = L @ Z
26 C_hat = np.cov(X)
27
28 A = np.array([[1.0, 1.0], [1.0, -1.0]])
29 Y = A @ X
30 CY_pred = A @ C @ A.T
31 CY_hat = np.cov(Y)
32
33 lam, R = np.linalg.eigh(C)          # columns of R are unit eigenvectors, lam ascending
34 W = R.T @ X                         # coordinates along the eigenvectors
35 CW_hat = np.cov(W)
```

Lines 22–25 build L and generate $\boldsymbol{X} = L\boldsymbol{Z}$ for 2×10^5 pairs; their sample covariance (line 26) is $\left(\begin{smallmatrix} 3.998 & 1.798 \\ 1.798 & 0.999 \end{smallmatrix}\right)$, the target $\mathbf{C}$. Lines 28–31 apply the sum-and-difference matrix and compare $A\mathbf{C}A^{\mathsf{T}}$ with the sample covariance of $\boldsymbol{Y}$. Lines 33–35 diagonalise: `np.linalg.eigh` returns the eigenvalues in ascending order and the unit eigenvectors as the columns of `R`, and $\boldsymbol{W} = R^{\mathsf{T}}\boldsymbol{X}$ is uncorrelated.

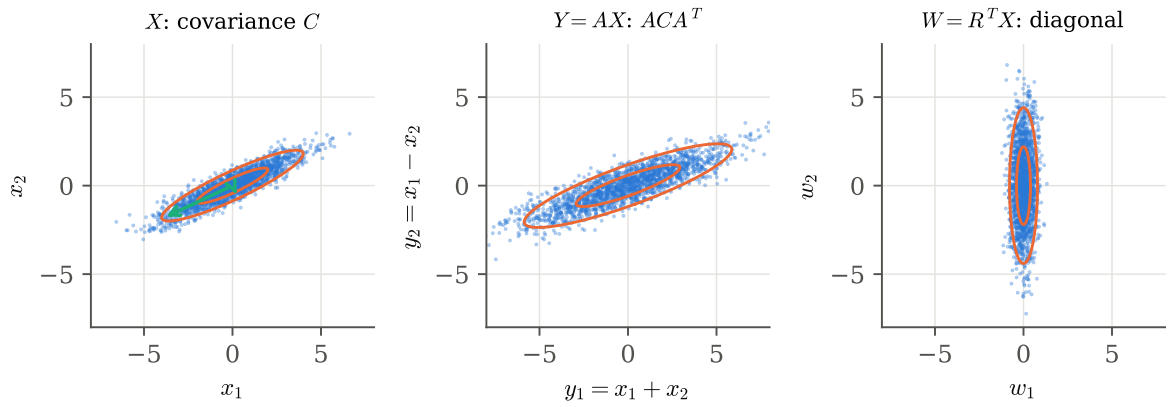

Figure 1.45: One cloud of correlated pairs seen in three coordinate systems, with the predicted 1σ and 2σ ellipses. Left: the original channels, with the two eigenvectors of $\mathbf{C}$ drawn as green arrows. Middle: sum and difference; the ellipse is the one predicted by $A\mathbf{C}A^{\mathsf{T}}$. Right: components along the eigenvectors; the ellipse is aligned with the axes, so the new variables are uncorrelated.

1.13.6 A first look at error propagation

Most derived quantities are not linear in the measured ones: a mass from two momenta, a ratio of two rates, a distance from a flux. If the input uncertainties are small, we can linearise [Cowan §1.6]. Expand $y(\boldsymbol{x})$ to first order about the means, $y(\boldsymbol{x}) \approx y(\boldsymbol{\mu}) + \sum_i A_i(x_i - \mu_i)$ with $A_i = \partial y/\partial x_i$ at $\boldsymbol{\mu}$. The constant does not affect the spread, and the rest is linear, so the sandwich rule applies to the Jacobian matrix $A_{ki} = \partial y_k/\partial x_i$:

$$\mathbb{E}\, y_k \approx y_k(\boldsymbol{\mu}), \qquad \operatorname{Cov}(y_k, y_l) \approx \sum_{i,j} \frac{\partial y_k}{\partial x_i}\frac{\partial y_l}{\partial x_j}\,\mathbf{C}_{ij}, \qquad \mathbf{C}_y \approx A\,\mathbf{C}\,A^{\mathsf{T}} \tag{1.60}$$

[Cowan (1.53)–(1.55)]. For a linear map this is exact (1.58); otherwise it is the first term of an expansion.

Example: products add relative errors in quadrature. For $y = x_1x_2$ the Jacobian is $A = (\mu_2,\ \mu_1)$, so

$$\sigma_y^2 \overset{(1)}{=} \mu_2^2\sigma_1^2 + \mu_1^2\sigma_2^2 + 2\mu_1\mu_2\,\mathbf{C}_{12}, \qquad \frac{\sigma_y^2}{y^2} \overset{(2)}{=} \frac{\sigma_1^2}{\mu_1^2} + \frac{\sigma_2^2}{\mu_2^2} + 2\frac{\mathbf{C}_{12}}{\mu_1\mu_2}.$$

(1) (1.60) with $\partial y/\partial x_1 = x_2$, $\partial y/\partial x_2 = x_1$ at the means.
(2) Divide by $y^2 \approx \mu_1^2\mu_2^2$.

For uncorrelated inputs, absolute errors add in quadrature for a sum and relative errors add in quadrature for a product [Cowan (1.59)–(1.60)]. The approximation fails when y curves appreciably over a range of one standard deviation; the classic case is $1/x$ with σ_x not small compared with μ_x. Then one simulates (Chapter 6). Error propagation, and its limits, is developed properly in Chapter 3.

How research uses it. In a real analysis the covariance matrix is rarely computed on paper. The band powers of a CMB or galaxy power spectrum measured on a masked, noisy sky (Chapters 7 and 8) are correlated in ways no formula captures, so one simulates N_s mock data sets and uses the sample covariance, the matrix version of S_n^2 with its $1/(N_s - 1)$. The χ^2 likelihood needs the *inverse*, and the inverse of a noisy estimate is biased; it must be rescaled by

$(N_s - p - 2)/(N_s - 1)$ for p data points [6]. The Fisher matrix of Chapter 10 is the inverse of a forecast parameter covariance, and its eigenvectors are the principal axes above: the best- and worst-constrained combinations of parameters. The simulations here *verified* $A\mathbf{C}A^{\mathsf{T}}$, a known result; in those analyses the same simulate-and-average machinery is the only way to obtain $\mathbf{C}$ at all.

1.14 Moments, generating functions and characteristic functions

A physicist has two standard ways of packing a whole function into something easier to handle. One is a list of moments: the total charge, the dipole moment and the quadrupole moment of a charge distribution describe it from far away, better and better as more terms are kept. The other is a transform: a Fourier or Laplace transform turns a messy operation on functions into a simple one on their transforms. Probability uses both, and statistical mechanics has used them all along. The partition function $Z(\beta) = \int g(E)\, e^{-\beta E}\, \mathrm{d}E$ is the Laplace transform of the density of states $g(E)$, and the mean energy and its fluctuations, $\langle E\rangle = -\partial_\beta \ln Z$ and $\langle E^2\rangle - \langle E\rangle^2 = \partial_\beta^2 \ln Z = k_B T^2 C_V$, are read off from its derivatives.

Higher moments describe the shape of a distribution. Two transforms, the moment generating function and the characteristic function, produce all the moments at once. Their more important use is a different one: sums. In Section 1.11 the density of a sum of independent variables was a convolution (1.39), an integral that gets worse with every term added. After a Fourier transform, convolution becomes multiplication. That single fact is what makes the central limit theorem of Chapter 2 provable in a few lines. Three questions organise the topic.

1. Which numbers beyond the mean and the variance describe the shape of a distribution, and do they determine it?
2. How do we get the distribution of a sum of independent variables without doing convolution integrals?
3. What do we do when the moments, or the transform itself, do not exist?

1.14.1 Moments and the shape of a distribution

The k-th **moment** of X is $\mathbb{E}(X^k)$ and the k-th **central moment** is $\mathbb{E}\big[(X-\mu)^k\big]$, assuming $\mathbb{E}\,|X|^k < \infty$ [Wasserman p. 49–50] ([Cowan (1.41)–(1.42)] writes them μ'_n and μ_n). The first moment is the mean and the second central moment the variance. The standardised third and fourth central moments describe shape:

$$\gamma_1 = \frac{\mathbb{E}(X-\mu)^3}{\sigma^3} \ \text{(skewness)}, \qquad \gamma_2 = \frac{\mathbb{E}(X-\mu)^4}{\sigma^4} - 3 \ \text{(excess kurtosis)}. \tag{1.61}$$

Both are pure numbers. The skewness is positive when a long tail extends to the right (the exponential has $\gamma_1 = 2$), zero for a symmetric distribution. The -3 is chosen so that a Gaussian has $\gamma_2 = 0$; distributions with heavier tails than the Gaussian have $\gamma_2 > 0$. In the multipole language the mean is the centre of charge, and the variance is the moment of inertia about it.

A higher moment existing guarantees the lower ones [Wasserman Thm. 3.10, p. 49]. For $j < k$,

$$\begin{aligned}\mathbb{E}\,|X|^j &\overset{(1)}{=} \int_{|x|\le 1} |x|^j f(x)\,\mathrm{d}x + \int_{|x|>1} |x|^j f(x)\,\mathrm{d}x \\ &\overset{(2)}{\le} \int_{|x|\le 1} f(x)\,\mathrm{d}x + \int_{|x|>1} |x|^k f(x)\,\mathrm{d}x \overset{(3)}{\le} 1 + \mathbb{E}\,|X|^k .\end{aligned}$$

(1) Split the range at $|x| = 1$.
(2) On $|x| \le 1$, $|x|^j \le 1$. On $|x| > 1$, $|x|^j \le |x|^k$ because $j < k$.
(3) The first integral is at most the total probability 1; the second is at most the full integral of $|x|^k f$.

The converse fails, and tails decide: the Cauchy density has no moments at all (Section 1.12), and a density falling like $1/|x|^4$ has a mean and a variance but no third moment.

Do the moments, if they all exist, determine the distribution? Not always. Here are two different densities on $x > 0$ [CasellaBerger Ex. 2.3.10]:

$$f_1(x) = \frac{1}{\sqrt{2\pi}\, x} e^{-(\ln x)^2/2}, \qquad f_2(x) = f_1(x)\big[1 + \sin(2\pi \ln x)\big],$$

with identical moments of every order. (f_1 is the lognormal: $\ln X$ is standard normal.) With $u = \ln x$, so that $f_1(x)\,\mathrm{d}x = \varphi(u)\,\mathrm{d}u$ with φ the standard normal density, the extra piece of the r-th moment of f_2 is

$$\int_0^\infty x^r f_1(x) \sin(2\pi \ln x)\,\mathrm{d}x \overset{(1)}{=} \int_{-\infty}^\infty e^{ru} \varphi(u) \sin(2\pi u)\,\mathrm{d}u \overset{(2)}{=} e^{r^2/2} \int_{-\infty}^\infty \varphi(u - r) \sin(2\pi u)\,\mathrm{d}u$$
$$\overset{(3)}{=} e^{r^2/2} \int_{-\infty}^\infty \varphi(y) \sin(2\pi y)\,\mathrm{d}y \overset{(4)}{=} 0.$$

(1) Substitute $x = e^u$; $x^r = e^{ru}$.
(2) Complete the square: $ru - u^2/2 = r^2/2 - (u - r)^2/2$.
(3) Substitute $y = u - r$. For integer r, $\sin(2\pi(y + r)) = \sin(2\pi y)$.
(4) φ is even and sin is odd, so the integrand is odd.

So f_1 and f_2 share all moments, $\mathbb{E}\, X^r = e^{r^2/2}$ for both, though they are visibly different densities. The problem is again the tails: the moments grow so fast that they fail to pin down the function. When the support is bounded, or when the moment generating function below exists in an interval around $t = 0$, the moments do determine the distribution [CasellaBerger Thm. 2.3.11].

1.14.2 The moment generating function

The **moment generating function** (mgf) of X is [Wasserman Def. 3.29, p. 56]

$$\psi_X(t) = \mathbb{E}\big(e^{tX}\big) = \int e^{tx} f(x)\,\mathrm{d}x, \tag{1.62}$$

for the real t where the expectation is finite. It is the Laplace transform of the density (with $t \to -t$), and we assume it is finite on some interval around $t = 0$. The name comes from expanding the exponential: $e^{tX} = \sum_k t^k X^k/k!$, so

$$\psi_X(t) = \sum_{k=0}^\infty \frac{t^k}{k!}\, \mathbb{E}(X^k), \qquad \text{hence} \qquad \psi_X^{(k)}(0) = \mathbb{E}(X^k). \tag{1.63}$$

The moments are the Taylor coefficients of ψ at 0 (times $k!$). Moving $\mathbb{E}$ through the sum, or through $\mathrm{d}/\mathrm{d}t$ as [Wasserman p. 56] does, is legitimate precisely because ψ is finite near 0.

Example: the exponential. For $X \sim \mathrm{Exp}(1)$, $f(x) = e^{-x}$ on $x > 0$ [Wasserman Ex. 3.30, p. 57]:

$$\psi_X(t) \overset{(1)}{=} \int_0^\infty e^{tx} e^{-x}\,\mathrm{d}x \overset{(2)}{=} \int_0^\infty e^{-(1-t)x}\,\mathrm{d}x \overset{(3)}{=} \frac{1}{1-t} \overset{(4)}{=} \sum_{k=0}^\infty t^k \qquad (t < 1).$$

(1) Definition (1.62).
(2) Combine the exponents.
(3) The integral converges only for $t < 1$; for $t \geq 1$ it diverges.
(4) Geometric series, valid for $|t| < 1$.

Matching with (1.63), $\mathbb{E}(X^k)/k! = 1$, so $\mathbb{E}(X^k) = k!$: mean 1, $\mathbb{E}\,X^2 = 2$, variance $2 - 1 = 1$, all without an integral beyond the first. We can run the same computation on data. Replace ψ by the empirical mgf, the average of e^{tX_j} over simulated draws, and differentiate it numerically at 0:

Listing 1.18: Moments from the empirical mgf (`code/ch01/19_characteristic_function.py`)

```
23 X = rng.exponential(1.0, size=1_000_000)
24 h = 0.01
25 psi = lambda t: np.mean(np.exp(t * X))
26 m1 = (psi(h) - psi(-h)) / (2 * h)
27 m2 = (psi(h) - 2 * psi(0.0) + psi(-h)) / h**2
```

Line 25 defines $\hat{\psi}(t)$ as a sample mean over 10^6 draws; lines 26–27 are the central finite differences for $\psi'(0)$ and $\psi''(0)$ with step $h = 0.01$. They give 0.9993 and 1.9993 (exact 1 and 2).

Linear changes and sums. Two properties make the mgf useful [Wasserman Lemma 3.31, p. 57]. For $Y = aX + b$, $\psi_Y(t) = \mathbb{E}\big(e^{t(aX+b)}\big) = e^{bt}\psi_X(at)$. For a sum of independent variables,

$$\psi_{X_1+\cdots+X_n}(t) \overset{(1)}{=} \mathbb{E}\big(e^{tX_1}e^{tX_2}\cdots e^{tX_n}\big) \overset{(2)}{=} \mathbb{E}\big(e^{tX_1}\big)\cdots\mathbb{E}\big(e^{tX_n}\big) = \prod_{i=1}^{n}\psi_{X_i}(t). \tag{1.64}$$

(1) The exponential of a sum is the product of exponentials.
(2) Independence: the mean of a product of functions of independent variables is the product of the means (Section 1.12).

Combined with uniqueness (if two mgfs agree on an interval around 0, the distributions are equal, [Wasserman Thm. 3.33, p. 57]), this identifies the distribution of a sum by recognising its mgf.

Example: binomial and Poisson sums. A Bernoulli trial has $\psi(t) = (1-p) + pe^t$. A binomial count is a sum of n independent trials, so $\psi(t) = (pe^t + q)^n$ with $q = 1-p$ [Wasserman Ex. 3.32, p. 57]. Adding two independent binomials with the same p gives $(pe^t+q)^{n_1}(pe^t+q)^{n_2} = (pe^t+q)^{n_1+n_2}$, the mgf of Binomial$(n_1+n_2, p)$: pooling two runs of trials is one longer run [Wasserman Ex. 3.34, p. 57]. For a Poisson count,

$$\psi(t) \overset{(1)}{=} \sum_{k=0}^{\infty} e^{tk}\,\frac{e^{-\lambda}\lambda^k}{k!} \overset{(2)}{=} e^{-\lambda}\sum_{k=0}^{\infty}\frac{(\lambda e^t)^k}{k!} \overset{(3)}{=} e^{-\lambda}e^{\lambda e^t} = e^{\lambda(e^t-1)}.$$

(1) Lazy statistician with the Poisson pmf.
(2) Collect $e^{tk}\lambda^k = (\lambda e^t)^k$.
(3) Exponential series $\sum_k a^k/k! = e^a$.

Then independent $Y_1 \sim \text{Poisson}(\lambda_1)$ and $Y_2 \sim \text{Poisson}(\lambda_2)$ have $\psi_{Y_1+Y_2} = e^{\lambda_1(e^t-1)}e^{\lambda_2(e^t-1)} = e^{(\lambda_1+\lambda_2)(e^t-1)}$, so $Y_1 + Y_2 \sim \text{Poisson}(\lambda_1+\lambda_2)$ [Wasserman Ex. 3.35, p. 58].[6] Signal events and background events counted in the same window form one Poisson count with the summed rate, the starting point of every counting experiment in Chapter 4.

[6] The text writes the sum as "$Y = Y_1 + Y + 2$"; it should read $Y = Y_1 + Y_2$.

Example: the Gaussian, by completing the square. For $X \sim \mathcal{N}(\mu, \sigma^2)$ write $x = \mu + \sigma z$:

$$\psi_X(t) \overset{(1)}{=} e^{\mu t} \int \frac{e^{-z^2/2}}{\sqrt{2\pi}}\, e^{\sigma t z}\, \mathrm{d}z \overset{(2)}{=} e^{\mu t}\, e^{\sigma^2 t^2/2} \int \frac{e^{-(z-\sigma t)^2/2}}{\sqrt{2\pi}}\, \mathrm{d}z \overset{(3)}{=} e^{\mu t + \sigma^2 t^2/2}.$$

(1) $e^{tx} = e^{\mu t} e^{\sigma t z}$, and $f(x)\,\mathrm{d}x = \varphi(z)\,\mathrm{d}z$.
(2) Complete the square: $-z^2/2 + \sigma t z = -(z - \sigma t)^2/2 + \sigma^2 t^2/2$.
(3) The remaining integral is a shifted standard normal density, which integrates to 1.

A sum of independent Gaussians therefore has mgf $\exp\big[(\sum_i \mu_i)t + (\sum_i \sigma_i^2)t^2/2\big]$: it is Gaussian, with the means added and the variances added. The table of [Wasserman p. 58] also lists Gamma(α, β), $\psi(t) = (1 - \beta t)^{-\alpha}$ for $t < 1/\beta$. Since an exponential with mean β is Gamma$(1, \beta)$, the sum of n independent exponential lifetimes has mgf $(1 - \beta t)^{-n}$ and is Gamma(n, β) [Wasserman Exercise 3.24, p. 61]. The named distributions and their mgfs are the subject of Chapter 2.

Cumulants. Because sums multiply mgfs, their logarithms add. The **cumulant generating function** $K(t) = \ln \psi(t)$ has Taylor coefficients $K(t) = \sum_n \kappa_n t^n / n!$ called **cumulants** [CasellaBerger §2.6.2]. The first two are

$$\kappa_1 = K'(0) \overset{(1)}{=} \frac{\psi'(0)}{\psi(0)} = \mu, \qquad \kappa_2 = K''(0) \overset{(2)}{=} \frac{\psi''(0)}{\psi(0)} - \Big(\frac{\psi'(0)}{\psi(0)}\Big)^2 = \sigma^2,$$

(1) Derivative of a logarithm; $\psi(0) = \mathbb{E}(1) = 1$ and $\psi'(0) = \mu$.
(2) Quotient rule, then $\psi''(0) = \mathbb{E}\, X^2$ and the shortcut (1.46).

and $\kappa_3 = \mathbb{E}(X - \mu)^3$. For independent X, Y every cumulant adds, $\kappa_n(X + Y) = \kappa_n(X) + \kappa_n(Y)$. For the Gaussian $K(t) = \mu t + \sigma^2 t^2/2$ exactly, so every cumulant beyond the second is zero. Non-zero higher cumulants therefore measure non-Gaussianity: the skewness is $\kappa_3/\kappa_2^{3/2}$. The primordial non-Gaussianity parameter f_{NL} of cosmology is a third cumulant of this kind, and the topological summaries of Chapter 12 are one way to detect such departures from Gaussianity.

Return to the partition function $Z(\beta) = \int g(E)\, e^{-\beta E}\, \mathrm{d}E$ of the opening. The mgf of the energy in the canonical ensemble is $\mathbb{E}\, e^{tE} = Z(\beta - t)/Z(\beta)$, so $K(t) = \ln Z(\beta - t) - \ln Z(\beta)$ and $\kappa_1 = -\partial_\beta \ln Z$, $\kappa_2 = \partial_\beta^2 \ln Z$: the free energy is a cumulant generating function.

1.14.3 The characteristic function

The mgf has a weakness: it may not exist. For the Cauchy density $e^{tx}/(1 + x^2)$ grows without bound in one tail for every $t \neq 0$, so $\psi(t) = \infty$. The lognormal f_1 above has all its moments, yet $\psi(t) = \infty$ for every $t > 0$, which is how it escapes the uniqueness theorem. The cure is to put an i in the exponent.

Working definition 1.25 (characteristic function)

The **characteristic function** of X is

$$\phi_X(t) = \mathbb{E}\big(e^{itX}\big) = \int e^{itx} f(x)\,\mathrm{d}x, \qquad t \in \mathbb{R}, \tag{1.65}$$

[the Fourier transform of the density]. It always exists, since $\big|e^{itx}\big| = 1$ gives $\big|\phi(t)\big| \leq \int f = 1$, and it determines the distribution uniquely. The density is recovered by the inverse

transform

$$f(x) = \frac{1}{2\pi} \int \phi_X(t)\, e^{-itx}\, \mathrm{d}t \tag{1.66}$$

whenever ϕ_X is integrable. *Operational test:* the average of $\cos(tX_j) + i\sin(tX_j)$ over draws.

([Wasserman p. 56, footnote 2] mentions it in one line; [CasellaBerger §2.6.2] states the existence and uniqueness.) In the Fourier convention used throughout, $\tilde{h}(f) = \int h(x)e^{-2\pi i f x}\mathrm{d}x$, the characteristic function is $\phi(t) = \tilde{f}(-t/2\pi)$: the same transform with the sign of the exponent flipped and the frequency measured in radians. The properties follow directly from (1.65): $\phi(0) = 1$; $\phi(-t) = \overline{\phi(t)}$; ϕ is real if and only if the distribution is symmetric about 0; $\phi_{aX+b}(t) = e^{ibt}\phi_X(at)$; the product rule (1.64) holds with it in place of t; and when the moments exist, $\phi^{(k)}(0) = i^k\,\mathbb{E}(X^k)$, so the Taylor expansion near 0 is

$$\phi_X(t) = 1 + i\mu t - \tfrac{1}{2}\,\mathbb{E}(X^2)\,t^2 + o(t^2). \tag{1.67}$$

For the Gaussian, replacing t by it in the mgf gives $\phi(t) = e^{i\mu t - \sigma^2 t^2/2}$: the Fourier transform of a Gaussian is a Gaussian, with the width inverted, as in the uncertainty relation between position and momentum wave packets.

Example: the uniform and its sums. For $U \sim \mathrm{Uniform}(-1, 1)$,

$$\phi_U(t) \overset{(1)}{=} \frac{1}{2}\int_{-1}^{1} e^{itx}\,\mathrm{d}x \overset{(2)}{=} \frac{1}{2}\cdot\frac{e^{it} - e^{-it}}{it} \overset{(3)}{=} \frac{\sin t}{t}.$$

(1) Definition (1.65) with density $\frac{1}{2}$ on $(-1, 1)$.
(2) Antiderivative $e^{itx}/(it)$.
(3) $e^{it} - e^{-it} = 2i\sin t$.

It is real because U is symmetric, and it is the diffraction pattern of a single slit, since a uniform density is a slit aperture. The sum of n independent copies has $\phi(t) = (\sin t/t)^n$. For $n = 2$, the inverse transform (1.66) of $(\sin t/t)^2$ must be the triangle density $(1 - |s|/2)/2$ on $(-2, 2)$ found by convolution in Example 1.49. Figure 1.46 checks both directions numerically. With 10^5 draws, the empirical characteristic functions of U, $U_1 + U_2$ and $U_1 + U_2 + U_3$ agree with $(\sin t/t)^n$ to within 0.0073 at every t (the expected sampling noise is about $1/\sqrt{10^5} \approx 0.003$ per point). A numerical inverse Fourier transform of $(\sin t/t)^2$ reproduces the triangle to within 0.0004.

The picture behind this is the convolution theorem, drawn in Figure 1.47. For independent X and Y the density of $X + Y$ is the convolution $f_X * f_Y$ (1.39), and its characteristic function is the product $\phi_X\phi_Y$. Going around the square the long way, through Fourier space, replaces an integral by a multiplication.

Key idea: Sums of independent variables

For independent $X_1, \ldots, X_n$ the characteristic function of the sum is the product $\prod_i \phi_{X_i}(t)$, and the characteristic function determines the distribution. The same holds for the mgf wherever it exists.

Example: the Cauchy, and why its average never settles. The characteristic function of the Cauchy density is $e^{-|t|}$. The cleanest proof applies the inversion formula (1.66) to $e^{-|t|}$ and

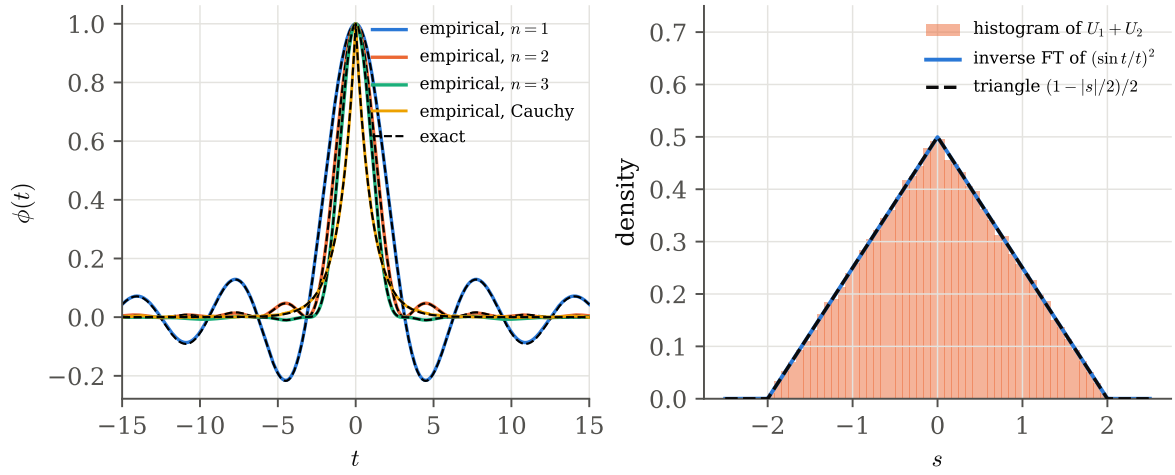

Figure 1.46: Left: characteristic functions estimated from simulated draws (coloured) against the exact ones (black dashed): $(\sin t/t)^n$ for sums of $n = 1, 2, 3$ uniforms, which narrow and flatten their side lobes as n grows, and $e^{-|t|}$ for the Cauchy, with its kink at $t = 0$. Right: the histogram of $U_1 + U_2$, the numerical inverse transform of $(\sin t/t)^2$, and the exact triangle lie on top of each other.

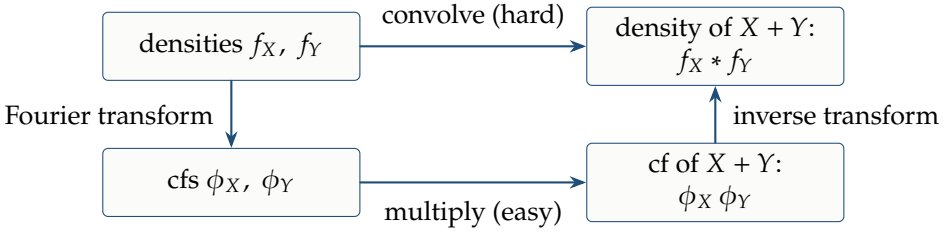

Figure 1.47: Two routes from the densities of two independent variables to the density of their sum. The top route is the convolution integral. The bottom route transforms each density, multiplies the transforms, and transforms back.

checks that the result is the Cauchy density:

$$\frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-|t|}e^{-itx}\,\mathrm{d}t \overset{(1)}{=} \frac{1}{2\pi}\left[\int_0^{\infty} e^{-t(1+ix)}\,\mathrm{d}t + \int_0^{\infty} e^{-t(1-ix)}\,\mathrm{d}t\right]$$
$$\overset{(2)}{=} \frac{1}{2\pi}\left[\frac{1}{1+ix} + \frac{1}{1-ix}\right] \overset{(3)}{=} \frac{1}{\pi(1+x^2)}.$$

(1) Split at $t = 0$ and substitute $t \to -t$ in the negative half.
(2) $\int_0^{\infty} e^{-ct}\mathrm{d}t = 1/c$ for $\mathrm{Re}\, c > 0$.
(3) Common denominator $(1 + ix)(1 - ix) = 1 + x^2$, numerator 2.

By uniqueness, $\phi(t) = e^{-|t|}$. It has a kink at $t = 0$, so it has no derivative there, which by (1.67) is the transform-side sign that the mean does not exist. Now average n independent Cauchy draws:

$$\phi_{\bar{X}_n}(t) \overset{(1)}{=} \prod_{i=1}^{n} \phi_X\left(\frac{t}{n}\right) \overset{(2)}{=} \left(e^{-|t|/n}\right)^n = e^{-|t|}.$$

(1) $\bar{X}_n = \sum_i X_i/n$: scaling rule $\phi_{aX}(t) = \phi_X(at)$ with $a = 1/n$, and the product rule for the independent sum.
(2) The Cauchy characteristic function.

The average of n Cauchy draws has exactly the distribution of one draw, for every n. Averaging gains nothing, which is what the running averages of Figure 1.39 showed. A physicist measuring the centre of a resonance line with a pure Breit–Wigner shape by averaging event positions would find the same.

1.14.4 Setting up the central limit theorem

The characteristic function makes the most important theorem of the next chapter almost mechanical. Let $X_1, \dots, X_n$ be iid with mean 0 and variance σ^2, and standardise their sum, $Z_n = (X_1 + \cdots + X_n)/(\sigma\sqrt{n})$. Then

$$\phi_{Z_n}(t) \overset{(1)}{=} \left[\phi_X\!\left(\frac{t}{\sigma\sqrt{n}}\right)\right]^n \overset{(2)}{=} \left[1 - \frac{\sigma^2}{2}\,\frac{t^2}{\sigma^2 n} + o\!\left(\frac{1}{n}\right)\right]^n = \left[1 - \frac{t^2}{2n} + o\!\left(\frac{1}{n}\right)\right]^n \xrightarrow[n\to\infty]{} e^{-t^2/2}.$$

(1) Scaling and product rules, as for the Cauchy average.
(2) Taylor expansion (1.67) with $\mu = 0$ and $\mathbb{E}\,X^2 = \sigma^2$, at the small argument $t/(\sigma\sqrt{n})$.

The last step is the limit $(1 + a/n)^n \to e^a$. The limit $e^{-t^2/2}$ is the characteristic function of $\mathcal{N}(0,1)$, and convergence of characteristic functions implies convergence of the CDFs [CasellaBerger Thm. 2.6.1]. So the standardised sum of many iid variables with finite variance is approximately Gaussian, whatever their own distribution: the central limit theorem. Only the first two terms of (1.67) survived, which is why only the mean and the variance of the X_i matter in the limit. The Cauchy fails the hypothesis, having no finite variance and a kinked ϕ, and is not Gaussianised. The proper statement, its conditions, the rate of convergence and its failures are the business of Chapter 2.

One more generating function is handy for counts. The **probability generating function** $G(s) = \mathbb{E}(s^X) = \sum_k \mathrm{P}(X = k)\, s^k$ of a variable taking values $0, 1, 2, \dots$ is a power series whose coefficients are the probabilities themselves, $\mathrm{P}(X = k) = G^{(k)}(0)/k!$, and whose derivatives at $s = 1$ give the factorial moments $\mathbb{E}[X(X-1)\cdots]$ [CasellaBerger §2.6.2]. It is the mgf with $s = e^t$; for a Poisson count $G(s) = e^{\lambda(s-1)}$.

Recap

- A random variable is a map from outcomes to numbers. Its distribution is given by a CDF, and by a pmf (mass) or a pdf (probability per unit x, with units).
- Marginals average out nuisance variables; conditionals slice and renormalise; independence means the joint factorises.
- Change of variables: $f_Y\,|\mathrm{d}y| = f_X\,|\mathrm{d}x|$, summed over branches, with $|J|$ in several dimensions.
- $\mathbb{E}\,r(X) = \int r(x) f(x)\,\mathrm{d}x$. Expectation is linear always; products factorise under independence. The mean minimises the expected squared miss, the median the absolute miss.
- $\mathrm{Var}(X) = \mathbb{E}\,X^2 - \mu^2$; independent variances add; $\mathrm{Var}(\bar{X}_n) = \sigma^2/n$; S_n^2 divides by $n - 1$.
- $\mathbb{E}[\mathbb{E}(Y \mid X)] = \mathbb{E}\,Y$ and $\mathrm{Var}\,Y = \mathbb{E}\,\mathrm{Var}(Y \mid X) + \mathrm{Var}\,\mathbb{E}(Y \mid X)$.
- Covariance measures linear co-movement; $|\rho| \le 1$; zero correlation does not imply independence (except for jointly Gaussian variables).
- $\mathbf{C}_{AX+b} = A\mathbf{C}A^{\mathsf{T}}$; eigenvectors of $\mathbf{C}$ give uncorrelated combinations; $\boldsymbol{X} = L\boldsymbol{Z}$ with $LL^{\mathsf{T}} = \mathbf{C}$ generates them.

- mgf and cf generate moments; sums of independent variables multiply them; the cf always exists and leads straight to the central limit theorem.

Chapter summary

Every later statement of the form "the probability of this is that" rests on the ideas of this chapter. The first part worked with events: what has a probability, which rules the numbers obey, how conditioning shrinks the sample space, how trees chain conditions, and how reading a tree backwards turns a prediction $\mathrm{P}(E \mid H)$ into an inference $\mathrm{P}(H \mid E)$. The second part turned outcomes into numbers, gave them densities, and compressed the densities into means, variances, covariance matrices and transforms. A data analysis in physics runs along a chain,

$$\text{model} \to \text{data} \to \text{summary } S \to P(S \mid \theta) \to \text{inference :}$$

a physical model with parameters θ produces data, we compress the data into a summary S, we work out how S is distributed for each θ, and we infer θ. Probability is the language of every arrow. The fourth arrow has already been walked once. The sample mean $\bar{X}_n$ is a summary, and $\mathbb{E}\,\bar{X}_n = \mu$, $\mathrm{Var}\,\bar{X}_n = \sigma^2/n$ are the first two moments of its sampling distribution. The two tables list each concept, what it means operationally (how to compute or test it), and where it is used next.

Events and their probabilities

concept	operational meaning	used later in
sample space, event	list every outcome; an event is a subset, in code a boolean mask over simulated outcomes	every chapter
axioms of P	non-negative, total 1, additive over disjoint events; all other rules (complement, inclusion–exclusion, Boole) follow	Chapters 2 and 4
frequency vs degree of belief	long-run fraction of repetitions vs a coherent state of knowledge; same rules, different reading	Chapters 3 and 5
counting	equally likely outcomes: favourable over total, via multiplication principle and binomial coefficients	Chapter 2
conditional probability	shrink the sample space to where the evidence is true and re-measure: $\mathrm{P}(A \mid B) = \mathrm{P}(AB)/\mathrm{P}(B)$; in code, filter then count	Chapters 4 and 5
trees, total probability	multiply along a path, add across paths: $\mathrm{P}(E) = \sum_i \mathrm{P}(E \mid H_i)\,\mathrm{P}(H_i)$	Chapters 5 and 9
independence	$\mathrm{P}(AB) = \mathrm{P}(A)\,\mathrm{P}(B)$; learning B does not change $\mathrm{P}(A)$; pairwise is weaker than mutual	Chapters 2 and 6
Bayes' theorem	read the tree backwards: from $\mathrm{P}(E \mid H)$ and $\mathrm{P}(H)$ to $\mathrm{P}(H \mid E)$	Chapters 5, 9 and 10

Random variables and their summaries

concept	operational meaning	used later in
random variable	a function on outcomes; one simulated outcome gives every observable at once	every chapter
Bernoulli, binomial	one yes/no trial vs the number of successes in n independent identical trials, $\binom{n}{k}p^k(1-p)^{n-k}$	Chapters 2 and 4
CDF, quantiles	$F(x) = \mathrm{P}(X \le x)$, estimated by the empirical CDF; $F^{-1}(u)$ of a uniform u samples X	Chapters 4 and 6
pmf, pdf	mass at a point; density = probability per unit x (a normalised histogram of width $\to 0$)	Chapters 2 and 3
HDI, equal-tailed interval	shortest region of given probability vs equal tail areas	Chapter 5
joint, marginal	marginal = integrate (average) out the nuisance variables; in code, ignore the column	Chapters 5, 9 and 10
conditional density	slice at the observed value and renormalise; $f(x,y) = f(y \mid x)f(x)$	Chapters 3 and 5
independence of variables	joint density factorises; test by comparing conditional slices	Chapters 2 and 6
change of variables	$f_Y \lvert dy\rvert = f_X \lvert dx\rvert$ summed over branches; Jacobian determinant in n dimensions; check by histogramming	Chapters 2, 5 and 6
sampling prescription	say what is chosen at random: uniform instant gives the arcsine law for x, uniform x gives $(\omega/4)\lvert\sin\omega t\rvert$ for t; conservation laws give accessibility, not equal probability	Chapters 6 and 9
maximum entropy (microcanonical, canonical)	maximise $-k_B \sum p_i \ln p_i$ under the constraints: normalisation alone gives uniform on the energy shell, a fixed mean energy gives $e^{-E_i/k_BT}/Z$	Chapters 2 and 5
virial theorem, negative heat capacity	bounded motion: $2\langle K\rangle = n\langle V\rangle$ for $V \propto r^n$; gravity gives $E = -\frac{3}{2}Nk_BT$, $C < 0$, which the canonical $C = \mathrm{Var}\,E/k_BT^2 \ge 0$ forbids	when the canonical distribution applies
expectation	probability-weighted average; long-run mean of draws; $\mathbb{E}\,r(X) = \int rf$; linear always	every chapter
variance, standard deviation	mean squared deviation; independent variances add; errors add in quadrature	Chapters 2 and 3
sample mean and variance	$\bar{X}$ has variance σ^2/n; S^2 divides by $n-1$ to be unbiased	Chapters 3 and 4
conditional expectation, total variance	$\mathbb{E}\,Y = \mathbb{E}[\mathbb{E}(Y \mid X)]$; spread = mean within-group spread + spread of group means	Chapters 3 and 5
covariance, correlation	mean product of deviations; $\lvert\rho\rvert \le 1$ measures linear co-movement only; plot before trusting $\rho \approx 0$	Chapters 3 and 7
covariance matrix	$\mathbf{C}_{AX+b} = A\mathbf{C}A^{\mathsf{T}}$; eigenvectors give uncorrelated combinations; $\boldsymbol{X} = L\boldsymbol{Z}$ generates correlated Gaussians	Chapters 7, 8 and 10
error propagation	linearise: $\mathbf{C}_y \approx A\mathbf{C}A^{\mathsf{T}}$ with the Jacobian A; exact only for linear maps	Chapters 3 and 10
moments, cumulants	shape numbers; cumulants add for independent sums and vanish beyond order two for a Gaussian	Chapters 2 and 12
mgf, characteristic function	generate moments; sums of independent variables multiply them; cf always exists and gives the CLT	Chapter 2

Reading the literature

- **Main line.** [Wasserman Chs. 1–3] covers probability, random variables and expectation compactly, with many short examples and exercises; most of the examples of Chapter 1 are worked out from there in full.
- **The clearest first reading.** [Kruschke Ch. 4]: what a distribution is, mass versus density (with the density exceeding 1), means, variances, HDIs, and two-way tables, all in small steps.
- **Pictures.** [SeeingTheory Chs. 1–3]: interactive visual versions of events, expectation, variance and random variables.
- **The physicist's version.** [Cowan Ch. 1]: densities as normalised histograms, marginals as projections, conditionals as thin bands, functions of random variables, the covariance matrix, error propagation and the orthogonal transformation to uncorrelated variables.
- **Careful statements.** [CasellaBerger Chs. 1–2, 4]: transformations with full hypotheses, the minimising-distance property of the mean, non-unique moments, generating functions, conditional variance, and the correlation bounds.
- **Bayesian framing.** [Lambert Ch. 3] for probability trees and the two directions of probability, prediction and inference, which Chapter 5 develops.
- **Going further.** Characteristic functions and the continuity theorem are treated in any graduate probability text; for the physicist, [Cowan Ch. 10] applies them to sums of random variables.

Chapter 2

Probability Distributions from First Principles

Where this chapter is going

A physicist rarely invents a probability distribution. It is forced on us by the way the data were made. A paddle that either fires or does not fire, a histogram filled one event at a time, a Geiger counter clicking at random, a photomultiplier waiting for its tenth photon: each of these is a small machine, and each machine produces its own distribution. We build the common distributions from the machines that generate them. We state the assumptions in words, derive the probability law line by line, compute its mean and variance, and then run the machine in Python to check that the histogram of simulated outcomes lands on the formula.

Building a distribution from its machine is the *prediction* direction of probability (Chapter 1). We fix a hypothesis, say "the source emits at rate λ", and ask which outcomes it produces and how often. Recall the book's pipeline (Chapter 0): a theory produces data, we compress the data into a statistic S, we work out how S scatters when the experiment is repeated, and from that we infer the physics, labelled by parameters θ. The distributions of counts, histograms and waiting times in this chapter supply the scatter step, $P(S \mid \theta)$, for the simplest statistics. Once we have $P(S \mid \theta)$, we can read it the other way round: hold the observed S fixed and let θ vary. Read that way it is the likelihood (Chapter 3), and Bayes' theorem turns the likelihood into a posterior (Chapter 5).

The counting distributions come first, from a single yes/no trial up to the waiting times between random events. The continuous distributions follow. With them come the reason the Gaussian appears everywhere, the distributions built from Gaussians (χ^2, Student-t, F), and the remaining common distributions.

A distribution is the fingerprint of a mechanism. Every counting distribution answers one forward question: *if the world works like this machine, how often does each outcome occur?* To use a distribution correctly, we must recognise the machine behind it. So we meet each distribution in the same four steps:

1. **The story:** which physical process are we modelling, and which assumptions (independence, constant probability, constant rate) does it satisfy?
2. **The derivation:** count the ways the outcome can happen and multiply their probabilities.
3. **The summary numbers:** mean and variance, derived rather than quoted.
4. **The check:** simulate the machine itself, not the formula, and compare the histogram with the derived law.

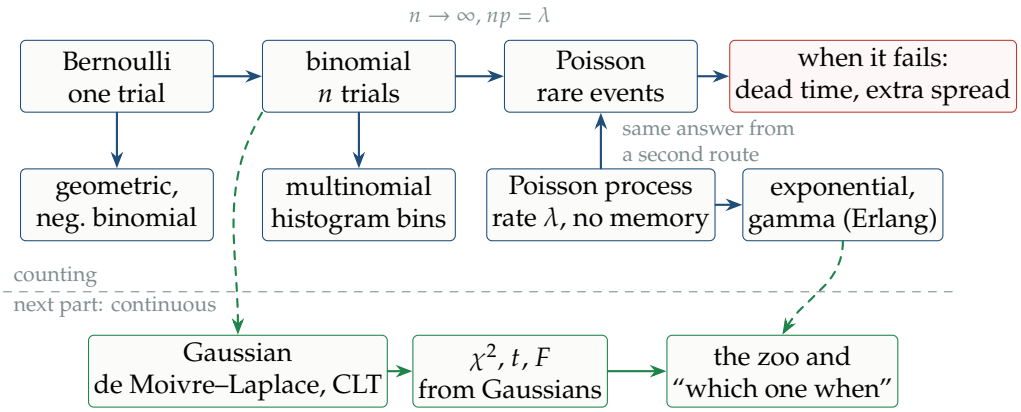

Figure 2.1: The road through the chapter. Blue boxes are the counting distributions, each from the one before it or from a second, independent route (the Poisson distribution appears both as a limit of the binomial and from three physical inputs about the arrivals). The red box collects the ways real detectors break the assumptions. Green boxes are the continuous distributions of the next part; the dashed arrows mark where the binomial and the waiting times feed into them.

2.1 One trial: the Bernoulli distribution

A cosmic-ray muon crosses a plastic scintillator paddle. Either the photomultiplier behind the paddle produces a pulse above threshold, or it does not. Nothing else can happen. The paddle has an *efficiency* ϵ: the probability that it fires when a muon really goes through. This single yes/no trial is the building block of every coincidence trigger, every tracking efficiency and every "did this event pass the cut?" in an analysis. One number describes the trial completely: the probability of a "yes", which we call p in general (for the paddle, $p = \epsilon$). Every counting distribution in this chapter is assembled from copies of this trial.

Physical picture: a two-level system measured once. A spin-$\frac{1}{2}$ particle in the state $\alpha|\uparrow\rangle + \beta|\downarrow\rangle$, measured along z, gives "up" with probability $|\alpha|^2$ and "down" with probability $|\beta|^2 = 1 - |\alpha|^2$. One measurement, two outcomes, one number. The paddle is the same situation without the Hilbert space. Its microscopic history is unknown (how many photons were made, how many reached the photocathode), and the threshold collapses all of it into a single bit: fired or not.

The question, step by step.

1. What can the outcome be? Two things. We code them as numbers: 1 ("success", fired) and 0 ("failure", did not fire).
2. How many numbers do we need to describe the trial? One: the probability p of a 1. The probability of a 0 is then forced to be $1 - p$.
3. Can we write both probabilities as one formula in the outcome x? Yes. That single formula is what makes products over many trials simple later.
4. What are its average and spread? Derive them, then check by simulation.

2.1.1 The notation of distributions

Three pieces of notation are used for the rest of the book: the symbol $\sim$, the probability mass function, and the parameter.

Working definition 2.1 (has distribution, pmf, parameter)

We write $X \sim F$ and read it "X *has distribution* F". The symbol $\sim$ does *not* mean "approximately" here. For a random variable X [a rule that assigns a number to each outcome of the experiment] that takes whole-number values, the **probability mass function** (pmf) is

$$f(x) \;=\; \mathrm{P}(X = x),$$

the probability that X comes out equal to the particular number x. A **parameter** [a fixed number, such as p, that selects one member of a family of distributions] is not random. It is written after a bar or a semicolon when we want to stress it: $f(x \mid p)$ or $f(x; p)$.

Watch out: three kinds of letter

In $\mathrm{P}(X = x) = p^x(1-p)^{1-x}$ there are three different kinds of object. X (capital) is the random variable: it has not been observed yet, and it has a distribution. x (lower case) is a possible value: an ordinary number we plug in. p is a parameter: fixed, usually unknown, and the thing statistical inference tries to learn from data. Mixing them up is the commonest source of nonsense in statistics [Wasserman p. 26]. The whole of Chapter 3 is about reading the same formula as a function of p for fixed x.

2.1.2 The two simplest distributions

Two very simple distributions mark the extreme cases of everything that follows. The first has no randomness at all; the second has no preferred outcome.

Working definition 2.2 (point mass and discrete uniform)

X has a **point mass** at a, written $X \sim \delta_a$, if $\mathrm{P}(X = a) = 1$ [the outcome is certain, there is no randomness at all]. Its cumulative distribution function (CDF) $F(x) = \mathrm{P}(X \le x)$ is a single step,

$$F(x) = \begin{cases} 0 & x < a, \\ 1 & x \ge a. \end{cases}$$

X has the **discrete uniform** distribution on $\{1, \dots, N\}$ if $f(x) = 1/N$ for $x = 1, \dots, N$ and 0 otherwise [all N outcomes equally likely, like a fair die with N faces].

The point mass is what any distribution becomes when its spread shrinks to zero: a perfectly stable voltage reference, a noise-free measurement. Its mean is a and its variance is 0. The discrete uniform is the other extreme: no outcome is preferred. Its mean and variance need two standard sums, which we recall and derive once here.

Example: mean and variance of a fair N-sided die. We need $\sum_{i=1}^{N} i = \frac{N(N+1)}{2}$ and $\sum_{i=1}^{N} i^2 = \frac{N(N+1)(2N+1)}{6}$. The first follows by writing the sum forwards and backwards and adding: each of the N columns sums to $N+1$. For the second, sum the identity $(i+1)^3 - i^3 = 3i^2 + 3i + 1$ from $i = 1$ to N. The left side telescopes (each i^3 cancels against the next term) to $(N+1)^3 - 1$. The right side is $3\sum i^2 + 3\sum i + N$. Solving, $3\sum i^2 = (N+1)^3 - 1 - \frac{3N(N+1)}{2} - N$, which simplifies to $\frac{N(N+1)(2N+1)}{2}$; divide by 3. With both sums in hand,

$$\mathbb{E}\,X \overset{(1)}{=} \sum_{x=1}^{N} x\,\frac{1}{N} \overset{(2)}{=} \frac{1}{N}\,\frac{N(N+1)}{2} = \frac{N+1}{2},$$

$$\mathbb{E}\,X^2 \overset{(1)}{=} \sum_{x=1}^{N} x^2\,\frac{1}{N} \overset{(2)}{=} \frac{(N+1)(2N+1)}{6},$$

$$\operatorname{Var} X \overset{(3)}{=} \mathbb{E}\,X^2 - (\mathbb{E}\,X)^2 = \frac{(N+1)(2N+1)}{6} - \frac{(N+1)^2}{4} \overset{(4)}{=} \frac{(N+1)(N-1)}{12}.$$

(1) The expectation of $g(X)$ is the sum of $g(x)$ times the probability of x (Chapter 1).
(2) The two power sums recalled above.
(3) The shortcut $\operatorname{Var} X = \mathbb{E}[(X-\mu)^2] = \mathbb{E}\,X^2 - 2\mu\,\mathbb{E}\,X + \mu^2 = \mathbb{E}\,X^2 - \mu^2$ with $\mu = \mathbb{E}\,X$.
(4) Take out $(N+1)/12$: $2(2N+1) - 3(N+1) = N - 1$.

For an ordinary die ($N = 6$) this gives mean 3.5 and variance $35/12 \approx 2.92$ [CasellaBerger §3.2, p. 70]. For a digitiser that reports one of N equally likely codes, the standard deviation is $\sqrt{(N^2-1)/12} \approx N/\sqrt{12}$, the famous "$1/\sqrt{12}$ of a bin" of quantisation noise.

2.1.3 The Bernoulli trial

Working definition 2.3 (Bernoulli distribution)

$X \sim \text{Bernoulli}(p)$ if X takes the value 1 with probability p and the value 0 with probability $1-p$, for some $p \in [0,1]$ [one trial with two outcomes, success coded as 1]. Its pmf is

$$f(x \mid p) \;=\; p^x(1-p)^{1-x}, \qquad x \in \{0,1\}. \tag{2.1}$$

Recognise it by: a single trial, exactly two outcomes, a fixed probability p.

The exponents in (2.1) act as switches that pick the right factor. To see this, put in the two possible values. At $x = 1$: $p^1(1-p)^0 = p$. At $x = 0$: $p^0(1-p)^1 = 1-p$. The switches pay off when we multiply many such factors, one per trial: the exponents simply add up.

A random variable that is 1 when something happens and 0 otherwise is also called an **indicator**. We write I_A for the indicator of an event A. Every Bernoulli variable is the indicator of its success event, and every indicator is Bernoulli with $p = \mathrm{P}(A)$.

Mean and variance. One fact does all the work: $0^2 = 0$ and $1^2 = 1$, so $X^2 = X$ for a Bernoulli variable.

$$\mathbb{E}\,X \overset{(1)}{=} 0\cdot(1-p) + 1\cdot p = p,$$

$$\mathbb{E}\,X^2 \overset{(2)}{=} \mathbb{E}\,X = p,$$

$$\operatorname{Var} X \overset{(3)}{=} \mathbb{E}\,X^2 - (\mathbb{E}\,X)^2 = p - p^2 = p(1-p). \tag{2.2}$$

(1) Sum of value times probability over the two values.
(2) $X^2 = X$ because the only values are 0 and 1.
(3) The variance shortcut used for the fair die above.

The variance $p(1-p)$ is zero at $p = 0$ and $p = 1$ (a certain outcome is a point mass) and largest, $1/4$, at $p = 1/2$. A fair coin is the most unpredictable yes/no trial there is.

2.1.4 Where does the randomness live? An explicit sample space

A random variable is a map from the sample space Ω of Chapter 1 (the set of all possible outcomes of the experiment) to numbers. In the formulas above Ω never appeared, but it is still

there. For the Bernoulli trial we can build it explicitly [Wasserman p. 27], and the construction is exactly how a computer makes a Bernoulli variable.

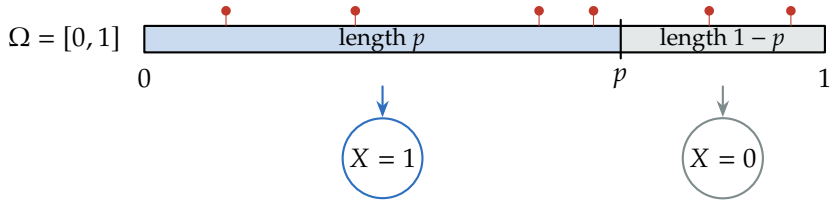

Figure 2.2: The Bernoulli trial as a map. A point ω is thrown uniformly on the unit interval (red dots are six such throws). Every ω in the blue part, of length p, is sent to $X = 1$; every ω in the grey part is sent to $X = 0$. The probability of $X = 1$ is just the length of the blue part.

Take $\Omega = [0, 1]$ with the "length" probability $\mathrm{P}([a, b]) = b - a$ for $0 \le a \le b \le 1$ [a point thrown uniformly on the unit interval]. Fix p and define the map

$$X(\omega) = \begin{cases} 1 & \omega \le p, \\ 0 & \omega > p. \end{cases}$$

Then $\mathrm{P}(X = 1) = \mathrm{P}(\omega \le p) = \mathrm{P}([0, p]) = p$ and $\mathrm{P}(X = 0) = 1 - p$. So $X \sim \text{Bernoulli}(p)$ (Figure 2.2). Every counting distribution can be built this way from uniform numbers. This is the basis of Monte Carlo simulation; Chapter 6 develops it in general (inverse-transform sampling). Here we only use it.

2.1.5 Worked examples

Example: the paddle, and a veto. A paddle has efficiency $\epsilon = 0.9$. Let X be the indicator "paddle fired". Then $\mathbb{E}\,X = 0.9$ and $\mathrm{Var}\,X = 0.9 \times 0.1 = 0.09$, so the standard deviation of a single trial is 0.3.

Now use the same paddle as a *veto*: we keep the event only if the paddle did *not* fire. The indicator of "kept" is $Y = 1 - X$. It is 1 exactly when $X = 0$, which happens with probability $1 - \epsilon$. So $Y \sim \text{Bernoulli}(1 - \epsilon)$, with $\mathbb{E}\,Y = 0.1$ and $\mathrm{Var}\,Y = 0.1 \times 0.9 = 0.09$. The same variance also follows directly from X:

$$\mathrm{Var}\,Y \overset{(1)}{=} \mathrm{Var}(1 - X) \overset{(2)}{=} (-1)^2\,\mathrm{Var}\,X = 0.09.$$

(1) Definition of Y.
(2) Adding a constant does not change a spread, and multiplying by a multiplies the variance by a^2 (Chapter 1).

The veto and the paddle have the same variance: $p(1 - p)$ is symmetric under $p \to 1 - p$, because relabelling success and failure cannot change how unpredictable the trial is.

Example: one trial read two ways. The formula $p^x(1 - p)^{1-x}$ can be read in two directions, exactly the two directions of probability, prediction and inference (Chapter 1).

Prediction. Fix $p = 0.9$. The formula is a distribution over x: $f(1) = 0.9$, $f(0) = 0.1$, and $\sum_x f(x) = 1$.

Inference. Suppose we observed one firing, $x = 1$. Read the same formula as a function of p: $\mathcal{L}(p) = p^1(1 - p)^0 = p$. This is the **likelihood** of p. It is *not* a probability distribution over p:

$$\int_0^1 \mathcal{L}(p)\,\mathrm{d}p \overset{(1)}{=} \int_0^1 p\,\mathrm{d}p \overset{(2)}{=} \left[\tfrac{p^2}{2}\right]_0^1 = \tfrac{1}{2} \neq 1.$$

(1) The likelihood for the observation $x = 1$.
(2) Elementary integral.

The likelihood tells us that values of p near 1 make the observed firing more plausible than values near 0, and nothing more [Kruschke §6.1, p. 125]. Turning it into a distribution over p needs a prior and Bayes' theorem (Chapter 5).

Example: many independent trials of the same paddle. Record N muons, with outcomes $x_1, \ldots, x_N$, each 0 or 1, and assume the trials are independent. The probability of this particular sequence is

$$\mathrm{P}(x_1, \ldots, x_N \mid p) \overset{(1)}{=} \prod_{i=1}^{N} p^{x_i}(1-p)^{1-x_i} \overset{(2)}{=} p^{\sum_i x_i}(1-p)^{\sum_i (1-x_i)} \overset{(3)}{=} p^{z}(1-p)^{N-z},$$

(1) Independence: the joint probability is the product of the single-trial probabilities (Chapter 1).
(2) Powers of the same base multiply by adding exponents.
(3) Write $z = \sum_i x_i$ for the number of firings. Then $\sum_i (1 - x_i) = N - z$.

Only the count z survives: the order in which the firings happened does not matter. This collapse is what the switch exponents in (2.1) were for, and it is the seed of the binomial distribution in the next section [Kruschke (6.2), p. 125].

2.1.6 Python: build the trial from a uniform number

The script `code/ch02/01_bernoulli.py` does exactly what Figure 2.2 shows. The core is three lines:

Listing 2.1: One Bernoulli trial per uniform number (`code/ch02/01_bernoulli.py`)

```
# --- one trial = one uniform number compared with p -----------------------
def bernoulli(p, size):
    u = rng.uniform(0.0, 1.0, size)      # omega, uniform on [0,1]
    return (u <= p).astype(int)          # X(omega) = 1 if omega <= p else 0
```

Line by line: `rng.uniform` throws the points ω on $[0, 1]$; the comparison `u <= p` is the map $X(\omega)$, returning `True` or `False`; `astype(int)` codes these as 1 and 0. The rest of the script runs 5000 trials for three values of p and plots the running fraction of successes, then draws 10^6 trials at $p = 0.9$ and compares the observed frequencies with (2.1).

For 10^6 trials at $p = 0.9$ the sample mean is 0.9002 and the sample variance is 0.0898, against the derived $p = 0.9$ and $p(1-p) = 0.09$ (Figure 2.3). On the left, the running fraction slowly settles onto p: this is the law of large numbers at work. Its typical distance from p after n trials shrinks like $\sqrt{p(1-p)/n}$, which follows from the binomial variance in the next section.

What this bought us. A yes/no trial is fully described by one number p. The pmf $p^x(1-p)^{1-x}$ is built so that products over many independent trials collapse onto the number of successes. The mean is p and the variance is $p(1-p)$, largest for a fair coin.

2.2 Many successive trials: the binomial distribution

A cosmic-ray telescope is a stack of four scintillator layers. A muon going straight down crosses all four. Each layer fires independently with efficiency $\epsilon = 0.95$, the probability that it fires

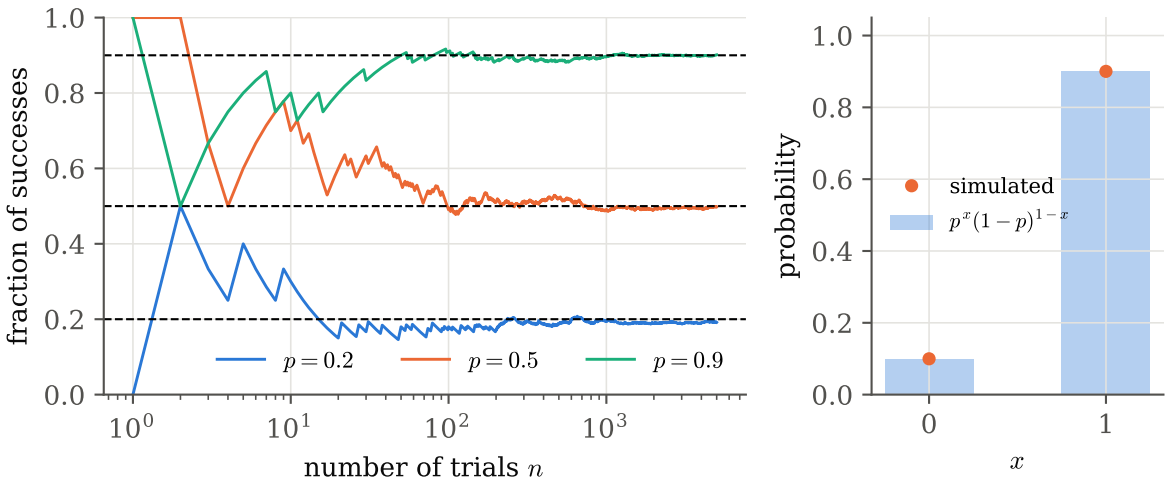

Figure 2.3: Left: the fraction of successes after n trials, for three paddles. Early on the fraction jumps around wildly; by a few thousand trials each curve has settled onto its dashed line at p. Right: for $p = 0.9$ the bars are the pmf and the dots the frequencies in a million simulated trials; they coincide.

when a muon crosses it. To reject noise, the trigger demands that *at least three* of the four layers fire. What fraction of real muons does the trigger keep? Requiring all four would be cleaner, but how many muons would it cost? Both questions need the same thing: the probability of exactly k successes in n independent trials. The binomial distribution supplies it. It turns "each trial succeeds with probability p" into the full distribution of the number of successes.

Physical picture: paths through a tree. Picture each trial as a fork in a road: up for success, down for failure. After n forks, every possible history is a path, and the number of successes is the number of "up" steps along that path. A random walk in one dimension has the same combinatorics. So do n non-interacting spin-$\frac{1}{2}$ particles: the number of spin-up particles is binomially distributed. The binomial coefficient $\binom{n}{k}$ that appears below is the *multiplicity* of the macrostate "k up", the same multiplicity that statistical mechanics uses to define entropy.

The question, step by step.

1. What is the probability of one *particular* sequence of outcomes, say success, failure, success? Multiply, because the trials are independent.
2. Does that probability depend on the order? No: only on how many successes there are.
3. How many sequences have exactly k successes? Count them.
4. So the probability of k successes is (number of sequences) × (probability of each one).

2.2.1 Deriving the pmf by counting paths

Take n independent trials, each a Bernoulli(p). A history is a string of n letters, S (success) or F (failure). By the product formula for independent Bernoulli trials (Section 2.1), a string with k S's has probability $p^k(1-p)^{n-k}$ whatever the order.

How many strings have exactly k S's? We must choose which k of the n positions carry an S. Count ordered choices first: there are n ways to pick the first position, $n-1$ for the second,

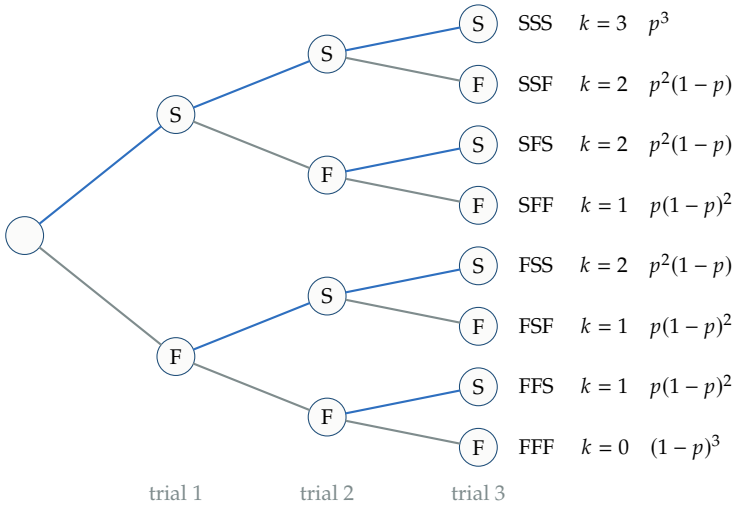

Figure 2.4: All $2^3 = 8$ histories of three trials. Blue branches are successes (probability p), grey ones failures (probability $1-p$). Each path's probability is the product along it and depends only on its number of successes k. Counting paths per k gives $1, 3, 3, 1$, the third row of Pascal's triangle.

and so on down to $n-k+1$ for the k-th, giving $n(n-1)\cdots(n-k+1) = \frac{n!}{(n-k)!}$ ordered choices. Each set of k positions has been counted $k!$ times, once for each order in which we could have picked the same positions. So the number of sets is

$$\binom{n}{k} = \frac{n!}{k!\,(n-k)!}, \tag{2.3}$$

the **binomial coefficient**, read "n choose k". (By convention $0! = 1$, so $\binom{n}{0} = \binom{n}{n} = 1$.)

Working definition 2.4 (binomial distribution)

$X \sim \text{Binomial}(n, p)$ if X is the number of successes in n independent trials, each succeeding with the same probability p [n fixed in advance, trials do not influence each other, p the same for every trial]. Its pmf is

$$f(k \mid n, p) = \binom{n}{k} p^k (1-p)^{n-k}, \qquad k = 0, 1, \ldots, n. \tag{2.4}$$

Recognise it by: multiple successive trials (where Bernoulli is for a single trial), a fixed number of them, each yes/no, independent, with constant p, and we record only the total number of successes.

It is normalised. The probabilities (2.4) add up to one. The tool is the **binomial theorem**: $(a+b)^n = \sum_{k=0}^{n} \binom{n}{k} a^k b^{n-k}$. Here is why it is true. Expanding the product of n factors $(a+b)(a+b)\cdots(a+b)$ means choosing a or b from each factor. A term $a^k b^{n-k}$ arises once for each way of choosing which k factors give a, and there are $\binom{n}{k}$ such ways. Then

$$\sum_{k=0}^{n} f(k \mid n, p) \overset{(1)}{=} \sum_{k=0}^{n} \binom{n}{k} p^k (1-p)^{n-k} \overset{(2)}{=} \big(p + (1-p)\big)^n = 1^n = 1.$$

(1) Definition (2.4).
(2) The binomial theorem with $a = p$ and $b = 1-p$.

With $p = \frac{1}{2}$ the same line says $\sum_k \binom{n}{k} = 2^n$: the total number of paths in the tree [CasellaBerger (3.2.4), p. 74].

2.2.2 Mean and variance, two ways

The slick way: a sum of indicators. Let X_i be the indicator of success on trial i: it is 1 if trial i succeeds and 0 otherwise. Counting successes is adding up these indicators, so $X = X_1 + \cdots + X_n$, and the X_i are independent Bernoulli(p).

$$\mathbb{E}\,X \overset{(1)}{=} \sum_{i=1}^{n} \mathbb{E}\,X_i \overset{(2)}{=} np,$$
$$\operatorname{Var} X \overset{(3)}{=} \sum_{i=1}^{n} \operatorname{Var} X_i \overset{(4)}{=} np(1-p). \tag{2.5}$$

(1) Expectation is linear: $\mathbb{E}(\sum X_i) = \sum \mathbb{E}\,X_i$, with or without independence (Chapter 1).
(2) $\mathbb{E}\,X_i = p$ from (2.2).
(3) For *independent* variables the covariances vanish, so the variance of a sum is the sum of variances.
(4) $\operatorname{Var} X_i = p(1-p)$ from (2.2).

The direct way: sum the pmf. This route uses a trick that recurs throughout the chapter: absorb the factor k into the binomial coefficient, then recognise the sum that is left as the total probability of a smaller distribution. The identity we need is

$$k\binom{n}{k} = k\frac{n!}{k!(n-k)!} = \frac{n!}{(k-1)!(n-k)!} = n\binom{n-1}{k-1} \qquad (k \geq 1).$$

Then

$$\mathbb{E}\,X \overset{(1)}{=} \sum_{k=1}^{n} k\binom{n}{k}p^k(1-p)^{n-k} \overset{(2)}{=} np\sum_{k=1}^{n}\binom{n-1}{k-1}p^{k-1}(1-p)^{(n-1)-(k-1)}$$
$$\overset{(3)}{=} np\sum_{j=0}^{n-1}\binom{n-1}{j}p^j(1-p)^{n-1-j} \overset{(4)}{=} np.$$

(1) Definition of the mean. The $k = 0$ term is zero, so we start at $k = 1$.
(2) The identity above, and one factor p taken out of p^k.
(3) Rename $j = k - 1$.
(4) The sum is the total probability of a Binomial($n-1, p$), which is 1.

For the variance, the same trick works on the *factorial moment* $\mathbb{E}[X(X-1)]$, using $k(k-1)\binom{n}{k} = n(n-1)\binom{n-2}{k-2}$:

$$\mathbb{E}[X(X-1)] \overset{(1)}{=} n(n-1)p^2\sum_{j=0}^{n-2}\binom{n-2}{j}p^j(1-p)^{n-2-j} \overset{(2)}{=} n(n-1)p^2,$$
$$\operatorname{Var} X \overset{(3)}{=} \mathbb{E}[X(X-1)] + \mathbb{E}\,X - (\mathbb{E}\,X)^2 = n(n-1)p^2 + np - n^2p^2 = np(1-p).$$

(1) The same three steps as for the mean, with two factors of k absorbed and $j = k - 2$.
(2) A Binomial($n-2, p$) sums to one.
(3) $\mathbb{E}\,X^2 = \mathbb{E}[X(X-1)] + \mathbb{E}\,X$, and then the variance shortcut.

Both ways agree with [Cowan (2.3)–(2.4), p. 27].[1]

[1] Cowan writes the upper limit of the sum in (2.3) as ∞. It should be n, the number of trials, since the count cannot exceed it.

What the numbers mean. The mean count np grows like n, but the standard deviation $\sqrt{np(1-p)}$ grows only like $\sqrt{n}$. Dividing both by n, the *fraction* of successes X/n has mean p and standard deviation $\sqrt{p(1-p)/n}$. This is the rate at which the running fractions in Figure 2.3 settle, and the origin of every "$1/\sqrt{N}$" error bar on an efficiency.

2.2.3 The moment generating function and sums of binomials

The **moment generating function** (mgf) $M_X(t) = \mathbb{E}\, e^{tX}$ (Chapter 1) packs all the moments into one function: its r-th derivative at $t = 0$ is $\mathbb{E}\, X^r$. For the binomial,

$$M_X(t) \overset{(1)}{=} \sum_{k=0}^{n} e^{tk}\binom{n}{k}p^k(1-p)^{n-k} \overset{(2)}{=} \sum_{k=0}^{n}\binom{n}{k}(pe^t)^k(1-p)^{n-k} \overset{(3)}{=} \left(1-p+pe^t\right)^n. \tag{2.6}$$

(1) Definition of the mgf.
(2) $e^{tk}p^k = (pe^t)^k$.
(3) The binomial theorem with $a = pe^t$ and $b = 1-p$.

Check: $M'(0) = n(1-p+p)^{n-1}p = np$, the mean again.

Key idea: binomials with the same p add

If $X_1 \sim \text{Binomial}(n_1, p)$ and $X_2 \sim \text{Binomial}(n_2, p)$ are independent, then $X_1 + X_2 \sim \text{Binomial}(n_1 + n_2, p)$.

Why: the counting story gives it at once. X_1 counts successes in n_1 trials, and X_2 counts them in another n_2 independent trials with the same p. So $X_1 + X_2$ counts successes in $n_1 + n_2$ such trials. The mgf says the same. The mgf of a sum of independent variables is the product of their mgfs, and $(1-p+pe^t)^{n_1}(1-p+pe^t)^{n_2} = (1-p+pe^t)^{n_1+n_2}$, the mgf (2.6) of Binomial(n_1+n_2, p). The same p is essential: with different p's the product is not of binomial form.

2.2.4 Worked examples

Example: the coincidence trigger. Return to the four-layer telescope from the start of the section. Each layer fires with $\epsilon = 0.95$, independently, so the number of layers that fire is $X \sim \text{Binomial}(4, 0.95)$. The trigger needs $X \geq 3$.

$$\begin{aligned} \mathrm{P}(X \geq 3) &\overset{(1)}{=} \binom{4}{3}\epsilon^3(1-\epsilon) + \binom{4}{4}\epsilon^4 \\ &\overset{(2)}{=} 4(0.857375)(0.05) + 0.81450625 \\ &= 0.171475 + 0.814506 = 0.98598. \end{aligned}$$

(1) Only $k = 3$ and $k = 4$ satisfy the condition. Add their pmf values.
(2) $0.95^3 = 0.857375$ and $0.95^4 = 0.81450625$.

The 3-out-of-4 trigger keeps 98.6% of muons. Demanding all four keeps only $\epsilon^4 = 0.8145$, so the cleaner trigger loses about one muon in five. The simulation in `02_binomial.py` (one million four-layer events) gives 0.9859 against the exact 0.986.

Example: the Chevalier de Méré's two bets. Is it more likely to get at least one six in 4 rolls of a die, or at least one double six in 24 rolls of two dice? The number of successes is binomial

in both cases, and "at least one" is the complement of "none":

$$\mathrm{P}(\text{at least one six in 4}) \overset{(1)}{=} 1 - \binom{4}{0}\left(\tfrac{1}{6}\right)^0\left(\tfrac{5}{6}\right)^4 = 1 - 0.4823 = 0.518,$$

$$\mathrm{P}(\text{at least one double six in 24}) \overset{(2)}{=} 1 - \left(\tfrac{35}{36}\right)^{24} = 1 - 0.5086 = 0.491.$$

(1) Binomial$(4, 1/6)$ at $k = 0$.
(2) Binomial$(24, 1/36)$ at $k = 0$: two dice show a double six with probability $1/36$.

The gambler's intuition ($4 \times \frac{1}{6} = 24 \times \frac{1}{36} = \frac{2}{3}$) is wrong because it adds probabilities of events that are not mutually exclusive [CasellaBerger Ex. 3.2.3, p. 75]. The same mistake appears in "the probability of at least one fake signal in N search bins is N times the single-bin probability": true only while that product is small (the look-elsewhere effect, Chapter 4).

Example: drawing without replacement: the hypergeometric. The binomial needs the same p on every trial. That fails when we sample *without replacement* from a small population, because each draw changes what is left. A batch of $N = 25$ front-end chips contains M faulty ones. We test $K = 10$ chips at random and find none faulty. How surprising is this if $M = 6$?

The number of faulty chips in the sample follows the **hypergeometric** distribution. Count equally likely samples: there are $\binom{N}{K}$ ways to choose K chips, and $\binom{M}{x}\binom{N-M}{K-x}$ of them contain exactly x faulty ones (choose x of the M faulty and $K - x$ of the $N - M$ good ones). So

$$\mathrm{P}(X = x \mid N, M, K) = \frac{\binom{M}{x}\binom{N-M}{K-x}}{\binom{N}{K}},$$

with mean KM/N and variance $\frac{KM}{N}\frac{(N-M)(N-K)}{N(N-1)}$. For our batch,

$$\mathrm{P}(X = 0) \overset{(1)}{=} \frac{\binom{6}{0}\binom{19}{10}}{\binom{25}{10}} \overset{(2)}{=} \frac{92378}{3268760} = 0.028.$$

(1) Hypergeometric with $N = 25$, $M = 6$, $K = 10$, $x = 0$.
(2) $\binom{19}{10} = 92378$ and $\binom{25}{10} = 3268760$.

If six chips were faulty, a clean sample is unlikely: under 3% [CasellaBerger Ex. 3.2.1, p. 73]. The binomial with $p = M/N = 0.24$ would give $(0.76)^{10} = 0.064$, more than twice as large. Why the difference? Without replacement, each good chip drawn leaves a remaining pool that is *more* faulty, so a clean run is rarer. The factor $(N - K)/(N - 1)$ in the variance is the "finite-population correction". When the batch is much larger than the sample, $N \gg K$, this factor goes to one and the hypergeometric becomes the binomial.

2.2.5 Python: repeat the n trials, histogram the count

The script `code/ch02/02_binomial.py` simulates the generating process itself, not the formula. It builds a table of uniform numbers, one row per experiment and one column per trial.

Listing 2.2: Binomial counts by running the trials (`code/ch02/02_binomial.py`)

```
21 def binomial_by_trials(n, p, reps):
22     """Run 'reps' experiments; each is n independent Bernoulli(p) trials."""
23     trials = rng.uniform(size=(reps, n)) <= p    # True = success
24     return trials.sum(axis=1)                     # number of successes per experiment
```

`rng.uniform(size=(reps, n)) <= p` is a `reps`×n table of Bernoulli trials, built exactly as in Section 2.1. Summing along a row (`axis=1`) counts the successes in one experiment. The script does this 20 000 times for six (n, p) pairs and overlays `scipy.stats.binom.pmf` as black ticks (Figure 2.5).

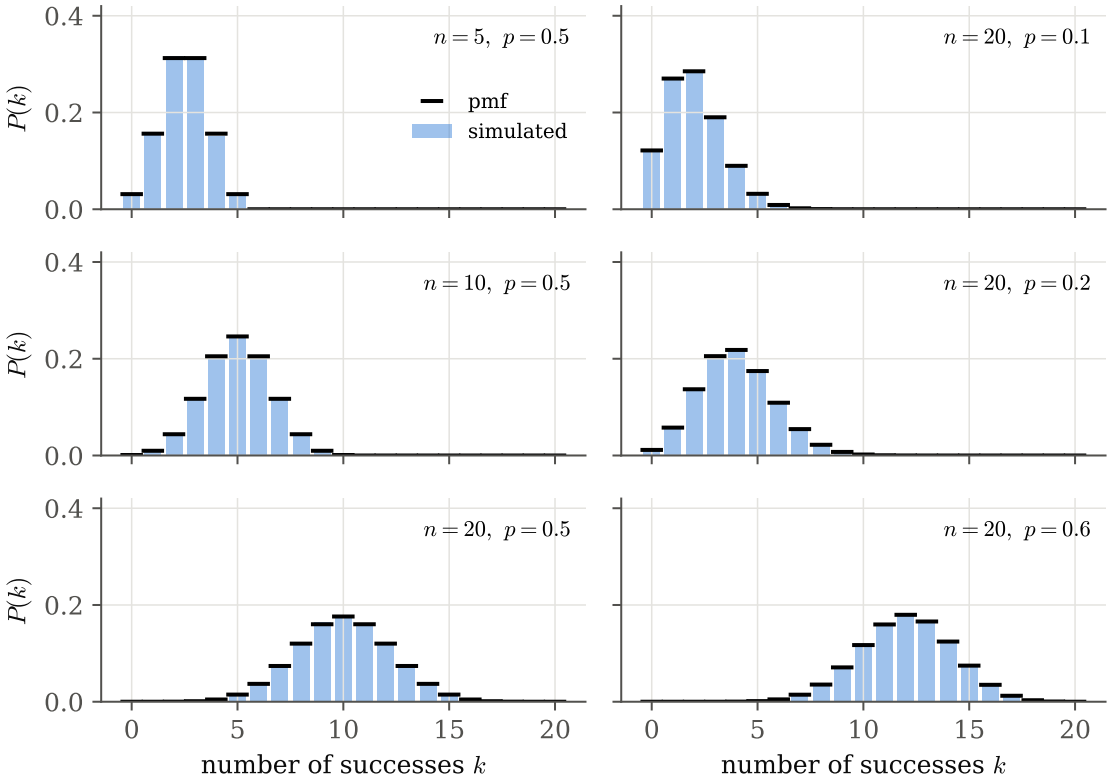

Figure 2.5: Histograms of simulated success counts (bars) against the pmf (black ticks). Left column: $p = \frac{1}{2}$ and more trials; the distribution stays symmetric, moves right and widens like $\sqrt{n}$. Right column: $n = 20$ and growing p; at small p the distribution is squashed against $k = 0$ and skewed, at $p = 0.6$ it leans the other way.

For $n = 20$, $p = 0.2$ and 200 000 experiments the sample mean is 4.001 and the sample variance 3.205, against $np = 4$ and $np(1-p) = 3.2$. Figure 2.5 shows two features that matter later. For $p = \frac{1}{2}$ and growing n the shape is already bell-like: this is the de Moivre–Laplace limit, derived in the next part. For small p the distribution piles up near zero with a tail to the right: this is the regime that becomes the Poisson distribution in Section 2.4.

Watch out: when the binomial is the wrong model

Three assumptions go into (2.4), and each can fail in a real detector.

- *Fixed n.* If the number of trials is itself random (the number of muons in a run), the count of successes is not binomial. We return to this in Section 2.5.
- *Independence.* Layers that share a high-voltage supply fail together, so the number of dead layers is spread wider than binomial.
- *Constant p.* Efficiency that varies across the paddle (edges versus centre), or between runs, also inflates the spread. The *beta-binomial* distribution models a p that itself varies [Lambert §8.4.5]. Sampling without replacement (the hypergeometric example above) is the opposite case: the spread is *narrower* than binomial.

A quick check is to compare the observed variance of a count with $np(1-p)$ computed

from its observed mean.

2.3 Histogram bins: the multinomial distribution

A calorimeter records the energy of $N = 50$ electrons from a beta source, and we fill a histogram with $m = 5$ energy bins. Each electron lands in bin j with probability p_j, set by the shape of the spectrum. The number of electrons in bin j, the bin count n_j, fluctuates from one run to the next. To fit the spectrum later (Chapter 3) we need the *joint* distribution of all the bin contents, including how the bins fluctuate together. That joint distribution is the multinomial: the binomial with more than two outcomes. Its main lesson is that, with N fixed, the bins of a histogram are *negatively correlated*.

Physical picture: a fixed number of balls in boxes. Fifty balls are thrown one at a time into five boxes. If box 1 happens to catch more than its share, there are fewer balls left for the other boxes. The total is fixed, so the counts cannot all go up together. Statistical mechanics has the same situation in the canonical ensemble, where the particle number is fixed. Letting the total fluctuate, as in the grand canonical ensemble, removes the constraint. We will see that it also removes the correlation.

The question, step by step.

1. What is the probability of one *particular* sequence of bin assignments (electron 1 in bin 3, electron 2 in bin 1, ...)? Multiply the p's.
2. Which feature of the sequence does that probability depend on? Only how many electrons went into each bin.
3. How many sequences give the counts $(n_1, \dots, n_m)$? Count them.
4. What does one bin look like on its own, and how do two bins co-vary?

2.3.1 Deriving the pmf

Each of N independent trials ends in one of m outcomes, with probabilities $p_1, \dots, p_m$ and $\sum_j p_j = 1$. A particular sequence with n_1 outcomes of type 1, n_2 of type 2, and so on, has probability $p_1^{n_1} p_2^{n_2} \cdots p_m^{n_m}$ by independence, whatever the order.

How many sequences have these counts? Start by treating the N trials as labelled objects in a row: there are $N!$ orderings. Many orderings give the same assignment of outcomes. Shuffling the n_1 trials of type 1 among themselves ($n_1!$ ways) does not change which trials are of type 1, and the same holds for every type. So each distinct assignment has been counted $n_1!\, n_2! \cdots n_m!$ times, and the number of distinct assignments is

$$\binom{N}{n_1, n_2, \dots, n_m} = \frac{N!}{n_1!\, n_2! \cdots n_m!}, \tag{2.7}$$

the **multinomial coefficient**. For $m = 2$ it is $N!/(n_1!(N - n_1)!)$, the binomial coefficient.

Working definition 2.5 (multinomial distribution)

The vector of counts $\boldsymbol{n} = (n_1, \dots, n_m)$ is Multinomial$(N, \boldsymbol{p})$ if it records how many of N independent trials fell into each of m categories, each trial landing in category j with the

same probability p_j [N fixed, categories exclusive and exhaustive, $\sum_j p_j = 1$]. Its pmf is

$$f(n_1, \ldots, n_m \,|\, N, \boldsymbol{p}) \;=\; \frac{N!}{n_1! \cdots n_m!}\, p_1^{n_1} \cdots p_m^{n_m}, \qquad n_j \geq 0, \quad \sum_j n_j = N. \tag{2.8}$$

Recognise it by: a histogram of a fixed number of independent entries, or any tally of categorical outcomes (particle species, decay channels, blood types).

The pmf (2.8) sums to one by the *multinomial theorem*, $(p_1 + \cdots + p_m)^N = \sum \frac{N!}{n_1! \cdots n_m!} p_1^{n_1} \cdots p_m^{n_m}$. It is proved exactly like the binomial theorem: expanding the product means picking one p_j from each of the N factors. The left side is $1^N = 1$.

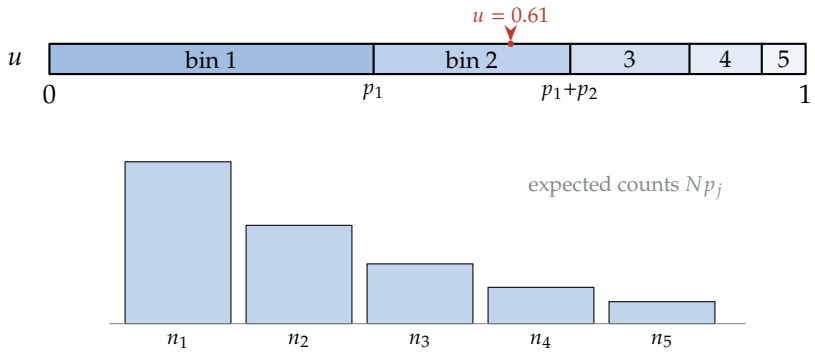

Figure 2.6: How one event chooses its bin. The unit interval is cut into pieces of lengths $p_1, \ldots, p_5$ (a falling spectrum). A uniform number u lands in one piece, here bin 2, and that bin's count goes up by one. Repeating this N times fills the histogram below, whose bar heights are the expected counts Np_j for $N = 50$.

2.3.2 One bin at a time: the marginal is binomial

Often we care about one bin only. Then the other bins are *nuisance* variables, and we **marginalise**: sum the joint pmf over all values of the variables we do not care about (Chapter 1).

Key idea: each bin is binomial

If $\boldsymbol{n} \sim \text{Multinomial}(N, \boldsymbol{p})$, then $n_j \sim \text{Binomial}(N, p_j)$ for every j.

Why: look at bin j alone. Each trial either lands in bin j (probability p_j) or does not (probability $1 - p_j$). Lump all the other bins into the single outcome "not in bin j", and we have N independent yes/no trials with the same probability: the binomial story. The algebra confirms it. Take three categories (bin i, bin j, "everything else"), where the pmf is the *trinomial*

$$f(n_i, n_j) = \frac{N!}{n_i!\, n_j!\, (N - n_i - n_j)!}\, p_i^{n_i} p_j^{n_j} (1 - p_i - p_j)^{N - n_i - n_j}.$$

Summing out n_j:

$$\sum_{n_j=0}^{N-n_i} f(n_i, n_j) \overset{(1)}{=} \frac{N!}{n_i!\,(N-n_i)!} p_i^{n_i} \sum_{n_j=0}^{N-n_i} \frac{(N-n_i)!}{n_j!\,(N-n_i-n_j)!}\, p_j^{n_j} (1 - p_i - p_j)^{N-n_i-n_j}$$

$$\overset{(2)}{=} \binom{N}{n_i} p_i^{n_i} \left(p_j + 1 - p_i - p_j\right)^{N-n_i} \overset{(3)}{=} \binom{N}{n_i} p_i^{n_i} (1 - p_i)^{N-n_i}.$$

(1) Multiply and divide by $(N-n_i)!$, and take out everything that does not depend on n_j.
(2) The remaining sum is the binomial theorem with $n = N - n_i$, $a = p_j$, $b = 1 - p_i - p_j$.
(3) The two p_j's cancel.

The result is the Binomial(N, p_i) pmf, so $\mathbb{E}\, n_i = Np_i$ and $\operatorname{Var} n_i = Np_i(1-p_i)$ from (2.5), and the same holds for every bin. Summing over the nuisance bin removed it and left the distribution of the one bin we care about.

2.3.3 Two bins together: the covariance

The question is how two bin counts n_i and n_j fluctuate together. The tool is the same as for the binomial mean: write each count as a sum of indicators, one per event. Let I_{ej} be the indicator that event e landed in bin j (it is 1 if so, 0 if not). Then $n_j = \sum_{e=1}^{N} I_{ej}$. Two facts about these indicators do all the work:

- *same event, different bins:* one event lands in exactly one bin, so $I_{ei} I_{ej} = 0$ for $i \neq j$;
- *different events:* I_{ei} and $I_{e'j}$ are independent for $e \neq e'$, so their covariance is zero.

For $i \neq j$,

$$\begin{aligned}\operatorname{Cov}(n_i, n_j) &\overset{(1)}{=} \sum_{e=1}^{N}\sum_{e'=1}^{N} \operatorname{Cov}(I_{ei}, I_{e'j}) \overset{(2)}{=} \sum_{e=1}^{N} \operatorname{Cov}(I_{ei}, I_{ej}) \\ &\overset{(3)}{=} \sum_{e=1}^{N} \big(\mathbb{E}[I_{ei} I_{ej}] - \mathbb{E}\, I_{ei}\ \mathbb{E}\, I_{ej}\big) \overset{(4)}{=} \sum_{e=1}^{N} (0 - p_i p_j) = -N p_i p_j. \end{aligned} \tag{2.9}$$

(1) Covariance is linear in each argument, so the covariance of two sums is the sum of all pairwise covariances.
(2) Terms with $e \neq e'$ vanish: different events are independent.
(3) Definition $\operatorname{Cov}(A, B) = \mathbb{E}[AB] - \mathbb{E}\, A\ \mathbb{E}\, B$.
(4) $I_{ei} I_{ej} = 0$, and $\mathbb{E}\, I_{ej} = p_j$ because an indicator is Bernoulli.

Together with the variances, the full **covariance matrix** of the histogram is

$$\mathbf{C}_{ij} \;=\; \operatorname{Cov}(n_i, n_j) \;=\; N\big(p_i \delta_{ij} - p_i p_j\big), \qquad \mathbf{C} = N\big(\operatorname{diag}(\boldsymbol{p}) - \boldsymbol{p}\boldsymbol{p}^{\mathsf{T}}\big), \tag{2.10}$$

and the correlation of two bins is

$$\operatorname{Corr}(n_i, n_j) = \frac{-N p_i p_j}{\sqrt{N p_i (1-p_i)\, N p_j (1-p_j)}} = -\sqrt{\frac{p_i p_j}{(1-p_i)(1-p_j)}}.$$

It does not depend on N: more events do not make the anti-correlation go away.

The matrix is singular. Every row of $\mathbf{C}$ sums to zero: $\sum_j N(p_i \delta_{ij} - p_i p_j) = N(p_i - p_i \sum_j p_j) = 0$. So the vector $\mathbf{1} = (1, \ldots, 1)$ is a zero mode, $\mathbf{C}\,\mathbf{1} = 0$, and $\operatorname{Var}(\sum_j n_j) = \mathbf{1}^{\mathsf{T}}\mathbf{C}\mathbf{1} = 0$. This is no surprise: the total $\sum_j n_j = N$ does not fluctuate at all. A χ^2 built from the full $\mathbf{C}$ must therefore drop one bin or use a pseudo-inverse, a point that returns when we fit histograms (Chapter 3).

2.3.4 Worked examples

Example: a die rolled twelve times. What is the probability that a fair die rolled 12 times shows each face exactly twice?

$$f(2,2,2,2,2,2) \overset{(1)}{=} \frac{12!}{(2!)^6}\left(\tfrac{1}{6}\right)^{12} \overset{(2)}{=} \frac{479001600}{64}\cdot\frac{1}{2176782336} = \frac{7484400}{2176782336} = 0.00344.$$

(1) Multinomial with $N = 12$, $m = 6$, all $p_j = 1/6$, all $n_j = 2$.
(2) $12! = 479001600$, $(2!)^6 = 64$ and $6^{12} = 2176782336$.

The "perfectly flat" histogram is rare: about one run in 290. A histogram that looks too flat should make us as suspicious as one that looks too bumpy.

Example: blood groups in a sample. In a population the ABO blood groups O, A, B, AB have frequencies roughly $p = (0.45, 0.40, 0.11, 0.04)$. In a sample of $N = 10$ donors, what is the probability of exactly 5 O, 4 A, 1 B and no AB?

$$f \overset{(1)}{=} \frac{10!}{5!\,4!\,1!\,0!}(0.45)^5(0.40)^4(0.11)^1(0.04)^0 \overset{(2)}{=} 1260 \times 0.018453 \times 0.0256 \times 0.11 = 0.0655.$$

(1) Multinomial pmf with $N = 10$, $m = 4$.
(2) $10!/(5!\,4!) = 3628800/(120 \times 24) = 1260$, $0.45^5 = 0.018453$, $0.40^4 = 0.0256$.

Each donor is one categorical trial. The multinomial aggregates the categorical outcomes into counts [Lambert §8.4.10], exactly as a histogram aggregates individual events into bins.

Example: the covariance of the first two bins of the spectrum. Return to the beta spectrum from the start of the section: $N = 50$ electrons in five bins. Take a falling spectrum, with the five bin probabilities proportional to $e^{-j/2}$ for $j = 0, \ldots, 4$. Normalising them to sum to one gives $p_1 = 0.4287$ and $p_2 = 0.26$ for the first two bins. Then

$$\begin{aligned} \operatorname{Var} n_1 &= N p_1(1-p_1) = 50 \times 0.4287 \times 0.5713 = 12.25, \\ \operatorname{Cov}(n_1, n_2) &= -N p_1 p_2 = -50 \times 0.4287 \times 0.2600 = -5.57, \\ \operatorname{Corr}(n_1, n_2) &= -\sqrt{\frac{0.4287 \times 0.2600}{0.5713 \times 0.7400}} = -0.513. \end{aligned}$$

A strong anti-correlation: a run with an excess in the first bin very probably has a deficit in the second.

2.3.5 Python: drop the events into the bins

Listing 2.3: Filling many histograms event by event (`code/ch02/03_multinomial.py`)

```
# a falling "energy spectrum": bin probabilities proportional to exp(-bin/2)
m, N, reps = 5, 50, 30_000
p = np.exp(-np.arange(m) / 2.0)
p /= p.sum()

def histogram_of_events(N):
    """Drop N events into bins one by one: each event picks bin j with prob p_j."""
    u = rng.uniform(size=N)
    bins = np.searchsorted(np.cumsum(p), u)      # the bin whose cumulative interval
    contains u
    return np.bincount(bins, minlength=m)
```

```
30
31 H = np.array([histogram_of_events(N) for _ in range(reps)])        # fixed N
32 Hp = np.array([histogram_of_events(rng.poisson(N)) for _ in range(reps)])  # N ~ Poisson
```

The function `histogram_of_events` is Figure 2.6 in code. `np.cumsum(p)` gives the cut points p_1, p_1+p_2, ... of the unit interval; `np.searchsorted` returns, for each uniform number, the index of the piece it fell into, that is, the bin; `np.bincount` counts the events per bin. Line 31 fills 30 000 histograms with exactly $N = 50$ events. Line 32 does the same but first draws the number of events from a Poisson distribution with mean 50 (the distribution of Section 2.4), to see what happens when the total is allowed to fluctuate.

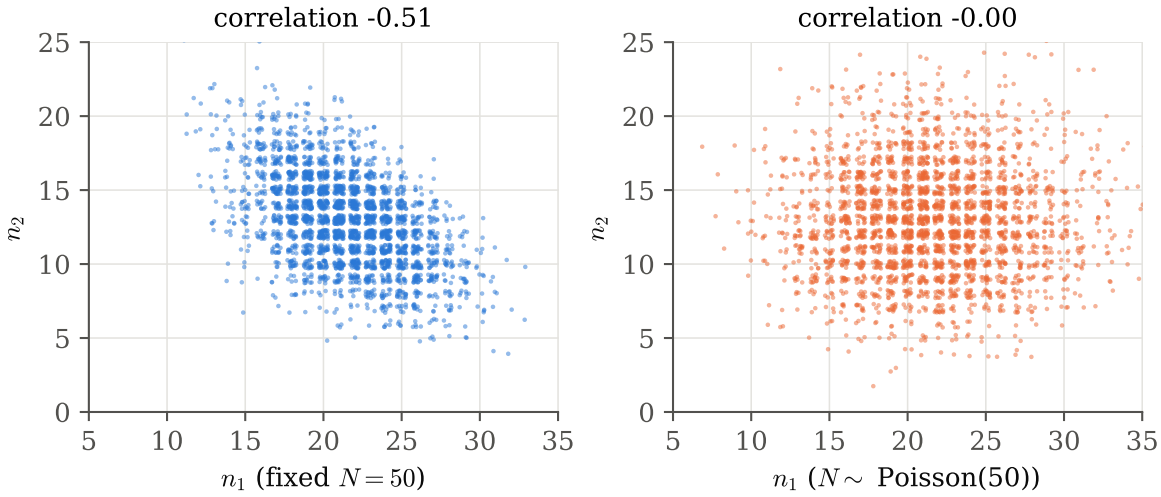

Figure 2.7: Contents of bin 2 against bin 1 for 3000 simulated histograms (a small random jitter separates the integer points). Left: with exactly 50 events per histogram the cloud slopes downwards, because an extra event in bin 1 is an event missing from somewhere else. Right: when the number of events is itself Poisson, the cloud is round and the two bins are uncorrelated.

The simulated variance of bin 1 is 12.27 (theory 12.25), the covariance of bins 1 and 2 is -5.577 (theory -5.572) and their correlation is -0.5119 (theory -0.5134). The variance of the row sums is exactly 0: the zero mode of $\mathbf{C}$. With a Poisson number of events the correlation drops to -0.002175, compatible with zero (Figure 2.7). We prove in Section 2.5 that Poisson-distributed totals make the bins *exactly* independent. This is why fits to histograms whose total is not fixed in advance (most collider analyses) may treat bins as independent Poisson counts.

Watch out: independent bins are an assumption

It is tempting to treat histogram bins as independent, each with error $\sqrt{n_j}$. With a fixed number of entries that is wrong: the bins are anti-correlated by (2.9). For many bins with small p_j the correlation $\approx -\sqrt{p_i p_j}$ is small and the independent approximation is usually fine; for a histogram with a few dominant bins it is not. Normalised shapes ("unit-area" histograms) always carry this constraint.

2.4 Rare events in many trials: the Poisson distribution

A microgram of a long-lived isotope contains of order 10^{15} nuclei. In one second each nucleus decays with a tiny probability p, and the decays are independent. A Geiger counter records the number of decays in each one-second window. Strictly, this count is Binomial(n, p) with

$n \approx 10^{15}$ nuclei. But nobody knows n or p separately, and nobody wants to evaluate $\binom{10^{15}}{k}$. What we *can* measure is the average number of clicks per window, $\lambda = np$. The Poisson distribution is what the binomial becomes when the trials are very many, each is very unlikely to succeed, and only their product λ matters. It is the distribution of *counts of rare events*.

Physical picture: rare, independent, many. Photons arriving at a CCD pixel, dark counts in a photomultiplier, cosmic rays through a detector, events in one bin of a collider histogram, galaxies in a small cell of a sparse survey: each count is the sum of a huge number of chances, each tiny, none influencing the others. In every one of these cases only the mean count λ enters the answer. The microscopic details, such as how many photons were emitted upstream or how many protons collided, drop out.

The question, step by step.

1. Start from the exact binomial for n trials with $p = \lambda/n$, so that the mean $np = \lambda$ stays fixed.
2. Let $n \to \infty$. Which factors change and which survive?
3. Is the limit a proper distribution? What are its mean and variance?
4. How large must n be for the approximation to be good?

2.4.1 The limit, line by line

The derivation needs one limit from calculus. We prove it first.

The compound-interest limit. For any fixed real λ, $\lim_{n\to\infty}\left(1 - \frac{\lambda}{n}\right)^n = e^{-\lambda}$. *Why:* take the logarithm and use the Taylor series $\ln(1-x) = -x - \frac{x^2}{2} - \frac{x^3}{3} - \cdots$, valid for $|x| < 1$:

$$\ln\left(1-\frac{\lambda}{n}\right)^n \overset{(1)}{=} n\ln\left(1-\frac{\lambda}{n}\right) \overset{(2)}{=} n\left(-\frac{\lambda}{n} - \frac{\lambda^2}{2n^2} - \cdots\right) = -\lambda - \frac{\lambda^2}{2n} - \cdots \xrightarrow{n\to\infty} -\lambda.$$

(1) $\ln a^n = n \ln a$.
(2) Taylor series with $x = \lambda/n$, which is less than one in size once $n > |\lambda|$.

Exponentiate: the limit is $e^{-\lambda}$. Figure 2.8 shows how fast it is approached. The correction $-\lambda^2/(2n)$ in the exponent tells us that $(1-\lambda/n)^n$ is always a little *below* $e^{-\lambda}$, by a relative amount of about $\lambda^2/2n$.

With this limit in hand, we can take the binomial to the Poisson. Put $p = \lambda/n$ into the binomial pmf (2.4), so that the mean $np = \lambda$ stays fixed, and hold the count k fixed while n grows:

$$\begin{aligned}
\binom{n}{k}p^k(1-p)^{n-k} &\overset{(1)}{=} \frac{n!}{k!\,(n-k)!}\,\frac{\lambda^k}{n^k}\left(1-\frac{\lambda}{n}\right)^n\left(1-\frac{\lambda}{n}\right)^{-k} \\
&\overset{(2)}{=} \frac{\lambda^k}{k!}\cdot\frac{n(n-1)\cdots(n-k+1)}{n^k}\cdot\left(1-\frac{\lambda}{n}\right)^n\cdot\left(1-\frac{\lambda}{n}\right)^{-k} \\
&\overset{(3)}{=} \frac{\lambda^k}{k!}\cdot\left(1-\frac{1}{n}\right)\left(1-\frac{2}{n}\right)\cdots\left(1-\frac{k-1}{n}\right)\cdot\left(1-\frac{\lambda}{n}\right)^n\cdot\left(1-\frac{\lambda}{n}\right)^{-k} \\
&\xrightarrow{n\to\infty} \frac{\lambda^k}{k!}\cdot 1\cdot e^{-\lambda}\cdot 1. \qquad (2.11)
\end{aligned}$$

(1) Substitute $p = \lambda/n$ and split $(1-p)^{n-k} = (1-p)^n(1-p)^{-k}$.

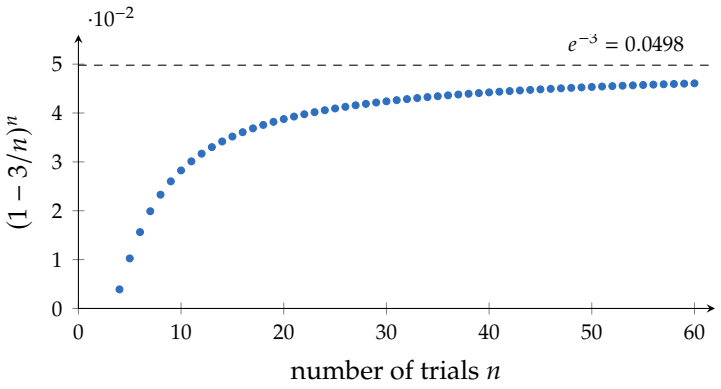

Figure 2.8: The probability that none of n nuclei decays, when each decays with probability $3/n$. With four nuclei it is tiny; as the nuclei become more numerous and individually less likely to decay, it climbs towards the dashed limit e^{-3}, getting within ten per cent of it by $n \approx 50$.

(2) Regroup. $n!/(n-k)! = n(n-1)\cdots(n-k+1)$ has exactly k factors.
(3) Divide each of the k factors by one of the k powers of n.

Now take the four factors in the third line of the chain one at a time as $n \to \infty$. The first, $\lambda^k/k!$, does not involve n. In the second, each of the $k-1$ brackets $(1 - j/n)$ goes to 1; there is a *fixed* number of them because k is fixed, so their product goes to 1. The third, $(1-\lambda/n)^n$, goes to $e^{-\lambda}$ by the compound-interest limit. The fourth is a fixed power, $-k$, of something that goes to one, so it goes to one.

Working definition 2.6 (Poisson distribution)

$X \sim \text{Poisson}(\lambda)$ if

$$f(k \mid \lambda) \;=\; e^{-\lambda}\,\frac{\lambda^k}{k!}, \qquad k = 0, 1, 2, \ldots \tag{2.12}$$

for some $\lambda > 0$ [the mean number of events, a real number, not necessarily an integer]. There is no upper limit on k. *Recognise it by:* a count of events that are individually rare and mutually independent, out of a very large (or unknown) number of opportunities.

The number of trials n has disappeared. The only parameter left is the mean count λ, the one thing we can measure.

2.4.2 Normalisation, mean, variance, mgf

Every sum here is the exponential series $e^x = \sum_{k=0}^{\infty} x^k/k!$, valid for every real (or complex) x, in disguise.

$$\sum_{k=0}^{\infty} f(k) \overset{(1)}{=} e^{-\lambda} \sum_{k=0}^{\infty} \frac{\lambda^k}{k!} \overset{(2)}{=} e^{-\lambda} e^{\lambda} = 1,$$

$$\mathbb{E}\,X \overset{(3)}{=} e^{-\lambda} \sum_{k=1}^{\infty} k \frac{\lambda^k}{k!} \overset{(4)}{=} \lambda e^{-\lambda} \sum_{k=1}^{\infty} \frac{\lambda^{k-1}}{(k-1)!} \overset{(2)}{=} \lambda e^{-\lambda} e^{\lambda} = \lambda,$$

$$\mathbb{E}[X(X-1)] \overset{(5)}{=} e^{-\lambda} \sum_{k=2}^{\infty} k(k-1) \frac{\lambda^k}{k!} = \lambda^2 e^{-\lambda} \sum_{k=2}^{\infty} \frac{\lambda^{k-2}}{(k-2)!} \overset{(2)}{=} \lambda^2,$$

$$\text{Var}\,X \overset{(6)}{=} \mathbb{E}[X(X-1)] + \mathbb{E}\,X - (\mathbb{E}\,X)^2 = \lambda^2 + \lambda - \lambda^2 = \lambda.$$

(1) Take the constant $e^{-\lambda}$ out of the sum.

(2) Exponential series (after renaming $j = k-1$ or $j = k-2$).
(3) The $k = 0$ term vanishes.
(4) $k/k! = 1/(k-1)!$, and one factor λ taken out.
(5) The same trick with $k(k-1)/k! = 1/(k-2)!$; the $k = 0, 1$ terms vanish.
(6) As for the binomial.

Key idea: mean equals variance

For a Poisson count, $\mathbb{E}\,X = \operatorname{Var} X = \lambda$. The standard deviation is $\sqrt{\lambda}$, and the *relative* fluctuation is $1/\sqrt{\lambda}$.

So a Poisson count has mean and variance both equal to λ. Its standard deviation is $\sqrt{\lambda}$, and its *relative* fluctuation, standard deviation over mean, is $1/\sqrt{\lambda}$. This is the origin of the "$\sqrt{N}$" error bar on a count, and of photon shot noise: to measure a flux to 1% we need $1/\sqrt{\lambda} = 0.01$, that is, about 10^4 photons. The same results follow from the binomial ones by taking the limit: $np = \lambda$ and $np(1-p) = \lambda(1-\lambda/n) \to \lambda$.

The mgf is

$$M_X(t) \overset{(1)}{=} e^{-\lambda} \sum_{k=0}^{\infty} \frac{(\lambda e^t)^k}{k!} \overset{(2)}{=} e^{-\lambda} e^{\lambda e^t} = \exp\bigl[\lambda(e^t - 1)\bigr]. \tag{2.13}$$

(1) $e^{tk}\lambda^k = (\lambda e^t)^k$.
(2) Exponential series with $x = \lambda e^t$.

It is also the limit of the binomial mgf: $(1 + p(e^t - 1))^n = (1 + \lambda(e^t - 1)/n)^n \to e^{\lambda(e^t-1)}$ by the same compound-interest limit.

The shape: a recursion. Dividing consecutive terms of (2.12),

$$\frac{f(k)}{f(k-1)} = \frac{e^{-\lambda}\lambda^k/k!}{e^{-\lambda}\lambda^{k-1}/(k-1)!} = \frac{\lambda}{k}. \tag{2.14}$$

Each step from $k-1$ to k multiplies the probability by λ/k. That factor is larger than one while $k < \lambda$ and smaller than one once $k > \lambda$. So the pmf rises while $k < \lambda$ and falls once $k > \lambda$. The most probable count is $\lfloor \lambda \rfloor$ (and if λ is an integer, $\lambda - 1$ and λ are equally probable). The recursion is also the numerically stable way to compute the pmf: start at $f(0) = e^{-\lambda}$ and multiply by λ/k, never forming λ^k or $k!$ separately [CasellaBerger (3.2.6)–(3.2.7), p. 77].

2.4.3 How good is the approximation?

A convenient single number for the distance between two distributions f and g on the integers is the **total variation distance** $\mathrm{TV}(f, g) = \frac{1}{2}\sum_k |f(k) - g(k)|$ [the largest possible difference between the probabilities the two distributions give to the same event]. For the binomial with $p = \lambda/n$ and the Poisson with the same mean, a classical inequality due to Le Cam states

$$\mathrm{TV}\bigl(\text{Binomial}(n, \lambda/n),\ \text{Poisson}(\lambda)\bigr) \ \le\ np^2 \ =\ \frac{\lambda^2}{n}.$$

Why np^2? Each Bernoulli trial differs from a Poisson(p) variable only in the rare event of two or more "successes" in one trial, which has probability of order p^2. There are n trials, so the differences add up to at most about np^2. The script `code/ch02/04_poisson_limit.py` computes the actual distance for $\lambda = 3$: 0.2191 at $n = 5$, 0.0402 at $n = 20$, 0.007607 at $n = 100$ and 7.515×10^{-4} at $n = 1000$. It falls like $1/n$, as the bound says, but is about ten times smaller than the bound.

2.4.4 Worked examples

Example: a typesetter's errors, exact and Poisson. A typesetter makes on average one error per 500 words. Five pages of 300 words hold 1500 words. What is the probability of at most two errors? Exactly, $X \sim \text{Binomial}(1500, 1/500)$; approximately, $X \sim \text{Poisson}(3)$.

$$\mathrm{P}(X \le 2) \approx e^{-3}\left(1 + 3 + \frac{3^2}{2}\right) \overset{(1)}{=} 0.049787 \times 8.5 = 0.4232.$$

(1) Sum of (2.12) for $k = 0, 1, 2$ with $\lambda = np = 1500/500 = 3$.

The exact binomial gives 0.423; the Poisson approximation gives 0.4232, wrong in the fourth decimal [CasellaBerger Ex. 3.2.5, p. 77].

Example: photomultiplier dark counts. A photomultiplier produces on average 5 dark pulses every 3 ms. In the next 1 ms, what is the probability of no dark pulse, and of at least two? The count in 1 ms is Poisson with $\lambda = 5/3$.

$$\mathrm{P}(X = 0) = e^{-5/3} = 0.189,$$

$$\mathrm{P}(X \ge 2) \overset{(1)}{=} 1 - \mathrm{P}(X = 0) - \mathrm{P}(X = 1) \overset{(2)}{=} 1 - 0.189 - \tfrac{5}{3}(0.189) = 1 - 0.189 - 0.315 = 0.496.$$

(1) Complement of "zero or one".
(2) $\mathrm{P}(X = 1) = \lambda e^{-\lambda}$, which is λ times $\mathrm{P}(X = 0)$ by the recursion (2.14).

So a 1 ms coincidence window contains at least two dark pulses half the time: at this rate, a two-fold coincidence of dark noise is not rare. The numbers are those of a telephone switchboard in [CasellaBerger Ex. 3.2.4, p. 76], a reminder that the Poisson story does not care what is being counted.

Example: events in a collider signal region. A new process has cross-section $\sigma = 0.5$ fb, the data set has integrated luminosity $L = 20$ fb^{-1} and the selection efficiency is $\epsilon = 0.3$. Each of the enormous number of proton–proton collisions has a tiny, independent chance to produce a selected signal event, so the number of selected events is Poisson with mean [Cowan (2.12), p. 30]

$$\lambda = \sigma L \epsilon = 0.5 \times 20 \times 0.3 = 3.$$

The chance of seeing *nothing* is $f(0\,|\,3) = e^{-3} = 0.0498$, about 5%. Read backwards, this is the classic "three events" rule: if we see zero events, any model predicting $\lambda \ge 3$ is excluded at about 95% confidence (Chapter 4).

2.4.5 Python: literally many nuclei

Listing 2.4: Counting decays of 2000 nuclei per window (`code/ch02/04_poisson_limit.py`)

```
# (a) the generating process, literally: many nuclei, each with a tiny chance
n_nuclei, windows = 2000, 20_000
counts = np.empty(windows, dtype=int)
for w in range(windows):
    counts[w] = np.count_nonzero(rng.uniform(size=n_nuclei) <= lam / n_nuclei)
```

Each counting window gets 2000 fresh uniform numbers, one per nucleus, and a nucleus "decays" if its number is below $\lambda/n = 3/2000$. The count per window is the number of decays. Nothing in this code mentions $e^{-\lambda}$ or $k!$: the Poisson law has to emerge from the process. The script then computes the total variation distances quoted above and the typesetter example.

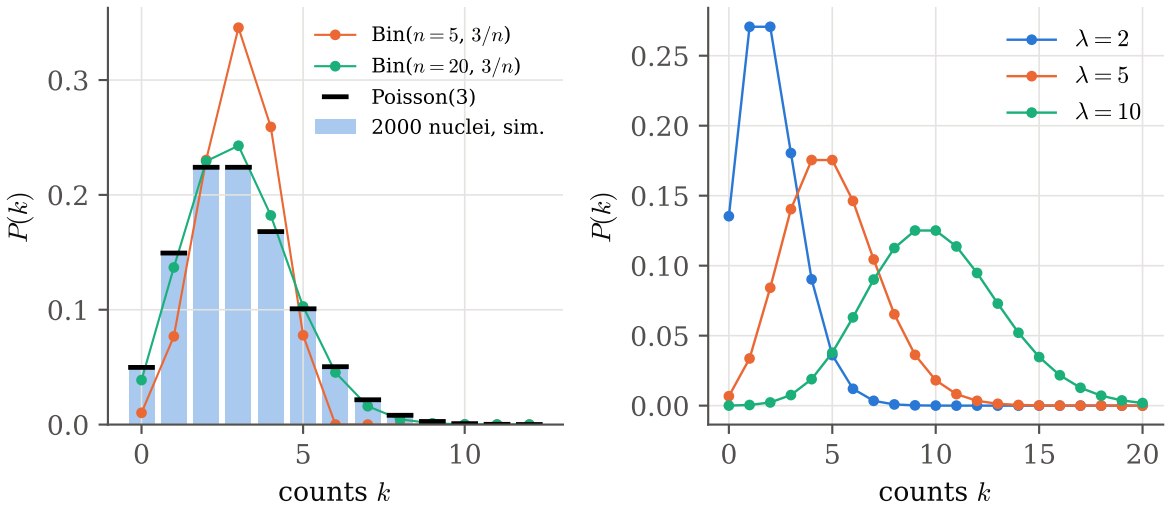

Figure 2.9: Left: the histogram of decay counts from 2000 simulated nuclei per window (bars) sits on the Poisson(3) pmf (black ticks). The binomials with only 5 or 20 trials and the same mean are visibly narrower, because each trial can produce at most one event. Right: Poisson shapes for $\lambda = 2, 5, 10$; skewed to the right at small λ, nearly symmetric by $\lambda = 10$.

Over 20 000 windows the sample mean is 3 and the sample variance is 2.986, equal within the statistical error as *mean = variance* demands. The fraction of empty windows is 0.04965, against $e^{-3} = 0.04979$ (Figure 2.9). The right panel reproduces the shapes of [Cowan Fig. 2.3, p. 29]. The growing symmetry with λ is the start of the Gaussian limit, previewed in Section 2.8.

What this bought us. When many independent chances each have a small probability, the count is Poisson with the single parameter $\lambda = np$. Its variance equals its mean, so the relative scatter of a count is $1/\sqrt{\lambda}$. The approximation error is of order λ^2/n, negligible for any macroscopic number of trials.

Watch out: "rare" refers to each trial, not to the count

The count itself need not be small: a CCD pixel may collect 10^5 photons, and that count is still Poisson, because each of the 10^{20} photons emitted by the star had a tiny chance of landing in this pixel. What must be small is the probability per opportunity, and what must hold is independence. Conversely, a small count is not automatically Poisson: the number of dead channels in a 4-channel module is binomial with $n = 4$, and Figure 2.9 shows how different that can be.

2.5 The Poisson process: constant rate, no memory

In Section 2.4 the Poisson distribution came from a binomial over n nuclei, each with a tiny chance to decay. Often there is no such n to imagine. Cosmic rays arrive from the sky, photons from a distant quasar, dark pulses from a photocathode. All we know is that events come *at random in time*, with some average rate λ (events per second), and that the process has no memory: what happened in the last second does not affect the next. These two physical statements are enough. Through a differential equation, they force the count in any window of length t to be Poisson(λt). The same machinery then shows that three common operations give Poisson counts again: thinning a Poisson stream (losing events at random), adding two streams, and splitting one into histogram bins.

Physical picture: a master equation with one-way hops. Think of the count $N(t)$, the number of events up to time t, as the state of a system that can only climb a ladder: $0 \to 1 \to 2 \to \cdots$, one rung at a time, with hopping rate λ from every rung. The probability of being on rung n is fed from rung $n-1$ and drains into rung $n+1$. The rate equations for a radioactive decay chain have exactly this form, and so does the master equation of a birth process in statistical mechanics.

The question, step by step.

1. What exactly do "random in time at rate λ" and "no memory" assume? State the inputs, then derive what they imply for a very short interval h.
2. How does the probability of having n events by time t change between t and $t+h$?
3. Let $h \to 0$ to get differential equations, and solve them.
4. What happens to such a stream when we lose some events, add another stream, or sort the events into bins?

2.5.1 From three physical inputs to the short-interval rules

Think of photons from a star whose brightness does not change. Even a perfect detector does not count the same number in every exposure, because the photons arrive one at a time at random instants. That scatter is **shot noise**. It is not interference added to the signal. It is what counting discrete, independent arrivals means. We now find its distribution from first principles: we say exactly what we assume about the arrivals, and derive everything else.

The inputs. Three are physical, and one is a mathematical regularity condition.

(P1) *No memory.* The numbers of events in non-overlapping time windows are independent. An arrival tells us nothing about when the next one comes.

(P2) *Constant rate.* The distribution of the count in a window depends only on its length, not on when it starts. The source does not brighten or fade during the exposure.

(P3) *One at a time.* Events arrive singly, never in bunches at the same instant.

(R) *Regularity.* The probability $P_0(h)$ that a window of length h is empty changes continuously with h. This is a property we demand of the mathematics, not a statement about photons.

The empty window. Split a window of length $h_1 + h_2$ into two pieces. It is empty exactly when both pieces are empty, so

$$P_0(h_1+h_2) \overset{(1)}{=} \text{P(first piece empty)}\ \text{P(second piece empty)} \overset{(2)}{=} P_0(h_1)\,P_0(h_2). \tag{2.15}$$

(1) (P1): the two pieces do not overlap, so their counts are independent and the probabilities multiply.

(2) (P2): each piece behaves like any window of the same length, wherever it sits.

Write $g(h) = -\ln P_0(h)$. Then (2.15) says $g(h_1+h_2) = g(h_1) + g(h_2)$: g turns sums of lengths into sums of values. Applying it n times gives $g(n\,h) = n\,g(h)$, so $g(m/n) = (m/n)\,g(1)$ for every rational length, and by (R) the same holds for every length. Hence, with $\lambda \equiv g(1) \geq 0$,

$$P_0(h) = e^{-\lambda h}. \tag{2.16}$$

Nothing was assumed about the size of λ; it is simply the constant that the inputs leave free, and below it turns out to be the mean number of events per unit time, the **rate**.

At least one event in a short window. Expanding (2.16) for small h,

$$\mathrm{P}(\text{at least one event in } h) = 1 - e^{-\lambda h} \overset{(1)}{=} \lambda h - \tfrac{1}{2}(\lambda h)^2 + \cdots = \lambda h + O(h^2).$$

(1) The Taylor series $e^{-x} = 1 - x + \frac{1}{2}x^2 - \cdots$.

So "probability proportional to the length" is not an assumption. It is the first term of the exact answer, and it holds for any short window.

Two or more in a short window. By (P3) two events never share an instant, so two arrivals in one window are two separate events. Cut the window into two halves: two events in the window means at least one event in each half, or two in one half. The first has probability $\left(\lambda\frac{h}{2} + O(h^2)\right)^2 = O(h^2)$ by (P1), and repeating the halving shows the second is also $O(h^2)$. So

$$\mathrm{P}(\text{two or more in } h) = O(h^2), \qquad \mathrm{P}(\text{exactly one in } h) = \lambda h + O(h^2).$$

Two arrivals need two rare events to coincide, a product of two small probabilities. That is why, in a short enough window, the only outcomes that matter are "nothing" and "exactly one".

We need one piece of notation for what follows. A function $g(h)$ is $o(h)$ ("little-o of h") if $g(h)/h \to 0$ as $h \to 0$ [it vanishes faster than h itself]. For example $h^2 = o(h)$, but $\sqrt{h}$ and $3h$ are not. Every $O(h^2)$ above is $o(h)$.

Working definition 2.7 (Poisson process)

A **counting process** $N(t)$ is the number of events in $[0, t]$. Inputs (P1)–(P3) and (R) give it the five properties of a **homogeneous Poisson process** with rate λ:

(i) $N(0) = 0$ [we start counting at $t = 0$];

(ii) the counts in non-overlapping intervals are independent [input (P1)];

(iii) the distribution of the count in $(t, t + h]$ depends only on the length h [input (P2)];

(iv) $\mathrm{P}(\text{exactly one event in } (t, t + h]) = \lambda h + o(h)$ [derived above, not assumed];

(v) $\mathrm{P}(\text{two or more events in } (t, t + h]) = o(h)$ [derived above from (P3)].

Recognise it by: events that arrive one at a time, independently, at a steady average rate.

Watch out: When the inputs fail

Each input can fail, and then the counts are not Poisson. A source whose brightness changes during the exposure breaks (P2) (the count is then Poisson with mean $\int \lambda(t)\,\mathrm{d}t$, see below). Dead time after each detection breaks (P1): a detector that is blind for a while after a hit makes the next arrival depend on the last. Events that come in bursts break (P3): an air shower fires many detectors at once, and thermal light shows photon bunching. In each case the variance of the count differs from its mean, which is the quickest test.

Figure 2.10 already suggests the answer. Cut $[0, t]$ into $n = t/h$ slices. Each slice is a Bernoulli trial with success probability $p = \lambda h = \lambda t/n$, and the trials are independent by (ii). So $N(t)$ is binomial with $np = \lambda t$, and as $h \to 0$ we are in the limit of Section 2.4: $N(t) \sim \mathrm{Poisson}(\lambda t)$. Now we derive the same result a second way, which does not rely on the binomial at all and which generalises to rates that vary in time.

2.5.2 The differential equations

Let $P_n(t) = \mathrm{P}(N(t) = n)$. At $t = 0$, $P_0(0) = 1$ and $P_n(0) = 0$ for $n \geq 1$, by property (i).

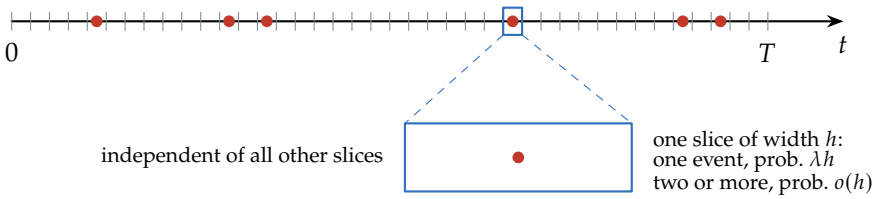

Figure 2.10: The short-interval rules as a picture. The time axis is cut into short slices; each slice independently contains an event (red dots) with probability λh, and practically never two. Counting the dots in $[0, T]$ means counting successes in T/h Bernoulli trials with $p = \lambda h$.

No events. To have no events by $t + h$ we need no events by t *and* none in $(t, t + h]$:

$$P_0(t+h) \overset{(1)}{=} P_0(t)\ \mathrm{P}(\text{no event in } (t, t+h]) \overset{(2)}{=} P_0(t)\big(1 - \lambda h - o(h)\big),$$
$$\frac{P_0(t+h) - P_0(t)}{h} \overset{(3)}{=} -\lambda P_0(t) - P_0(t)\frac{o(h)}{h} \xrightarrow{h\to 0} \frac{\mathrm{d}P_0}{\mathrm{d}t} = -\lambda P_0.$$

(1) Property (ii): the count in $(t, t + h]$ is independent of the count in $[0, t]$, so the probabilities multiply.
(2) Properties (iv) and (v): the probability of zero events is 1 minus the probability of one minus the probability of two or more, and both $o(h)$ terms combine into one $o(h)$.
(3) Subtract $P_0(t)$ and divide by h. The last term vanishes as $h \to 0$ by the definition of $o(h)$.

With $P_0(0) = 1$ the solution is $P_0(t) = e^{-\lambda t}$: the probability of an empty window decays exponentially with its length, just as the survival probability of an unstable nucleus does.

$n \geq 1$ events. To have n events by $t + h$, either we had n by t and none arrive, or we had $n - 1$ and one arrives, or we had $n - j$ for $j \geq 2$ and j arrive:

$$P_n(t+h) \overset{(1)}{=} P_n(t)\big(1 - \lambda h\big) + P_{n-1}(t)\,\lambda h + o(h),$$
$$\frac{\mathrm{d}P_n}{\mathrm{d}t} \overset{(2)}{=} -\lambda P_n(t) + \lambda P_{n-1}(t).$$

(1) The three routes are mutually exclusive, so their probabilities add, and each is a product by property (ii). All routes with two or more arrivals, and the corrections to the first two, are $o(h)$ by (iv) and (v).
(2) Subtract $P_n(t)$, divide by h and let $h \to 0$.

This is the **master equation** of the process (Figure 2.11): rung n gains probability from rung $n - 1$ at rate λP_{n-1} and loses it to rung $n + 1$ at rate λP_n.

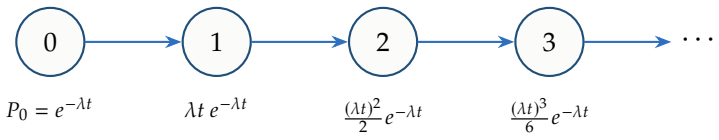

Figure 2.11: The count as a system climbing a ladder. Every hop goes one rung up and happens at the same rate λ, whatever the rung; no hop ever goes down. Below each rung is its occupation probability at time t, the solution derived in the text.

Solving the ladder. The master equation has the form $y' + \lambda y = g(t)$, a linear first-order equation, with $y = P_n$ and $g = \lambda P_{n-1}$. Such an equation is solved with the *integrating factor* $e^{\lambda t}$.

Multiplying by it turns the left side into a single derivative: $(e^{\lambda t}y)' = e^{\lambda t}(y' + \lambda y) = e^{\lambda t}g$. So define $Q_n(t) = e^{\lambda t}P_n(t)$. Then

$$\frac{\mathrm{d}Q_n}{\mathrm{d}t} \overset{(1)}{=} e^{\lambda t}\Big(\frac{\mathrm{d}P_n}{\mathrm{d}t} + \lambda P_n\Big) \overset{(2)}{=} e^{\lambda t}\lambda P_{n-1} = \lambda Q_{n-1}, \qquad Q_0(t) = 1, \quad Q_n(0) = 0\ (n \geq 1).$$

(1) Product rule.
(2) The master equation: $\mathrm{d}P_n/\mathrm{d}t + \lambda P_n = \lambda P_{n-1}$.

Now climb the ladder by induction. Suppose $Q_{n-1}(t) = (\lambda t)^{n-1}/(n-1)!$. This is true for $n - 1 = 0$, since $Q_0 = e^{\lambda t}P_0 = e^{\lambda t}e^{-\lambda t} = 1$. Then

$$Q_n(t) \overset{(1)}{=} \int_0^t \lambda\, Q_{n-1}(s)\,\mathrm{d}s \overset{(2)}{=} \int_0^t \frac{\lambda^n s^{n-1}}{(n-1)!}\,\mathrm{d}s \overset{(3)}{=} \frac{\lambda^n t^n}{n!}.$$

(1) Integrate $\mathrm{d}Q_n/\mathrm{d}s = \lambda Q_{n-1}$ from 0 to t, using $Q_n(0) = 0$.
(2) The induction hypothesis.
(3) $\int_0^t s^{n-1}\mathrm{d}s = t^n/n$, and $(n-1)!\, n = n!$.

Key idea: the count of a Poisson process

For a homogeneous Poisson process with rate λ,

$$\mathrm{P}\big(N(t) = n\big) = e^{-\lambda t}\frac{(\lambda t)^n}{n!}, \qquad N(t) \sim \mathrm{Poisson}(\lambda t), \tag{2.17}$$

and by (iii) the count in *any* window of length t has the same distribution.

Undoing the substitution, $P_n(t) = e^{-\lambda t}Q_n(t) = e^{-\lambda t}(\lambda t)^n/n!$: the count $N(t)$ is Poisson with mean λt, as in (2.17). The two routes, the binomial limit and the master equation, give the same answer. So whenever events are rare, independent and at a steady rate, the Poisson distribution is forced on us.

A rate that varies in time. Suppose the rate is a function $\lambda(t)$: a source that fades, or a beam whose intensity falls during a fill. Then input (P2), and with it property (iii), is dropped, and (iv) becomes $\lambda(t)h + o(h)$. The master equation keeps its form with λ replaced by $\lambda(t)$. The integrating factor becomes $e^{m(t)}$, where $m(t) = \int_0^t \lambda(s)\,\mathrm{d}s$ is the expected number of events up to t. Because $\mathrm{d}m/\mathrm{d}t = \lambda(t)$, the same induction gives $Q_n = m(t)^n/n!$. So

$$N(t) \sim \mathrm{Poisson}\big(m(t)\big), \qquad N(s+t) - N(s) \sim \mathrm{Poisson}\big(m(s+t) - m(s)\big).$$

Only the *integrated* rate over the window matters [Wasserman Thm. 23.33, p. 395]. For a collider, m is $\sigma\epsilon$ times the integrated luminosity, whatever the luminosity did during the run.

2.5.3 Three closure properties

Real counting chains lose events, add sources and sort events into bins. Each of these operations keeps us inside the Poisson family.

Adding independent sources: sums of independent Poissons are Poisson. If $X_1 \sim \mathrm{Poisson}(\lambda_1)$ and $X_2 \sim \mathrm{Poisson}(\lambda_2)$ are independent, then $X_1 + X_2 \sim \mathrm{Poisson}(\lambda_1 + \lambda_2)$. The direct proof sums

over all the ways to split k events between the two sources (a *convolution*):

$$\mathrm{P}(X_1 + X_2 = k) \overset{(1)}{=} \sum_{j=0}^{k} \mathrm{P}(X_1 = j)\ \mathrm{P}(X_2 = k - j) \overset{(2)}{=} \sum_{j=0}^{k} e^{-\lambda_1} \frac{\lambda_1^j}{j!}\, e^{-\lambda_2} \frac{\lambda_2^{k-j}}{(k-j)!}$$
$$\overset{(3)}{=} \frac{e^{-(\lambda_1+\lambda_2)}}{k!} \sum_{j=0}^{k} \binom{k}{j} \lambda_1^j \lambda_2^{k-j} \overset{(4)}{=} e^{-(\lambda_1+\lambda_2)} \frac{(\lambda_1+\lambda_2)^k}{k!}.$$

(1) The event $\{X_1 + X_2 = k\}$ is the disjoint union of $\{X_1 = j, X_2 = k - j\}$, and independence factorises each term.
(2) Poisson pmfs.
(3) Multiply and divide by $k!$ to form $\binom{k}{j} = k!/(j!(k-j)!)$.
(4) Binomial theorem.

With mgfs it is one line: $e^{\lambda_1(e^t-1)} e^{\lambda_2(e^t-1)} = e^{(\lambda_1+\lambda_2)(e^t-1)}$ [Wasserman Ex. 3.35, p. 58][2]. In the process picture the result is obvious. Interleave two independent streams, and each short slice holds one event with probability $(\lambda_1 + \lambda_2)h + o(h)$: the merged stream is a Poisson process with the summed rate. So signal plus background, with expected counts s and b, is Poisson with mean $s + b$.

Losing events: thinning. Each event of a Poisson(λ) stream is detected independently with efficiency ϵ. Given $N = n$ true events, the detected number is $Y \mid N = n \sim \mathrm{Binomial}(n, \epsilon)$. Marginalise over the unobserved N:

$$\mathrm{P}(Y = y) \overset{(1)}{=} \sum_{n=y}^{\infty} \mathrm{P}(Y = y \mid N = n)\, \mathrm{P}(N = n) \overset{(2)}{=} \sum_{n=y}^{\infty} \frac{n!}{y!\,(n-y)!} \epsilon^y (1-\epsilon)^{n-y}\, e^{-\lambda} \frac{\lambda^n}{n!}$$
$$\overset{(3)}{=} \frac{(\epsilon\lambda)^y}{y!} e^{-\lambda} \sum_{j=0}^{\infty} \frac{\big((1-\epsilon)\lambda\big)^j}{j!} \overset{(4)}{=} \frac{(\epsilon\lambda)^y}{y!} e^{-\lambda} e^{(1-\epsilon)\lambda} = e^{-\epsilon\lambda} \frac{(\epsilon\lambda)^y}{y!}.$$

(1) Law of total probability over the nuisance variable N (Chapter 1); $n < y$ is impossible.
(2) Binomial and Poisson pmfs.
(3) Cancel $n!$, write $\lambda^n = \lambda^y \lambda^{n-y}$, and rename $j = n - y$.
(4) Exponential series.

So $Y \sim \mathrm{Poisson}(\epsilon\lambda)$ [Wasserman p. 395]. A detector with efficiency ϵ looking at a Poisson source records a Poisson count with mean $\epsilon\lambda$. This is why $\lambda = \sigma L \epsilon$ in the collider example of Section 2.4 could simply include the efficiency as a factor.

Sorting into bins: Poissonisation. Now let a Poisson(ν) number of events be sorted into m histogram bins with probabilities p_j (Section 2.3). Given the total $N = \sum n_j$, the bins are multinomial. The joint pmf of the bins is

$$\mathrm{P}(n_1, \ldots, n_m) \overset{(1)}{=} \mathrm{P}(N = \textstyle\sum_j n_j)\ \frac{N!}{n_1! \cdots n_m!} p_1^{n_1} \cdots p_m^{n_m} \overset{(2)}{=} e^{-\nu} \frac{\nu^N}{N!} \frac{N!}{\prod_j n_j!} \prod_j p_j^{n_j}$$
$$\overset{(3)}{=} \prod_{j=1}^{m} e^{-\nu p_j} \frac{(\nu p_j)^{n_j}}{n_j!}.$$

(1) The counts determine N, so the joint probability is $\mathrm{P}(N)$ times the multinomial given N.

[2] The line "$Y = Y_1 + Y + 2$" in the source is a misprint for $Y = Y_1 + Y_2$.

(2) Poisson pmf of N.
(3) Cancel $N!$; write $\nu^N = \prod_j \nu^{n_j}$ and $e^{-\nu} = \prod_j e^{-\nu p_j}$ using $\sum_j p_j = 1$.

The joint pmf *factorises* into a product of Poisson(νp_j) pmfs, one per bin. So the bins are *independent* Poisson counts. This is the proof promised in Section 2.3: the anti-correlation came entirely from fixing the total. It is also why a binned likelihood with a Poisson term per bin, $\prod_j e^{-\nu_j} \nu_j^{n_j}/n_j!$, is the standard model of a collider histogram (Chapter 3).

2.5.4 Worked examples

Example: an empty window. A counter sees background at $\lambda = 2$ counts/s. What is the probability that a 5 s window is empty, and that a 1 s window is? By (2.17), $\mathrm{P}(N(5) = 0) = e^{-10} = 4.540 \times 10^{-5}$ and $\mathrm{P}(N(1) = 0) = e^{-2} = 0.135$. The five-second window is five one-second windows in a row, and by independence (input P1) $e^{-10} = (e^{-2})^5$: the empty-window probabilities multiply, which is precisely why P_0 had to be an exponential.

Example: signal on top of background. A search window expects $b = 2.4$ background and $s = 1.2$ signal events, both Poisson and independent. The total count is Poisson(3.6). The probability of observing at least 6 events is

$$\mathrm{P}(N \geq 6) \overset{(1)}{=} 1 - e^{-3.6} \sum_{k=0}^{5} \frac{3.6^k}{k!} \overset{(2)}{=} 1 - 0.02732\,(1 + 3.6 + 6.48 + 7.776 + 6.998 + 5.039)$$
$$= 1 - 0.02732 \times 30.893 = 1 - 0.8441 = 0.156,$$

(1) Sum of Poissons is Poisson; complement of $k \leq 5$.
(2) $e^{-3.6} = 0.02732$, and the terms $3.6^k/k!$ built with the recursion (2.14): multiply successively by $3.6/1, 3.6/2, \ldots, 3.6/5$.

while with background alone ($\lambda = 2.4$) the same calculation gives $1 - 0.9643 = 0.036$. Six events would be four times more likely with the signal than without: the *ratio* of these two probabilities is the germ of the likelihood ratio of Chapter 4.

Example: a detector that sees 30% of the events. A source emits into the detector at $\lambda = 2\ \mathrm{s}^{-1}$ and each photon is detected with $\epsilon = 0.3$. In $T = 5$ s the true count is Poisson(10) and the detected count is Poisson(3). The detected count is *not* "0.3 times a Poisson(10) count". That scaled count could only take the values $0, 0.3, 0.6, \ldots$, and its variance would be $0.3^2 \times 10 = 0.9$. Thinning keeps the counts integer, and the thinned count has variance equal to its mean, 3. The extra variance comes from the losses: each event is lost at random, and the random losses add binomial noise.

2.5.5 Python: the short-interval rules, slice by slice

The script `05_poisson_process.py` implements Figure 2.10 literally: $T = 5$ s is cut into 5000 slices of $h = 1$ ms, and each slice holds an event with probability $\lambda h = 0.002$.

Listing 2.5: Events slice by slice, thinned, and a second source (`code/ch02/05_poisson_process.py`)

```
N = np.empty(windows, int); Ndet = np.empty(windows, int); Nsum = np.empty(windows, int)
for s in range(0, windows, chunk):
    ev = rng.uniform(size=(chunk, slices)) < lam * h          # the postulate, slice by slice
```

```
31      det = ev & (rng.uniform(size=(chunk, slices)) < eps)      # each event survives with
        prob eps
32      ev2 = rng.uniform(size=(chunk, slices)) < lam2 * h        # an independent second source
33      N[s:s + chunk] = ev.sum(1)
34      Ndet[s:s + chunk] = det.sum(1)
35      Nsum[s:s + chunk] = ev.sum(1) + ev2.sum(1)
```

Line 30 is property (iv): one uniform number per slice, an event if it is below λh. Line 31 is thinning: each event survives only if a second, independent uniform number is below ϵ. Line 32 is an independent second source at 1 s^{-1}. The chunks of 1000 windows keep the memory use small. A second block integrates the master equation with Euler steps of 1 ms:

Listing 2.6: Euler integration of the master equation (`code/ch02/05_poisson_process.py`)

```
37  # Euler integration of the master equation, P_n(0) = delta_{n0}
38  dt, tmax, nmax = 1e-3, 4.0, 5
39  t = np.arange(0, tmax + dt / 2, dt)
40  P = np.zeros((t.size, nmax)); P[0, 0] = 1.0
41  for i in range(1, t.size):
42      prev = P[i - 1]
43      gain = np.concatenate([[0.0], prev[:-1]])          # P_{n-1}, with P_{-1} = 0
44      P[i] = prev + dt * lam * (gain - prev)
```

`gain` is the vector of P_{n-1} (with $P_{-1} = 0$), and line 44 is $P_n(t + \mathrm{d}t) = P_n(t) + \mathrm{d}t\,\lambda(P_{n-1} - P_n)$.

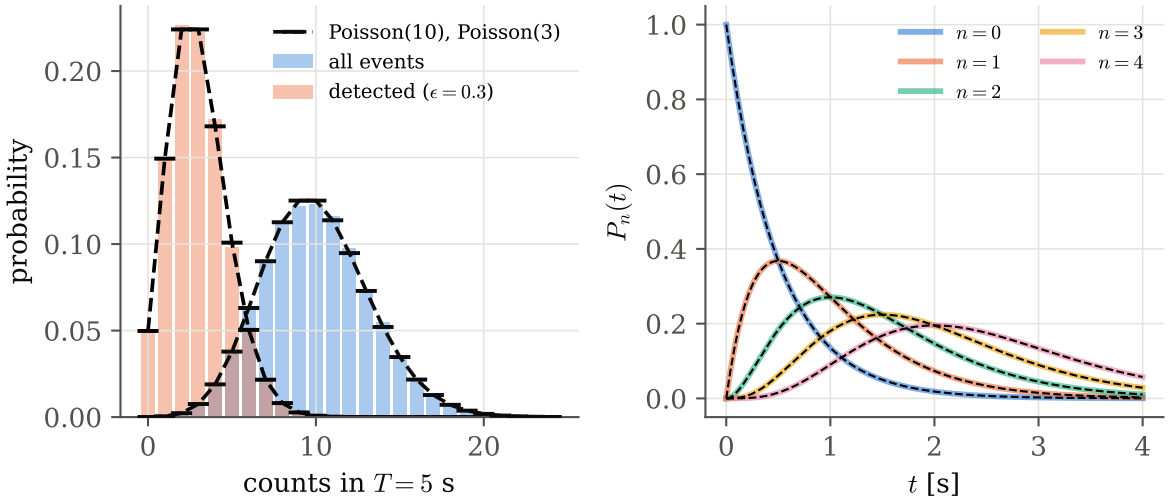

Figure 2.12: Left: counts in 5 s windows built slice by slice, for all events (blue) and for the 30% that are detected (orange); the black ticks are Poisson(10) and Poisson(3). Right: the ladder probabilities $P_0, \ldots, P_4$ from integrating the master equation (thick coloured curves) lie on the analytic Poisson curves (thin dashed). P_0 decays from one; each higher rung fills up later and peaks at $t = n/\lambda$.

Over 20 000 windows the total count has mean 10.01 and variance 9.866 (theory 10 and 10), the thinned count 3.004 and 3.008 (theory 3 and 3), and the sum of the two sources 15 and 14.76 (theory 15 and 15). Empty windows are rare: with $e^{-10} = 4.540 \times 10^{-5}$ we expect $20\,000\,e^{-10} \approx 0.9$ of them, and this run has 0. The Euler solution of the master equation differs from $e^{-\lambda t}(\lambda t)^n/n!$ by at most 4.619×10^{-4} over $0 \le t \le 4$ s (Figure 2.12), an error that shrinks in proportion to the step size.

How this is used in real research: verification versus research

Everything above is *verification*: the simulation checks an analytic result we already had. The same slice-by-slice machinery becomes a research instrument as soon as the inputs

(P1)–(P3) are only approximately true and no formula exists: a rate that depends on the recent history (afterpulsing in a PMT, pile-up in a calorimeter), events that trigger other events (cosmic-ray air showers, aftershocks), or a detector whose efficiency depends on the previous hit (Section 2.8). Then we simulate the process and histogram the counts, and that histogram *is* the sampling distribution $P(S \mid \theta)$ fed into the likelihood.

2.6 Waiting times: the exponential and gamma distributions

The same Geiger counter can be read in two ways. We can count the clicks in fixed windows (Section 2.5), or we can record the *time* of each click and look at the gaps between them. A timing detector with a photomultiplier does the second: it waits for the first photon, or for the tenth, and its time resolution is set by how much that waiting time fluctuates. A muon stopped in a scintillator waits a random time before it decays. For a Poisson process these waiting times have simple laws. The time to the first event is exponential. The time to the n-th event is gamma (also called Erlang). And the "no memory" input becomes the statement that a waiting time never "ages".

Physical picture: the survival law of an unstable particle. An unstable nucleus has no clock inside it. If it has survived a thousand years, its chance of decaying in the next second is the same as on the day it was made. This is why the survival fraction is $e^{-t/\tau}$, and why we can speak of *the* lifetime τ of a species without saying how old the sample is. The time between Poisson events is the same law: the process never "remembers" when the last event happened.

The question, step by step.

1. The first event comes after time t exactly when the window $[0, t]$ is empty. We already know the probability of that.
2. The n-th event comes before time w exactly when the window $[0, w]$ holds at least n events. We know that too.
3. Differentiate these probabilities to get densities. Compute means and variances.
4. Check the "no memory" property directly, and simulate a stream from its gaps.

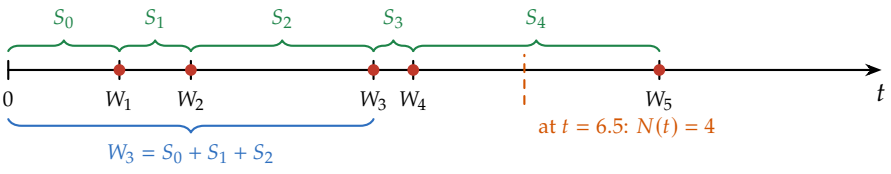

Figure 2.13: One stretch of a Poisson stream. The green braces are the gaps (sojourn times) $S_0, S_1, \ldots$ between successive events; the arrival times W_n are their running sums. At the dashed line four events have happened, so $W_4 \le t < W_5$: counts and waiting times are two descriptions of the same stream.

2.6.1 The first event: exponential

Let $T = W_1$ be the time of the first event, and recall that $N(t)$ is the number of events in $[0, t]$. Figure 2.13 shows the link between the two descriptions: the first event comes after t if and

only if there is no event in $[0, t]$, that is, $T > t$ exactly when $N(t) = 0$. This duality between waiting times and counts turns a question about times into one about counts, which we have already answered. So

$$\mathrm{P}(T > t) \overset{(1)}{=} \mathrm{P}(N(t) = 0) \overset{(2)}{=} e^{-\lambda t}, \qquad F(t) = \mathrm{P}(T \le t) = 1 - e^{-\lambda t}, \qquad f(t) \overset{(3)}{=} \frac{\mathrm{d}F}{\mathrm{d}t} = \lambda e^{-\lambda t}. \quad (2.18)$$

(1) The duality between waiting times and counts.
(2) The empty-window probability $P_0(t)$ from Section 2.5.
(3) A density is the derivative of the CDF (Chapter 1).

Working definition 2.8 (exponential distribution)

$T \sim \mathrm{Exp}(\lambda)$ in the *rate* parameterisation if $f(t) = \lambda e^{-\lambda t}$ for $t \ge 0$ [λ is events per unit time]; equivalently, in the *scale* parameterisation used by AoS, $f(t) = \frac{1}{\beta} e^{-t/\beta}$ with $\beta = 1/\lambda$ [β is a time, the mean wait]. For a decaying particle $\beta = \tau$, the mean lifetime. *Recognise it by:* the waiting time until something that happens at a constant rate and does not age.

The moments of the exponential, and those of the gamma distribution below, need one special function. The **gamma function** is, for $\alpha > 0$, $\Gamma(\alpha) = \int_0^\infty y^{\alpha-1} e^{-y}\,\mathrm{d}y$ [a continuous extension of the factorial, with $\Gamma(n) = (n-1)!$]. Its three essential properties:

$$\Gamma(1) = \int_0^\infty e^{-y}\mathrm{d}y = 1,$$
$$\Gamma(\alpha+1) \overset{(1)}{=} \Big[-y^\alpha e^{-y}\Big]_0^\infty + \alpha \int_0^\infty y^{\alpha-1} e^{-y}\mathrm{d}y \overset{(2)}{=} \alpha\,\Gamma(\alpha),$$
$$\Gamma(\tfrac{1}{2}) \overset{(3)}{=} \int_0^\infty y^{-1/2} e^{-y}\mathrm{d}y \overset{(4)}{=} 2\int_0^\infty e^{-x^2}\mathrm{d}x = \sqrt{\pi}.$$

(1) Integration by parts, with $u = y^\alpha$ and $\mathrm{d}v = e^{-y}\mathrm{d}y$.
(2) The boundary term vanishes at both ends for $\alpha > 0$.
(3) Definition with $\alpha = \frac{1}{2}$.
(4) Substitute $y = x^2$, $\mathrm{d}y = 2x\,\mathrm{d}x$, and use the Gaussian integral $\int_{-\infty}^{\infty} e^{-x^2}\mathrm{d}x = \sqrt{\pi}$.

From the first two, $\Gamma(n) = (n-1)(n-2)\cdots 1\cdot\Gamma(1) = (n-1)!$ for integer n [CasellaBerger (3.3.2)–(3.3.4), p. 81].

Now the moments of the exponential, substituting $y = \lambda t$:

$$\mathbb{E}\,T^r \overset{(1)}{=} \int_0^\infty t^r \lambda e^{-\lambda t}\mathrm{d}t \overset{(2)}{=} \frac{1}{\lambda^r}\int_0^\infty y^r e^{-y}\mathrm{d}y \overset{(3)}{=} \frac{\Gamma(r+1)}{\lambda^r} = \frac{r!}{\lambda^r}.$$

(1) Definition of the r-th moment.
(2) $t = y/\lambda$, $\mathrm{d}t = \mathrm{d}y/\lambda$.
(3) Definition of $\Gamma(r+1)$.

So $\mathbb{E}\,T = 1/\lambda$, $\mathbb{E}\,T^2 = 2/\lambda^2$ and $\mathrm{Var}\,T = 2/\lambda^2 - 1/\lambda^2 = 1/\lambda^2$. The mean waiting time is the inverse rate, and the standard deviation equals the mean: an exponential wait is as uncertain as it is long.

2.6.2 No memory

Key idea: the exponential is memoryless

For all $t, s \geq 0$, $\mathrm{P}(T > t + s \,|\, T > t) = \mathrm{P}(T > s)$.

$$\mathrm{P}(T > t+s \,|\, T > t) \overset{(1)}{=} \frac{\mathrm{P}(T > t+s \text{ and } T > t)}{\mathrm{P}(T > t)} \overset{(2)}{=} \frac{\mathrm{P}(T > t+s)}{\mathrm{P}(T > t)} \overset{(3)}{=} \frac{e^{-\lambda(t+s)}}{e^{-\lambda t}} = e^{-\lambda s} = \mathrm{P}(T > s).$$

(1) Definition of conditional probability (Chapter 1).
(2) $T > t + s$ already implies $T > t$.
(3) Survival function (2.18).

In words: having waited a time t without an event, the remaining wait has the same distribution as a fresh one (Figure 2.14). The converse is also true: the exponential is the *only* continuous distribution with this property. To see why, write $G(t) = \mathrm{P}(T > t)$ for the survival function. Memorylessness says $G(t + s)/G(t) = G(s)$, that is, $G(t + s) = G(t)G(s)$. Taking logarithms, $\ln G(t + s) = \ln G(t) + \ln G(s)$: the function $\ln G$ is additive. The only continuous additive functions are linear, so $\ln G(t) = -\lambda t$ for some constant $\lambda > 0$. So memorylessness *forces* $G(t) = e^{-\lambda t}$ [CasellaBerger (3.3.11), p. 83].

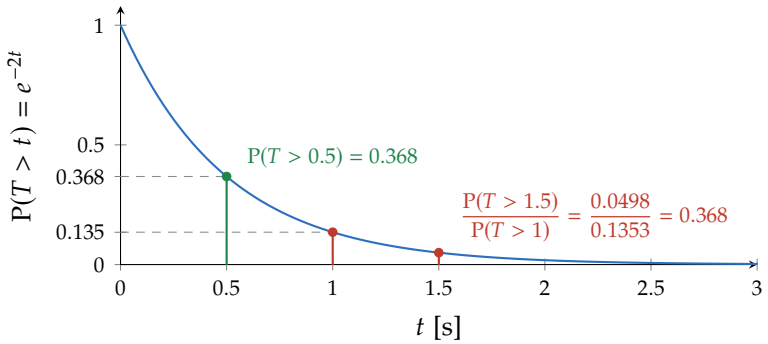

Figure 2.14: The survival curve of an exponential wait with $\lambda = 2\ \mathrm{s}^{-1}$. The chance of waiting a further half second is the same whether we start the clock at zero (green: height at 0.5) or after an empty first second (red: ratio of the heights at 1.5 and 1). Every stretch of the curve is a scaled copy of the whole.

The gaps are independent exponentials. Recall from Figure 2.13 that $S_0, S_1, \ldots$ are the gaps between successive events and W_n is the time of the n-th event. The argument for the first wait restarts at every event. Given that the first event is at $W_1 = s$, the second gap S_1 exceeds t exactly when $(s, s + t]$ is empty:

$$\mathrm{P}(S_1 > t \,|\, W_1 = s) \overset{(1)}{=} \mathrm{P}(\text{no events in } (s, s+t] \,|\, W_1 = s) \overset{(2)}{=} \mathrm{P}(\text{no events in } (s, s+t]) \overset{(3)}{=} e^{-\lambda t}.$$

(1) Duality between the gap and an empty interval.
(2) Independent increments: what happens in $(s, s + t]$ does not care about $[0, s]$.
(3) Stationarity: an interval of length t is empty with probability $e^{-\lambda t}$ wherever it sits.

The answer does not depend on s, so S_1 is independent of $W_1 = S_0$ and is again $\mathrm{Exp}(\lambda)$. Repeating the argument, the gaps $S_0, S_1, S_2, \ldots$ are independent and identically distributed (iid) $\mathrm{Exp}(\lambda)$ [Wasserman Thm. 23.35, p. 396]. This gives a second, equivalent definition of the Poisson process: *a stream of events whose gaps are iid exponential*. It is the one we use to simulate.

2.6.3 The n-th event: gamma (Erlang)

The time of the n-th event is $W_n = S_0 + S_1 + \cdots + S_{n-1}$, a sum of n independent exponentials. Use the duality again: $W_n \le w$ exactly when at least n events happened by w.

$$\begin{aligned} \mathrm{P}(W_n \le w) &\overset{(1)}{=} \mathrm{P}(N(w) \ge n) \overset{(2)}{=} 1 - \sum_{k=0}^{n-1} e^{-\lambda w} \frac{(\lambda w)^k}{k!}, \\ f_{W_n}(w) &\overset{(3)}{=} \lambda e^{-\lambda w} \sum_{k=0}^{n-1} \frac{(\lambda w)^k}{k!} - e^{-\lambda w} \sum_{k=1}^{n-1} \frac{\lambda^k w^{k-1}}{(k-1)!} \\ &\overset{(4)}{=} \lambda e^{-\lambda w} \Big[\sum_{k=0}^{n-1} \frac{(\lambda w)^k}{k!} - \sum_{j=0}^{n-2} \frac{(\lambda w)^j}{j!} \Big] \overset{(5)}{=} \frac{\lambda^n w^{n-1}}{(n-1)!} e^{-\lambda w}. \end{aligned} \tag{2.19}$$

(1) The n-th arrival is before w if and only if the count at w is at least n.
(2) $N(w) \sim \text{Poisson}(\lambda w)$; complement of $k \le n-1$.
(3) Differentiate with the product rule: the derivative of $e^{-\lambda w}$ gives the first sum (with the sign flipped by the leading minus), the derivative of $(\lambda w)^k/k!$ is $\lambda^k w^{k-1}/(k-1)!$ (zero for $k = 0$).
(4) In the second sum take out λ and rename $j = k - 1$.
(5) The two sums *telescope*: every term cancels except $k = n - 1$ in the first.

This is the **Erlang** density.[3] With $\Gamma(n) = (n-1)!$ and the scale $\beta = 1/\lambda$ it is a special case of the general gamma family.

Working definition 2.9 (gamma distribution)

$X \sim \text{Gamma}(\alpha, \beta)$ (shape $\alpha > 0$, scale $\beta > 0$) if

$$f(x \mid \alpha, \beta) = \frac{1}{\Gamma(\alpha)\,\beta^\alpha} x^{\alpha-1} e^{-x/\beta}, \qquad x > 0. \tag{2.20}$$

[for integer $\alpha = n$ and $\beta = 1/\lambda$, the waiting time for the n-th event of a rate-λ Poisson process]. Exp is Gamma$(1, \beta)$. *Recognise it by:* a sum of independent exponential waits, or more generally a positive quantity whose density rises like a power and falls like an exponential.

It is normalised because substituting $y = x/\beta$ turns $\int_0^\infty x^{\alpha-1} e^{-x/\beta} \mathrm{d}x$ into $\beta^\alpha \Gamma(\alpha)$. Its moments follow from the *kernel trick*: recognise the integrand as another gamma density, up to its constant.

$$\mathbb{E}\, X \overset{(1)}{=} \int_0^\infty \frac{x^\alpha e^{-x/\beta}}{\Gamma(\alpha)\beta^\alpha} \mathrm{d}x \overset{(2)}{=} \frac{\Gamma(\alpha+1)\beta^{\alpha+1}}{\Gamma(\alpha)\beta^\alpha} \overset{(3)}{=} \alpha\beta, \qquad \mathbb{E}\, X^2 \overset{(2)}{=} \frac{\Gamma(\alpha+2)\beta^{\alpha+2}}{\Gamma(\alpha)\beta^\alpha} = \alpha(\alpha+1)\beta^2.$$

(1) One extra factor of x raises the power to x^α.
(2) $\int_0^\infty x^{(\alpha+1)-1} e^{-x/\beta} \mathrm{d}x = \Gamma(\alpha+1)\beta^{\alpha+1}$, the normalisation of Gamma$(\alpha+1, \beta)$; likewise with $\alpha + 2$.
(3) $\Gamma(\alpha+1) = \alpha\Gamma(\alpha)$.

So $\mathrm{Var}\, X = \alpha(\alpha+1)\beta^2 - \alpha^2\beta^2 = \alpha\beta^2$ [CasellaBerger (3.3.7)–(3.3.8), p. 82]. For the Erlang wait, $\mathbb{E}\, W_n = n/\lambda$ and $\mathrm{Var}\, W_n = n/\lambda^2$, exactly n times the exponential values, as a sum of n independent gaps must give.

[3] The density printed in [Wasserman Thm. 23.35, p. 396] has $e^{-\lambda t}$ where $e^{-\lambda w}$ is meant. The proof there also writes S_1 for the first gap after defining the gaps from S_0.

The mgf, by the same substitution, is $M_X(t) = (1-\beta t)^{-\alpha}$ for $t < 1/\beta$. Multiplying mgfs shows that independent Gamma(α_i, β) variables with a *common scale* add to Gamma$(\sum \alpha_i, \beta)$: n gaps of Gamma$(1, 1/\lambda)$ make Gamma$(n, 1/\lambda)$, and the first n gaps followed by the next m make W_{n+m}.

The gamma–Poisson identity. The first line of (2.19) is a useful identity in its own right. For integer α and $X \sim \text{Gamma}(\alpha, \beta)$,

$$\mathrm{P}(X \le x) = \mathrm{P}(Y \ge \alpha), \qquad Y \sim \text{Poisson}(x/\beta).$$

A tail probability of a continuous waiting time equals a tail probability of a discrete count [CasellaBerger (3.3.9), p. 82]. Casella and Berger prove it by repeated integration by parts; the duality "n-th event before x $\Leftrightarrow$ at least n events by x" makes it obvious.

2.6.4 Worked examples

Example: muon survival. Stopped muons decay with mean lifetime $\tau = 2.197\ \mu$s. What fraction survives 5 μs? By (2.18) with $\lambda = 1/\tau$, $\mathrm{P}(T > 5\ \mu\text{s}) = e^{-5/2.197} = 0.1027$. By memorylessness, a muon that has already survived 5 μs again has about a 10% chance to survive the next 5 μs. So measuring τ does not require knowing when each muon was produced. Any start time after the muon stops gives the same exponential shape with the same τ. This is why a muon-lifetime experiment can start its clock at the stop signal and ignore everything earlier.

Example: waiting for the third photon. Photons reach a photocathode at $\lambda = 2$ per ns (after thinning by the quantum efficiency). The discriminator fires on the third photoelectron. What is the probability that it has fired within 1 ns? By the gamma–Poisson identity,

$$\mathrm{P}(W_3 \le 1) \overset{(1)}{=} \mathrm{P}(N(1) \ge 3) \overset{(2)}{=} 1 - e^{-2}\left(1 + 2 + \frac{2^2}{2}\right) = 1 - 5e^{-2} = 1 - 0.677 = 0.323.$$

(1) Duality; $N(1) \sim \text{Poisson}(2)$.
(2) Complement of $k = 0, 1, 2$.

The timing jitter of this trigger is the spread of W_3. With $\beta = 1/\lambda = 0.5$ ns, $W_3 \sim \text{Gamma}(3, 0.5\text{ ns})$ has mean $\alpha\beta = 1.5$ ns and standard deviation $\sqrt{\alpha}\,\beta = \sqrt{3} \times 0.5 = 0.87$ ns. In general, firing on the n-th photon gives mean n/λ and standard deviation $\sqrt{n}/\lambda$, so the relative jitter is $1/\sqrt{n}$. The more photons we wait for, the later the trigger, but the more *predictable*.

Example: counts or gaps: the same information about λ. We watch a Poisson stream for a time T and see N events at times $w_1 < \cdots < w_N$. From the counts alone, the probability of the data is $e^{-\lambda T}(\lambda T)^N/N!$. From the gaps: N gaps of the observed lengths (density $\lambda e^{-\lambda s_i}$ each) and then no event in the last stretch $T - w_N$ (probability $e^{-\lambda(T-w_N)}$). The product is

$$\prod_{i=1}^{N} \lambda e^{-\lambda s_i} \times e^{-\lambda(T-w_N)} \overset{(1)}{=} \lambda^N e^{-\lambda w_N} e^{-\lambda(T-w_N)} = \lambda^N e^{-\lambda T}.$$

(1) The gaps add up to the time of the last event, $\sum_i s_i = w_N$.

As functions of λ, the count probability and the gap product are both proportional to $\lambda^N e^{-\lambda T}$ [Wasserman Ex. 23.36, p. 396]. So the detailed arrival times carry no information about a constant rate beyond N and T. Both likelihoods peak at the same estimate, $\hat{\lambda} = N/T$ (Chapter 3). The exact times *do* matter as soon as we want to test whether the rate is constant.

2.6.5 Python: a stream built from its gaps

To simulate the gaps we need exponential numbers, made from uniform ones. One fact does it [Cowan (2.16)–(2.18), p. 30]: if X has a continuous CDF F, then $U = F(X)$ is uniform on $[0, 1]$. Reading it backwards, $X = F^{-1}(U)$ has CDF F. For the exponential, $U = 1 - e^{-\lambda T}$ gives $T = -\ln(1-U)/\lambda$. Since $1 - U$ is also uniform, $T = -\ln U/\lambda$ does the same job. This is *inverse-transform sampling*, developed in general in Chapter 6.

Listing 2.7: Exponential gaps, arrival times, counts per window (code/ch02/06_waiting_times.py)

```
23 # (a) gaps by inverse transform, then the event times are the running sums
24 gaps = -np.log(rng.uniform(size=200_000)) / lam
25 times = np.cumsum(gaps)
26 Tmax = np.floor(times[-1])
27 counts = np.bincount(np.floor(times[times < Tmax]).astype(int), minlength=int(Tmax))  #
       events per 1 s window
28
29 # (b) arrival time of the n-th event: sum of n independent gaps
30 def erlang_pdf(w, n):
31     return lam**n * w**(n - 1) * np.exp(-lam * w) / factorial(n - 1)
```

Line 24 draws 200 000 exponential gaps with $\lambda = 2\ \mathrm{s}^{-1}$; line 25 turns them into arrival times by a running sum, exactly as in Figure 2.13. Line 27 counts the arrivals in each 1 s window: `np.floor(times)` is the window index of each event and `np.bincount` counts events per index. The function `erlang_pdf` is (2.19). Further down, the gaps are grouped in blocks of n and summed to give samples of W_n.

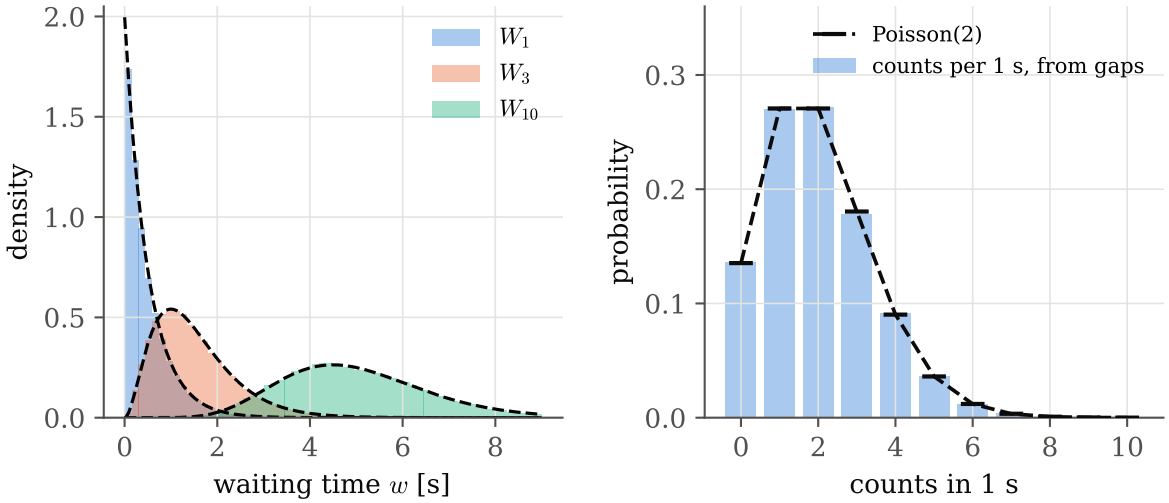

Figure 2.15: Left: histograms of the arrival time of the first, third and tenth event, built by summing 1, 3 or 10 simulated gaps, with the Erlang densities as dashed curves. The first arrival is most likely immediately; later arrivals have a peak that moves right and a width that grows only like $\sqrt{n}$. Right: counting the same stream in 1 s windows gives the Poisson(2) distribution, closing the loop from gaps back to counts.

The gaps have sample mean 0.4993 s and variance 0.2501 s^2 (theory $1/\lambda = 0.5$ and $1/\lambda^2 = 0.25$). The counts per second have mean 2.003 and variance 2.017 (theory 2 and 2). The tenth arrival has mean 4.993 s and variance 2.539 s^2 (theory 5 and 2.5). For memorylessness, among the gaps that exceeded 1 s the fraction that exceeded 1.5 s is 0.3694, against 0.3675 for all gaps exceeding 0.5 s and the theoretical $e^{-1} = 0.3679$ (Figure 2.15).

Watch out: rate or scale? three conventions for one distribution

The same gamma distribution is written with a *scale* β (AoS, Casella–Berger, `scipy.stats.gamma(a, scale=beta)`, `numpy`'s `rng.gamma(shape, scale)`), or with a *rate* $1/\beta$ (Lambert, most Bayesian texts and Stan). "Exp(2)" means mean 2 in one book and mean 1/2 in another. Always check by computing the mean. Lambert's lottery example is a warning: three prize-claiming times, each exponential with rate 1 per day, sum to a gamma with *shape* 3 and rate 1, which the text describes with the words "scale" and "shape" swapped [Lambert §8.4.9].

Not every lifetime is exponential. Memorylessness means a constant *hazard* $h(t) = f(t)/\mathrm{P}(T > t)$ [the probability per unit time of failing now, given survival so far]. For the exponential $h(t) = \lambda$. Components that wear out have a rising hazard and are better described by the Weibull distribution, $\mathrm{P}(T > t) = e^{-(t/\beta)^{\gamma}}$ with $\gamma > 1$ [CasellaBerger (3.3.12), p. 83]. Particles and nuclei have no wear, which is why the exponential law of decay is exact (to the extent quantum mechanics allows).

2.7 Discrete waiting times and extra spread: geometric and negative binomial

At a collider, bunches cross every 25 ns and each crossing fires a rare trigger with probability p. How many crossings do we wait until the first trigger? Until the third? This is the waiting-time question of Section 2.6, but with time coming in discrete ticks. A second puzzle has the same answer. A galaxy survey counts galaxies in cells of equal volume. The mean is 10 per cell, but the variance is 30, not the 10 a Poisson count would have. The counts are *overdispersed*: they scatter more than Poisson, because galaxies cluster and the underlying density varies from cell to cell. Two distributions answer both questions. The geometric and negative binomial distributions count trials until a given number of successes. The negative binomial then reappears as a Poisson count whose mean itself fluctuates, and in that role it is the standard model for counts that scatter more than Poisson.

Physical picture: ticks of a clock, and a Poisson with a wobbling rate. The geometric wait is the exponential wait with time chopped into ticks; shrink the ticks and it becomes the exponential. The overdispersed count is a Poisson count seen through a fluctuating medium, in two stages. First nature picks the local rate. Then a Poisson count is drawn with that rate. The total scatter is the sum of the scatter from the two stages: the Poisson "shot noise" plus the variance of the rate. Photon counts from a twinkling star behave this way.

The question, step by step.

1. The first success is on trial k exactly when trials $1, \ldots, k-1$ fail and trial k succeeds. Multiply.
2. The r-th success is on trial x exactly when trial x succeeds and the first $x-1$ trials contain $r-1$ successes. That is a binomial count times one more trial.
3. If a Poisson mean is itself random, average the Poisson pmf over its distribution (marginalise).

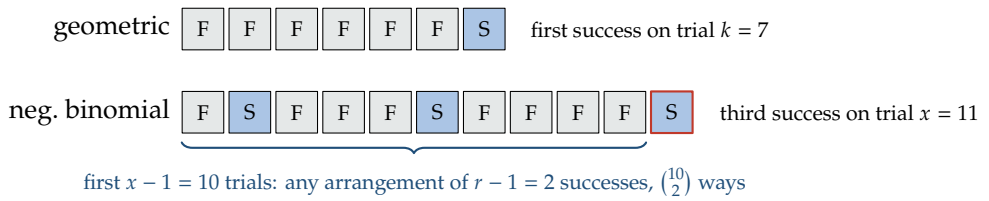

Figure 2.16: Two waits in a sequence of Bernoulli trials. Top: the first success after six failures. Bottom: the third success (outlined in red) is the last trial; before it, the two earlier successes can sit in any of $\binom{10}{2} = 45$ arrangements among the first ten trials, each equally probable.

2.7.1 The geometric distribution

Working definition 2.10 (geometric distribution)

$X \sim \text{Geom}(p)$ if X is the number of the trial on which the first success occurs, in a sequence of independent Bernoulli(p) trials [X counts the successful trial too, so $X \geq 1$]:

$$\mathrm{P}(X = k) = (1-p)^{k-1}p, \qquad k = 1, 2, 3, \ldots \tag{2.21}$$

Recognise it by: the number of tries until the first success, with a constant chance per try.

The formula follows from the first step listed above. The first success is on trial k when $k-1$ failures, each with probability $1-p$, are followed by a success, all independent; multiplying gives $(1-p)^{k-1}p$. Some books (and `scipy.stats.nbinom`) count instead the number of *failures* before the first success, $Y = X - 1 \in \{0, 1, \ldots\}$, with $\mathrm{P}(Y = y) = (1-p)^y p$.[4]

Geometric series. Everything follows from $\sum_{j=0}^{\infty} r^j = \frac{1}{1-r}$ for $|r| < 1$. Proof: the partial sum $S_n = 1 + r + \cdots + r^n$ satisfies $S_n - rS_n = 1 - r^{n+1}$, so $S_n = \frac{1-r^{n+1}}{1-r} \to \frac{1}{1-r}$. Differentiating term by term (allowed inside the radius of convergence) gives $\sum_{j=1}^{\infty} j r^{j-1} = \frac{1}{(1-r)^2}$ and $\sum_{j=2}^{\infty} j(j-1) r^{j-2} = \frac{2}{(1-r)^3}$. With $r = 1 - p$:

$$\sum_{k=1}^{\infty} \mathrm{P}(X = k) \overset{(1)}{=} p \sum_{k=1}^{\infty} (1-p)^{k-1} \overset{(2)}{=} \frac{p}{1-(1-p)} = 1,$$

$$\mathbb{E}\, X \overset{(3)}{=} p \sum_{k=1}^{\infty} k(1-p)^{k-1} \overset{(4)}{=} \frac{p}{p^2} = \frac{1}{p},$$

$$\mathbb{E}[X(X-1)] \overset{(3)}{=} p(1-p) \sum_{k=2}^{\infty} k(k-1)(1-p)^{k-2} \overset{(4)}{=} \frac{2p(1-p)}{p^3} = \frac{2(1-p)}{p^2},$$

$$\mathrm{Var}\, X \overset{(5)}{=} \frac{2(1-p)}{p^2} + \frac{1}{p} - \frac{1}{p^2} = \frac{1-p}{p^2}.$$

(1) Take out p.
(2) Geometric series with $j = k - 1$ running from 0.
(3) Definition of the (factorial) moment; for the second line one factor $(1-p)$ is taken out so that the power is $k-2$.
(4) The differentiated series with $1 - r = p$.
(5) $\mathrm{Var}\, X = \mathbb{E}[X(X-1)] + \mathbb{E}\, X - (\mathbb{E}\, X)^2$; put over p^2: $2 - 2p + p - 1 = 1 - p$.

[4] The normalisation check for the geometric distribution in [Wasserman pp. 26–27] has a misprint in its middle sum, which is printed as $p \sum_{k \geq 1} (1-p)^k$. That sum equals $1 - p$, not 1. The exponent must be $k - 1$, as below.

A trigger with $p = 0.1$ fires on average every 10 crossings, with a standard deviation $\sqrt{0.9}/0.1 = 9.5$ crossings: nearly as large as the mean, just like the exponential.

The tail and no memory. The first success comes after trial k exactly when the first k trials all fail, so $\mathrm{P}(X > k) = (1-p)^k$. Then

$$\mathrm{P}(X > s+t \mid X > t) \overset{(1)}{=} \frac{\mathrm{P}(X > s+t)}{\mathrm{P}(X > t)} = \frac{(1-p)^{s+t}}{(1-p)^t} = (1-p)^s = \mathrm{P}(X > s)$$

(1) $X > s+t$ implies $X > t$, and the definition of conditional probability.

for integers $s, t \geq 0$. The geometric is memoryless: a trigger that has not fired for 1000 crossings is not "due" [CasellaBerger (3.2.11), p. 80].

From ticks to continuous time. Let the trials be ticks of length h with $p = \lambda h$. The waiting time is $T = hX$, and

$$\mathrm{P}(T > t) = \mathrm{P}(X > t/h) = (1-\lambda h)^{t/h} \xrightarrow{h \to 0} e^{-\lambda t},$$

by the compound-interest limit of Section 2.4 with $n = t/h$. The geometric becomes the exponential, just as the binomial became the Poisson. The slices of Figure 2.10 are exactly these ticks.

2.7.2 The negative binomial

Working definition 2.11 (negative binomial distribution)

In a sequence of independent Bernoulli(p) trials, let X be the number of the trial on which the r-th success occurs. Then $X \sim \mathrm{NegBin}(r, p)$ with

$$\mathrm{P}(X = x) = \binom{x-1}{r-1} p^r (1-p)^{x-r}, \qquad x = r, r+1, \ldots \tag{2.22}$$

Equivalently, the number of failures before the r-th success, $Y = X - r$, has

$$\mathrm{P}(Y = y) = \binom{r+y-1}{y} p^r (1-p)^y, \qquad y = 0, 1, 2, \ldots \tag{2.23}$$

[for $r = 1$ these are the two forms of the geometric]. *Recognise it by:* the number of tries until a fixed number r of successes, or (see below) a count that is more spread out than Poisson.

Derivation of (2.22). This is the second step listed above (Figure 2.16). The r-th success is on trial x if and only if two things happen. First, the first $x-1$ trials contain exactly $r-1$ successes; this has the binomial probability $\binom{x-1}{r-1} p^{r-1}(1-p)^{x-r}$. Second, trial x succeeds, with probability p, independently of the earlier trials. Multiplying the two gives (2.22). Replacing $x = y + r$ and using $\binom{n}{k} = \binom{n}{n-k}$ gives (2.23) [CasellaBerger (3.2.9)–(3.2.10), p. 78].

Mean and variance: a sum of geometric waits. After each success the process starts afresh, because the trials are independent. So Y, the number of failures before the r-th success, is the sum of r independent copies of $Y_1 = X_1 - 1$, the number of failures before the first

success; here $X_1 \sim \mathrm{Geom}(p)$. From the geometric moments, Y_1 has $\mathbb{E}\,Y_1 = \frac{1}{p} - 1 = \frac{1-p}{p}$ and $\mathrm{Var}\,Y_1 = \mathrm{Var}\,X_1 = \frac{1-p}{p^2}$. Hence

$$\mathbb{E}\,Y = \frac{r(1-p)}{p}, \qquad \mathrm{Var}\,Y = \frac{r(1-p)}{p^2} = \mathbb{E}\,Y + \frac{(\mathbb{E}\,Y)^2}{r}. \tag{2.24}$$

The last form follows by writing $\mu = r(1-p)/p$: then $\mu + \mu^2/r = \frac{r(1-p)}{p}\big(1 + \frac{1-p}{p}\big) = \frac{r(1-p)}{p^2}$. *The variance always exceeds the mean*, by μ^2/r.

Why "negative" binomial. Write out the coefficient with $r+y-1$ over y and pull out a sign from each of the y factors:

$$\binom{r+y-1}{y} \overset{(1)}{=} \frac{(r+y-1)(r+y-2)\cdots r}{y!} \overset{(2)}{=} (-1)^y \frac{(-r)(-r-1)\cdots(-r-y+1)}{y!} \overset{(3)}{=} (-1)^y \binom{-r}{y}.$$

(1) Cancel $(r-1)!$ from $(r+y-1)!/(y!(r-1)!)$, leaving y factors on top.
(2) Each factor $(r+j) = -(-r-j)$, for $j = 0, \ldots, y-1$, read in reverse order.
(3) The *generalised* binomial coefficient $\binom{a}{y} = a(a-1)\cdots(a-y+1)/y!$ makes sense for any real a, including $a = -r$.

Newton's binomial series $(1+z)^a = \sum_y \binom{a}{y} z^y$ for $|z| < 1$ then normalises (2.23): $\sum_y \binom{-r}{y}(-(1-p))^y p^r = (1-(1-p))^{-r} p^r = 1$. The pmf is a term of a binomial expansion with a negative exponent.

Its mgf and the Poisson limit. For one geometric failure count, $\mathbb{E}\,e^{tY_1} = \sum_y p(1-p)^y e^{ty} = p/(1-(1-p)e^t)$ (geometric series, valid for $(1-p)e^t < 1$). A sum of r independent copies has the r-th power. Now let $r \to \infty$ while holding the mean $r(1-p)/p$ close to a fixed λ; to leading order $1 - p = \lambda/r$:

$$M_Y(t) = \left(\frac{p}{1-(1-p)e^t}\right)^r \overset{(1)}{=} \frac{(1-\lambda/r)^r}{(1-\lambda e^t/r)^r} \xrightarrow{r\to\infty} \frac{e^{-\lambda}}{e^{-\lambda e^t}} = e^{\lambda(e^t-1)}.$$

(1) Substitute $p = 1 - \lambda/r$.

The limit is the Poisson mgf (2.13): with many required successes and rare failures, the failure count becomes Poisson, and the excess variance μ^2/r disappears [CasellaBerger p. 79].

2.7.3 A Poisson count with a fluctuating mean

The most important appearance of the negative binomial in physics is not about waiting at all. Suppose the count in a cell is Poisson with mean Λ, but Λ itself varies: from cell to cell (clustering), from run to run (beam intensity) or from pixel to pixel (a twinkling source). Take Λ to follow a gamma distribution with shape κ and scale μ/κ. By the gamma moments of Section 2.6, $\mathbb{E}\,\Lambda = \kappa \cdot \mu/\kappa = \mu$ and $\mathrm{Var}\,\Lambda = \kappa(\mu/\kappa)^2 = \mu^2/\kappa$. The distribution of the count is then the **mixture**: the marginal over the nuisance variable Λ. Write $\theta = \mu/\kappa$ for the gamma scale:

$$\begin{aligned} \mathrm{P}(N=n) &\overset{(1)}{=} \int_0^\infty e^{-\lambda}\frac{\lambda^n}{n!}\,\frac{\lambda^{\kappa-1}e^{-\lambda/\theta}}{\Gamma(\kappa)\theta^\kappa}\,\mathrm{d}\lambda \overset{(2)}{=} \frac{1}{n!\,\Gamma(\kappa)\,\theta^\kappa}\int_0^\infty \lambda^{n+\kappa-1}e^{-\lambda(1+\theta)/\theta}\,\mathrm{d}\lambda \\ &\overset{(3)}{=} \frac{\Gamma(n+\kappa)}{n!\,\Gamma(\kappa)\,\theta^\kappa}\Big(\frac{\theta}{1+\theta}\Big)^{n+\kappa} \overset{(4)}{=} \frac{\Gamma(n+\kappa)}{n!\,\Gamma(\kappa)}\Big(\frac{\kappa}{\kappa+\mu}\Big)^\kappa\Big(\frac{\mu}{\kappa+\mu}\Big)^n. \end{aligned}$$

(1) Law of total probability for a continuous nuisance variable: Poisson pmf given $\Lambda = \lambda$, times the gamma density of Λ, integrated.
(2) Collect the powers of λ and the exponentials: $\lambda + \lambda/\theta = \lambda(1+\theta)/\theta$.
(3) The integral is the gamma normalisation with shape $n + \kappa$ and scale $\theta/(1+\theta)$.
(4) $\theta^{-\kappa}(\theta/(1+\theta))^{\kappa} = (1+\theta)^{-\kappa}$, and $\theta/(1+\theta) = \mu/(\kappa+\mu)$, $1/(1+\theta) = \kappa/(\kappa+\mu)$.

For integer κ, $\Gamma(n+\kappa)/(n!\,\Gamma(\kappa)) = \binom{\kappa+n-1}{n}$, and this is (2.23) with $r = \kappa$ and $p = \kappa/(\kappa+\mu)$. The formula makes sense for any real $\kappa > 0$, and in this role κ is called the **inverse dispersion** [Lambert §8.4.4].

The variance is cleanest by the law of total variance (Chapter 1). It splits the scatter into the two stages of the physical picture above: nature picks the rate, then the Poisson count is drawn.

$$\operatorname{Var} N \overset{(1)}{=} \mathbb{E}\big[\operatorname{Var}(N \mid \Lambda)\big] + \operatorname{Var}\big(\mathbb{E}[N \mid \Lambda]\big) \overset{(2)}{=} \mathbb{E}\,\Lambda + \operatorname{Var}\Lambda \overset{(3)}{=} \mu + \frac{\mu^2}{\kappa}. \tag{2.25}$$

(1) Law of total variance: average of the conditional variance plus variance of the conditional mean.
(2) Given Λ, N is Poisson, so its conditional mean and variance both equal Λ.
(3) Gamma moments.

The variance is the Poisson shot noise μ plus the variance of the rate, μ^2/κ. Nothing in the second step used the gamma form: *any* fluctuating mean gives $\operatorname{Var} N = \mu + \operatorname{Var}\Lambda > \mu$. The gamma only makes the full distribution a closed form.

2.7.4 Worked examples

Example: how long until the trigger fires? With $p = 0.1$ per crossing, what is the probability of waiting more than 30 crossings for the first trigger? $\mathrm{P}(X > 30) = (0.9)^{30} = 0.04239$. And for a light bulb that fails on any given day with probability 0.001, $\mathrm{P}(X > 30) = 0.999^{30} = 0.970$: a 97% chance to last a month [CasellaBerger Ex. 3.2.7, p. 80]. By memorylessness, the same 97% applies to the next month of a bulb that has already lasted a year. Real bulbs age, so the geometric is only a rough model for them; a trigger has no memory, so for it the model is exact.

Example: inverse binomial sampling. To measure a rare branching fraction p we can fix the number of trials and count successes (binomial), or keep collecting until we have r successes (negative binomial) [CasellaBerger Ex. 3.2.6, p. 79]. Suppose $p = 0.02$ and we stop at $r = 100$ signal events. The number of events examined is $X = Y + r$ with

$$\mathbb{E}\,X \overset{(1)}{=} \frac{r}{p} = 5000, \qquad \operatorname{sd}(X) \overset{(2)}{=} \frac{\sqrt{r(1-p)}}{p} = \frac{\sqrt{98}}{0.02} = 495.$$

(1) $\mathbb{E}\,X = \mathbb{E}\,Y + r = r(1-p)/p + r = r/p$.
(2) $\operatorname{Var} X = \operatorname{Var} Y = r(1-p)/p^2$ from (2.24).

The relative uncertainty of the stopping point is $\sqrt{1-p}/\sqrt{r} \approx 10\%$, set by r alone. Stopping rules like this matter for inference: Chapter 3 and Chapter 5 show that the binomial and negative binomial give proportional likelihoods for p, so a Bayesian analysis does not care which rule was used, while a p-value does.

Example: counts in cells of a clustered galaxy field. Cells of a survey contain on average $\mu = 10$ galaxies. If galaxies were placed independently (a Poisson process in space, Section 2.5), the variance of the cell counts would be 10. But galaxies trace a fluctuating matter density. The

local mean in a cell is $\Lambda = \mu(1+\delta)$, where δ is the density contrast smoothed over the cell, with variance σ^2_{cell}. So $\operatorname{Var}\Lambda = \mu^2\sigma^2_{\text{cell}}$, and by (2.25),

$$\operatorname{Var} N = \mu + \mu^2\sigma^2_{\text{cell}}.$$

If $\sigma^2_{\text{cell}} = 0.2$, then $\operatorname{Var} N = 10 + 20 = 30$, three times the Poisson value. This is the gamma–Poisson model with $1/\kappa = \sigma^2_{\text{cell}}$, that is, $\kappa = 5$. Read backwards, the formula is a measurement. The *excess* variance of counts in cells over the Poisson value measures the clustering amplitude σ^2_{cell}. That excess is the one-point statistic behind the two-point function of Chapter 7. The Poisson term μ is the *shot noise* that every galaxy power spectrum must subtract.

2.7.5 Python: trials one after another, and a wobbling rate

Listing 2.8: Geometric and negative binomial by running trials; the gamma–Poisson mixture (`code/ch02/07_geometric_negbin.py`)

```
# (a),(b): run Bernoulli trials one after another and record where successes fall
p, r, reps = 0.1, 3, 50_000
first, fails_before_r = np.empty(reps, int), np.empty(reps, int)
for i in range(reps):
    trials = rng.uniform(size=400) <= p            # 400 trials is (much) more than enough here
    s = np.flatnonzero(trials) + 1                 # trial numbers (1-based) of the successes
    first[i] = s[0]                                # geometric: trial of the first success
    fails_before_r[i] = s[r - 1] - r               # negative binomial: failures before r-th success

# (c): gamma-distributed mean, then a Poisson count with that mean
mu, kappa, runs = 10.0, 5.0, 200_000
lam_run = rng.gamma(shape=kappa, scale=mu / kappa, size=runs)   # mean mu, variance mu^2/kappa
N = rng.poisson(lam_run)
```

For each of 50 000 experiments the script runs 400 Bernoulli(0.1) trials (the chance that fewer than three successes occur in 400 trials is negligible) and finds the trial numbers of the successes with `np.flatnonzero`. The first one is the geometric wait; the third one minus $r = 3$ is the number of failures before the third success. For the mixture, line 34 draws a rate for each run from a gamma distribution with shape $\kappa = 5$ and scale μ/κ (numpy's convention is scale), and line 35 draws one Poisson count with that rate.

The geometric wait has sample mean 10.03 and variance 91.61 (theory $1/p = 10$ and $(1-p)/p^2 = 90$); 0.04384 of the experiments waited more than 30 crossings, against $0.9^{30} = 0.04239$. The failures before the third success have mean 26.97 and variance 271 (theory 27 and 270). The mixture counts have mean 9.997 and variance 29.87, against $\mu + \mu^2/\kappa = 30$ (Figure 2.17).

What this bought us. Discrete waits (geometric, negative binomial) are the tick-by-tick versions of the exponential and gamma. The negative binomial also describes a Poisson count with a gamma-distributed mean, with variance $\mu + \mu^2/\kappa$. Whenever counts scatter more than their mean, look for a fluctuating rate.

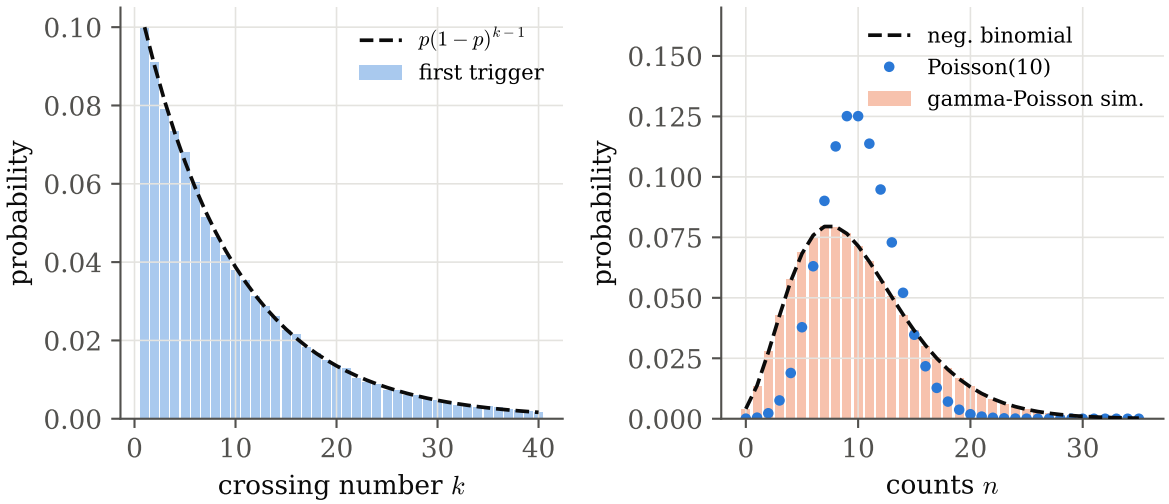

Figure 2.17: Left: the crossing number of the first trigger (bars) against $p(1-p)^{k-1}$ (dashed): a geometric staircase, highest at $k = 1$, falling by a factor 0.9 per crossing. Right: counts whose Poisson mean wobbles from run to run (bars) follow the negative binomial (dashed), far wider than the Poisson with the same mean 10 (blue dots).

2.8 When the Poisson assumptions fail, and where the Poisson goes for large λ

Point a Geiger counter at a radioactive source and move it closer. At first the count rate rises like $1/r^2$, as the solid angle says it should. Closer in, it rises more slowly than $1/r^2$, and with some counters, very close to a strong source, it even *falls*. Now look at the counts in successive short windows at a fixed distance. A second oddity appears: at high rate they scatter *less* than the $\sqrt{\text{mean}}$ that the Poisson distribution promises. A clustered galaxy survey shows the opposite oddity, as we saw in the counts-in-cells example of Section 2.7: the counts in cells scatter *more* than Poisson.

Both oddities are the Poisson inputs of Section 2.5 failing, in opposite directions. Each physical effect breaks a particular input (P1)–(P3) of Section 2.5.1. One number computed from the data detects the failure. And the commonest failure in counting detectors, dead time, can be corrected. A separate question concerns large means: there the Poisson distribution becomes close to a Gaussian, and the replacement is safe in some places and badly wrong in others.

The questions.

1. Which Poisson input does each physical effect break, and does it push the variance of the counts up or down?
2. Given a set of counts, how do we test whether they are Poisson?
3. For a counter that is blind for a time τ after each hit, what is the recorded rate, how do we get the true rate back, and how much do the recorded counts scatter?
4. For large λ, how close is Poisson(λ) to the Gaussian $\mathcal{N}(\lambda, \lambda)$, and where does the approximation fail?

2.8.1 Three inputs, two directions of failure

Recall the three physical inputs from which the Poisson process was derived (Section 2.5.1):

(P1) what happens in one time slice is independent of what happened in all the others [no memory, no triggering, no suppression];

(P2) the rate λ is the *same* at all times [the source does not drift];

(P3) events come one at a time [never two at the same instant].

From these came the pmf $e^{-\lambda t}(\lambda t)^n/n!$ for the count N in a window of length t, and with it the defining fingerprint $\operatorname{Var} N = \mathbb{E}\, N$. The Poisson is the distribution of "counts of rare events" [Wasserman p. 27]. Here "rare" means precisely that the events do not interact with each other and are not modulated by anything. The same point holds from the user's side [Lambert §8.4.3]: the mean and the variance are the same parameter, so the Poisson is useful only for data with $\operatorname{Var} N \approx \mathbb{E}\, N$.

Real effects break the inputs in one of two directions.

More spread than Poisson (overdispersion). Two kinds of effect make the counts clump.

- *The rate itself fluctuates* (input P2 fails). The beam intensity drifts from run to run, the sky background varies across the field, the density of dark matter modulates where galaxies form. In Section 2.7 we proved that a Poisson count with a random mean Λ has $\operatorname{Var} N = \mathbb{E}\,\Lambda + \operatorname{Var}\Lambda$, eq. (2.25). The extra term can only add.
- *Events trigger further events* (input P1 fails in the positive direction). A photomultiplier pulse is followed by an afterpulse from an ion drifting back to the photocathode. A cosmic-ray primary makes an air shower of secondaries. Events arrive in bunches, and a window either catches a bunch or misses it.

The binomial has the same failure mode. When the success probability p varies from group to group, for example between detector modules or between clinical trials, the number of successes is spread wider than $np(1-p)$. Its standard model is the beta-binomial, the binomial analogue of the negative binomial [Lambert §8.4.5].

Less spread than Poisson (underdispersion). Other effects make the events avoid each other, so that the stream becomes more regular than random.

- *Events suppress further events* (input P1 fails in the negative direction). After recording a hit the counter is blind for a **dead time** τ. A neuron cannot fire again during its refractory period. Pile-up rejection throws away events that come too close together.
- *The pool of possible events is finite.* With n nuclei and decay probability p per window the count is binomial, with $\operatorname{Var} N = np(1-p) < np = \mathbb{E}\, N$. This is negligible for a macroscopic source ($n \sim 10^{20}$), but not for a handful of trapped ions, or for a short-lived isotope that decays appreciably during the measurement (then input P2 fails as well: the rate falls with time).

Input (P3) fails when two events in one slice are recorded as one. This **pile-up** (two photons in one X-ray CCD pixel within one readout frame, two particles in one calorimeter cell in one bunch crossing) loses events and distorts the recorded energies. As far as the counts are concerned, it acts like a dead time of one frame.

Figure 2.18 shows the three kinds of stream. The eye reads clumping and regularity immediately. What we need is a number that does the same for a data set of thousands of windows.

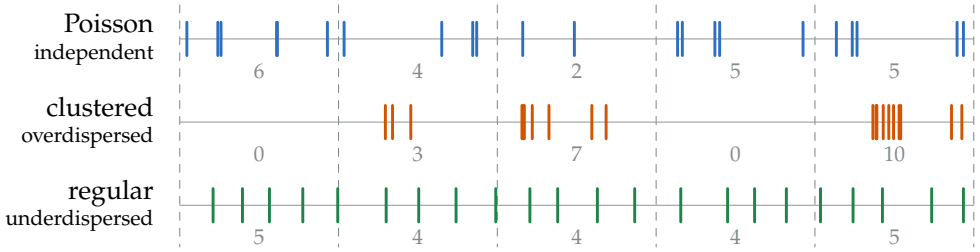

Figure 2.18: Three streams of about twenty events, each cut into five equal windows (dashed lines); the small numbers are the counts per window. Top: a Poisson stream, with the irregular gaps and chance near-coincidences of genuine randomness. Middle: the same kind of stream in clumps (a few independent "parents", each with a small bunch of offspring): whole windows are empty and others are crowded. Bottom: a dense Poisson stream passed through a counter that is blind for a fixed time after each recorded hit: no two events are close, the gaps are almost equal, and the counts barely change from window to window.

2.8.2 The Fano factor: a one-number test

Since a Poisson count has variance equal to its mean, the natural diagnostic is their ratio.

Working definition 2.12 (Fano factor (index of dispersion))

For a count N with mean $\mu > 0$, the **Fano factor** is

$$F = \frac{\operatorname{Var} N}{\mathbb{E}\, N}.$$

$F = 1$ for a Poisson count, $F > 1$ is **overdispersion** [clumped events or a fluctuating rate], and $F < 1$ is **underdispersion** [events that avoid each other, or a finite pool]. From k independent counts $n_1, \dots, n_k$ of the same window we estimate it by

$$\hat{F} = \frac{s^2}{\bar{n}}, \qquad \bar{n} = \frac{1}{k}\sum_{i=1}^{k} n_i, \quad s^2 = \frac{1}{k-1}\sum_{i=1}^{k}(n_i - \bar{n})^2.$$

For Poisson counts with $\bar{n} \gg 1$, $\hat{F}$ scatters about 1 with standard deviation $\sqrt{2/(k-1)}$.

Values of F we already know: Poisson $F = 1$; binomial $F = 1 - p$; negative binomial $F = 1 + \mu/\kappa$, from (2.25). The name comes from the physics of ionisation detectors, where U. Fano showed that the number of electron–ion pairs made by a particle of fixed energy fluctuates less than Poisson (the energy budget is fixed, so the pairs are not independent). The same ratio minus one is Mandel's Q parameter in quantum optics (see the example on sub-Poissonian light below).

How far from 1 is "significantly" far? A sample Fano factor is itself a random number, so a measured $\hat{F} = 0.97$ need not mean anything. To judge it we need the spread of $\hat{F}$ when the counts really are Poisson. Two facts give it. The first: for any independent sample of size k, the sample variance s^2 has

$$\operatorname{Var}(s^2) = \frac{2\sigma^4}{k-1} + \frac{\kappa_4}{k},$$

where σ^2 is the variance and κ_4 the fourth **cumulant** [the excess of the fourth central moment over its Gaussian value, $\kappa_4 = \mathbb{E}(N-\mu)^4 - 3\sigma^4$] of one count. The first term is the Gaussian result, derived with the χ^2 distribution in the next part. The second is the correction for a

non-Gaussian parent. The second fact: for a Poisson count every cumulant equals λ (proved in Section 2.8.5 below), so $\sigma^2 = \kappa_4 = \lambda$. The mean $\bar{n}$ fluctuates by only a relative $1/\sqrt{k\lambda}$, so in the ratio we may treat it as the constant λ. Then

$$\mathrm{sd}(\hat{F}) \overset{(1)}{=} \frac{\mathrm{sd}(s^2)}{\lambda} \overset{(2)}{=} \frac{1}{\lambda}\sqrt{\frac{2\lambda^2}{k-1} + \frac{\lambda}{k}} \overset{(3)}{=} \sqrt{\frac{2}{k-1} + \frac{1}{k\lambda}} \overset{(4)}{\approx} \sqrt{\frac{2}{k-1}}. \tag{2.26}$$

(1) $\hat{F} = s^2/\bar{n}$ with $\bar{n}$ replaced by its expected value λ; its relative fluctuation $1/\sqrt{k\lambda}$ is tiny next to that of s^2.
(2) The variance of s^2 with $\sigma^2 = \kappa_4 = \lambda$.
(3) Take λ^2 out of the square root.
(4) For $\lambda \gg 1$ the second term is negligible: $1/(k\lambda) \ll 2/(k-1)$.

The spread depends only on the number of windows k, not on the rate. The combination $D = (k-1)\hat{F} = \sum_i (n_i - \bar{n})^2/\bar{n}$ is the classical **index-of-dispersion statistic**. For Poisson counts it is close to a χ^2 variable with $k-1$ degrees of freedom, and using it to reject "the counts are Poisson" is a hypothesis test in the sense of Chapter 4.

Example: reading a Fano factor. We record $k = 4000$ windows. By (2.26), $\mathrm{sd}(\hat{F}) = \sqrt{2/3999} = 0.0224$.

- $\hat{F} = 0.96$ is $(0.96 - 1)/0.0224 = -1.8$ standard deviations from 1. That happens by chance in about 7% of Poisson data sets (two-sided), so it is no evidence against Poisson.
- $\hat{F} = 0.62$ is -17 standard deviations. The counts are certainly not Poisson, and they are underdispersed: look for dead time.
- $\hat{F} = 3.0$ is $+89$ standard deviations. Look for a fluctuating rate or clustering, as in the galaxy counts of Section 2.7, where $F = 1 + \mu\sigma^2_{\mathrm{cell}} = 3$.

With only $k = 20$ windows, $\mathrm{sd}(\hat{F}) = 0.32$, and even $\hat{F} = 0.62$ is barely more than one standard deviation from 1. A few windows cannot distinguish these streams. That is why the five windows of Figure 2.18 are only an illustration.

2.8.3 Dead time

The commonest failure in a counting detector is dead time. After a hit, the electronics need a time τ to shape the pulse, digitise it and reset. Anything arriving in that interval is lost. Typical values are $\tau \sim 100$–300 μs for a Geiger–Müller tube, ~ 10–100 ns for a photomultiplier with fast electronics, and one readout frame (seconds) for an X-ray CCD. Two idealised models bracket the real behaviour of most systems.

- **Non-paralysable**: the counter is blind for τ after each *recorded* hit. Hits that arrive during the dead period are lost and have no further effect.
- **Paralysable**: *every* hit, recorded or not, restarts the dead period. A hit is recorded only if the previous true hit came at least τ earlier. A burst of closely spaced hits keeps the counter blind for the whole burst.

Let n be the true rate (hits per second) and m the recorded rate. Figure 2.19 runs one stream of true hits through both models.

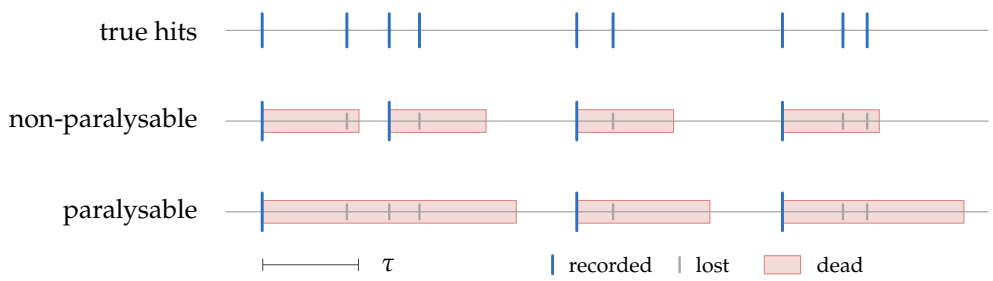

Figure 2.19: Nine true hits (top) seen by two counters with the same dead time τ (the bar at the bottom left). The non-paralysable counter (middle) is blind for exactly τ after each recorded hit, so it records four hits: the third true hit arrives just after the first dead period ends. The paralysable counter (bottom) is blind for τ after every hit, so the rapid run of four early hits keeps extending one long dead period and only three hits are recorded.

The recorded rate, non-paralysable. Count for a long time T. The counter records mT hits and is blind for τ after each, so it is dead for a total time $mT\tau$ and live for $T(1-m\tau)$. During live time the true stream is untouched (input P1 for the true hits), so it delivers $nT(1-m\tau)$ hits, and each of them is recorded:

$$mT \overset{(1)}{=} nT(1-m\tau) \quad\Longrightarrow\quad m \overset{(2)}{=} \frac{n}{1+n\tau}, \qquad n \overset{(3)}{=} \frac{m}{1-m\tau}. \tag{2.27}$$

(1) Recorded hits = true hits that arrive while the counter is live.
(2) Solve for m: $m + nm\tau = n$.
(3) Solve instead for n. This is the dead-time correction: from the recorded rate and τ we recover the true rate.

At low rate, $n\tau \ll 1$, we get $m \approx n(1-n\tau)$: the fractional loss is $n\tau$, the expected number of true hits in one dead period. At high rate, $m \to 1/\tau$: the counter records one hit per dead period and saturates.

The recorded rate, paralysable. A hit is recorded if and only if the gap since the previous *true* hit is at least τ. For a Poisson stream every gap is exponential with rate n (Section 2.6), so

$$m \overset{(1)}{=} n\ \mathrm{P}(\text{gap} \geq \tau) \overset{(2)}{=} n\, e^{-n\tau}. \tag{2.28}$$

(1) Of the nT true hits in time T, the recorded ones are those whose preceding gap is at least τ; by the law of large numbers their fraction is the probability of that.
(2) Survival function of the exponential gap, $\mathrm{P}(\text{gap} > t) = e^{-nt}$ from (2.18).

Now m is not monotonic in n. It rises, reaches its maximum $1/(e\tau)$ at $n\tau = 1$ (set $\mathrm{d}m/\mathrm{d}n = e^{-n\tau}(1-n\tau) = 0$), and then falls back towards zero as the counter spends almost all its time paralysed. That is the Geiger counter whose rate fell as it approached the source. At low rate both models agree, $m \approx n(1-n\tau)$, as the left panel of Figure 2.20 shows.

Watch out: a recorded rate can have two true rates

For a paralysable counter, every recorded rate below $1/(e\tau)$ is produced by *two* true rates, one below $1/\tau$ and one above. The measurement alone cannot tell which. Change the rate in a known way (move the source, add a second source) and see whether the recorded rate goes up or down. And a recorded rate above $1/(e\tau)$ is impossible for a paralysable counter: if one is seen, the model or the value of τ is wrong.

The scatter of the recorded counts. Dead time removes precisely the hits that come soon after another hit, so the recorded stream is more regular than the true one (Figure 2.18, bottom). How much more regular?

The recorded stream of either model is a **renewal process** [the gaps between successive recorded hits are independent and all have the same distribution]. Why? After each recorded hit, the future depends only on true hits that have not happened yet, and those are independent of the past (input P1 for the true stream).

For a renewal process the count's scatter follows from the gaps. Let the gap I between recorded hits have mean m_I and variance σ_I^2. Count in a window $T \gg m_I$, and let S_k be the time of the k-th recorded hit, the sum of k independent gaps. The count reaches k when S_k reaches T. Write $S_k = km_I + \delta S$, with $\operatorname{Var}\delta S = k\sigma_I^2$. Suppose the gaps happen to add up to a little more time than average, $\delta S > 0$. Then fewer hits fit into T. Each missing hit is worth one mean gap, so the count changes by $\delta N \approx -\delta S/m_I$. Hence

$$\mathbb{E}\,N \overset{(1)}{=} \frac{T}{m_I}, \qquad \operatorname{Var} N \overset{(2)}{=} \frac{\operatorname{Var}\delta S}{m_I^2} \overset{(3)}{=} \frac{k\,\sigma_I^2}{m_I^2} \overset{(4)}{=} \frac{T\sigma_I^2}{m_I^3}, \qquad F = \frac{\operatorname{Var} N}{\mathbb{E}\,N} \overset{(5)}{=} \frac{\sigma_I^2}{m_I^2}. \tag{2.29}$$

(1) On average one hit per mean gap.
(2) $\delta N \approx -\delta S/m_I$, and the sign does not affect the variance.
(3) The k gaps are independent, so their variances add.
(4) $k \approx \mathbb{E}\,N = T/m_I$.
(5) Divide the two results: T cancels.

For a long window, the Fano factor of the counts equals the square of the relative spread of the gaps, σ_I/m_I. Check on the Poisson stream itself: exponential gaps have $\sigma_I = m_I = 1/\lambda$, so $F = 1$.

For the *non-paralysable* counter, a gap between recorded hits is the dead period τ followed by a fresh exponential wait for the next true hit (memorylessness, Section 2.6): $I = \tau + G$ with $G \sim$ Exp of rate n. So $m_I = \tau + 1/n$ and $\sigma_I^2 = 1/n^2$, and

$$m \overset{(1)}{=} \frac{1}{m_I} = \frac{n}{1+n\tau}, \qquad F \overset{(2)}{=} \frac{1/n^2}{(\tau+1/n)^2} = \frac{1}{(1+n\tau)^2}. \tag{2.30}$$

(1) The recorded rate is one over the mean gap; this re-derives (2.27) by a second route.
(2) Eq. (2.29) with the mean and variance of $\tau + G$ (a constant shift does not change a variance).

For the *paralysable* counter the gap is harder. After a recorded hit, true hits keep arriving, separated by true gaps $g_1, g_2, \ldots$ (independent, exponential with rate n). The next recorded hit is the first true hit whose own preceding gap is at least τ. So $I = g_1 + \cdots + g_J$, where J is the index of the first gap with $g_j \geq \tau$. The cleanest tool is the moment generating function $M_I(s) = \mathbb{E}\,e^{sI}$ (Chapter 1). Split one exponential gap by whether it is short or long:

$$a(s) = \mathbb{E}\big[e^{sg}\mathbb{1}\{g < \tau\}\big] = \frac{n}{n-s}\big(1 - e^{-(n-s)\tau}\big), \qquad b(s) = \mathbb{E}\big[e^{sg}\mathbb{1}\{g \geq \tau\}\big] = \frac{n}{n-s}e^{-(n-s)\tau},$$

both from $\int ne^{-(n-s)g}\,\mathrm{d}g$ over $[0,\tau)$ and $[\tau,\infty)$ (for $s < n$). Then

$$M_I(s) \overset{(1)}{=} \sum_{j=1}^{\infty} a(s)^{j-1}b(s) \overset{(2)}{=} \frac{b(s)}{1-a(s)} \overset{(3)}{=} \frac{n\,e^{-(n-s)\tau}}{(n-s)-n+n\,e^{-(n-s)\tau}} \overset{(4)}{=} \frac{1}{1-\frac{s}{n}\,e^{(n-s)\tau}}.$$

(1) $J = j$ means $j-1$ short gaps followed by one long gap. The gaps are independent, so $\mathbb{E}\,e^{sI}$ on that event factorises into $a^{j-1}b$, and we sum over j.
(2) Geometric series, valid for s near 0 where $a(s) < 1$.

(3) Insert a and b and multiply top and bottom by $n - s$.
(4) The denominator is $ne^{-(n-s)\tau} - s$; divide top and bottom by $ne^{-(n-s)\tau}$.

The mean and variance come from the **cumulant generating function** $K_I(s) = \ln M_I(s)$, whose first two Taylor coefficients are $K_I(s) = \mathbb{E}\,I\,s + \operatorname{Var} I\,s^2/2 + O(s^3)$. With $Q = e^{n\tau}$ and $u = \frac{s}{n}e^{(n-s)\tau} = \frac{sQ}{n}(1 - s\tau + O(s^2))$,

$$K_I(s) \overset{(1)}{=} -\ln(1-u) \overset{(2)}{=} u + \frac{u^2}{2} + O(s^3) \overset{(3)}{=} \frac{Q}{n}\,s + \Big(\frac{Q^2}{2n^2} - \frac{\tau Q}{n}\Big)s^2 + O(s^3). \tag{2.31}$$

(1) The logarithm of the result above.
(2) Taylor series $-\ln(1-u) = u + u^2/2 + \ldots$; u is of order s, so $u^3 = O(s^3)$.
(3) Insert $u = \frac{sQ}{n} - \frac{s^2\tau Q}{n} + O(s^3)$ and $u^2 = \frac{s^2Q^2}{n^2} + O(s^3)$.

Reading off, $\mathbb{E}\,I = e^{n\tau}/n$, so $m = 1/\mathbb{E}\,I = ne^{-n\tau}$, which re-derives (2.28). And $\operatorname{Var} I = Q^2/n^2 - 2\tau Q/n$, so by (2.29)

$$F = \frac{\operatorname{Var} I}{(\mathbb{E}\,I)^2} = 1 - 2n\tau\,e^{-n\tau}. \tag{2.32}$$

Both counters are underdispersed. At low rate both give $F \approx 1 - 2n\tau$. At $n\tau = 1$ the paralysable counter is at its most regular, $F = 1 - 2/e = 0.26$. At very high rate it becomes nearly Poisson again. The reason: the few recorded hits are then the rare long gaps of the true stream, and those are almost independent of each other.

Example: correcting a Geiger counter. A Geiger–Müller tube has $\tau = 200\ \mu$s and records $m = 1500$ counts per second, so $m\tau = 0.3$. If it is non-paralysable, (2.27) gives

$$n \overset{(1)}{=} \frac{m}{1 - m\tau} = \frac{1500}{0.7} = 2143\ \mathrm{s}^{-1}.$$

(1) Dead-time correction (2.27).

So 30% of the true hits were lost ($m\tau$ is exactly the dead fraction of the time). If the tube is paralysable, we must solve $n\tau e^{-n\tau} = m\tau = 0.3$. Numerically the two roots are $n\tau = 0.489$ and $n\tau = 1.781$, that is $n = 2447\ \mathrm{s}^{-1}$ or $n = 8907\ \mathrm{s}^{-1}$. This is the two-root ambiguity of a paralysable counter: one recorded rate, two possible true rates, and only a change of the true rate in a known way can tell them apart. The largest rate this counter could ever record is $1/(e\tau) = 1839\ \mathrm{s}^{-1}$, so a reading of $2000\ \mathrm{s}^{-1}$ would already be impossible for it.

Example: the error bar of a corrected rate. After the correction the rate is right on average, but the corrected count is *not* Poisson, and its error bar is not $\sqrt{\text{corrected counts}}$. For the non-paralysable counter, let M be the number recorded in a long time T, with $\mathbb{E}\,M = mT$ and $\operatorname{Var} M = F\,mT$. The estimate is $\hat{n} = g(\hat{m})$, with $\hat{m} = M/T$ and $g(m) = m/(1 - m\tau)$. For small fluctuations a smooth function of an estimate varies by the derivative times the fluctuation, $\delta\hat{n} = g'(m)\,\delta\hat{m}$ (the **delta method**, Chapter 3):

$$\operatorname{Var}\hat{n} \overset{(1)}{=} g'(m)^2 \operatorname{Var}\hat{m} \overset{(2)}{=} \frac{1}{(1-m\tau)^4}\,\frac{F\,m}{T} \overset{(3)}{=} (1+n\tau)^4\,\frac{1}{(1+n\tau)^2}\,\frac{n}{(1+n\tau)\,T} \overset{(4)}{=} \frac{n\,(1+n\tau)}{T}. \tag{2.33}$$

(1) Delta method.
(2) $g'(m) = \frac{(1-m\tau)+m\tau}{(1-m\tau)^2} = \frac{1}{(1-m\tau)^2}$, and $\operatorname{Var}\hat{m} = \operatorname{Var} M/T^2 = Fm/T$.
(3) $1 - m\tau = 1/(1+n\tau)$ from (2.27), together with F from (2.30) and $m = n/(1+n\tau)$.
(4) Collect the powers of $(1+n\tau)$: $4 - 2 - 1 = 1$.

Had we counted the true hits with a perfect counter, $\mathrm{Var}(\hat{n}) = n/T$ (Poisson). So dead time inflates the variance of the corrected rate by the factor $1 + n\tau$: the corrected count $\hat{n}T$ has variance $(1 + n\tau)$ times its mean. The correction removes the bias, but the information lost in the dead periods does not come back. For the Geiger counter above, $1 + n\tau = 1.43$: the corrected rate is $\sqrt{1.43} = 1.2$ times more uncertain than naive Poisson error bars claim.

Example: sub-Poissonian light, or dead time? In quantum optics the photocount statistics of a light beam are summarised by Mandel's parameter $Q = F - 1 = (\mathrm{Var}\, N - \mathbb{E}\, N)/\mathbb{E}\, N$. Coherent laser light gives Poisson photocounts, $Q = 0$. Thermal light is bunched, $Q > 0$: for a single mode the photocount is geometric (the Bose–Einstein distribution), and for many modes it is negative binomial, the gamma–Poisson mixture of Section 2.7 with the fluctuating intensity playing the role of Λ. A measured $Q < 0$, called *sub-Poissonian* light, has no classical explanation. A classical intensity can only add variance: $\mathrm{Var}\,\Lambda \geq 0$ in (2.25). So $Q < 0$ is a signature of non-classical light, such as that from single-photon sources. But a non-paralysable photon counter with dead time τ records $F = 1/(1 + n\tau)^2$ even for a perfect laser, by (2.30), and that is $Q \approx -2n\tau$. At $n = 10^6$ s^{-1} and $\tau = 50$ ns this is $Q \approx -0.1$, a fake non-classical signal. Any claim of $Q < 0$ must first remove the detector's own dead time. This is why such experiments use two detectors behind a beam splitter and look at coincidences, so that neither detector has to record two photons in quick succession.

2.8.4 Python: a counter that goes blind

Listing 2.9: A Poisson stream of true hits, and the two dead-time models (`code/ch02/08_deadtime_gauss.py`)

```
28 def true_hits(n, duration):
29     """Arrival times of a Poisson stream of rate n on [0, duration): exponential gaps."""
30     gaps = -np.log(rng.uniform(size=int(n * duration + 10 * np.sqrt(n * duration) + 10))) /
       n
31     t = np.cumsum(gaps)
32     return t[t < duration]
33
34
35 def record(t, paralysable):
36     """Times the counter records. Non-paralysable: blind for tau after each RECORDED hit.
37     Paralysable: blind for tau after EVERY hit, so a hit is recorded only if the
38     previous true hit is at least tau earlier."""
39     if paralysable:
40         gap_before = np.diff(t, prepend=-np.inf)
41         return t[gap_before >= tau]
42     kept, last = [], -np.inf
43     for ti in t:                        # a plain loop: the state is 'when did the last
       recorded hit start?'
44         if ti - last >= tau:
45             kept.append(ti)
46             last = ti
47     return np.array(kept)
```

The function `true_hits` builds the true stream exactly as in Section 2.6: exponential gaps $-\ln U/n$ from uniform numbers U, summed into arrival times. The `record` function implements the two models of Figure 2.19 literally. The paralysable rule needs no memory beyond the previous true hit, so it is one vectorised comparison of each gap with τ (lines 40–41). The non-paralysable rule needs to remember when the last *recorded* hit happened, so it is a plain loop that keeps that one number, `last` (lines 42–47). The script then cuts a 40 s stream at $n = 5 \times 10^4$ s^{-1} into 4000 windows of 10 ms (so $n\tau = 0.25$ with $\tau = 5$ μs), counts the recorded

hits per window, and repeats the rate measurement for a range of true rates.

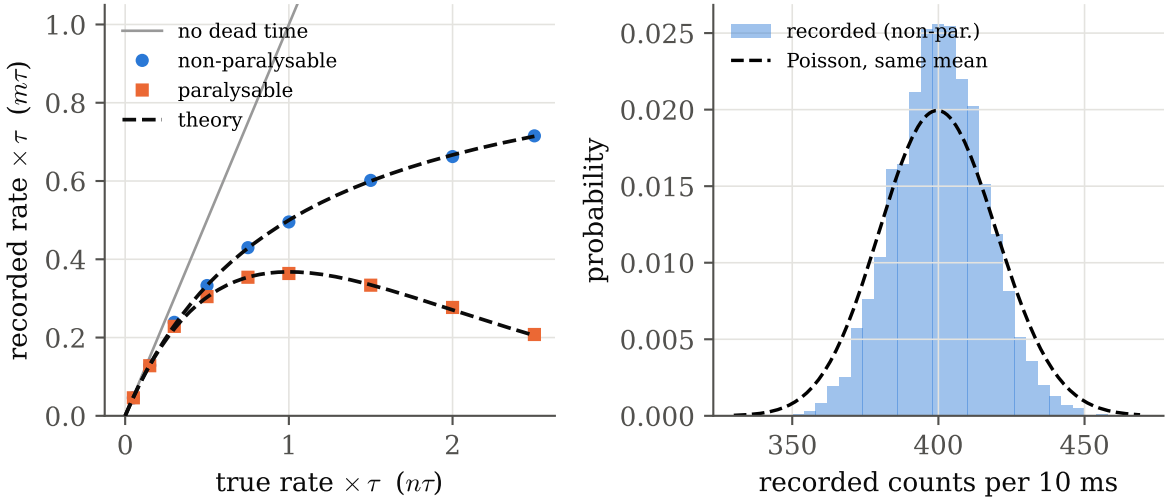

Figure 2.20: Left: recorded rate against true rate, both in units of $1/\tau$. The simulated counters (dots and squares) sit on the derived curves $n\tau/(1+n\tau)$ and $n\tau e^{-n\tau}$ (dashed). The grey line is a perfect counter. The non-paralysable counter saturates at one hit per dead time; the paralysable one peaks at $n\tau = 1$ and then falls. Right: the recorded counts per 10 ms window at $n\tau = 0.25$ (bars) form a visibly narrower histogram than a Poisson distribution with the same mean (dashed).

The numbers it produced are these. The true hits give 500.3 counts per window on average (expected 500) with $\hat{F} = 0.9597$; by (2.26) the Poisson scatter of $\hat{F}$ is 0.02236, so $\hat{F} - 1$ is -1.8 times this scatter. The non-paralysable counter records a mean of 400.1 per window, against 400 from (2.27), and its Fano factor is 0.6156, against $1/(1+n\tau)^2 = 0.64$. The paralysable counter records 389.5 (theory 389.4) with $\hat{F} = 0.5861$ (theory $1 - 2n\tau e^{-n\tau} = 0.6106$). In units of their own scatter (for $F \neq 1$ it is about $F\sqrt{2/(k-1)}$), the two dead-time Fano factors minus their predictions are -1.7 and -1.8. The three numbers are not independent: all three come from the *same* stream of true hits, so a chance fluctuation of that stream shows up in all three. Correcting the non-paralysable mean with (2.27) gives $\hat{n} = 5.002 \times 10^4\ \mathrm{s}^{-1}$ for the true rate of $5 \times 10^4\ \mathrm{s}^{-1}$, off by 0.5 times its statistical error $\sqrt{n(1+n\tau)/T} \approx 40\ \mathrm{s}^{-1}$ from (2.33). The right panel of Figure 2.20 is the underdispersion made visible.

How research uses it. Here the simulation *verified* formulas we had derived. Real detectors rarely match either idealised model: the dead time can depend on the pulse height, several stages of electronics can each have their own τ, and afterpulsing adds clustering on top. For them the analytic route stops, and the same few lines of code become the instrument: simulate the true stream, pass it through a model of the electronics, and histogram the recorded counts. That histogram is the sampling distribution $P(S \mid \theta)$ of the recorded count, and it goes into the likelihood (Chapter 3). In a collider analysis, the Fano factor of event counts in stable running periods is a routine check that the luminosity and trigger were steady; in a survey, the excess over $F = 1$ is the clustering signal itself.

2.8.5 Large λ: the Poisson count becomes Gaussian (a preview)

In Figure 2.9 the Poisson pmf became more symmetric as λ grew. For a large mean, a Poisson variable can be treated as a continuous Gaussian variable [Cowan §2.2, p. 29]. Cumulants show why most quickly. The Poisson mgf is $M_X(t) = \exp[\lambda(e^t - 1)]$, eq. (2.13), so its cumulant

generating function is

$$K_X(t) = \ln M_X(t) \overset{(1)}{=} \lambda(e^t - 1) \overset{(2)}{=} \lambda \sum_{r=1}^{\infty} \frac{t^r}{r!} \quad \Longrightarrow \quad \kappa_r(X) \overset{(3)}{=} \lambda \quad \text{for every } r \geq 1. \tag{2.34}$$

(1) Logarithm of the Poisson mgf.
(2) Taylor series of e^t with the $r = 0$ term cancelled by the -1.
(3) By definition the r-th cumulant κ_r is $r!$ times the coefficient of t^r in K_X. The first three cumulants are the mean, the variance and the third central moment.

Now standardise, $Z = (X - \lambda)/\sqrt{\lambda}$. Since $K_{aX+b}(t) = bt + K_X(at)$, shifting by b changes only κ_1 and scaling by a multiplies κ_r by a^r. With $a = 1/\sqrt{\lambda}$,

$$\kappa_1(Z) = 0, \qquad \kappa_2(Z) = 1, \qquad \kappa_3(Z) = \frac{\lambda}{\lambda^{3/2}} = \frac{1}{\sqrt{\lambda}}, \qquad \kappa_r(Z) = \lambda^{1-r/2} \xrightarrow{\lambda\to\infty} 0 \quad (r \geq 3).$$

So $K_Z(t) \to t^2/2$, which is the cumulant generating function of $\mathcal{N}(0, 1)$: *Poisson*(λ) *is approximately* $\mathcal{N}(\lambda, \lambda)$ *for large* λ. The leading correction is the skewness $\kappa_3(Z) = 1/\sqrt{\lambda}$, which shrinks only slowly: at $\lambda = 25$ it is still 0.2. The next part derives this limit properly (de Moivre–Laplace for the binomial, and the central limit theorem), with the corrections. It also explains why the limit holds. For integer λ, a Poisson(λ) count is the sum of λ independent Poisson(1) counts, by the sum rule of Section 2.5, and sums of many independent terms tend to a Gaussian.

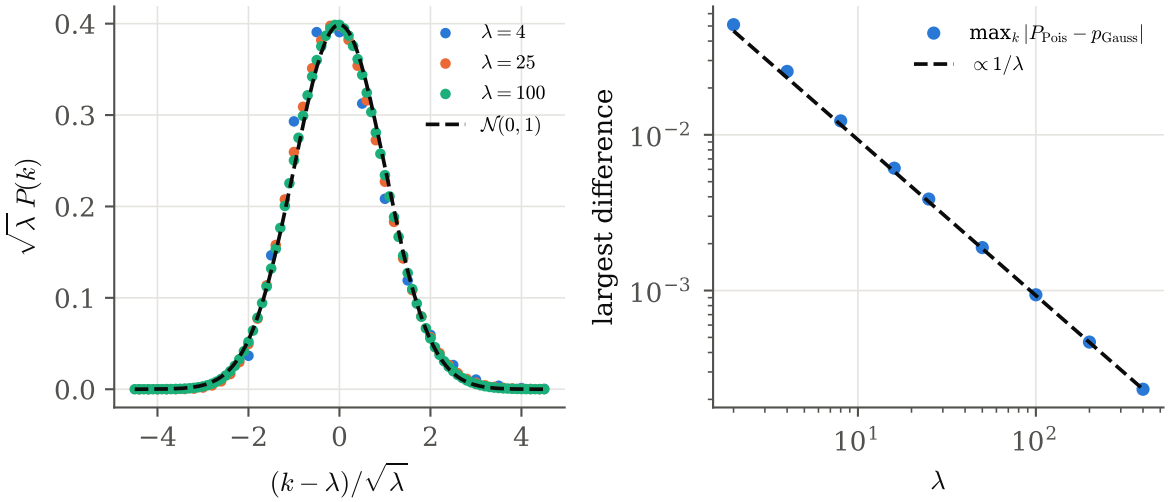

Figure 2.21: Left: Poisson pmfs for $\lambda = 4$, 25 and 100, standardised so that the horizontal axis is the distance from the mean in standard deviations, and rescaled by $\sqrt{\lambda}$ so that they are comparable with a density. They crowd onto the standard Gaussian (dashed); at $\lambda = 4$ the points are still lopsided, higher on the left of the peak and with a longer right tail. Right: the largest pointwise difference between the Poisson pmf and the Gaussian density falls like $1/\lambda$ (dashed line).

Figure 2.21 shows the convergence. The largest difference $\max_k |P(k) - p_{\text{Gauss}}(k)|$ is 0.02554 at $\lambda = 4$, 0.003868 at $\lambda = 25$, 9.388×10^{-4} at $\lambda = 100$ and 2.323×10^{-4} at $\lambda = 400$. The $1/\lambda$ law has a simple reason: the peak height is about $1/\sqrt{2\pi\lambda}$, and the skewness correction to it is a fraction of order $\kappa_3(Z) = 1/\sqrt{\lambda}$ of that height, so the absolute error is of order $1/\lambda$.

Example: a 4σ excess on a background of 25. A search region expects $b = 25$ background events, with Poisson standard deviation 5, and we observe 45, which is $(45 - 25)/5 = 4$ standard deviations above the background. How often does background alone give 45 or more? The

Gaussian answer is $\mathrm{P}(Z \geq 4) = 3.167 \times 10^{-5}$. The exact Poisson answer, $\sum_{k \geq 45} e^{-25} 25^k / k!$, is 2.001×10^{-4}: 6.319 times larger. Even the **continuity correction** [treating the integer 45 as the interval from 44.5 up], which gives 4.810×10^{-5}, is still wrong by a factor of four. Why so wrong? The Gaussian is good near the peak, where the $1/\lambda$ errors of Figure 2.21 are small in absolute terms. In the tail both probabilities are tiny, and a small absolute error is a large relative one. The Poisson right tail is heavier than the Gaussian one, because the Poisson is positively skewed. So the Gaussian *understates* the chance of an upward fluctuation and overstates the significance of an excess. Tail probabilities, p-values and discovery claims (Chapter 4) must use the exact Poisson distribution.

2.8.6 Choosing a counting distribution

Every counting distribution came from a mechanism, so recognising the mechanism is how we choose the distribution. The table collects them, with the Fano factor $F = \mathrm{Var}\, N / \mathbb{E}\, N$ as the quick check against data.

Taxonomy: which counting distribution, when

mechanism	distribution	mean	Fano F
one yes/no trial	Bernoulli(p)	p	$1 - p$
successes in n independent trials, same p	Binomial(n, p)	np	$1 - p$
N events sorted into bins, total fixed	Multinomial($N, \boldsymbol{p}$)	Np_j per bin	$1 - p_j$ per bin
many trials, rare successes; or a stream at constant rate with no memory	Poisson(λ)	λ	1
Poisson with a gamma-distributed rate, or clumped events	NegBin	μ	$1 + \mu/\kappa$
counter blind for τ after each recorded hit	renewal count	$nT/(1 + n\tau)$	$(1 + n\tau)^{-2}$
trials until the first / r-th success	Geometric / NegBin	$1/p, r/p$	—
time to the first / n-th event of a stream	Exponential / Gamma	$1/\lambda, n/\lambda$	—

The Fano column is the one to remember when data arrive. A value near 1, judged against $\sqrt{2/(k-1)}$, supports a Poisson model. A value clearly above 1 points to a fluctuating rate or clumping, and the negative binomial is the standard next model. A value clearly below 1 points to dead time, pile-up rejection or a finite pool, and calls for a model of the detector. For large means the Poisson itself may be replaced by a Gaussian with variance equal to the mean, but only near the peak, never in the tails.

Recap: Part summary: counting distributions

- **Bernoulli** (one trial): $p^x(1-p)^{1-x}$, mean p, variance $p(1-p)$. Many independent trials give the product $p^z(1-p)^{N-z}$, which depends only on the number of successes.
- **Binomial** (successes in n successive trials): count the $\binom{n}{k}$ paths, each of probability $p^k(1-p)^{n-k}$; mean np, variance $np(1-p)$; sums with the same p stay binomial.

- **Multinomial** (histogram with fixed total): marginals binomial, covariance $-Np_ip_j$ between bins; with a Poisson total the bins become independent Poisson counts.
- **Poisson**: the $n \to \infty$, $np = \lambda$ limit of the binomial, and independently the count of a constant-rate, memoryless stream (from the ladder of differential equations $\mathrm{d}P_n/\mathrm{d}t = \lambda(P_{n-1} - P_n)$). Mean = variance = λ. Closed under sums, thinning and binning.
- **Waiting times**: first event exponential (memoryless), n-th event Gamma$(n, 1/\lambda)$ (Erlang); discrete versions geometric and negative binomial.
- **Failures**: a fluctuating rate or clumping gives $F > 1$ (negative binomial); dead time gives $F < 1$, with recorded rate $n/(1 + n\tau)$ or $ne^{-n\tau}$ and $F = \sigma_I^2/m_I^2$ from the gaps; the dead-time correction removes the bias but inflates the variance by $1 + n\tau$.
- **Large** λ: all Poisson cumulants equal λ, so the standardised count tends to $\mathcal{N}(0, 1)$ with skewness $1/\sqrt{\lambda}$; use the exact Poisson in the tails.

2.9 The Gaussian, first way: the shape of a binomial with many trials

The same bell-shaped curve describes a calorimeter energy, a timing residual, a CMB temperature and a strain sample. None of these is a count: the counting distributions of the first half of the chapter live on the integers, and these quantities do not. There are three separate routes to the bell curve, and each route tells us *when* to trust it. The oldest route starts from a count after all. Take a binomial distribution with a very large number of trials and ask what shape it takes.

Ten thousand photo-electrons. A scintillator bar is hit by a cosmic muon. It produces $n = 10\,000$ photons, and each photon independently reaches the photomultiplier and makes a photo-electron with probability $p = 0.3$. The number of photo-electrons k is Binomial(n, p) (see the counting part of this chapter). To compute $\mathrm{P}(k \le 2950)$ exactly we would add 2951 terms, each containing factorials of numbers near 10^4. Nobody does that. Instead everyone replaces the binomial by a smooth bell curve with mean $np = 3000$ and standard deviation $\sqrt{np(1-p)} \approx 45.8$.

That replacement raises four questions. Which bell curve, exactly? Why a bell and not some other shape? How large must n be? And how do we correct for the fact that k is an integer while the curve is smooth? The large-n limit of the binomial answers all four.

Zooming in on the peak of a mountain. The Gaussian is what *every* smooth, single-peaked, sharply concentrated distribution looks like near its maximum. Here is why. For large n the binomial pmf is a tall, narrow mountain centred at np, and its width grows only like $\sqrt{n}$. Plot the *logarithm* of any smooth mountain: near its summit it looks like a downward parabola. The exponential of a parabola is a Gaussian. This is the same move as the harmonic approximation in mechanics: expand the potential to second order about its minimum and the motion becomes simple harmonic. Here we expand $\ln \mathrm{P}(k)$ to second order about its maximum.

The plan.

1. Which quantity do we want? The probability of k successes in n trials when n is large.

2. What makes it hard? Factorials of large numbers. So first find a good formula for $n!$ (Stirling).
3. Where is the probability concentrated? Near $k = np$, in a window of width $\sqrt{np(1-p)}$.
4. What does $\ln \mathrm{P}(k)$ look like in that window? Expand it in powers of the distance from the peak and keep what survives as $n \to \infty$.
5. How do we turn a statement about integers into one about a continuous variable, and what does that cost? (The continuity correction.)

2.9.1 The Gaussian density and what its two parameters do

Working definition 2.13 (Gaussian (normal) distribution)

A continuous random variable X has a **Gaussian** or **normal** distribution with parameters μ and σ^2, written $X \sim \mathcal{N}(\mu, \sigma^2)$, if its density [probability per unit x, so it has units of $1/x$] is

$$p(x \mid \mu, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right], \qquad -\infty < x < \infty, \tag{2.35}$$

with $\mu \in \mathbb{R}$ and $\sigma > 0$. The case $\mu = 0$, $\sigma = 1$ is the **standard normal** $Z \sim \mathcal{N}(0,1)$, with density $\varphi(z) = e^{-z^2/2}/\sqrt{2\pi}$ and cumulative distribution function [the probability of landing at or below z] $\Phi(z) = \int_{-\infty}^{z} \varphi(z')\,\mathrm{d}z'$. *Operational test:* standardise, $z = (x-\mu)/\sigma$, and compare the histogram of z with φ (or the ordered z values with the quantiles Φ^{-1}).

Three facts make the Gaussian usable. We check each one.

It is normalised. The function $e^{-z^2/2}$ has no elementary antiderivative, so the normalisation needs a trick: square the integral and go to polar coordinates [CasellaBerger p. 84–85]. Let $I = \int_{-\infty}^{\infty} e^{-z^2/2}\mathrm{d}z$. Then

$$\begin{aligned} I^2 &\overset{(1)}{=} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{-(u^2+v^2)/2}\,\mathrm{d}u\,\mathrm{d}v \\ &\overset{(2)}{=} \int_{0}^{2\pi}\int_{0}^{\infty} e^{-r^2/2}\, r\,\mathrm{d}r\,\mathrm{d}\phi \\ &\overset{(3)}{=} 2\pi\left[-e^{-r^2/2}\right]_0^{\infty} \\ &= 2\pi. \end{aligned} \tag{2.36}$$

(1) The two copies of the integral use independent dummy variables u and v, and a product of two integrals is a double integral over the plane.
(2) Polar coordinates $u = r\cos\phi$, $v = r\sin\phi$: then $u^2 + v^2 = r^2$ and the area element is $\mathrm{d}u\,\mathrm{d}v = r\,\mathrm{d}r\,\mathrm{d}\phi$.
(3) The ϕ integral gives 2π. The extra factor r makes the r integral elementary, since $\frac{\mathrm{d}}{\mathrm{d}r}\left(-e^{-r^2/2}\right) = r\,e^{-r^2/2}$.

So $I = \sqrt{2\pi}$, which is the constant in φ. Substituting $z = (x-\mu)/\sigma$, $\mathrm{d}x = \sigma\,\mathrm{d}z$, gives the constant $1/\sqrt{2\pi\sigma^2}$ in (2.35). A by-product: with $w = z^2/2$ the half-line integral becomes $\int_0^{\infty} w^{-1/2}e^{-w}\mathrm{d}w = \Gamma(\tfrac{1}{2})$, so

$$\Gamma(\tfrac{1}{2}) = \sqrt{\pi}, \tag{2.37}$$

where $\Gamma(\alpha) = \int_0^\infty t^{\alpha-1}e^{-t}\,\mathrm{d}t$ is the Gamma function, with $\Gamma(\alpha+1) = \alpha\Gamma(\alpha)$ (integrate by parts) and $\Gamma(n+1) = n!$ for integers. We need all three facts for χ^2 later.

μ is the mean and σ^2 the variance. With $x = \mu + \sigma z$,

$$\begin{aligned}\mathbb{E}(X) &\overset{(1)}{=} \mu + \sigma\int_{-\infty}^{\infty} z\,\varphi(z)\,\mathrm{d}z \overset{(2)}{=} \mu,\\ \mathrm{Var}(X) &\overset{(3)}{=} \sigma^2\int_{-\infty}^{\infty} z^2\varphi(z)\,\mathrm{d}z \overset{(4)}{=} \sigma^2\Big\{\big[-z\varphi(z)\big]_{-\infty}^{\infty} + \int_{-\infty}^{\infty}\varphi(z)\,\mathrm{d}z\Big\} \overset{(5)}{=} \sigma^2.\end{aligned} \tag{2.38}$$

(1) Change variables and use $\int \varphi = 1$ for the constant term.
(2) The integrand $z\varphi(z)$ is odd, so the integral over a symmetric range vanishes.
(3) $\mathrm{Var}(X) = \mathbb{E}(X-\mu)^2$ and $(x-\mu)^2 = \sigma^2 z^2$.
(4) Integrate by parts with $u = z$ and $\mathrm{d}v = z\varphi(z)\mathrm{d}z$, whose integral is $v = -\varphi(z)$ because $\varphi'(z) = -z\varphi(z)$.
(5) The boundary term vanishes because φ decays faster than any power, and the remaining integral is 1.

So the two parameters are exactly the mean and the variance [Cowan (2.23)–(2.24)]. This is special: for most distributions the parameters are *not* the mean and variance (the log-normal of Section 2.15 is a warning example).

Standardising reduces everything to one table. If $X \sim \mathcal{N}(\mu, \sigma^2)$ then $Z = (X-\mu)/\sigma \sim \mathcal{N}(0,1)$ and, conversely, $X = \mu + \sigma Z$ [Wasserman p. 28]. Hence

$$\mathrm{P}(a < X < b) = \Phi\!\left(\frac{b-\mu}{\sigma}\right) - \Phi\!\left(\frac{a-\mu}{\sigma}\right). \tag{2.39}$$

Two numbers are worth knowing by heart. First, the probability within 1, 2, 3 standard deviations of the mean is 0.6827, 0.9545, 0.9973 (Figure 2.22). Second, "one sigma" can be read off a plot by eye: it is where the curve stops bending down and starts bending up. To see this, note that the density has its maximum at $x = \mu$, and its second derivative $\varphi''(z) = (z^2-1)\varphi(z)$ vanishes at $z = \pm 1$. So the inflection points sit at $x = \mu \pm \sigma$.

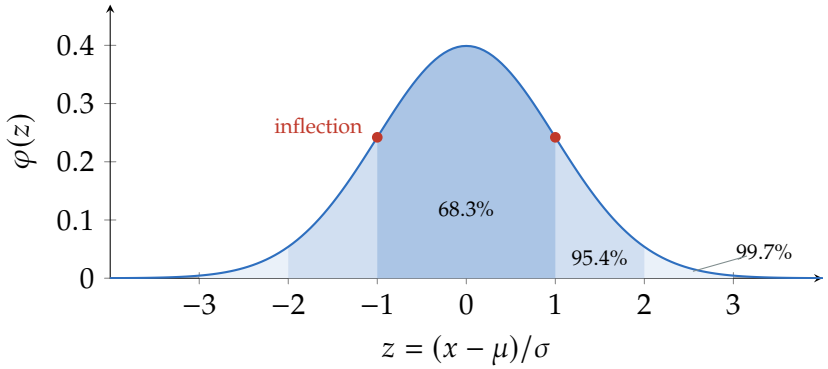

Figure 2.22: The standard normal density. The darkest band ($|z| < 1$) holds 68.3% of the probability, the band out to $|z| < 2$ holds 95.4%, and out to $|z| < 3$ holds 99.7%. The red dots are the inflection points at $z = \pm 1$: one standard deviation is where the curve changes from bending down to bending up.

Example: Reading the table both ways. Let $X \sim \mathcal{N}(3, 5)$. The second argument is the *variance*, so $\sigma = \sqrt{5}$. A table of Φ answers two kinds of question. The forward question gives a cut and asks for a probability: what is $\mathrm{P}(X > 1)$?

$$\mathrm{P}(X > 1) \overset{(1)}{=} 1 - \mathrm{P}(X < 1) \overset{(2)}{=} 1 - \Phi\left(\frac{1-3}{\sqrt{5}}\right) = 1 - \Phi(-0.8944) \overset{(3)}{=} 0.81.$$

(1) Complement rule. For a continuous variable $\mathrm{P}(X = 1) = 0$, so $<$ and $\leq$ do not matter.
(2) Standardise with (2.39).
(3) From a table or `scipy.stats.norm.cdf`: $\Phi(-0.8944) = 0.1855$.

The quantile question goes the other way. It gives a probability and asks for the cut: which q has $\mathrm{P}(X < q) = 0.2$?

$$0.2 = \mathrm{P}(X < q) \overset{(1)}{=} \Phi\left(\frac{q-3}{\sqrt{5}}\right) \implies \frac{q-3}{\sqrt{5}} \overset{(2)}{=} \Phi^{-1}(0.2) = -0.8416$$
$$\implies q \overset{(3)}{=} 3 - 0.8416\sqrt{5} = 1.1181.$$

(1) Standardise.
(2) Φ is strictly increasing, so it can be inverted. Φ^{-1} is `scipy.stats.norm.ppf`.
(3) Solve the linear equation for q.

These are the two numbers of [Wasserman p. 29, Example 2.17].

Watch out: $\mathcal{N}(\mu, \sigma^2)$ or $\mathcal{N}(\mu, \sigma)$?

AoS, Cowan and CasellaBerger write the *variance* as the second argument. Lambert and most software (`scipy.stats.norm(loc, scale)`, `numpy.random.normal(loc, scale)`) take the *standard deviation*. $\mathcal{N}(3, 5)$ in AoS is `norm(3, sqrt(5))` in scipy. Always check which one a formula or a function expects.

2.9.2 Stirling's formula from Laplace's method

The binomial is built from factorials, so we need a good formula for $n!$ when n is large. That formula is Stirling's:

$$n! \simeq \sqrt{2\pi n}\, n^n e^{-n} \qquad (n \to \infty), \qquad \text{i.e.} \qquad \ln n! = n \ln n - n + \tfrac{1}{2}\ln(2\pi n) + O(1/n). \tag{2.40}$$

It comes from the same zoom-in on a peak, now applied to an integral. *The starting point.* The Gamma function gives $n!$ as an integral, $n! = \Gamma(n+1) = \int_0^\infty t^n e^{-t} \mathrm{d}t$, and for large n its integrand is sharply peaked. *Where is the peak, and how sharp is it?* Write the integrand as $e^{f(t)}$ with $f(t) = n \ln t - t$. The slope $f'(t) = n/t - 1$ vanishes at $t = n$, so the peak is at $t = n$. The curvature $f''(t) = -n/t^2$ equals $-1/n$ there. *Only then the integral.* Expanding f to second order about its maximum,

$$\begin{aligned} n! &\overset{(1)}{=} \int_0^\infty \exp\Big[f(n) + f'(n)(t-n) + \tfrac{1}{2}f''(n)(t-n)^2 + \dots\Big]\mathrm{d}t \\ &\overset{(2)}{=} n^n e^{-n} \int_0^\infty \exp\Big[-\frac{(t-n)^2}{2n} + \dots\Big]\mathrm{d}t \\ &\overset{(3)}{=} n^n e^{-n} \int_{-\infty}^\infty e^{-s^2/(2n)}\mathrm{d}s\ \big(1 + O(1/n)\big) \\ &\overset{(4)}{=} \sqrt{2\pi n}\, n^n e^{-n}\big(1 + O(1/n)\big). \end{aligned} \tag{2.41}$$

(1) Taylor expansion of f about $t = n$ inside the exponential.
(2) $f(n) = n \ln n - n$ gives $e^{f(n)} = n^n e^{-n}$, the linear term vanishes because $t = n$ is the maximum, and $\frac{1}{2} f''(n) = -1/(2n)$.
(3) Substitute $s = t - n$. The integrand is negligible beyond a few multiples of $\sqrt{n}$ from the peak, so extending the lower limit from $s = -n$ to $-\infty$ adds only a Gaussian tail of order $e^{-n/2}$. The cubic and higher terms of the expansion give the relative correction of order $1/n$ (it is $1/(12n)$).
(4) The Gaussian integral (2.36) with $\sigma^2 = n$.

This is **Laplace's method**: a sharply peaked integrand $e^{f(t)}$ is replaced by a Gaussian with the same peak height and the same curvature. We will meet it again as the Gaussian (Laplace) approximation to a posterior in Chapter 5. Figure 2.23 shows how good the approximation already is at $n = 10$.

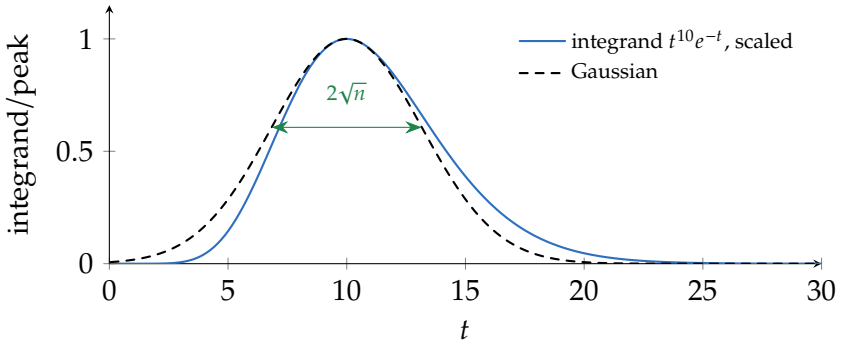

Figure 2.23: Laplace's method for $10! = \int_0^\infty t^{10} e^{-t} \mathrm{d}t$. The integrand (blue) is scaled to peak height one at $t = n = 10$. The dashed Gaussian has the same peak and the same curvature there, so its width is $\sqrt{n}$. The two areas differ by less than one percent, and the mismatch is the slight skew of the blue curve, which the $1/(12n)$ correction describes.

Stirling's formula is accurate even for small n. The script below finds $n!/\text{Stirling} = 1.0844$ at $n = 1$ and 1.00837 at $n = 10$, in agreement with $1 + 1/(12n)$ (Figure 2.25a). Even 1! is off by only eight percent.

2.9.3 The de Moivre–Laplace limit

Key idea: de Moivre–Laplace

Let $k \sim \text{Binomial}(n, p)$ and $q = 1 - p$. For large n and k within a few $\sqrt{npq}$ of np,

$$\mathrm{P}(k) = \binom{n}{k} p^k q^{n-k} \simeq \frac{1}{\sqrt{2\pi npq}} \exp\left[-\frac{(k - np)^2}{2npq}\right]. \tag{2.42}$$

The binomial pmf becomes a Gaussian density with $\mu = np$ and $\sigma^2 = npq$, the binomial mean and variance.

The derivation takes two steps. First, replace each factorial by Stirling's formula. Second, Taylor-expand the exponent about the peak. *Step one.* Insert (2.40) for $n!$, $k!$ and $(n - k)!$:

$$\begin{aligned} \ln \mathrm{P}(k) &\overset{(1)}{=} \ln n! - \ln k! - \ln(n-k)! + k \ln p + (n-k) \ln q \\ &\overset{(2)}{=} \left[n \ln n - k \ln k - (n-k) \ln(n-k) + k \ln p + (n-k) \ln q \right] - \tfrac{1}{2} \ln \frac{2\pi k(n-k)}{n} \end{aligned}$$

$$\overset{(3)}{=} -k\ln\frac{k}{np} - (n-k)\ln\frac{n-k}{nq} - \tfrac{1}{2}\ln\frac{2\pi k(n-k)}{n}. \tag{2.43}$$

(1) The logarithm of the binomial pmf.
(2) Stirling for the three factorials. The $-n+k+(n-k)$ from the three "$-m$" terms cancels. The three $\frac{1}{2}\ln(2\pi m)$ terms combine into the last logarithm.
(3) Write $n\ln n = k\ln n + (n-k)\ln n$ and collect: $k\ln n - k\ln k + k\ln p = -k\ln\frac{k}{np}$, and the same for the $n-k$ terms.

Step two. Measure k from the centre of the binomial, $k = np+\delta$, so that δ is the distance from the peak. Then $n-k = nq-\delta$, $k/(np) = 1+\delta/(np)$ and $(n-k)/(nq) = 1-\delta/(nq)$. Each logarithm in (2.43) now has the form $\ln(1+x)$ with x small, so we use $\ln(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \dots$:

$$\begin{aligned}(np+\delta)\ln\Big(1+\frac{\delta}{np}\Big) &\overset{(1)}{=} (np+\delta)\Big(\frac{\delta}{np} - \frac{\delta^2}{2n^2p^2} + \frac{\delta^3}{3n^3p^3}\Big) + O\Big(\frac{\delta^4}{n^3}\Big)\\ &\overset{(2)}{=} \delta + \frac{\delta^2}{2np} - \frac{\delta^3}{6n^2p^2} + O\Big(\frac{\delta^4}{n^3}\Big),\\ (nq-\delta)\ln\Big(1-\frac{\delta}{nq}\Big) &\overset{(3)}{=} -\delta + \frac{\delta^2}{2nq} + \frac{\delta^3}{6n^2q^2} + O\Big(\frac{\delta^4}{n^3}\Big).\end{aligned} \tag{2.44}$$

(1) Taylor series of the logarithm to third order.
(2) Multiply out: δ^2 terms $\frac{\delta^2}{np} - \frac{\delta^2}{2np} = \frac{\delta^2}{2np}$, and δ^3 terms $-\frac{\delta^3}{2n^2p^2} + \frac{\delta^3}{3n^2p^2} = -\frac{\delta^3}{6n^2p^2}$.
(3) The same calculation with $p \to q$ and $\delta \to -\delta$.

The exponent in (2.43) is minus the sum of these two lines:

$$\begin{aligned}-k\ln\frac{k}{np} - (n-k)\ln\frac{n-k}{nq} &\overset{(1)}{=} -\frac{\delta^2}{2n}\Big(\frac{1}{p}+\frac{1}{q}\Big) + \frac{\delta^3}{6n^2}\Big(\frac{1}{p^2}-\frac{1}{q^2}\Big) + \dots\\ &\overset{(2)}{=} -\frac{\delta^2}{2npq} + \frac{\delta^3}{6n^2}\,\frac{q^2-p^2}{p^2q^2} + \dots\end{aligned} \tag{2.45}$$

(1) The $\pm\delta$ terms cancel. This cancellation is what puts the peak at np.
(2) $\frac{1}{p}+\frac{1}{q} = \frac{p+q}{pq} = \frac{1}{pq}$ because $p+q=1$.

Which terms survive? Only the quadratic one. The probability sits where δ is of order $\sqrt{npq}$, so we judge each term there. The quadratic term $\delta^2/(2npq)$ is of order 1. The cubic term is of order $n^{3/2}/n^2 = n^{-1/2}$, which goes to zero. The prefactor also simplifies: $k(n-k)/n = npq + \delta(q-p) - \delta^2/n = npq\,[1+O(n^{-1/2})]$. Dropping the terms that vanish gives (2.42).

The cubic term also says how fast the limit is reached, in two ways. For $p = q = \frac{1}{2}$ it is exactly zero, so the symmetric binomial converges faster. And the leading corrections are *odd* in δ: they skew the curve but leave its height at the peak unchanged. So the largest pointwise error is the relative correction $n^{-1/2}$ times the height of the pmf, also of order $n^{-1/2}$, which gives n^{-1}.

Watch out: The approximation is local

(2.42) was derived for $\delta = O(\sqrt{n})$. Far in the tails, say $\delta \sim n$, the neglected cubic and higher terms are *not* small and the relative error can be enormous, even though both probabilities are tiny. A "5σ" tail probability computed from the Gaussian approximation to a binomial or Poisson count can be off by a large factor. For tail probabilities use the exact distribution (`scipy.stats.binom.sf`).

Example: The continuity correction. An integer count has to be matched to a smooth curve, and the match is best when we cut half-way between integers. Let $X \sim \text{Binomial}(25, 0.6)$, so $\mu = 15$ and $\sigma = \sqrt{25 \cdot 0.6 \cdot 0.4} = 2.449$. We want $\text{P}(X \le 13)$. Think of each integer k as a bar of width one centred on k, so the bar for $k = 13$ reaches up to 13.5. The plain Gaussian approximation cuts at 13 and misses half of that bar. The **continuity correction** cuts at 13.5 instead:

$$\text{P}(X \le 13) \overset{(1)}{=} \text{P}(X \le 13.5) \overset{(2)}{=} \Phi\left(\frac{13.5 - 15}{2.449}\right) = 0.270.$$

(1) X is an integer, so $X \le 13$ and $X \le 13.5$ are the same event. The bar picture tells us to use the second when replacing the pmf by a density.
(2) de Moivre–Laplace with $\mu = np$, $\sigma^2 = npq$, then standardise.

The exact binomial sum is 0.268 and the uncorrected approximation $\Phi\big((13 - 15)/2.449\big) = 0.207$. The half-bar is worth six percentage points here. In general, $\text{P}(X \le x) \approx \Phi\big((x + \tfrac{1}{2} - \mu)/\sigma\big)$ and $\text{P}(X \ge x) \approx 1 - \Phi\big((x - \tfrac{1}{2} - \mu)/\sigma\big)$.

Example: How many photo-electrons? Back to the scintillator bar of the opening: $n = 10^4$ photons, each making a photo-electron with probability $p = 0.3$, so $\mu = np = 3000$ and $\sigma = \sqrt{npq} = \sqrt{2100} = 45.83$. We wanted $\text{P}(k \le 2950)$:

$$\text{P}(k \le 2950) \overset{(1)}{=} \Phi\left(\frac{2950.5 - 3000}{45.83}\right) = \Phi(-1.080) \overset{(2)}{=} 0.140.$$

(1) de Moivre–Laplace with the continuity correction.
(2) Table value. The exact binomial sum (`binom.cdf(2950, 10000, 0.3)`) agrees to three decimal places.

The same numbers give the bar's energy resolution. The relative width $\sigma/\mu = \sqrt{q/(np)} = 1.5\%$ is its photo-statistics term. It falls like $1/\sqrt{\text{number of photo-electrons}}$, the famous $a/\sqrt{E}$ term of calorimetry.

Exercise: when is n large enough. CasellaBerger's rule of thumb is $\min(np, nq) \ge 5$ [CasellaBerger p. 85]. Use (2.45) to explain why the rule involves the *smaller* of np and nq. (Answer: the relative size of the cubic term at $\delta = \sigma$ is $\frac{\sigma^3}{6n^2}\frac{|q^2 - p^2|}{p^2q^2} = \frac{|q-p|}{6\sqrt{npq}}$, which is large when either np or nq is small, i.e. when the distribution is squeezed against $k = 0$ or $k = n$.)

2.9.4 Python: watching the binomial become a Gaussian

The script computes Stirling's ratio, overlays the Gaussian on three binomials, and measures the largest pointwise error as n grows from 10 to 10^4. The first key lines check Stirling's formula:

Listing 2.10: Stirling's formula against the exact $\ln n!$ (`code/ch02/20_demoivre_laplace.py`)

```
29 # ------------------------------------------------------------------ Stirling
30 n_st = np.arange(1, 31)
31 ln_fact = special.gammaln(n_st + 1)                       # ln n!, exact
32 ln_stirling = n_st * np.log(n_st) - n_st + 0.5 * np.log(2 * np.pi * n_st)
33 ratio = np.exp(ln_fact - ln_stirling)                     # n! / Stirling
```

Line 31 uses `gammaln`, the logarithm of the Gamma function, because $n!$ itself overflows a double for $n > 170$. Any likelihood code works with logarithms of factorials for the same reason. The next lines measure how far the binomial is from its Gaussian:

Listing 2.11: The largest error of the de Moivre–Laplace approximation (code/ch02/20_demoivre_laplace.py)

```
54 fig.legend(h[::-1], l[::-1], loc="upper center", bbox_to_anchor=(0.5, 0.0), ncol=2,
       frameon=False)
55 savefig(fig, "ch02", "demoivre_panels")
56
57 # ---------------------------------------------------------------- error vs n
58 n_grid = np.unique(np.round(np.logspace(1, 4, 25)).astype(int))
59 maxerr = []
60 for n in n_grid:
61     k = np.arange(0, n + 1)
62     mu, sd = n * p, np.sqrt(n * p * (1 - p))
```

For each n on a logarithmic grid, line 60 compares the exact pmf with the Gaussian density at the same integers and keeps the worst case. Line 62 fits a straight line in log–log space. The slope comes out as -1.00, the n^{-1} predicted above from the odd (skewing) corrections. At $n = 10$ the largest error is 0.0168, at $n = 10000$ it is 1.8×10^{-5} (Figure 2.25b).

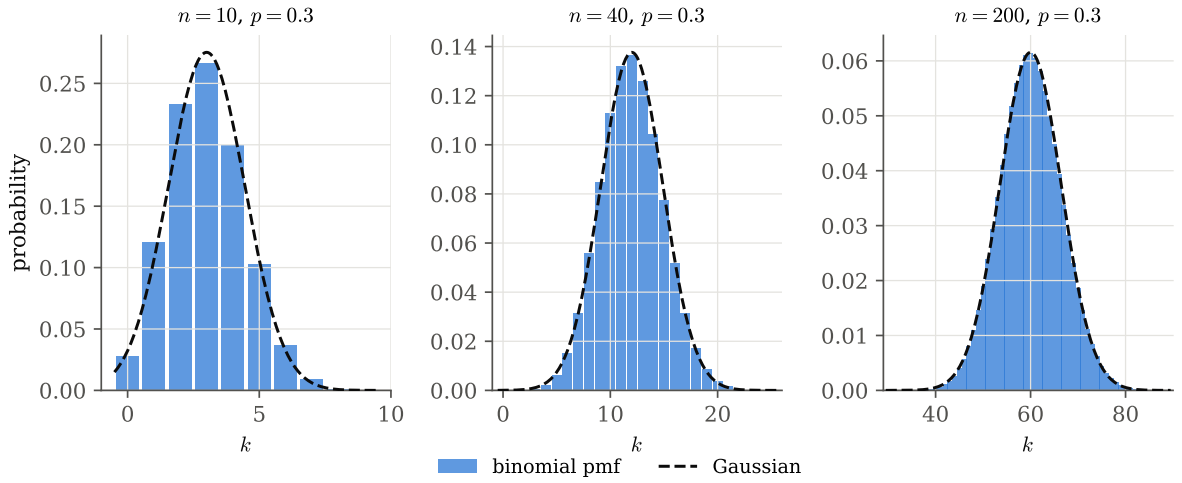

Figure 2.24: Binomial$(n, 0.3)$ probabilities (bars) with the Gaussian of the same mean and variance (dashed) for $n = 10, 40, 200$. At $n = 10$ the bars lean to the right of the curve: the distribution is squeezed against $k = 0$ and is skewed. By $n = 200$ the skew is invisible by eye.

What this bought us. The Gaussian appears whenever a distribution is sharply peaked and we look on the scale of its width: the logarithm is a parabola there. For the binomial the parabola has curvature $1/(npq)$, which fixes the Gaussian completely. The first correction is a skew of relative size $|q - p|/\sqrt{npq}$, and it is the skew, not the width, that tells us whether n is large enough.

How this is used in real research: Verifying a limit versus relying on it

Here the plot only *verifies* a known limit: the exact pmf is cheap, so nothing hangs on the approximation. Research uses the same Gaussian replacement where no exact answer is at hand. A binned χ^2 fit to a histogram treats each bin count, a binomial or Poisson number, as Gaussian with variance equal to its mean. That is fine with thousands of counts per bin and biased with a handful (the skew term above). High-energy physicists therefore switch to the exact Poisson likelihood for sparse bins (Chapters 3 and 4). CMB analyses meet the same issue at low multipoles, where each $\widehat{C}_\ell$ is a sum of only $2\ell + 1$ squared Gaussians and is visibly skewed (Chapter 7).

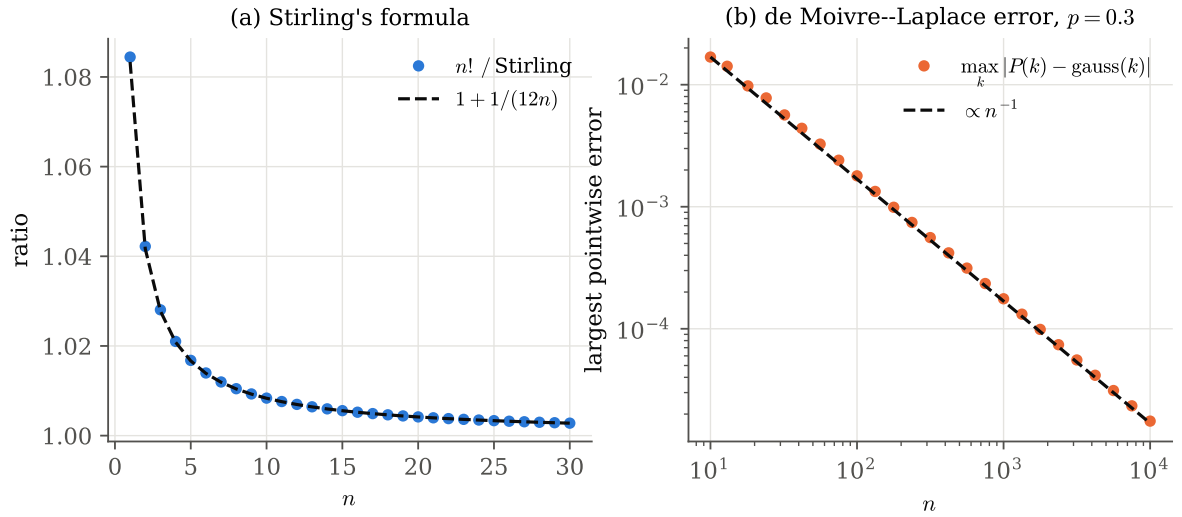

Figure 2.25: (a) The ratio of the exact $n!$ to Stirling's formula approaches one from above, following $1 + 1/(12n)$. (b) The largest pointwise difference between the binomial pmf and its Gaussian approximation falls as $1/n$ (dashed line).

Reading the numbers in the literature. AoS states the density as [Wasserman (2.3)] and works Example 2.17 (our worked example above), remarking only that "many phenomena in nature have approximately Normal distributions". Cowan's (2.22)–(2.27) is the same density with φ, Φ and the quantiles $x_\alpha = \Phi^{-1}(\alpha)$. CasellaBerger quotes the $1, 2, 3\sigma$ contents as .6826, .9544, .9974 (truncated rather than rounded), and in Example 3.3.2 the values .206, .267, .271 for the plain, exact and continuity-corrected results. Those differ slightly from ours because the book rounds z to -0.82 and -0.61 before entering the table.

2.10 The Gaussian, second way: the central limit theorem

A binomial count is a sum of n Bernoulli variables, one per trial (each is 1 for a success and 0 for a failure). So de Moivre–Laplace is really a statement about *sums*. The central limit theorem says that sums of almost anything become Gaussian. That is why measurement errors are modelled as Gaussian. Knowing exactly what the theorem assumes tells us when *not* to.

Where a timing error comes from. A drift-chamber hit time is shifted by the drift of the ionisation cluster, the rise time of the amplifier, the discriminator walk, cable delays that depend on temperature, the jitter of the clock, and a dozen smaller effects. None of these is Gaussian. A walk correction leaves a residual that is roughly uniform; a photon arrival delay is roughly exponential. Yet the histogram of timing residuals in a well-calibrated detector is a clean bell curve, until we look far out in its tails.

So the sum seems to forget the shapes of its ingredients. Three questions follow. Why does it forget? How fast does it forget, so that we know how many ingredients count as "many"? And which ingredients are never forgotten? A Breit–Wigner line shape and a Landau energy loss turn out to be two of them.

Convolution smooths, and Fourier space turns it into multiplication. Adding independent variables smooths their density, and the smoothing always ends in a Gaussian. *Why smoothing?* The density of a sum of two independent variables is the *convolution* of their densities: every

way of splitting the total between the two contributes. Convolving a box with a box gives a triangle. A triangle with a box gives three glued parabolas. After a handful of steps the shape is a smooth hump (Figure 2.26). *Why a Gaussian?* Follow the sum into Fourier space, one step at a time. There the convolution becomes a product. Taking logarithms turns the product into a sum. Each term of that sum is a power series in the frequency, and its coefficients are the *cumulants* (mean, variance, skewness, ...). When we rescale the sum to unit width, every cumulant beyond the second is suppressed by a power of n. What survives is a quadratic in the frequency, and a function whose logarithm is quadratic is a Gaussian. This is the diffusion equation in disguise: a drop of ink of any initial shape spreads into a Gaussian cloud.

The plan.

1. What do we add? n independent copies of one random variable with finite mean μ and variance σ^2.
2. What happens to the sum without rescaling? Its mean grows like n and its width like $\sqrt{n}$, so we centre it and divide by $\sigma\sqrt{n}$.
3. Which tool makes sums easy? The characteristic function, because it turns convolutions into products.
4. What does the characteristic function of the rescaled sum tend to? Expand for small frequency, raise to the power n, take the limit.
5. How fast is the limit reached, and what breaks it? Look at the first term we threw away, and at parents whose variance is infinite.

2.10.1 Characteristic functions: the tool that turns sums into products

The density of a sum is a convolution, which is awkward to handle directly. The Fourier transform of a density, called its characteristic function, turns the convolution into a product. We need its definition and three properties.

Working definition 2.14 (characteristic function)

The **characteristic function** of a random variable X with density $p(x)$ is

$$\phi_X(k) = \mathbb{E}\big(e^{ikX}\big) = \int_{-\infty}^{\infty} e^{ikx} p(x)\,\mathrm{d}x, \tag{2.46}$$

the Fourier transform of the density [with the sign $+ikx$ and no 2π in the exponent] [Cowan (10.1)]. It exists for *every* distribution, because $|e^{ikx}| = 1$. The density is recovered by the inverse transform $p(x) = \frac{1}{2\pi}\int \phi_X(k) e^{-ikx}\mathrm{d}k$ [Cowan (10.3)], so ϕ_X and p carry the same information. (A refresher of Chapter 1: the moment generating function $\mathbb{E}\,e^{tX}$ is the same object at imaginary frequency, $t = ik$, but it can be infinite.)

Three properties do all the work. First, the characteristic function of a sum of independent variables is the product of their characteristic functions. Let $X_1, \ldots, X_n$ be independent with densities $p_1, \ldots, p_n$ and characteristic functions $\phi_1, \ldots, \phi_n$, and let $S = \sum_j X_j$. Then

$$\begin{aligned}\phi_S(k) &\overset{(1)}{=} \int \cdots \int e^{ik(x_1+\cdots+x_n)}\, p_1(x_1)\cdots p_n(x_n)\,\mathrm{d}x_1 \cdots \mathrm{d}x_n \\ &\overset{(2)}{=} \int e^{ikx_1} p_1(x_1)\mathrm{d}x_1 \;\cdots \int e^{ikx_n} p_n(x_n)\mathrm{d}x_n = \phi_1(k)\cdots\phi_n(k).\end{aligned} \tag{2.47}$$

(1) Definition (2.46) for S, with the joint density of independent variables equal to the product of the marginals.
(2) The exponential of a sum is a product of exponentials, and each factor depends on one variable only, so the n-fold integral factorises.

Second, shifting multiplies by a phase and rescaling rescales the frequency: for constants a and b, $\phi_{aX+b}(k) = \mathbb{E}\, e^{ik(aX+b)} = e^{ikb}\phi_X(ak)$. Third, derivatives at the origin give moments, $\frac{\mathrm{d}^m \phi_X}{\mathrm{d}k^m}\big|_{k=0} = i^m\, \mathbb{E}(X^m)$ [Cowan (10.4)], so near $k = 0$

$$\phi_X(k) = 1 + ik\,\mathbb{E}\,X - \frac{k^2}{2}\,\mathbb{E}\,X^2 - \frac{ik^3}{6}\,\mathbb{E}\,X^3 + \dots \tag{2.48}$$

The characteristic function of a Gaussian. For $Z \sim \mathcal{N}(0,1)$ differentiate under the integral and integrate by parts:

$$\phi_Z'(k) \overset{(1)}{=} \int iz\, e^{ikz}\varphi(z)\,\mathrm{d}z \overset{(2)}{=} -i\int e^{ikz}\varphi'(z)\,\mathrm{d}z \overset{(3)}{=} i\int \big(ik\, e^{ikz}\big)\varphi(z)\,\mathrm{d}z = -k\,\phi_Z(k). \tag{2.49}$$

(1) Differentiate e^{ikz} with respect to k.
(2) $z\varphi(z) = -\varphi'(z)$.
(3) Integrate by parts. The boundary term vanishes because $\varphi \to 0$, and $\frac{\mathrm{d}}{\mathrm{d}z}e^{ikz} = ik\, e^{ikz}$ moves to the other factor with a minus sign.

The solution of $\phi' = -k\phi$ with $\phi(0) = 1$ is $\phi_Z(k) = e^{-k^2/2}$. For $X = \mu + \sigma Z$ the scaling rule gives

$$\phi_X(k) = \exp\big(i\mu k - \tfrac{1}{2}\sigma^2 k^2\big), \tag{2.50}$$

the entry in Cowan's Table 10.1. The Fourier transform of a Gaussian is a Gaussian, with the widths inverted: a narrow density has a wide characteristic function. A sum of independent Gaussians is therefore Gaussian, with the means and the variances adding [Cowan (10.11)]. The reason is the product rule: the product of two functions of the form (2.50) is again of that form, with $\mu = \mu_1 + \mu_2$ and $\sigma^2 = \sigma_1^2 + \sigma_2^2$. This is AoS's fact (iii) [Wasserman p. 28].

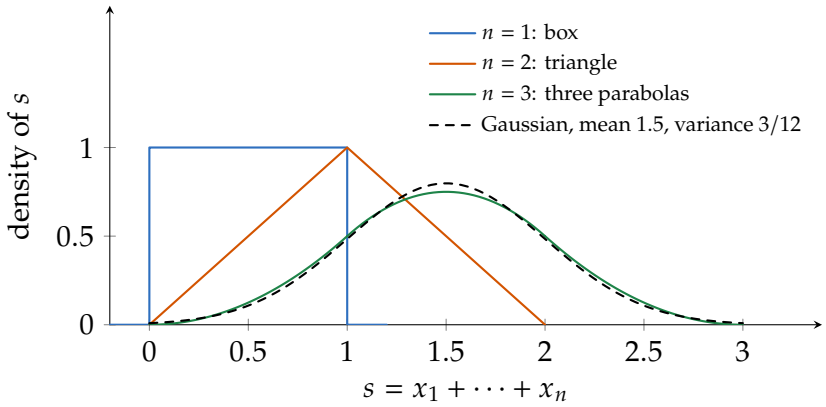

Figure 2.26: Repeated convolution of a flat density on $[0,1]$. One uniform is a box, the sum of two is a triangle, the sum of three is made of three parabolas joined smoothly. Already at $n = 3$ the green curve is hard to tell from the Gaussian with the same mean and variance (dashed). Each convolution also makes the curve one derivative smoother.

2.10.2 The theorem and its proof

The theorem asks three things of the terms in the sum: they are independent, they share one distribution, and that distribution has a finite variance. It asks nothing about the shape.

Key idea: Central limit theorem

Let $X_1, X_2, \ldots$ be independent and identically distributed with mean μ and *finite* variance $\sigma^2 > 0$. Let $\bar{X}_n = \frac{1}{n}\sum_{j=1}^n X_j$ and

$$Z_n = \frac{\sum_{j=1}^n X_j - n\mu}{\sigma\sqrt{n}} = \frac{\sqrt{n}(\bar{X}_n - \mu)}{\sigma}. \tag{2.51}$$

Then Z_n **converges in distribution** [the probabilities $\mathrm{P}(Z_n \le z)$ converge, for every z] to $\mathcal{N}(0,1)$:

$$\lim_{n\to\infty} \mathrm{P}(Z_n \le z) = \Phi(z) \qquad \text{for all } z. \tag{2.52}$$

Equivalently, $\bar{X}_n \approx \mathcal{N}(\mu, \sigma^2/n)$ and $\sum_j X_j \approx \mathcal{N}(n\mu, n\sigma^2)$ for large n.

The theorem approximates probabilities, not the random variable: "It's the probability statements that we are approximating, not the random variable itself" [Wasserman p. 77]. Z_n does not *become* a Gaussian variable. What happens is that the numbers $\mathrm{P}(Z_n \le z)$ approach the numbers $\Phi(z)$.

Proof. The plan is to show that the characteristic function of Z_n tends to $e^{-k^2/2}$, the one of $\mathcal{N}(0,1)$. Let $Y_j = (X_j - \mu)/\sigma$, so $\mathbb{E}\,Y_j = 0$, $\mathbb{E}\,Y_j^2 = 1$, and $Z_n = \sum_j Y_j/\sqrt{n}$. Because the second moment is finite, (2.48) holds to second order with a remainder that is small compared to k^2: $\phi_Y(k) = 1 - \frac{1}{2}k^2 + o(k^2)$. Then

$$\begin{aligned}
\phi_{Z_n}(k) &\overset{(1)}{=} \left[\phi_Y\!\left(\frac{k}{\sqrt{n}}\right)\right]^n \\
&\overset{(2)}{=} \left[1 - \frac{k^2}{2n} + o\!\left(\frac{1}{n}\right)\right]^n \\
&\overset{(3)}{=} \exp\left\{n \ln\left[1 - \frac{k^2}{2n} + o\!\left(\frac{1}{n}\right)\right]\right\} \\
&\overset{(4)}{=} \exp\left\{n\left[-\frac{k^2}{2n} + o\!\left(\frac{1}{n}\right)\right]\right\} \xrightarrow{n\to\infty} e^{-k^2/2}.
\end{aligned} \tag{2.53}$$

(1) Product rule (2.47) for n identical factors, and the scaling rule with $a = 1/\sqrt{n}$.
(2) The second-order expansion of ϕ_Y at the small frequency $k/\sqrt{n}$ (k is held fixed).
(3) $a^n = e^{n \ln a}$.
(4) $\ln(1+x) = x + O(x^2)$, and $x^2 = O(1/n^2)$ so $nx^2 \to 0$. This is the step AoS writes as $(1 + a_n/n)^n \to e^a$ when $a_n \to a$.

The limit is the characteristic function of $\mathcal{N}(0,1)$. Finally, **Lévy's continuity theorem** [if characteristic functions converge at every k to a function continuous at $k = 0$, the distributions converge] turns this into (2.52). ∎

Look at what the proof used. Independence, to multiply characteristic functions. A finite variance, to expand to second order. Identical distributions, only for convenience. It did *not* use anything about the shape of $p(x)$. That is the whole content of "regardless of the form of the individual p.d.f.s" [Cowan p. 33].

Why characteristic functions and not moment generating functions. AoS proves the CLT with the moment generating function $\psi(t) = \mathbb{E}\,e^{tX}$ and assumes it is finite near $t = 0$ [Wasserman p. 81–82]. That assumption excludes perfectly good cases. A Student t_3 variable (Section 2.14) has variance 3 but $\mathbb{E}\,e^{tX} = \infty$ for every $t \neq 0$, because its tails fall like a power. The CLT holds for it;

the MGF proof cannot show it. The characteristic function always exists, which is why Cowan and all rigorous treatments use it.

Not identically distributed. Terms with different variances still give a Gaussian sum, provided no single term dominates. If the X_j are independent with means μ_j and variances σ_j^2, the sum tends to $\mathcal{N}\big(\sum \mu_j, \sum \sigma_j^2\big)$ [Cowan p. 147–148] under "somewhat more restrictive conditions". The condition (Lindeberg's) says in words: *no single term may carry a finite fraction of the total variance*. A sum of one huge error and many tiny ones is as non-Gaussian as the huge error.

Vectors. The theorem also holds for vectors. If $\boldsymbol{X}_j$ are iid vectors with mean $\boldsymbol{\mu}$ and covariance matrix $\mathbf{C}$, then $\sqrt{n}(\bar{\boldsymbol{X}}_n - \boldsymbol{\mu})$ tends to the multivariate Gaussian $\mathcal{N}(\mathbf{0}, \mathbf{C})$ of Section 2.12 [Wasserman p. 78–79, Thm. 5.12]. This is why a histogram with many entries, or a set of band-powers built from many modes, has a Gaussian *joint* distribution.

Unknown σ: the studentised version. Replacing the unknown σ by its estimate from the data leaves the limit unchanged. In practice σ is not known, and we use the sample standard deviation S_n, with $S_n^2 = \frac{1}{n-1}\sum_j (X_j - \bar{X}_n)^2$. Then still $\sqrt{n}(\bar{X}_n - \mu)/S_n \to \mathcal{N}(0,1)$ [Wasserman p. 79, Thm. 5.10]. *Why?* This ratio equals $Z_n \cdot (\sigma/S_n)$, and $S_n^2 = \frac{n}{n-1}\big[\frac{1}{n}\sum X_j^2 - \bar{X}_n^2\big] \to \mathbb{E}\,X^2 - \mu^2 = \sigma^2$ by the law of large numbers, so the second factor tends to the constant 1. A quantity that tends to $\mathcal{N}(0,1)$ times one that tends to 1 still tends to $\mathcal{N}(0,1)$ (Slutsky's argument). For small n and Gaussian data the exact law of this ratio is Student's t (Section 2.14).

2.10.3 How fast? Cumulants, skewness and the Berry–Esseen bound

How large n must be is decided by the k^3 term that the proof threw away. To keep track of it, we take logarithms of characteristic functions.

Working definition 2.15 (cumulants)

The **cumulants** κ_r of X are the Taylor coefficients of the logarithm of its characteristic function,

$$\ln \phi_X(k) = \sum_{r \geq 1} \kappa_r \frac{(ik)^r}{r!}. \tag{2.54}$$

κ_1 is the mean, κ_2 the variance, $\kappa_3 = \mathbb{E}(X-\mu)^3$ the third central moment [it measures asymmetry]. The **skewness** is $\gamma_1 = \kappa_3/\sigma^3$ and the **excess kurtosis** $\gamma_2 = \kappa_4/\sigma^4$ [zero for a Gaussian, positive for heavier tails]. For a Gaussian, $\ln\phi = i\mu k - \sigma^2 k^2/2$, so *all* cumulants beyond the second vanish.

Two rules fix how cumulants behave in a sum. Cumulants of independent variables add, because logarithms turn the product (2.47) into a sum. And rescaling by a multiplies κ_r by a^r, by the scaling rule $\phi_{aX}(k) = \phi_X(ak)$. So for the standardised sum (2.51),

$$\kappa_r(Z_n) \overset{(1)}{=} n\,\kappa_r\!\left(\frac{X-\mu}{\sigma\sqrt{n}}\right) \overset{(2)}{=} n\,\frac{\kappa_r(X)}{\sigma^r n^{r/2}} = \frac{\kappa_r(X)}{\sigma^r}\,n^{1-r/2} \qquad (r \geq 2). \tag{2.55}$$

(1) Z_n is a sum of n independent copies of $(X-\mu)/(\sigma\sqrt{n})$, and cumulants add.
(2) Shifting changes only κ_1. Scaling by $1/(\sigma\sqrt{n})$ multiplies κ_r by $(\sigma\sqrt{n})^{-r}$.

This is the CLT again, now with rates. For $r = 2$ the result is 1 for every n (unit variance, by construction). For $r = 3$ it says the skewness of Z_n is $\gamma_1/\sqrt{n}$. For $r = 4$ the excess kurtosis is γ_2/n. Higher cumulants die faster still.

Example: Predicting how skewed a sum of exponentials is. For $X \sim \mathrm{Exp}(1)$ the characteristic function is $\phi(k) = (1 - ik)^{-1}$ [Cowan Table 10.1], so

$$\ln \phi(k) \overset{(1)}{=} -\ln(1 - ik) \overset{(2)}{=} \sum_{r \geq 1} \frac{(ik)^r}{r} \overset{(3)}{=} \sum_{r \geq 1} (r-1)! \, \frac{(ik)^r}{r!},$$

(1) Take the logarithm.
(2) $-\ln(1-u) = \sum_{r \geq 1} u^r / r$ with $u = ik$.
(3) Multiply and divide by $r!$ to read off the cumulants in the form (2.54).

so $\kappa_r = (r-1)!$: mean 1, variance 1, $\kappa_3 = 2$, skewness $\gamma_1 = 2$. By (2.55) a sum of n exponentials has skewness $2/\sqrt{n}$. The simulation (below) measures 2.01 at $n = 1$, 0.91 at $n = 5$ (predicted 0.894) and 0.366 at $n = 30$ (predicted 0.365). A sum of thirty exponentials is still visibly lopsided.

The first correction to the Gaussian (Edgeworth). The skewness term gives the leading error of the Gaussian approximation. Keep the $r = 3$ cumulant in the exponent and expand: $\phi_{Z_n}(k) \approx e^{-k^2/2}\left[1 + \frac{\gamma_1}{6\sqrt{n}}(ik)^3\right]$. Under the inverse transform each factor ik becomes $-\mathrm{d}/\mathrm{d}z$ (differentiate e^{-ikz}), so

$$\begin{aligned} \mathrm{P}(Z_n \leq z) &\overset{(1)}{=} \Phi(z) + \frac{\gamma_1}{6\sqrt{n}} \int_{-\infty}^{z} \left(-\frac{\mathrm{d}}{\mathrm{d}z'}\right)^3 \varphi(z') \, \mathrm{d}z' + O\left(\frac{1}{n}\right) \\ &\overset{(2)}{=} \Phi(z) - \frac{\gamma_1}{6\sqrt{n}} \, \varphi''(z) + O\left(\frac{1}{n}\right) \overset{(3)}{=} \Phi(z) - \frac{\gamma_1}{6\sqrt{n}} \, (z^2 - 1)\varphi(z) + O\left(\frac{1}{n}\right). \end{aligned} \tag{2.56}$$

(1) Inverse Fourier transform of the two terms of the expanded characteristic function, then integrate the density up to z.
(2) $(-\mathrm{d}/\mathrm{d}z)^3 = -\mathrm{d}^3/\mathrm{d}z^3$, and integrating φ''' from $-\infty$ gives φ'' (it vanishes at $-\infty$).
(3) $\varphi' = -z\varphi$, so $\varphi'' = (z^2 - 1)\varphi$.

The correction is largest at $z = 0$, where it has size $\gamma_1 \varphi(0)/(6\sqrt{n}) = 0.0665 \, \gamma_1/\sqrt{n}$. We check this against the exact worst-case gap, the **Kolmogorov distance** $D_n = \sup_z |\mathrm{P}(Z_n \leq z) - \Phi(z)|$, which the script computes without Monte Carlo noise. For exponentials ($\gamma_1 = 2$) and $n = 32$ the prediction is 0.0235 and the exact value is 0.0235. A *symmetric* parent behaves differently. Its skewness γ_1 is zero, so the $n^{-1/2}$ term is absent, and the error starts at order $1/n$ with a coefficient set by the kurtosis. For uniforms ($\gamma_2 = -6/5$) the next Edgeworth term predicts 8.6×10^{-4} at $n = 32$, and the exact value is 8.7×10^{-4}. The fitted slopes of $\ln D_n$ against $\ln n$ are -0.50 (exponential) and -1.02 (uniform), Figure 2.28.

A guaranteed bound. The Edgeworth term is an estimate; a proof needs a bound. The Berry–Esseen inequality gives one, with no expansion [Wasserman p. 78, (5.4)]:

$$\sup_z \left|\mathrm{P}(Z_n \leq z) - \Phi(z)\right| \leq C \, \frac{\mathbb{E}\,|X - \mu|^3}{\sigma^3 \sqrt{n}}, \tag{2.57}$$

with $C = 33/4$ in AoS. For Exp(1), $\mathbb{E}\,|X-1|^3 = \int_0^1 (1-x)^3 e^{-x} \mathrm{d}x + \int_1^\infty (x-1)^3 e^{-x} \mathrm{d}x = (6/e - 2) + 6/e = 12/e - 2 = 2.415$. At $n = 30$ the AoS bound is 3.64, larger than 1 and therefore useless, while the true distance is 0.0243. The best constant known today is below 0.48, which gives 0.209: a valid guarantee, but still an order of magnitude pessimistic. The bound is for proofs, the Edgeworth term for estimates.

Example: Programs with Poisson bugs. The number of errors in a computer program is Poisson with mean 5. We have 125 programs, and $\bar{X}_{125}$ is the average number of errors per program. What is the probability that this average is below 5.5, $\mathrm{P}(\bar{X}_{125} < 5.5)$? For Poisson($\lambda$) the mean and variance are both λ, so here $\mu = 5$ and $\sigma = \sqrt{5}$, and

$$\mathrm{P}(\bar{X}_n < 5.5) \overset{(1)}{=} \mathrm{P}\Big(\frac{\sqrt{n}(\bar{X}_n - \mu)}{\sigma} < \frac{\sqrt{125}\,(5.5-5)}{\sqrt{5}}\Big) \overset{(2)}{=} \mathrm{P}(Z_n < 2.5) \overset{(3)}{=} \Phi(2.5) = 0.9938.$$

(1) Subtract the mean, multiply by $\sqrt{n}/\sigma$ on both sides.
(2) $\sqrt{125} \times 0.5/\sqrt{5} = \sqrt{25} \times 0.5 = 2.5$.
(3) CLT (2.52).

This is [Wasserman p. 77–78, Example 5.9]. Here we can check the CLT against the exact answer. The sum $\sum X_j$ is itself Poisson(625), so the exact answer is $\mathrm{P}(\sum X_j \le 687) = 0.9932$. The CLT is good to six parts in ten thousand, because the Poisson skewness $1/\sqrt{625} = 0.04$ is small.

Example: Poisson becomes Gaussian, in Fourier space. The same limit can be watched directly in Fourier space. Let $n \sim \text{Poisson}(\nu)$, with characteristic function $\phi_n(k) = \exp[\nu(e^{ik} - 1)]$ [Cowan Table 10.1]. Standardise, $x = (n - \nu)/\sqrt{\nu}$:

$$\phi_x(k) \overset{(1)}{=} e^{-ik\sqrt{\nu}}\,\phi_n\Big(\frac{k}{\sqrt{\nu}}\Big) \overset{(2)}{=} \exp\Big[\nu\Big(e^{ik/\sqrt{\nu}} - 1\Big) - ik\sqrt{\nu}\Big]$$
$$\overset{(3)}{=} \exp\Big[\nu\Big(\frac{ik}{\sqrt{\nu}} - \frac{k^2}{2\nu} - \frac{ik^3}{6\nu^{3/2}} + \dots\Big) - ik\sqrt{\nu}\Big] \overset{(4)}{=} \exp\Big[-\frac{k^2}{2} - \frac{ik^3}{6\sqrt{\nu}} + \dots\Big] \xrightarrow{\nu\to\infty} e^{-k^2/2}.$$

(1) Scaling rule with $a = 1/\sqrt{\nu}$, $b = -\sqrt{\nu}$.
(2) Insert the Poisson characteristic function.
(3) Expand $e^u = 1 + u + u^2/2 + u^3/6 + \dots$ with $u = ik/\sqrt{\nu}$.
(4) The $ik\sqrt{\nu}$ terms cancel. The cubic term is $\kappa_3(x)(ik)^3/6$ with $\kappa_3(x) = 1/\sqrt{\nu}$, the skewness of a Poisson count.

This is Cowan's (10.8)–(10.10). The Poisson mean plays the role of n: a Poisson count is a sum of ν unit-mean Poisson counts.

Example: Inverting a characteristic function by residues. Sometimes the inverse transform can be done exactly, and then we get the distribution of the sum for every n, not only its limit. Take n independent lifetimes, each Exp(ξ) with mean ξ. Each has $\phi_x(k) = (1 - ik\xi)^{-1}$, so the sum $z = \sum x_j$ has $\phi_z(k) = (1 - ik\xi)^{-n}$ [Cowan (10.21)–(10.22)]. The inverse transform $g(z) = \frac{1}{2\pi}\int e^{-ikz}(1 - ik\xi)^{-n}\mathrm{d}k$ has a pole of order n at $k = -i/\xi$ in the lower half plane. For $z > 0$, e^{-ikz} decays when $\mathrm{Im}\,k < 0$, so we close the contour below (clockwise, a factor $-2\pi i$). With $(1 - ik\xi)^{-n} = (-i\xi)^{-n}(k + i/\xi)^{-n}$,

$$g(z) \overset{(1)}{=} \frac{-2\pi i}{2\pi}\,(-i\xi)^{-n}\,\frac{1}{(n-1)!}\,\frac{\mathrm{d}^{n-1}}{\mathrm{d}k^{n-1}} e^{-ikz}\Big|_{k=-i/\xi} \overset{(2)}{=} \frac{-i\,(-iz)^{n-1}}{(-i\xi)^n (n-1)!}\,e^{-z/\xi} \overset{(3)}{=} \frac{1}{(n-1)!}\,\frac{z^{n-1}}{\xi^n} e^{-z/\xi}.$$

(1) Residue of a pole of order n: $\frac{1}{(n-1)!}$ times the $(n-1)$-th derivative of the rest of the integrand.
(2) Each derivative of e^{-ikz} brings down $-iz$, and $e^{-i(-i/\xi)z} = e^{-z/\xi}$.
(3) $-i\,(-i)^{n-1}/(-i)^n = 1$.

This is the Gamma (Erlang) density of the waiting time for the n-th event, met in the counting part of this chapter [Cowan (10.24)]. So the estimate $\hat{\xi} = z/n$ of the mean lifetime has an exactly known, skewed distribution. Its skewness is the $2/\sqrt{n}$ found above for a sum of n exponentials.

2.10.4 Python: sums of uniforms and exponentials

Listing 2.12: Standardised sums of n uniforms and n exponentials (`code/ch02/21_clt_sums.py`)

```
42 for row, (name, (draw, mu, sd)) in enumerate(parents.items()):
43     for col, n in enumerate(ns):
44         s = draw((NSAMP, n)).sum(axis=1)                    # the sum of n copies
45         zn = (s - n * mu) / (sd * np.sqrt(n))               # standardised sum
46         if name == "exponential":
47             skew_meas[n] = stats.skew(zn)
```

Line 44 draws an array of shape $(200000, n)$ and sums along each row, so each row is one "experiment" with n ingredients. Line 45 standardises with the *exact* parent mean and standard deviation, which is (2.51). The histograms are in Figure 2.27.

Listing 2.13: Exact Kolmogorov distances, without Monte Carlo noise (`code/ch02/21_clt_sums.py`)

```
64 D_exp = []
65 for n in n_rate:
66     # S_n ~ Gamma(n,1): P(Z_n <= z) = GammaCDF(n + z sqrt(n))
67     D_exp.append(np.max(np.abs(stats.gamma.cdf(n + zz * np.sqrt(n), a=n) -
       stats.norm.cdf(zz))))
68 D_exp = np.array(D_exp)
69
70 dx = 2e-4                                   # grid step for the uniform convolutions
71 base = np.ones(int(round(1 / dx))) * 1.0    # density of U(0,1) sampled on the grid
72 dens = base.copy()
73 D_uni = []
74 for n in range(1, n_rate.max() + 1):
75     if n > 1:
76         dens = signal.fftconvolve(dens, base) * dx
77     if n in n_rate:
78         # U(0,1) is sampled at (i+1/2)dx, so the n-fold sum lives at (m + n/2)dx
79         x = (np.arange(dens.size) + 0.5 * n) * dx
80         cdf = np.cumsum(dens) * dx - 0.5 * dens * dx   # trapezoidal CDF at the grid points
81         zn = (x - n * 0.5) / (np.sqrt(n / 12))
82         D_uni.append(np.max(np.abs(cdf - stats.norm.cdf(zn))))
83 D_uni = np.array(D_uni)
```

A Monte Carlo histogram cannot resolve a distance of 10^{-3}, so the rate is computed exactly. For exponentials the sum is Gamma$(n, 1)$ (line 67). For uniforms, lines 74–82 build the density of the sum by repeated numerical convolution on a fine grid (FFT convolution, line 76), exactly the operation pictured in Figure 2.26, and integrate it to a CDF.

What this bought us. "Large n" is not a number; it depends on the skewness of what is being added. The error of the Gaussian approximation is about $0.07\,\gamma_1/\sqrt{n}$ in cumulative probability. Symmetric ingredients converge like $1/n$, lopsided ones like $1/\sqrt{n}$.

2.10.5 Where the theorem fails: Breit–Wigner resonances

Measuring the Z mass with a running average. The invariant mass of e^+e^- pairs from Z decays follows, to a first approximation, the (non-relativistic) **Breit–Wigner** or **Cauchy** line shape

$$p(m \mid M, \Gamma) = \frac{1}{\pi} \frac{\Gamma/2}{(m - M)^2 + \Gamma^2/4}, \tag{2.58}$$

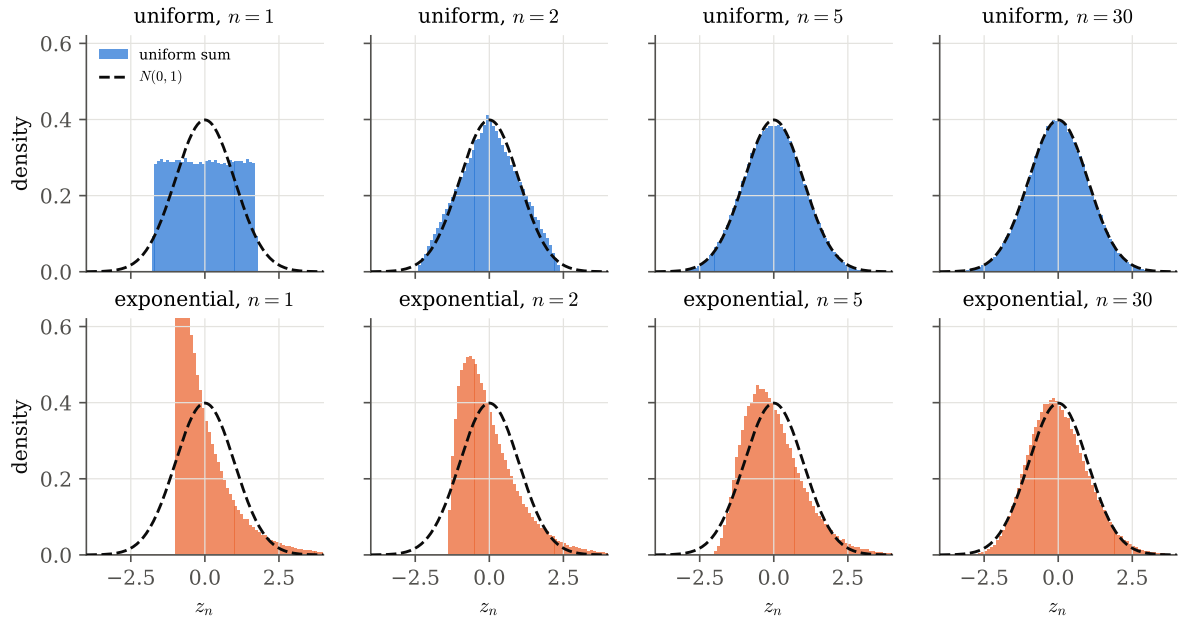

Figure 2.27: Histograms of the standardised sum z_n of n uniforms (top) and n exponentials (bottom), 200000 experiments each, with the standard normal density (dashed). The uniform sum is already bell-shaped at $n = 2$ to 5. The exponential sum keeps a visible skew, a steep left side and a long right tail, even at $n = 30$.

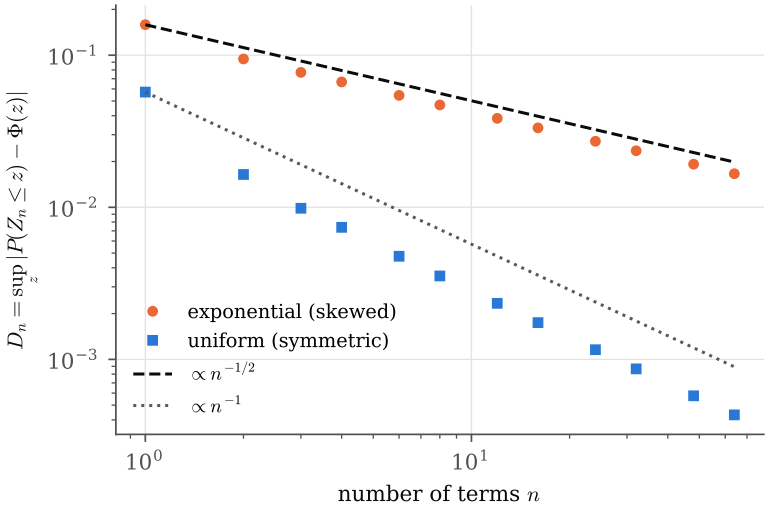

Figure 2.28: The worst-case gap between the distribution of z_n and Φ, as a function of the number of terms. For the skewed exponential parent it falls as $n^{-1/2}$ (dashed), for the symmetric uniform parent as n^{-1} (dotted). At $n = 30$ the symmetric case is more than twenty times closer to Gaussian.

with $M = 91.1876\,\text{GeV}$ the mass and $\Gamma = 2.4952\,\text{GeV}$ the full width at half maximum [Cowan (2.41)]. (We ignore detector resolution and radiation to keep the point clean.) A student averages the masses of the first N events and expects the average to settle down like $1/\sqrt{N}$.

The student's expectation fails, because the Breit–Wigner has no mean. It is a proper density: with $u = 2(m - M)/\Gamma$, $\int \frac{\mathrm{d}u}{\pi(1+u^2)} = \frac{1}{\pi}[\arctan u]_{-\infty}^{\infty} = 1$ [Wasserman p. 30]. But the two halves of the mean, $\int_M^{\infty} m\,p(m)\mathrm{d}m$ and $\int_{-\infty}^{M} m\,p(m)\mathrm{d}m$, diverge separately, because the integrand falls only like $1/m$. Their difference is therefore undefined [Cowan p. 36–37]; CasellaBerger's (3.3.20) states it as $\mathbb{E}\,|X| = \infty$. The variance is infinite too, so the CLT does not apply.

Instead, the mean of Cauchy variables is as wide as one of them. If $X_1, \dots, X_n$ are iid Cauchy with centre M and half-width $\gamma = \Gamma/2$, then $\bar{X}_n$ has *exactly the same* Cauchy distribution, for every n [CasellaBerger p. 177]. Averaging does not help at all.

The proof is two lines once we have the characteristic function. For the standard Cauchy $p(x) = 1/[\pi(1 + x^2)]$ and $k > 0$, close the contour in the upper half plane, where e^{ikx} decays, around the pole at $x = i$:

$$\phi(k) \overset{(1)}{=} \frac{1}{\pi} \oint \frac{e^{ikx}}{(x - i)(x + i)} \mathrm{d}x \overset{(2)}{=} \frac{1}{\pi}\, 2\pi i\, \frac{e^{ik\cdot i}}{2i} = e^{-k}, \tag{2.59}$$

(1) Factor $1 + x^2$. The semicircle at infinity contributes nothing for $k > 0$.
(2) Residue theorem: $2\pi i$ times the residue at $x = i$, which is $e^{ik\,i}/(i + i)$.

and by symmetry $\phi(k) = e^{-|k|}$ for all k [Cowan Table 10.1]. For centre M and scale γ, $\phi(k) = e^{iMk-\gamma|k|}$. Then

$$\phi_{\bar{X}_n}(k) \overset{(1)}{=} \left[\phi\left(\frac{k}{n}\right)\right]^n \overset{(2)}{=} \left[e^{iMk/n-\gamma|k|/n}\right]^n = e^{iMk-\gamma|k|}, \tag{2.60}$$

(1) Product and scaling rules with $a = 1/n$.
(2) The Cauchy characteristic function at frequency k/n.

which is the characteristic function of a single event. *Where did the CLT proof break?* At the expansion. The kink of $e^{-|k|}$ at $k = 0$ is the Fourier-space signature of the missing variance: ϕ has no second derivative there, so the expansion (2.48) does not exist [Cowan p. 145]. The width is controlled by $|k|$ rather than k^2. So in the exponent it scales as $n \times \frac{1}{n} = 1$, instead of the $n \times \frac{1}{n^2}$ that would have made it shrink.

One event can move the average anywhere. With a Gaussian, an event 10σ away is essentially impossible. With a Breit–Wigner, the probability of landing further than t from the peak falls only like $1/t$. Among N events, the most extreme one is typically at distance $\sim N\gamma$ from the peak, so its contribution to the average, $\sim N\gamma/N = \gamma$, never becomes small. The average is always at the mercy of the latest outlier. The *median* does not care how far out an outlier is, only on which side it lies.

The simulation shows both behaviours. The script draws 10^5 Breit–Wigner masses in three independent streams. After 10^5 events one running mean sits at 94.52 GeV, 3.3 GeV from the true mass, and all three keep jumping (Figure 2.29a). The running median of the same events is 91.186 GeV. Its standard error, $\pi\gamma/(2\sqrt{N}) = 0.0062$ GeV, does fall like $1/\sqrt{N}$: the median of any continuous density has asymptotic variance $1/[4Np(M)^2]$, and $p(M) = 1/(\pi\gamma)$ here. Panel (b) repeats the average of 1000 events twenty thousand times: its interquartile range is 2.463 GeV, equal to that of a *single* event, $2\gamma = \Gamma = 2.495$ GeV.

Listing 2.14: Running mean and running median of Breit–Wigner masses (`code/ch02/22_cauchy_landau.py`)

```
for s in range(3):
    m_bw = M + gam * rng.standard_cauchy(N)                # Breit-Wigner masses
    ax.semilogx(nn, np.cumsum(m_bw) / nn, color=SERIES[s], lw=1.0,
                label="Breit--Wigner, running mean" if s == 0 else None)
m_g = M + sig_g * rng.standard_normal(N)
ax.semilogx(nn, np.cumsum(m_g) / nn, color="k", lw=1.2, label="Gaussian, running mean")
# running median of the last Breit-Wigner stream, on a sparse grid
grid = np.unique(np.round(np.logspace(0, 5, 60)).astype(int))
ax.semilogx(grid, [np.median(m_bw[:k]) for k in grid], color=SERIES[3], ls="--",
            lw=1.4, label="Breit--Wigner, running median")
```

Line 42 generates Breit–Wigner masses as $M + \gamma\, C$, where $\gamma = \Gamma/2$ is the half-width and C is a standard Cauchy variable. Numpy draws C with `rng.standard_cauchy`. (A standard Cauchy variable is the same thing as the ratio of two independent standard normals.) Line 43 computes all running means at once with a cumulative sum. Line 49 evaluates the running median on a logarithmic grid of N values.

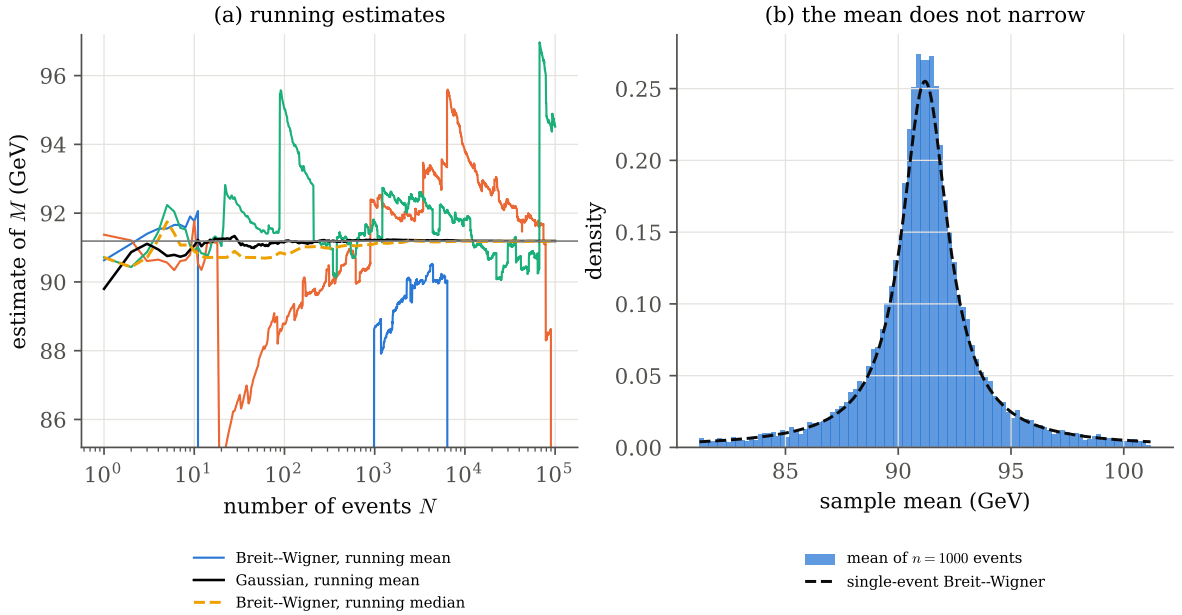

Figure 2.29: (a) Running estimates of the Z mass from Breit–Wigner events. The three coloured running means jump by GeV every time an extreme event arrives and never settle. The running mean of Gaussian events of the same half-width (black) and the running median of the Breit–Wigner events (dashed) both converge to the true mass (grey line). (b) The distribution of the average of 1000 events (histogram) is the single-event Breit–Wigner (dashed): no narrowing at all.

Watch out: The width convention

Cowan's Γ in (2.58) is the *full* width at half maximum, the convention of particle physics, where $\Gamma = \hbar/\tau$ is the decay rate. Many statistics texts write the Cauchy scale γ as the *half* width, and `scipy.stats.cauchy(loc, scale)` expects $\gamma = \Gamma/2$ [Cowan p. 37, footnote].

Strictly, real resonances do have a mean. The mass cannot be negative or exceed the collision energy, and the relativistic line shape with phase space and parton luminosities cuts the tails [Cowan p. 38–39]. But the cut sits so far out that the practical lesson stands: sample means of resonance masses converge painfully slowly and are dominated by a few events. Fit the line shape, or use the median or a truncated mean.

2.10.6 Where the theorem is slow: Landau energy loss

A charged particle crossing a thin layer loses energy Δ in many soft collisions and, occasionally, one hard collision that knocks out a fast δ-electron. The distribution of Δ, derived by Landau, is [Cowan (2.42)–(2.46)]

$$f(\Delta) = \frac{1}{\xi}\,\phi_L(\lambda), \qquad \lambda = \frac{1}{\xi}\left[\Delta - \xi\left(\ln\frac{\xi}{\epsilon'} + 1 - \gamma_E\right)\right], \qquad \phi_L(\lambda) = \frac{1}{\pi}\int_0^\infty e^{-u\ln u - \lambda u}\sin\pi u\,\mathrm{d}u, \tag{2.61}$$

where ξ grows with the layer thickness and falls like $1/\beta^2$ (β is the particle's speed in units of c), ϵ' depends on the ionisation energy of the material and on $\beta\gamma$, and $\gamma_E = 0.5772$ is Euler's constant. The high tail falls like $1/\lambda^2$, following the Rutherford cross-section for hard knock-ons. So, as for the Breit–Wigner, the mean and variance do not exist. The useful number is the most probable loss, $\Delta_{\mathrm{mp}} = \xi[\ln(\xi/\epsilon') + 0.198]$ [Cowan (2.48)]. It depends on the velocity, and it is the basis of particle identification by $\mathrm{d}E/\mathrm{d}x$.

Adding layers does not make the Landau tail Gaussian. Cowan's example [Cowan p. 148]: the ionisation in 1 m of argon is the sum over 25 layers of 4 cm, and one might hope the sum is Gaussian. The script adds 25 standard Landau variables and compares the result with a Gaussian of the same median and interquartile range (Figure 2.30). The core matches. The tail does not: a fraction 6.1×10^{-2} of the sums lie more than five matched standard deviations above the median, against 2.9×10^{-7} for a Gaussian. Rare hard collisions dominate the sum however many layers we add. (Mathematically the Landau distribution is *stable*: like the Cauchy, the suitably shifted and rescaled sum of Landau variables is again Landau.) Practical $\mathrm{d}E/\mathrm{d}x$ estimators therefore use a truncated mean, discarding the largest 30–40% of the samples.

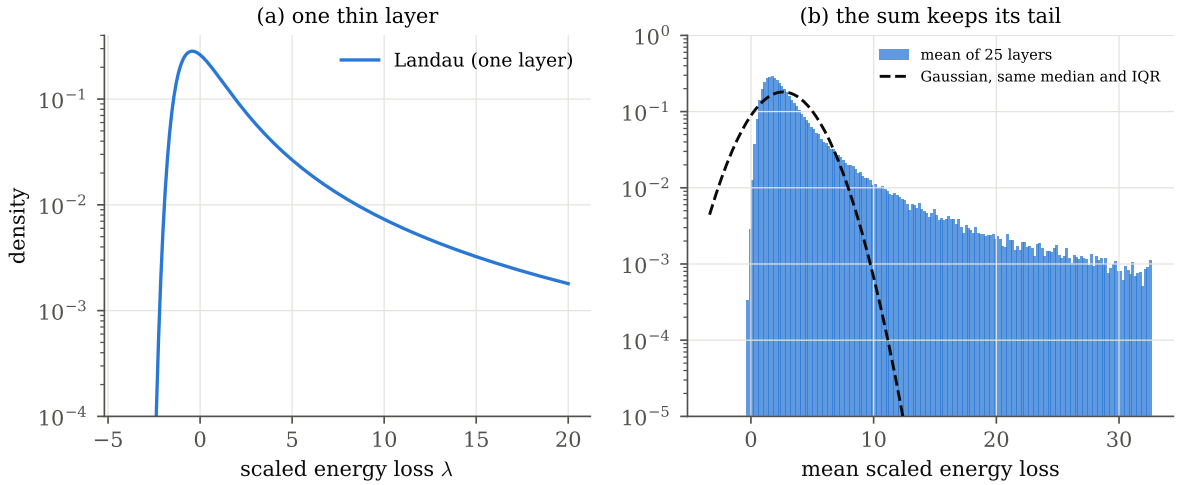

Figure 2.30: (a) The Landau density for one thin layer, on a logarithmic scale: a sharp peak and a long power-law tail to high energy loss. (b) The mean over 25 layers (histogram) against a Gaussian with the same median and interquartile range (dashed). The Gaussian describes the core and misses the tail by many orders of magnitude.

How research uses this. The sums of uniforms and exponentials *verify* a theorem whose answer we know. The same machinery becomes the research instrument when the ingredients are the actual detector effects. Cowan's warning [Cowan p. 148] is that a quoted "1σ" interval covers 68.3% only if the errors are Gaussian in their tails. The only way to learn the tails of a real resolution function (multiple Coulomb scattering has a Gaussian core and a single-scattering Rutherford tail) is a detailed Monte Carlo of the individual contributions. In cosmology the band-power $\widehat{C}_\ell$ is a sum of $2\ell+1$ squared Gaussian modes. At high ℓ the CLT makes it Gaussian; at low ℓ it is visibly skewed, and the likelihood of the CMB power spectrum has to be built with that skewness in it [16] (Chapters 7 and 8). Gravitational-wave detector noise is Gaussian in bulk, but "glitches" play the role of the Landau tail and must be vetoed or modelled.

Taxonomy: Does the CLT apply to my sum?

situation	what the sum does
independent, identical, finite variance	Gaussian; error $\approx 0.07\gamma_1/\sqrt{n}$ in probability
independent, different variances, none dominant	Gaussian (Lindeberg), variance $\sum \sigma_j^2$
one term dominates the variance	looks like that term
infinite variance (Breit–Wigner, Landau, power-law tails)	no Gaussian limit; a *stable* law with the same heavy tail
correlated terms	Gaussian only if correlations die off, with an *effective* n smaller than n
a *product* of positive factors	log-normal: apply the CLT to the logarithm (Section 2.15)
the *maximum*, not the sum	not Gaussian at all: extreme-value laws (Gumbel, Fréchet, Weibull)

2.11 The Gaussian, third way: the least committal assignment

A calibration note says: "the timing resolution of the chamber is 2 ns rms." Nothing more. No histogram, no list of contributions, no statement about tails. Yet the next step of every analysis is to write down a probability density for the timing residual, because a likelihood needs one. Which density should we write? The first two derivations of the Gaussian do not help here. De Moivre–Laplace needs a binomial, and the central limit theorem needs a sum of many independent pieces. Here we know neither. We know one number.

The third reason the Gaussian is everywhere is of a different kind. It is not about how the noise was produced. It is about what we *know*. The principle of maximum entropy picks out the one distribution that agrees with the facts we have and assumes nothing else. With it we can write a density when all we have is a mean, or a variance, or a covariance matrix. It shows why least squares, which is a Gaussian likelihood, is the natural fit when all we know is the size of the error bars. And it is the same variational principle that produces the Boltzmann distribution in statistical mechanics, so it rests on physics we already trust.

The question, stated in words: *among all distributions that satisfy a set of known averages, which one should we use, and what does it look like when the known average is a variance?*

2.11.1 A die with a loaded average

Start with Sivia's example, because it is discrete and we can see every number [Sivia p. 113–114]. A six-sided die has been rolled very many times. We are told only that the average number of dots was 4.5. What probabilities $p_1, \dots, p_6$ should we assign to the six faces?

The information is a single linear constraint,

$$\sum_{i=1}^{6} i\, p_i = 4.5, \qquad \sum_{i=1}^{6} p_i = 1. \tag{2.62}$$

The fair die, $p_i = 1/6$, has average 3.5, so it is ruled out. But infinitely many assignments remain. Here are three of them:

- $p = (0, 0, 0, \frac{1}{2}, \frac{1}{2}, 0)$: only faces 4 and 5 ever appear. The average is 4.5.

- $p = (0, 0, \frac{1}{2}, 0, 0, \frac{1}{2})$: only faces 3 and 6 appear. The average is $\frac{3}{2} + 3 = 4.5$.
- Something smooth that rises steadily from face 1 to face 6.

The first two are absurd. They claim that faces 1, 2, 3 and 6 (or 1, 2, 4 and 5) *never* appear, and nothing we were told supports that. They contain information we do not have. The third kind feels right. It leans towards the high faces just enough to move the average from 3.5 to 4.5, and otherwise treats the faces evenhandedly. To turn "feels right" into a rule, we need a number that measures how much an assignment commits to beyond the constraints. Then we pick the assignment for which that number is smallest.

2.11.2 Why the measure is the entropy: counting the ways

Sivia's "monkey argument" [Sivia p. 116–118] derives that number by counting, exactly as Boltzmann counted microstates. Imagine M boxes, one per possible outcome, and a team of monkeys throwing N pennies into them completely at random, each penny into each box with probability $1/M$. After the throw, box i holds n_i pennies, with $\sum_i n_i = N$, and we read off the candidate assignment

$$p_i = \frac{n_i}{N}. \tag{2.63}$$

If the candidate violates the constraint we throw it away. If it satisfies it we keep it. Repeat many times. The assignment the monkeys produce most often is the one we should use. *Why?* The monkeys have no preferences. So whatever structure the favoured assignment has beyond the constraint, it has only because overwhelmingly many throws produce it.

How often do the monkeys produce a given set of occupation numbers $\{n_i\}$? There are M^N equally likely sequences of throws (each of N pennies picks one of M boxes). The number of sequences that put n_1 pennies in box 1, n_2 in box 2, and so on, is the multinomial coefficient of Section 2.3. So the frequency is

$$F(\{p_i\}) = \frac{1}{M^N} \, \frac{N!}{n_1!\, n_2! \cdots n_M!}. \tag{2.64}$$

Now let N be very large, so that every n_i is large too, and use Stirling's formula in its crudest form $\ln n! \approx n \ln n - n$ (the leading terms of (2.40)):

$$\begin{aligned}
\ln F &\overset{(1)}{=} -N \ln M + \ln N! - \sum_{i=1}^{M} \ln n_i! \\
&\overset{(2)}{=} -N \ln M + \big(N \ln N - N\big) - \sum_{i=1}^{M} \big(n_i \ln n_i - n_i\big) \\
&\overset{(3)}{=} -N \ln M + N \ln N - \sum_{i=1}^{M} n_i \ln n_i \\
&\overset{(4)}{=} -N \ln M - \sum_{i=1}^{M} n_i \ln \frac{n_i}{N} \\
&\overset{(5)}{=} -N \ln M - N \sum_{i=1}^{M} p_i \ln p_i.
\end{aligned} \tag{2.65}$$

(1) Logarithm of (2.64): a quotient becomes a difference and a product becomes a sum.
(2) Stirling, $\ln n! \approx n \ln n - n$, for $N!$ and for each $n_i!$. The neglected terms grow only like $\ln n$, which is negligible next to n.

(3) The $-N$ and the $+\sum_i n_i = +N$ cancel.
(4) Write $N \ln N = \sum_i n_i \ln N$ (again because $\sum_i n_i = N$) and combine the two logarithms.
(5) Substitute $n_i = N p_i$ from (2.63).

The first term, $-N \ln M$, is the same for every candidate. So the monkeys produce the assignment $\{p_i\}$ with a frequency proportional to e^{NS}, where

$$S = -\sum_{i=1}^{M} p_i \ln p_i . \tag{2.66}$$

Because N is huge, e^{NS} is extremely sharply peaked. Two candidates whose values of S differ by only 0.01 are produced with frequencies in the ratio $e^{0.01N}$, which for $N = 10^4$ pennies is e^{100}. Among all candidates that pass the constraint, essentially only the one with the largest S ever comes out. This is the same mathematics that makes the equilibrium macrostate of a gas overwhelmingly the most probable: Boltzmann's $S = k_B \ln W$ with W the number of microstates is (2.65) with $k_B = 1$.

Unequal boxes. When the possible outcomes are not equally likely to begin with, the entropy acquires a reference distribution. So far all boxes were the same size. Suppose instead that the proposition "the face shows 3, 4, 5 or 6" is one box and "the face shows 1" and "shows 2" are two more. Then a fair monkey should hit the big box four times as often [Sivia p. 118–119]. If box i is hit with probability m_i (with $\sum_i m_i = 1$), the frequency (2.64) becomes the full multinomial probability $\frac{N!}{\prod_i n_i!} \prod_i m_i^{n_i}$, and the same Stirling steps give

$$\frac{1}{N} \ln F = -\sum_{i=1}^{M} p_i \ln \frac{p_i}{m_i} . \tag{2.67}$$

The only new term is $+\sum_i n_i \ln m_i = N \sum_i p_i \ln m_i$, and it joins the logarithm. When all $m_i = 1/M$ we recover (2.66) up to the constant $\ln M$.

Working definition 2.16 (entropy of a distribution, and the MaxEnt principle)

The **entropy** of a discrete assignment $\{p_i\}$ relative to a **measure** $\{m_i\}$ [the probabilities we would assign if we knew nothing at all, often equal] is

$$S = -\sum_i p_i \ln \frac{p_i}{m_i} .$$

For a continuous variable with density $p(x)$ and measure $m(x)$ it is [Sivia (5.29)]

$$S[p] = -\int p(x) \ln \frac{p(x)}{m(x)} \, \mathrm{d}x . \tag{2.68}$$

The **principle of maximum entropy** (MaxEnt): given **testable information** [constraints of the form $\mathbb{E}\, f_k(X) = F_k$, which any proposed distribution either obeys or violates], assign the distribution that maximises S subject to those constraints and to normalisation. *Operational recipe:* write $p \propto m\, e^{-\sum_k \lambda_k f_k}$ and solve the constraint equations for the multipliers λ_k.

The continuous formula needs the measure $m(x)$ because a density has units. If x is a time in ns and we switch to seconds, $p(x)$ is multiplied by 10^9, and $-\int p \ln p \, \mathrm{d}x$ shifts by $-\ln 10^9$. The ratio p/m has no units, since p and m transform the same way under a change of variable. So (2.68) is the same number in any coordinates [Sivia p. 119]. What is m? Maximising S with

only the normalisation constraint gives $p = m$ (Sivia's (5.30), and the case $K = 0$ of the recipe below). So m is the distribution of complete ignorance. For a location variable on the real line it is uniform, and then we may drop it. From now on we do so unless we say otherwise.

2.11.3 The recipe: Lagrange multipliers give exponentials

Maximising the entropy under known averages always gives an exponential. To see why, maximise S with K testable constraints $\sum_i p_i f_k(x_i) = F_k$, $k = 1, \dots, K$. We handle the constraints with Lagrange multipliers [one extra unknown per constraint, chosen at the end so the constraint holds]: find the stationary point of

$$Q = -\sum_i p_i \ln \frac{p_i}{m_i} + \lambda_0\Big(1 - \sum_i p_i\Big) + \sum_{k=1}^{K} \lambda_k \Big(F_k - \sum_i p_i f_k(x_i)\Big).$$

Differentiate with respect to one particular p_j. Only the terms containing p_j contribute:

$$\frac{\partial Q}{\partial p_j} \overset{(1)}{=} -\ln \frac{p_j}{m_j} - 1 - \lambda_0 - \sum_{k=1}^{K} \lambda_k f_k(x_j) \overset{(2)}{=} 0$$

$$\Longrightarrow \quad p_j \overset{(3)}{=} m_j\, e^{-(1+\lambda_0)} \exp\Big[-\sum_{k=1}^{K} \lambda_k f_k(x_j)\Big] \overset{(4)}{=} \frac{m_j}{Z} \exp\Big[-\sum_{k=1}^{K} \lambda_k f_k(x_j)\Big]. \tag{2.69}$$

(1) $\frac{\mathrm{d}}{\mathrm{d}p}(-p\ln(p/m)) = -\ln(p/m) - 1$, and each constraint is linear in p_j with coefficient -1 or $-f_k(x_j)$.
(2) A maximum of Q is a stationary point.
(3) Exponentiate and multiply by m_j.
(4) Normalisation fixes $e^{1+\lambda_0} = Z \equiv \sum_j m_j \exp[-\sum_k \lambda_k f_k(x_j)]$, the **partition function**.

Is it a maximum and not a minimum? Yes, and the only one. The second derivatives are $\partial^2 Q/\partial p_j \partial p_l = -\delta_{jl}/p_j < 0$, so Q is strictly concave, and a concave function on the convex set of allowed $\{p_i\}$ has exactly one stationary point, its global maximum. There is no risk of picking a saddle.

Every physicist has seen (2.69) before. With one constraint, the mean energy $\sum_i p_i E_i = U$, it reads $p_j = e^{-\beta E_j}/Z$, the Boltzmann distribution, with the Lagrange multiplier β playing the role of $1/k_B T$. Temperature *is* the Lagrange multiplier that enforces a given mean energy. Jaynes's reading of statistical mechanics, which Sivia summarises [Sivia p. 118], is exactly this: the canonical ensemble is the least committal assignment compatible with a known average energy.

Example: the die. For the die, $m_i = 1/6$ and there is one constraint, $f(i) = i$, $F = 4.5$. Writing $\lambda \equiv -\lambda_1$ for convenience, (2.69) says

$$p_i = \frac{e^{\lambda i}}{Z(\lambda)}, \qquad Z(\lambda) = \sum_{j=1}^{6} e^{\lambda j}, \qquad \sum_{i=1}^{6} i\, p_i = \frac{\mathrm{d}\ln Z}{\mathrm{d}\lambda} = 4.5. \tag{2.70}$$

This equation for λ has exactly one solution. The mean $\mathrm{d}\ln Z/\mathrm{d}\lambda$ increases with λ, because its derivative $\mathrm{d}^2 \ln Z/\mathrm{d}\lambda^2 = \sum i^2 p_i - (\sum i p_i)^2$ is a variance and so positive. At $\lambda = 0$ the mean is 3.5, and as $\lambda \to \infty$ it tends to 6. So it passes 4.5 exactly once, and a root finder gives $\lambda = 0.3710$. The probabilities are

$$(p_1, \dots, p_6) = (0.0544,\ 0.0788,\ 0.1142,\ 0.1654,\ 0.2398,\ 0.3475),$$

a geometric progression with ratio $e^{\lambda} \approx 1.45$: every step up in dots multiplies the probability by the same factor (Figure 2.31a, which reproduces Sivia's Fig. 5.2). The entropy is $S = 1.6136$, below the fair-die value $\ln 6 = 1.7918$: the constraint costs entropy, as it must.

Checking by brute force. No random die with the same average beats the MaxEnt die. The script draws 4×10^6 random assignments uniformly over all possible dice (a Dirichlet$(1, \ldots, 1)$ distribution, which we meet in Section 2.15). It keeps the 7888 whose mean lies within 0.005 of 4.5, and Figure 2.31b histograms their entropies. The largest entropy among them is 1.6139 (for a die of mean 4.4966), against 1.6136 for the MaxEnt die. The two are very close, and a random die can even come out a hair ahead. That is not a defeat: the window lets in means slightly below 4.5, closer to the fair 3.5, and a smaller tilt costs less entropy. Comparing like with like, each candidate against the MaxEnt die of *its own* mean, every one falls short, by at least 9.6×10^{-4}.

Listing 2.15: The MaxEnt die, and random dice with the same mean (`code/ch02/23_maxent.py`)

```
38 def die_mean(lam):
39     w = np.exp(lam * faces)
40     return np.sum(faces * w) / np.sum(w)
41
42
43 lam = optimize.brentq(lambda l: die_mean(l) - target, -5, 5)
44 p_me = np.exp(lam * faces)
45 p_me /= p_me.sum()
46 S_me = -np.sum(p_me * np.log(p_me))
47
48 # random distributions on the 6-simplex with mean 4.5 (accept within 0.005)
49 cand = rng.dirichlet(np.ones(6), size=4_000_000)
50 keep = cand[np.abs(cand @ faces - target) < 0.005]
51 S_rand = -np.sum(np.where(keep > 0, keep * np.log(keep), 0.0), axis=1)
```

Lines 38–40 compute the mean $\sum_i i\, p_i$ of the exponential family (2.70) for a given λ. Line 43 solves "mean = 4.5" for λ with Brent's bracketing root finder; the monotonicity argument above is what guarantees that the bracket $[-5, 5]$ contains exactly one root. Lines 49–51 draw random dice, keep those with the right mean, and compute their entropies, using the convention $0 \ln 0 = 0$.

Example: the kangaroo problem. Is entropy really special, or would any function that rewards spreading out do? Sivia's kangaroo problem answers this [Sivia p. 114–116]. We are told that one third of all kangaroos have blue eyes and one third are left-handed. What fraction are both? Call the four probabilities p_1 (blue, left), p_2 (blue, right), p_3 (not blue, left), p_4 (not blue, right). The two facts and normalisation leave one free number, $x = p_1$ (Figure 2.32a):

$$p_1 = x, \quad p_2 = \tfrac{1}{3} - x, \quad p_3 = \tfrac{1}{3} - x, \quad p_4 = \tfrac{1}{3} + x, \qquad 0 \le x \le \tfrac{1}{3}.$$

Common sense says $x = 1/9$: with no information about a link between eye colour and handedness, we should not invent one, and independence gives $\frac{1}{3} \times \frac{1}{3}$. Maximise the entropy:

$$\begin{aligned} \frac{\mathrm{d}S}{\mathrm{d}x} &\overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}x}\Big[-x \ln x - 2\big(\tfrac{1}{3} - x\big) \ln\big(\tfrac{1}{3} - x\big) - \big(\tfrac{1}{3} + x\big) \ln\big(\tfrac{1}{3} + x\big)\Big] \\ &\overset{(2)}{=} -\ln x - 1 + 2 \ln\big(\tfrac{1}{3} - x\big) + 2 - \ln\big(\tfrac{1}{3} + x\big) - 1 \\ &\overset{(3)}{=} \ln \frac{(\frac{1}{3} - x)^2}{x(\frac{1}{3} + x)}. \end{aligned} \tag{2.71}$$

(1) Entropy (2.66) of the four-cell table.

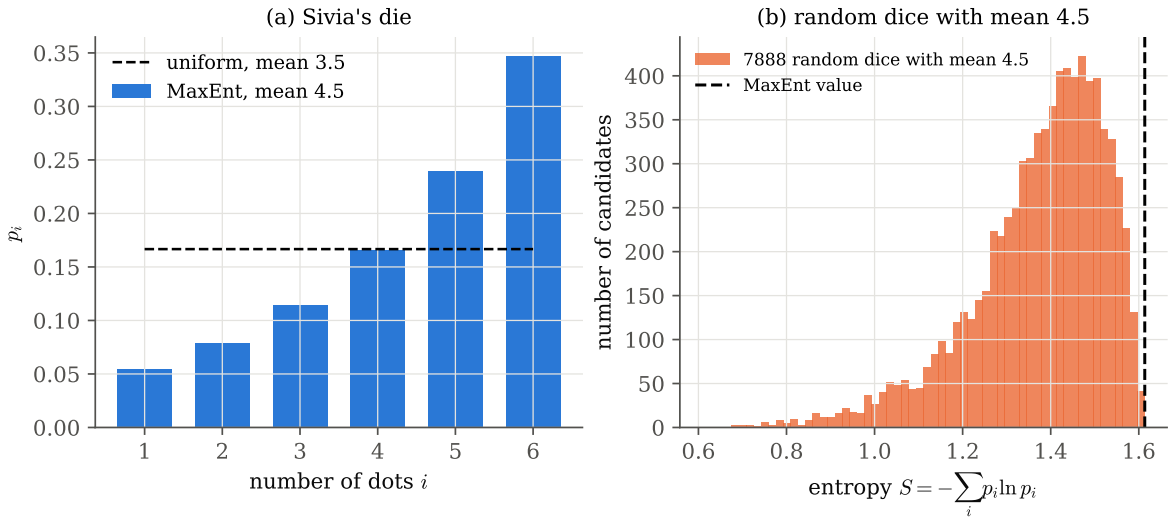

Figure 2.31: (a) The maximum-entropy die for a known average of 4.5 (bars) against the fair die (dashed). The probabilities grow by a constant factor from face to face. (b) Entropies of several thousand randomly drawn dice whose average is also 4.5. They pile up to the left of the MaxEnt value (dashed line), and compared with the MaxEnt die of its own average every one falls short: every other assignment assumes something extra.

(2) $\frac{\mathrm{d}}{\mathrm{d}x}(-u\ln u) = -(\ln u + 1)\frac{\mathrm{d}u}{\mathrm{d}x}$, with $\frac{\mathrm{d}u}{\mathrm{d}x} = +1, -1, -1, +1$ for the four cells.
(3) The constants cancel ($-1 + 2 - 1 = 0$) and the logarithms combine.

Setting this to zero gives $(\frac{1}{3} - x)^2 = x(\frac{1}{3} + x)$, that is $\frac{1}{9} - \frac{2}{3}x + x^2 = \frac{1}{3}x + x^2$, so $x = \frac{1}{9}$. Entropy reproduces independence exactly.

Other plausible-looking criteria do not. Maximising $-\sum p_i^2$ gives $\frac{\mathrm{d}}{\mathrm{d}x}\left[x^2 + 2(\frac{1}{3}-x)^2 + (\frac{1}{3}+x)^2\right] = 8x - \frac{2}{3} = 0$, so $x = \frac{1}{12}$: a negative correlation nobody asked for. The script maximises all four of Sivia's candidates numerically and finds $x = 0.1111$ (entropy), 0.0833 ($-\sum p_i^2$), 0.1301 ($\sum \ln p_i$) and 0.1218 ($\sum \sqrt{p_i}$), reproducing his Table 5.1. Only functions monotonically related to S give $1/9$ (Sivia quotes Skilling for the proof), and that is the strongest argument that entropy is the right measure of "assuming nothing extra".

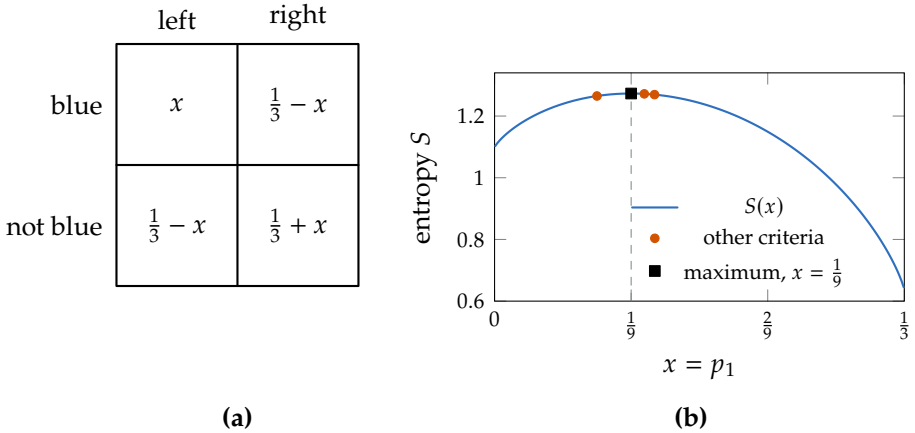

Figure 2.32: The kangaroo problem. (a) The two known marginals, one third blue-eyed and one third left-handed, leave a single free number x in the 2×2 table. (b) The entropy of the table as a function of x. It peaks at $x = 1/9$, the independent answer. The orange dots mark the maximisers of Sivia's three alternative criteria, which all build in a correlation that the information does not contain.

2.11.4 Continuous MaxEnt: a variance gives a Gaussian

Back to the timing residual of the calibration note, where all we were given was an rms of 2 ns. The testable information is that the residual x has mean μ and variance σ^2, and x can be any real number. The question: which density has the largest entropy under these two constraints? The continuous version of the recipe replaces sums by integrals and the partial derivative by a functional derivative [the change of Q when p is changed by a small bump δp at one point x, divided by the area of the bump]. We need

$$Q[p] = -\int p \ln p \, \mathrm{d}x + \lambda_0\Big(1 - \int p \, \mathrm{d}x\Big) + \lambda_1\Big(\sigma^2 - \int (x-\mu)^2 p \, \mathrm{d}x\Big)$$

to be stationary [Sivia p. 121–122]. Then

$$\begin{aligned}
\frac{\delta Q}{\delta p(x)} &\overset{(1)}{=} -\ln p(x) - 1 - \lambda_0 - \lambda_1 (x-\mu)^2 \overset{(2)}{=} 0 \quad \Longrightarrow \quad p(x) = e^{-1-\lambda_0}\, e^{-\lambda_1 (x-\mu)^2}, \\
1 &\overset{(3)}{=} e^{-1-\lambda_0} \int_{-\infty}^{\infty} e^{-\lambda_1 (x-\mu)^2} \mathrm{d}x \overset{(4)}{=} e^{-1-\lambda_0} \sqrt{\frac{\pi}{\lambda_1}}, \\
\sigma^2 &\overset{(5)}{=} \sqrt{\frac{\lambda_1}{\pi}} \int_{-\infty}^{\infty} (x-\mu)^2 e^{-\lambda_1 (x-\mu)^2} \mathrm{d}x \overset{(6)}{=} \frac{1}{2\lambda_1} \quad \Longrightarrow \quad p(x) = \frac{1}{\sqrt{2\pi\sigma^2}}\, e^{-(x-\mu)^2/2\sigma^2}.
\end{aligned} \tag{2.72}$$

(1) The same differentiation as in (2.69), applied pointwise: changing p near x changes each integral by its integrand at x times the size of the change.
(2) Stationarity; then solve for p. For the integral to exist we need $\lambda_1 > 0$.
(3) The normalisation constraint.
(4) The Gaussian integral (2.36), rescaled: substitute $z = \sqrt{2\lambda_1}(x-\mu)$.
(5) The variance constraint, with the constant from line (4), $e^{-1-\lambda_0} = \sqrt{\lambda_1/\pi}$.
(6) The normalised density $\sqrt{\lambda_1/\pi}\, e^{-\lambda_1(x-\mu)^2}$ is a Gaussian of variance $1/(2\lambda_1)$, by (2.38). Solving $\sigma^2 = 1/(2\lambda_1)$ gives $\lambda_1 = 1/(2\sigma^2)$.

So the maximum-entropy density with a given mean and variance is the Gaussian $\mathcal{N}(\mu, \sigma^2)$ of (2.35). Nothing was assumed about how the residual was produced.

A second proof, and a proof that it is the maximum. The Lagrange argument finds a stationary point. A short inequality shows directly that no other density with the same variance does better. We use one elementary fact, $\ln t \le t - 1$ for $t > 0$ (the tangent line at $t = 1$ lies above the concave logarithm). Let p be any density with mean μ and variance σ^2, and let g be the Gaussian with the same two numbers. Then

$$\begin{aligned}
S[p] - S[g] &\overset{(1)}{=} -\int p \ln p \, \mathrm{d}x + \int g \ln g \, \mathrm{d}x \\
&\overset{(2)}{=} -\int p \ln p \, \mathrm{d}x + \int p \ln g \, \mathrm{d}x \\
&\overset{(3)}{=} \int p \ln \frac{g}{p} \, \mathrm{d}x \\
&\overset{(4)}{\le} \int p\Big(\frac{g}{p} - 1\Big)\mathrm{d}x \overset{(5)}{=} \int g \, \mathrm{d}x - \int p \, \mathrm{d}x = 0.
\end{aligned} \tag{2.73}$$

(1) Definition (2.68) with uniform measure.
(2) $\ln g(x) = -\tfrac{1}{2}\ln(2\pi\sigma^2) - (x-\mu)^2/2\sigma^2$ is a constant plus a multiple of $(x-\mu)^2$. Its average is therefore fixed by the normalisation and the variance alone, and p and g share both.

(3) Combine the two integrals.
(4) $\ln t \le t - 1$ with $t = g/p$, at every x where $p > 0$.
(5) Both densities integrate to one.

Equality in step (4) needs $g/p = 1$ everywhere, so the Gaussian is the *unique* maximiser. The quantity $\int p \ln(p/g)\,dx \ge 0$ we just met is the **Kullback–Leibler divergence** of p from g. It will return in Chapter 3 (maximum likelihood minimises it) and in Chapter 5. The value itself is

$$S[g] = -\int g \ln g \,dx \overset{(1)}{=} \tfrac{1}{2}\ln(2\pi\sigma^2) + \frac{\mathbb{E}(x-\mu)^2}{2\sigma^2} = \tfrac{1}{2}\ln\bigl(2\pi e\sigma^2\bigr),$$

where (1) inserts $\ln g$ from step (2) above.

Key idea: The third origin of the Gaussian

Of all densities on the real line with a given mean μ and variance σ^2, the Gaussian $\mathcal{N}(\mu, \sigma^2)$ has the largest entropy, $\frac{1}{2}\ln(2\pi e\sigma^2)$. Assigning it claims nothing about the data except the mean and the variance. Assigning anything else claims more.

Example: five densities with unit variance. The script evaluates the entropy of five familiar densities, each scaled to variance one: uniform 1.2425, Laplace 1.3466, triangular 1.3959, logistic 1.4046, Gaussian $1.4189 = \frac{1}{2}\ln(2\pi e)$. The Gaussian wins, but the others are close. The logistic is only 0.014 behind: two densities with nearly the same core can have nearly the same entropy. Figure 2.33 shows three of the five, and why they lose. The uniform "wastes" its variance by having no tails at all. The Laplace concentrates probability in a cusp and pays for its variance with long exponential tails. The Gaussian spreads its probability in the most even way the variance allows.

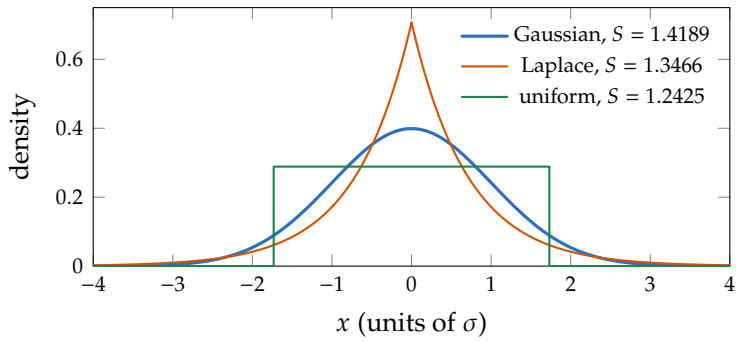

Figure 2.33: Three densities with the same mean (0) and variance (1). The uniform box stops dead at $\pm\sqrt{3}$; the Laplace density has a sharp peak and fat exponential tails. Among all densities with this variance the Gaussian has the largest entropy, and the numbers in the legend show by how much it beats these two.

2.11.5 The family tree: other constraints, other distributions

Each common distribution is the MaxEnt answer to some piece of partial knowledge. The recipe (2.69) works like a machine: feed in the constraint functions f_k and the range of x, and out comes $p \propto m\, e^{-\sum \lambda_k f_k}$. Sivia runs it for the common cases [Sivia p. 120–125]:

- *Nothing but the range* $[a, b]$. Then $p = m$, the uniform density $1/(b-a)$ (Bernoulli's principle of insufficient reason).

- *A mean μ, with $x \geq 0$.* One constraint $f = x$, so $p \propto e^{-\lambda_1 x}$. Normalisation on $[0, \infty)$ gives $\lambda_1 e^{-\lambda_1 x}$ and the mean gives $\lambda_1 = 1/\mu$: the exponential $p(x) = \mu^{-1} e^{-x/\mu}$ [Sivia (5.33)], the waiting-time law of (2.18). The same computation on the line with a mean alone fails: $e^{-\lambda_1 x}$ cannot be normalised on $(-\infty, \infty)$, which is the recipe's way of saying that a mean alone does not specify a spread.

- *A variance on the whole line.* The Gaussian, (2.72).

- *A mean absolute deviation $\mathbb{E}\,|x - \mu| = \epsilon$.* $f = |x - \mu|$ gives the Laplace (double-exponential) density $\frac{1}{2\epsilon} e^{-|x-\mu|/\epsilon}$ [Sivia (5.39)–(5.40)]. Its log-likelihood is $-\sum |x_k - \mu_k|/\epsilon_k$: the ℓ_1 "least absolute deviations" fit, which is more robust to outliers than least squares.

- *Many variables with known individual variances.* With N data x_k, predictions μ_k and known $\mathbb{E}(x_k - \mu_k)^2 = \sigma_k^2$, the multidimensional version gives the product of Gaussians [Sivia (5.36)–(5.38)]

$$p(\{x_k\}) = \prod_{k=1}^{N} \frac{1}{\sqrt{2\pi}\sigma_k} \exp\Big[-\frac{(x_k - \mu_k)^2}{2\sigma_k^2}\Big], \tag{2.74}$$

  which is exactly the likelihood behind least squares, $-2 \ln p = \chi^2 + \text{const}$. From the MaxEnt point of view least squares does not assume that the noise *is* Gaussian. It is the honest likelihood when all we know is the size of each error bar. If we also know the covariances $\mathbb{E}(x_j - \mu_j)(x_k - \mu_k)$, the same recipe returns the correlated multivariate Gaussian of the next section.

- *A mean count $\mathbb{E}\,N = \mu$ of events in an interval.* Here the measure matters. Cut the interval into M tiny cells, each of which can hold an event or not. The number of cell patterns giving N events among M indistinguishable cells is $M^N/N!$ for $M \gg N$, so $m(N) \propto M^N/N!$ [Sivia (5.43)]. Then

$$p(N) \propto \frac{M^N}{N!} e^{-\lambda N} = \frac{(Me^{-\lambda})^N}{N!} \quad \Longrightarrow \quad p(N) = e^{-\mu} \frac{\mu^N}{N!},$$

  where normalisation, $\sum_N (Me^{-\lambda})^N/N! = e^{Me^{-\lambda}}$, and the mean condition identify $Me^{-\lambda} = \mu$. The unknown M drops out, and we recover the Poisson distribution of Section 2.4 from knowledge of the mean alone.

- *The mean kinetic energy of a gas molecule.* The constraint $\mathbb{E}\,\frac{1}{2} m|\boldsymbol{v}|^2 = \frac{3}{2} k_B T$ with uniform measure on velocity space gives a Gaussian for each velocity component with variance $k_B T/m$. The speed distribution that follows is the Maxwell–Boltzmann law of Section 2.15.

Watch out: MaxEnt is a statement about knowledge, not about the noise

The MaxEnt Gaussian is the best assignment *given only* a variance. If the real residuals have a Landau tail (Section 2.10.6) or a Breit–Wigner shape, the Gaussian will misjudge the tails badly, and the cure is not to argue about entropy but to put the extra knowledge in as a constraint (a known tail fraction, a known fourth moment) or to model the mechanism. And when the variance is infinite, as for a Breit–Wigner, there is no variance constraint to impose in the first place.

How the three origins fit together. The three reasons for the Gaussian agree, and that is not a coincidence. De Moivre–Laplace and the central limit theorem are statements about *mechanisms*: many small independent contributions added together. MaxEnt is a statement about *information*: we know a variance and nothing else. The link is that adding independent

pieces and rescaling to fixed variance can only increase the entropy (convolution smooths). So the central limit theorem is the dynamics that drives a sum towards the maximum-entropy state, like a gas relaxing to equilibrium. When a physicist writes "Gaussian errors" she is usually relying on all of them at once: the CLT for why the errors should be close to Gaussian, and MaxEnt for why, knowing only the error bar, nothing else would be more honest.

The same principle supplies the forward model $P(\boldsymbol{d} \mid \boldsymbol{\theta})$, the probability of the data $\boldsymbol{d}$ given the parameters $\boldsymbol{\theta}$, whenever only the covariance of the noise is known. The prior assignments of Chapter 5 use it too. And the MaxEnt die's exponential form is the first example of the exponential families that make maximum likelihood and conjugate priors tractable (Chapters 3 and 5).

2.12 Many correlated Gaussians: the multivariate normal

Most measurements come as several numbers that move together, and one object describes them all: the multivariate Gaussian. A straight-line track fit returns two numbers, an intercept and a slope, and they are never independent: tilt the line a little and the intercept has to move to keep the line going through the hits. A fit of a CMB power spectrum returns $\Omega_m h^2$ and n_s, and they, too, move together. A CMB temperature map is a list of 10^6 pixel values, each Gaussian, and neighbouring pixels are strongly correlated. A stretch of gravitational-wave strain is a list of 10^5 samples whose correlations are set by the detector's noise spectrum. The Fisher matrix of Chapter 10 approximates every posterior by a multivariate Gaussian, and a Gaussian random field (Chapter 7) is a multivariate Gaussian with very many components.

Four things about it are used constantly. How to *sample* it, which follows from building it out of independent standard normals. The shape of its contours, the ellipses of every parameter-estimation plot. What fraction of the probability each ellipse contains. And two operations: *marginalising* (averaging out a nuisance variable) and *conditioning* (fixing one variable at a known value).

The questions, in words: *what is the joint density of several correlated Gaussian quantities, how do we draw from it, and what are the distributions of a subset of them, either ignoring the rest or with the rest held fixed?*

2.12.1 Building it: a linear map of independent standard normals

Start from what we know. Let $Z_1, \dots, Z_k$ be independent $\mathcal{N}(0,1)$ variables and collect them into a column vector $\boldsymbol{Z}$. Independence means the joint density is the product of the one-dimensional densities [Wasserman p. 40]:

$$p_{\boldsymbol{Z}}(\boldsymbol{z}) = \prod_{j=1}^{k} \frac{e^{-z_j^2/2}}{\sqrt{2\pi}} = \frac{1}{(2\pi)^{k/2}} \exp\!\left(-\tfrac{1}{2}\boldsymbol{z}^{\mathsf{T}}\boldsymbol{z}\right). \tag{2.75}$$

Its contours, $\boldsymbol{z}^{\mathsf{T}}\boldsymbol{z} = \text{const}$, are spheres, and its components are uncorrelated. Correlations appear when we mix the components linearly. Take a fixed invertible $k \times k$ matrix $\mathbf{A}$ and a fixed vector $\boldsymbol{\mu}$ and define

$$\boldsymbol{X} = \boldsymbol{\mu} + \mathbf{A}\boldsymbol{Z}. \tag{2.76}$$

Its mean is $\mathbb{E}\,\boldsymbol{X} = \boldsymbol{\mu} + \mathbf{A}\,\mathbb{E}\,\boldsymbol{Z} = \boldsymbol{\mu}$. Its covariance matrix [the $k \times k$ table of all $\mathrm{Cov}(X_i, X_j)$, with the variances on the diagonal] is

$$\mathbf{C} \equiv \mathbb{E}\big[(\boldsymbol{X}-\boldsymbol{\mu})(\boldsymbol{X}-\boldsymbol{\mu})^{\mathsf{T}}\big] \overset{(1)}{=} \mathbb{E}\big[\mathbf{A}\boldsymbol{Z}\boldsymbol{Z}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\big] \overset{(2)}{=} \mathbf{A}\,\mathbb{E}\big[\boldsymbol{Z}\boldsymbol{Z}^{\mathsf{T}}\big]\mathbf{A}^{\mathsf{T}} \overset{(3)}{=} \mathbf{A}\mathbf{A}^{\mathsf{T}}. \tag{2.77}$$

(1) $X - \mu = \mathbf{A}Z$, and $(\mathbf{A}Z)^{\mathsf{T}} = Z^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}$.
(2) $\mathbf{A}$ is not random, and expectation is linear, so it can be taken outside on both sides.
(3) $\mathbb{E}(Z_i Z_j) = \delta_{ij}$: unit variances and, by independence, zero covariances. So $\mathbb{E}\, ZZ^{\mathsf{T}} = \mathbb{1}$.

We know the mean and covariance of X; now we want its density. Change variables. The map $z \mapsto x = \mu + \mathbf{A}z$ is linear with inverse $z = \mathbf{A}^{-1}(x - \mu)$. A small box of volume $\mathrm{d}^k z$ is mapped to a parallelepiped of volume $|\det \mathbf{A}|\, \mathrm{d}^k z$, so probability conservation, $p_X\, \mathrm{d}^k x = p_Z\, \mathrm{d}^k z$, gives

$$\begin{aligned} p_X(x) &\overset{(1)}{=} p_Z\big(\mathbf{A}^{-1}(x-\mu)\big)\, \frac{1}{|\det \mathbf{A}|} \\ &\overset{(2)}{=} \frac{1}{(2\pi)^{k/2}|\det \mathbf{A}|} \exp\Big[-\tfrac{1}{2}(x-\mu)^{\mathsf{T}}(\mathbf{A}^{-1})^{\mathsf{T}}\mathbf{A}^{-1}(x-\mu)\Big] \\ &\overset{(3)}{=} \frac{1}{(2\pi)^{k/2}(\det \mathbf{C})^{1/2}} \exp\Big[-\tfrac{1}{2}(x-\mu)^{\mathsf{T}}\mathbf{C}^{-1}(x-\mu)\Big]. \end{aligned} \tag{2.78}$$

(1) The multidimensional change-of-variables rule: the Jacobian of the inverse map is $\det \mathbf{A}^{-1} = 1/\det \mathbf{A}$.
(2) Insert (2.75) with $z = \mathbf{A}^{-1}(x - \mu)$, so $z^{\mathsf{T}}z = (x-\mu)^{\mathsf{T}}(\mathbf{A}^{-1})^{\mathsf{T}}\mathbf{A}^{-1}(x-\mu)$.
(3) $(\mathbf{A}^{-1})^{\mathsf{T}}\mathbf{A}^{-1} = (\mathbf{A}\mathbf{A}^{\mathsf{T}})^{-1} = \mathbf{C}^{-1}$, and $\det \mathbf{C} = \det \mathbf{A}\, \det \mathbf{A}^{\mathsf{T}} = (\det \mathbf{A})^2$.

The matrix $\mathbf{A}$ has disappeared: only $\mathbf{C} = \mathbf{A}\mathbf{A}^{\mathsf{T}}$ is left. So the distribution is fixed by the mean and the covariance alone, and any two matrices with the same $\mathbf{A}\mathbf{A}^{\mathsf{T}}$ give the same distribution. That is the density quoted by all our sources [Wasserman (2.10)], [Cowan (2.28)].

Working definition 2.17 (multivariate normal distribution)

A random vector $X \in \mathbb{R}^k$ is **multivariate normal**, $X \sim \mathcal{N}(\mu, \mathbf{C})$, if its density is (2.78), where μ is its mean vector and $\mathbf{C}$ its covariance matrix, which must be symmetric and **positive definite** [$a^{\mathsf{T}}\mathbf{C}a > 0$ for every nonzero vector a. This says that every linear combination $a^{\mathsf{T}}X$ has a nonzero variance]. It has k means plus $k(k+1)/2$ independent entries of $\mathbf{C}$ as parameters [Cowan p. 33]. *Operational recipe (sampling):* factor $\mathbf{C} = \mathbf{L}\mathbf{L}^{\mathsf{T}}$ (Cholesky, $\mathbf{L}$ lower triangular, or the symmetric square root $\mathbf{C}^{1/2}$ of [Wasserman Thm 2.43]), draw k independent standard normals z, and return $\mu + \mathbf{L}z$. *Inverse (whitening):* $\mathbf{L}^{-1}(X - \mu) \sim \mathcal{N}(0, \mathbb{1})$.

Why must $\mathbf{C}$ be positive definite? Because $a^{\mathsf{T}}\mathbf{C}a = \mathrm{Var}(a^{\mathsf{T}}X)$, and a variance cannot be negative. If it is zero for some $a \neq 0$, then $a^{\mathsf{T}}X$ is a constant: one component is an exact linear function of the others, the distribution lives on a lower-dimensional plane, $\det \mathbf{C} = 0$, and (2.78) does not exist. (A fitted $\mathbf{C}$ that is singular or nearly singular almost always means a parameter that the data cannot distinguish from a combination of the others.)

Example: two dimensions, written out. For $k = 2$ write $\mathbf{C} = \begin{pmatrix} \sigma_x^2 & \rho\sigma_x\sigma_y \\ \rho\sigma_x\sigma_y & \sigma_y^2 \end{pmatrix}$, where $\rho = \mathrm{Cov}(x,y)/(\sigma_x\sigma_y)$ is the **correlation coefficient**, $-1 < \rho < 1$. The inverse of a 2×2 matrix is its adjugate over its determinant, so with $u = (x-\mu_x)/\sigma_x$ and $v = (y-\mu_y)/\sigma_y$,

$$\begin{aligned} (x-\mu)^{\mathsf{T}}\mathbf{C}^{-1}(x-\mu) &\overset{(1)}{=} \frac{1}{\sigma_x^2\sigma_y^2(1-\rho^2)} \begin{pmatrix} x-\mu_x & y-\mu_y \end{pmatrix} \begin{pmatrix} \sigma_y^2 & -\rho\sigma_x\sigma_y \\ -\rho\sigma_x\sigma_y & \sigma_x^2 \end{pmatrix} \begin{pmatrix} x-\mu_x \\ y-\mu_y \end{pmatrix} \\ &\overset{(2)}{=} \frac{u^2 - 2\rho uv + v^2}{1-\rho^2}, \end{aligned} \tag{2.79}$$

(1) $\det \mathbf{C} = \sigma_x^2\sigma_y^2 - \rho^2\sigma_x^2\sigma_y^2 = \sigma_x^2\sigma_y^2(1-\rho^2)$, and the adjugate swaps the diagonal entries and flips the sign of the off-diagonal ones.

(2) Multiply out: the three terms are $\sigma_y^2(x-\mu_x)^2$, $-2\rho\sigma_x\sigma_y(x-\mu_x)(y-\mu_y)$ and $\sigma_x^2(y-\mu_y)^2$; dividing each by $\sigma_x^2\sigma_y^2$ turns them into u^2, $-2\rho uv$, v^2.

and $(\det \mathbf{C})^{1/2} = \sigma_x\sigma_y\sqrt{1-\rho^2}$. This gives the bivariate normal density of [Cowan (2.30)] and [CasellaBerger Def. 4.5.10],

$$p(x,y) = \frac{1}{2\pi\sigma_x\sigma_y\sqrt{1-\rho^2}} \exp\Big[-\frac{u^2 - 2\rho uv + v^2}{2(1-\rho^2)}\Big]. \tag{2.80}$$

Our running example, used by the script and in the rest of this section, has $\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.8$ (and means $\mu_x = 1$, $\mu_y = 2$), so $\mathbf{C} = \begin{pmatrix} 1 & 1.6 \\ 1.6 & 4 \end{pmatrix}$ and $\det \mathbf{C} = 4 - 2.56 = 1.44$. Its Cholesky factor is $\mathbf{L} = \begin{pmatrix} 1 & 0 \\ 1.6 & 1.2 \end{pmatrix}$; check: $\mathbf{L}\mathbf{L}^\mathsf{T} = \begin{pmatrix} 1 & 1.6 \\ 1.6 & 1.6^2 + 1.2^2 \end{pmatrix} = \mathbf{C}$. So a sample is $x = \mu_x + z_1$, $y = \mu_y + 1.6z_1 + 1.2z_2$: the y component copies 80% of the x fluctuation, in units of its own width, and adds fresh noise of its own. That sentence is what a correlation of 0.8 *means* mechanically.

2.12.2 The shape: ellipses and how much they contain

The contours of the multivariate Gaussian are ellipsoids, and rotating to their axes removes the correlations. To see this, note that the density (2.78) depends on $\boldsymbol{x}$ only through the quadratic form

$$Q(\boldsymbol{x}) = (\boldsymbol{x}-\boldsymbol{\mu})^\mathsf{T}\mathbf{C}^{-1}(\boldsymbol{x}-\boldsymbol{\mu}),$$

so its contours are the surfaces $Q = c$. To find their shape, diagonalise $\mathbf{C}$. A real symmetric matrix has an orthonormal basis of eigenvectors: $\mathbf{C} = \mathbf{R}\boldsymbol{\Lambda}\mathbf{R}^\mathsf{T}$ with $\mathbf{R}$ a rotation whose columns are the eigenvectors and $\boldsymbol{\Lambda} = \mathrm{diag}(\lambda_1, \dots, \lambda_k)$, all $\lambda_i > 0$ by positive definiteness. In rotated coordinates $\boldsymbol{y} = \mathbf{R}^\mathsf{T}(\boldsymbol{x}-\boldsymbol{\mu})$,

$$Q \overset{(1)}{=} \boldsymbol{y}^\mathsf{T}\boldsymbol{\Lambda}^{-1}\boldsymbol{y} \overset{(2)}{=} \sum_{i=1}^{k} \frac{y_i^2}{\lambda_i} = c, \tag{2.81}$$

(1) $\mathbf{C}^{-1} = \mathbf{R}\boldsymbol{\Lambda}^{-1}\mathbf{R}^\mathsf{T}$ because $\mathbf{R}^{-1} = \mathbf{R}^\mathsf{T}$.
(2) $\boldsymbol{\Lambda}^{-1}$ is diagonal.

an ellipsoid with principal axes along the eigenvectors and semi-axes $\sqrt{c\lambda_i}$. In the y coordinates the components are independent, $y_i \sim \mathcal{N}(0, \lambda_i)$: rotating to the eigenbasis *removes* the correlations. This is the same step as finding the normal modes of coupled oscillators.

For the running example ($\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.8$), the eigenvalues solve $\lambda^2 - (\mathrm{tr}\,\mathbf{C})\lambda + \det\mathbf{C} = \lambda^2 - 5\lambda + 1.44 = 0$, so $\lambda = \frac{1}{2}\big(5 \pm \sqrt{25 - 5.76}\big)$, that is $\lambda_1 = 4.693$ and $\lambda_2 = 0.307$. The major axis, from $(1-\lambda_1)v_1 + 1.6v_2 = 0$, has slope $v_2/v_1 = (\lambda_1 - 1)/1.6 = 2.31$, an angle of 66.6° from the x axis.

How much probability is inside an ellipse? The question reduces to one about the length of a standard normal vector. Whiten: $\boldsymbol{Z} = \mathbf{L}^{-1}(\boldsymbol{X} - \boldsymbol{\mu})$, with $\mathbf{L}$ the Cholesky factor of $\mathbf{C}$, is a vector of independent standard normals, and $Q = \boldsymbol{Z}^\mathsf{T}\boldsymbol{Z}$ (the calculation in step (3) of (2.78), read backwards). So the probability inside $Q \le c$ is the probability that a k-dimensional standard normal vector has squared length at most c. In Section 2.13 we will show that this squared length has the χ^2_k distribution [Wasserman Thm 2.44(4)]. For $k = 2$ we can do it at once in polar coordinates, exactly as in (2.36):

$$\mathrm{P}(Q \le c) \overset{(1)}{=} \int_0^{2\pi}\int_0^{\sqrt{c}} \frac{e^{-r^2/2}}{2\pi}\, r\,\mathrm{d}r\,\mathrm{d}\phi \overset{(2)}{=} \Big[-e^{-r^2/2}\Big]_0^{\sqrt{c}} = 1 - e^{-c/2}. \tag{2.82}$$

(1) $Q = z_1^2 + z_2^2 = r^2$, and the density (2.75) with $k = 2$ is $e^{-r^2/2}/2\pi$.
(2) The angular integral gives 2π, and $r\,e^{-r^2/2}$ has antiderivative $-e^{-r^2/2}$.

Setting $1 - e^{-c/2}$ equal to the one-dimensional 1σ and 2σ probabilities, 0.6827 and 0.9545, gives $c = -2\ln(1-0.6827) = 2.296$ and $c = 6.180$. These are the familiar $\Delta\chi^2 = 2.30$ and 6.18 contours of two-parameter plots. So the ellipse $Q = 1$, which is often drawn as the "1σ ellipse", is too small: it contains only $1 - e^{-1/2} = 39.3\%$. In k dimensions the required c grows further. A random vector in many dimensions is almost never near its centre, because the χ^2_k distribution of its squared length has mean k.

Reading the ellipse: marginal box, conditional chord. One ellipse carries two different error bars for y, and they must not be confused. Figure 2.34 is drawn with the true numbers of the running example. *The box.* The ellipse $Q = 1$ is tangent to the box $|x - \mu_x| \le \sigma_x$, $|y - \mu_y| \le \sigma_y$. (Check the top point: with $x - \mu_x = z_1$, $y - \mu_y = 1.6z_1 + 1.2z_2$ and $z_1 = \cos t$, $z_2 = \sin t$, y is largest when $\tan t = 1.2/1.6$, giving $y - \mu_y = 1.6 \times 0.8 + 1.2 \times 0.6 = 2 = \sigma_y$.) So the projection of the $Q = 1$ ellipse on each axis is the marginal $\pm1\sigma$ range. *The chord.* The vertical chord through the centre is shorter: at $x = \mu_x$ the ellipse has $y - \mu_y = \pm1.2 = \pm\sigma_y\sqrt{1-\rho^2}$, which, as Section 2.12.4 shows, is the 1σ range of y when x is *known*. *The tilt.* The points where the ellipse has vertical tangents, $(\mu_x \pm 1, \mu_y \pm 1.6)$, lie on the line $y - \mu_y = \rho(\sigma_y/\sigma_x)(x - \mu_x)$, the conditional mean. This line is *not* the major axis: its angle is $\arctan 1.6 = 58°$, not 66.6°.

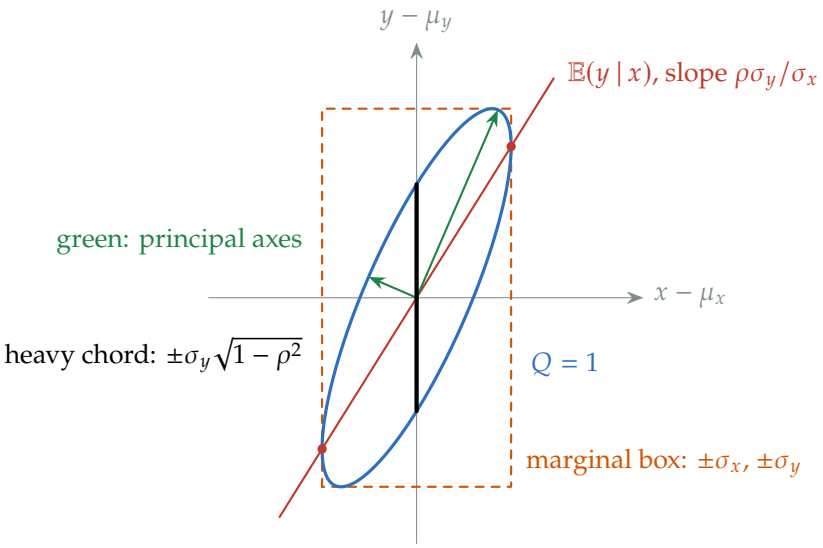

Figure 2.34: The $Q = 1$ contour of the example ($\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.8$), drawn exactly. It just touches the dashed box of the marginal $\pm1\sigma$ ranges. The heavy vertical chord at $x = \mu_x$ is the much shorter $\pm1\sigma$ range of y once x is fixed. The red line of conditional means passes through the two points of vertical tangency (dots), and it is tilted less steeply than the long principal axis (green).

2.12.3 Linear combinations and marginals

Every linear function of a Gaussian vector is again Gaussian, and marginals are a special case. The quickest proof uses the characteristic function, the k-dimensional version of (2.46), $\phi_X(\boldsymbol{t}) = \mathbb{E}\, e^{i\boldsymbol{t}^\top \boldsymbol{X}}$. With $\boldsymbol{X} = \boldsymbol{\mu} + \mathbf{A}\boldsymbol{Z}$,

$$\phi_X(\boldsymbol{t}) \overset{(1)}{=} e^{i\boldsymbol{t}^\top\boldsymbol{\mu}}\, \mathbb{E}\exp\big(i(\mathbf{A}^\top\boldsymbol{t})^\top\boldsymbol{Z}\big) \overset{(2)}{=} e^{i\boldsymbol{t}^\top\boldsymbol{\mu}} \prod_{j=1}^{k} e^{-(\mathbf{A}^\top\boldsymbol{t})_j^2/2} \overset{(3)}{=} \exp\Big(i\boldsymbol{t}^\top\boldsymbol{\mu} - \tfrac{1}{2}\boldsymbol{t}^\top\mathbf{C}\,\boldsymbol{t}\Big). \tag{2.83}$$

(1) $\boldsymbol{t}^{\mathsf{T}}\mathbf{A}\boldsymbol{Z} = (\mathbf{A}^{\mathsf{T}}\boldsymbol{t})^{\mathsf{T}}\boldsymbol{Z}$, and the constant phase comes out of the expectation.
(2) The Z_j are independent, so the expectation factorises, and each factor is the one-dimensional Gaussian characteristic function $e^{-s^2/2}$ (2.50) at $s = (\mathbf{A}^{\mathsf{T}}\boldsymbol{t})_j$.
(3) $\sum_j (\mathbf{A}^{\mathsf{T}}\boldsymbol{t})_j^2 = \boldsymbol{t}^{\mathsf{T}}\mathbf{A}\mathbf{A}^{\mathsf{T}}\boldsymbol{t} = \boldsymbol{t}^{\mathsf{T}}\mathbf{C}\boldsymbol{t}$.

Now let $\mathbf{B}$ be any $m \times k$ matrix and $\boldsymbol{Y} = \mathbf{B}\boldsymbol{X}$. Its characteristic function is $\mathbb{E}\, e^{i\boldsymbol{s}^{\mathsf{T}}\mathbf{B}\boldsymbol{X}} = \phi_{\boldsymbol{X}}(\mathbf{B}^{\mathsf{T}}\boldsymbol{s}) = \exp(i\boldsymbol{s}^{\mathsf{T}}\mathbf{B}\boldsymbol{\mu} - \frac{1}{2}\boldsymbol{s}^{\mathsf{T}}\mathbf{B}\mathbf{C}\mathbf{B}^{\mathsf{T}}\boldsymbol{s})$, which is again of the form (2.83). Since the characteristic function determines the distribution,

$$\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{C}) \quad \Longrightarrow \quad \mathbf{B}\boldsymbol{X} \sim \mathcal{N}\big(\mathbf{B}\boldsymbol{\mu},\ \mathbf{B}\mathbf{C}\mathbf{B}^{\mathsf{T}}\big). \tag{2.84}$$

Two special cases are the ones everybody uses [Wasserman Thm 2.44], [CasellaBerger p. 144].

- A single linear combination, $\mathbf{B} = \boldsymbol{a}^{\mathsf{T}}$: $\boldsymbol{a}^{\mathsf{T}}\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{a}^{\mathsf{T}}\boldsymbol{\mu}, \boldsymbol{a}^{\mathsf{T}}\mathbf{C}\boldsymbol{a})$. For two variables, $ax + by \sim \mathcal{N}(a\mu_x + b\mu_y,\ a^2\sigma_x^2 + b^2\sigma_y^2 + 2ab\rho\sigma_x\sigma_y)$. This is the exact form of the error-propagation formula for linear functions.
- The marginal of a subset. Split $\boldsymbol{X} = (\boldsymbol{X}_a, \boldsymbol{X}_b)$ and $\boldsymbol{\mu}$, $\mathbf{C}$ into the matching blocks $\boldsymbol{\mu}_a$, $\mathbf{C}_{aa}$, $\mathbf{C}_{ab}$, and so on. Choosing $\mathbf{B} = (\mathbb{1}\ \ 0)$ picks out $\boldsymbol{X}_a$, and $\mathbf{B}\mathbf{C}\mathbf{B}^{\mathsf{T}} = \mathbf{C}_{aa}$. So $\boldsymbol{X}_a \sim \mathcal{N}(\boldsymbol{\mu}_a, \mathbf{C}_{aa})$.

The second statement is marginalising in exactly the sense of Chapter 1. In words: to average out the nuisance variables $\boldsymbol{X}_b$ of a Gaussian, *delete their rows and columns* from $\boldsymbol{\mu}$ and $\mathbf{C}$. No integral needs to be done. In the running example the marginal of y is $\mathcal{N}(\mu_y, 4)$ whatever the value of ρ; the script finds a sample standard deviation of 1.997 for y.

2.12.4 Conditionals: fixing one variable

Suppose we learn the value of $\boldsymbol{X}_a$ exactly. What is the distribution of $\boldsymbol{X}_b$ now? Split $\boldsymbol{X}_b$ into the part that $\boldsymbol{X}_a$ can predict and a residual that it cannot. Define the residual

$$\boldsymbol{W} = \boldsymbol{X}_b - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\boldsymbol{X}_a.$$

$\boldsymbol{W}$ and $\boldsymbol{X}_a$ are uncorrelated:

$$\operatorname{Cov}(\boldsymbol{W}, \boldsymbol{X}_a) \overset{(1)}{=} \operatorname{Cov}(\boldsymbol{X}_b, \boldsymbol{X}_a) - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\operatorname{Cov}(\boldsymbol{X}_a, \boldsymbol{X}_a) \overset{(2)}{=} \mathbf{C}_{ba} - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{aa} = 0. \tag{2.85}$$

(1) Covariance is linear in each argument, and $\mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}$ is a constant matrix.
(2) The blocks of $\mathbf{C}$ are exactly these covariances.

For Gaussians, uncorrelated means independent. The vector $(\boldsymbol{W}, \boldsymbol{X}_a)$ is a linear function of $\boldsymbol{X}$, so by (2.84) it is jointly Gaussian, and its covariance matrix is block diagonal by (2.85). A block-diagonal $\mathbf{C}$ has a block-diagonal inverse and a determinant equal to the product of the blocks' determinants, so the density (2.78) factorises into a function of $\boldsymbol{w}$ times a function of $\boldsymbol{x}_a$. That is independence.

So knowing $\boldsymbol{X}_a = \boldsymbol{x}_a$ tells us nothing about $\boldsymbol{W}$, and $\boldsymbol{X}_b = \boldsymbol{W} + \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\boldsymbol{x}_a$ is a Gaussian vector shifted by a constant. Its mean and covariance are

$$\begin{aligned}
\mathbb{E}(\boldsymbol{X}_b \mid \boldsymbol{x}_a) &\overset{(1)}{=} \mathbb{E}\,\boldsymbol{W} + \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\boldsymbol{x}_a \overset{(2)}{=} \boldsymbol{\mu}_b + \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}(\boldsymbol{x}_a - \boldsymbol{\mu}_a), \\
\operatorname{Cov}(\boldsymbol{X}_b \mid \boldsymbol{x}_a) &\overset{(3)}{=} \operatorname{Cov}(\boldsymbol{W}) \overset{(4)}{=} \mathbf{C}_{bb} - 2\,\mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{ab} + \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{aa}\mathbf{C}_{aa}^{-1}\mathbf{C}_{ab} = \mathbf{C}_{bb} - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{ab}.
\end{aligned} \tag{2.86}$$

(1) $\boldsymbol{W}$ is independent of $\boldsymbol{X}_a$, so conditioning does not change its mean.
(2) $\mathbb{E}\,\boldsymbol{W} = \boldsymbol{\mu}_b - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\boldsymbol{\mu}_a$.
(3) A constant shift does not change a covariance, and $\boldsymbol{W}$ is unaffected by the conditioning.
(4) Expand $\operatorname{Cov}(\boldsymbol{X}_b - \mathbf{M}\boldsymbol{X}_a) = \mathbf{C}_{bb} - \mathbf{M}\mathbf{C}_{ab} - \mathbf{C}_{ba}\mathbf{M}^{\mathsf{T}} + \mathbf{M}\mathbf{C}_{aa}\mathbf{M}^{\mathsf{T}}$ with $\mathbf{M} = \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}$, using $\mathbf{C}_{ab}^{\mathsf{T}} = \mathbf{C}_{ba}$ and the symmetry of $\mathbf{C}_{aa}^{-1}$. The two middle terms are equal.

Key idea: Marginal and conditional of a Gaussian

For $\boldsymbol{X} = (\boldsymbol{X}_a, \boldsymbol{X}_b) \sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{C})$ [Wasserman Thm 2.44]:

- *marginal*: $\boldsymbol{X}_a \sim \mathcal{N}(\boldsymbol{\mu}_a, \mathbf{C}_{aa})$ (delete the other rows and columns);
- *conditional*: $\boldsymbol{X}_b \mid \boldsymbol{X}_a = \boldsymbol{x}_a \;\sim\; \mathcal{N}\big(\boldsymbol{\mu}_b + \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}(\boldsymbol{x}_a - \boldsymbol{\mu}_a),\; \mathbf{C}_{bb} - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{ab}\big)$.

The conditional mean moves linearly with $\boldsymbol{x}_a$; the conditional covariance does not depend on $\boldsymbol{x}_a$ at all, and is never larger than the marginal one.

For two variables the conditional is [CasellaBerger p. 145]

$$y \mid x \;\sim\; \mathcal{N}\Big(\mu_y + \rho\frac{\sigma_y}{\sigma_x}(x - \mu_x),\; \sigma_y^2(1-\rho^2)\Big), \tag{2.87}$$

since here $\mathbf{C}_{ba}\mathbf{C}_{aa}^{-1} = \rho\sigma_x\sigma_y/\sigma_x^2$ and $\mathbf{C}_{bb} - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{ab} = \sigma_y^2 - \rho^2\sigma_y^2$. As $|\rho| \to 1$ the conditional width goes to zero: y becomes a deterministic linear function of x.

Example: the slab. In the running example ($\mu_x = 1$, $\mu_y = 2$, $\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.8$), fix $x = \mu_x + 1 = 2$. Then (2.87) predicts $y \mid x \sim \mathcal{N}(2 + 0.8 \times 2 \times 1,\; 4 \times 0.36)$, a mean of 3.600 and a standard deviation of 1.200, compared with the marginal standard deviation of 2. The script cannot condition on an exact value, so it keeps the 9588 samples (out of 4×10^5) in the thin slab $|x - 2| < 0.05$ and finds mean 3.614 and standard deviation 1.187. Panel (b) of Figure 2.35 shows both histograms against the predicted Gaussians.

Example: conditional versus marginal errors. The conditional variance of one variable can be read straight off the inverse covariance: it is $1/(\mathbf{C}^{-1})_{bb}$, while the marginal variance is $\mathbf{C}_{bb}$. The reason is the block-inverse (Schur complement) formula, which says that the bb block of $\mathbf{C}^{-1}$ is $(\mathbf{C}_{bb} - \mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}\mathbf{C}_{ab})^{-1}$, the inverse of the conditional covariance. In the running example $(\mathbf{C}^{-1})_{yy} = 1/1.44$, so the conditional variance is 1.44 and the conditional standard deviation 1.2, as above. The same distinction matters for Fisher forecasts (Chapter 10), where the Fisher matrix $\mathbf{F}$ plays the role of $\mathbf{C}^{-1}$. There $1/\sqrt{F_{ii}}$ is the error on parameter i with all the others *fixed* (the chord), and $\sqrt{(\mathbf{F}^{-1})_{ii}}$ is the error with the others *marginalised* (the box). Quoting the first when you mean the second is a classic way to overstate a forecast.

Watch out: Gaussian marginals do not make a Gaussian vector

Every property above starts from *joint* normality, and the derivation does not run backwards [CasellaBerger p. 145]. Let $X \sim \mathcal{N}(0,1)$ and let $S = \pm 1$ be an independent fair sign. Then $Y = SX$ is also $\mathcal{N}(0,1)$, and $\mathrm{Cov}(X,Y) = \mathbb{E}(S)\,\mathbb{E}(X^2) = 0$. But $X + Y$ equals 0 with probability $\frac{1}{2}$, which no Gaussian does, and $|Y| = |X|$ exactly, so the two are uncorrelated but completely dependent. "Uncorrelated implies independent" holds only for jointly Gaussian variables.

Python: sampling and checking. The script draws 20000 points by the Cholesky recipe, computes Q for each, and checks the ellipse contents and the conditional.

Listing 2.16: Drawing a bivariate Gaussian and measuring the content of its ellipses (`code/ch02/24_mvn.py`)

```
mu = np.array([1.0, 2.0])
sx, sy, rho = 1.0, 2.0, 0.8
C = np.array([[sx ** 2, rho * sx * sy], [rho * sx * sy, sy ** 2]])
L = np.linalg.cholesky(C)                    # C = L L^T
N = 20_000
```

```
x = mu + rng.standard_normal((N, 2)) @ L.T  # each row: mu + L z

Cinv = np.linalg.inv(C)
r = x - mu
chi2 = np.einsum("ni,ij,nj->n", r, Cinv, r)
lev1, lev2 = stats.chi2.ppf([stats.chi2.cdf(1, 1), stats.chi2.cdf(4, 1)], df=2)
f1, f2 = np.mean(chi2 < lev1), np.mean(chi2 < lev2)
```

Line 33 computes the Cholesky factor $\mathbf{L}$, with $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$. Line 35 is the whole sampler: each row of the standard-normal array is a $\boldsymbol{z}$, and multiplying by $\mathbf{L}^{\mathsf{T}}$ from the right is the row-vector version of $\mathbf{L}\boldsymbol{z}$. Line 39 evaluates $Q = \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ for every sample at once with `np.einsum`. Line 40 converts the one-dimensional 1σ and 2σ probabilities into χ^2_2 quantiles, the $\Delta\chi^2$ levels, and line 41 counts the samples inside: 0.6873 and 0.9559, against 0.6827 and 0.9545. Is that agreement? With 20000 samples the binomial standard error of a fraction near 0.68 is $\sqrt{0.68 \times 0.32/20000} \approx 0.003$, so both agree within about 1.5 standard errors.

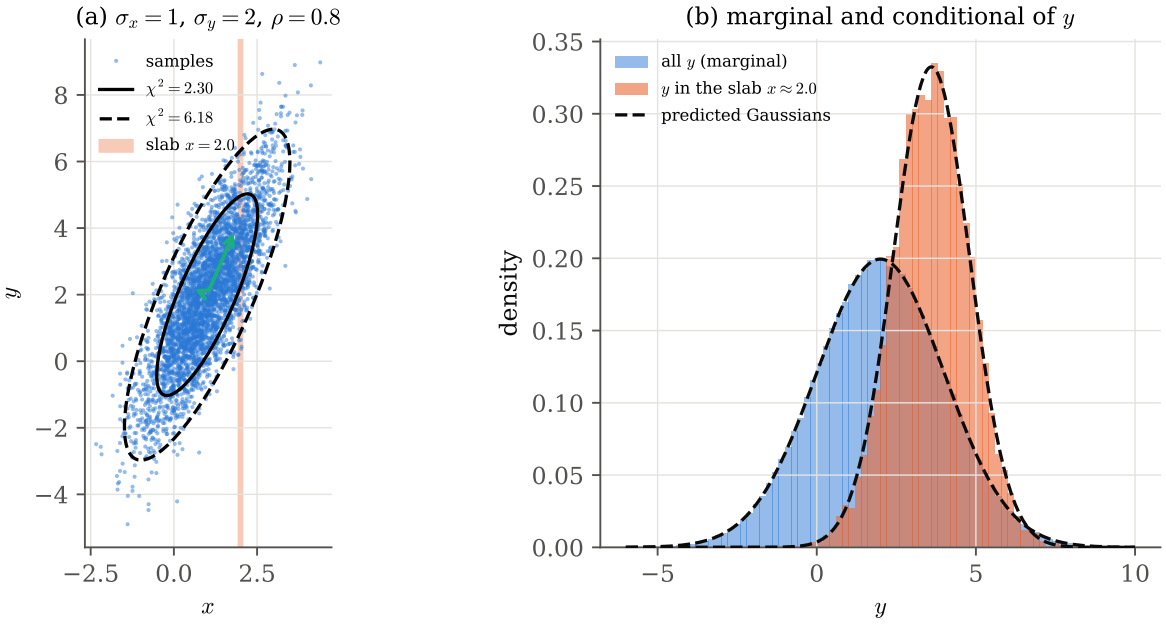

Figure 2.35: (a) Samples of the bivariate Gaussian with $\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.8$, with the $\Delta\chi^2 = 2.30$ and 6.18 ellipses and the principal axes (arrows, of length one standard deviation along each axis). The shaded strip is the slab used for conditioning. (b) All y values (the marginal) and the y values inside the slab (the conditional), each with its predicted Gaussian. Fixing x shifts the centre and shrinks the width.

The same object in three sciences. The multivariate Gaussian is the common core of the three kinds of data this book keeps returning to. *Colliders.* For Poisson counts in many bins it is the large-count limit of the product of Poissons. Its $\mathbf{C}$ is diagonal, with variances equal to the means, until systematic uncertainties shared between bins add correlations. *The CMB.* For a CMB map (Chapter 7) the vector is the list of pixel temperatures or of the harmonic coefficients $a_{\ell m}$, and $\mathbf{C}$ is built from the power spectrum C_ℓ. For an isotropic Gaussian field the $a_{\ell m}$ are independent with variance C_ℓ, so in harmonic space $\mathbf{C}$ is diagonal. *Gravitational waves.* For detector noise the vector is the time series and $\mathbf{C}$ is set by the power spectral density. Stationarity makes it a Toeplitz matrix (constant along each diagonal), and the Fourier transform diagonalises it, just as the eigenbasis did in (2.81). In each case the step that makes the likelihood computable is the same: whiten, and then everything is a sum of independent squares. That sum of squares

is the χ^2 variable of Section 2.13. When the tails of real data are heavier than Gaussian, the multivariate Student-t, a Gaussian with a randomly rescaled covariance (Section 2.14), is the standard robust replacement [Lambert §8.4.11].

2.13 Sums of squared Gaussians: the χ^2 distribution

We fit a straight line to ten points with error bars and get $\chi^2 = \sum_i (x_i - \mu_i)^2/\sigma_i^2 = 14.2$, where x_i is a measured value, μ_i the line's prediction and σ_i the error bar. Is the fit good? The number means nothing until we know how χ^2 is distributed when the model is right. Sums of squared Gaussians turn up throughout physics. A CMB band power $\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2$ is a sum of squares of Gaussian coefficients, and its scatter is cosmic variance. The power of Gaussian detector noise in one frequency bin of a gravitational-wave stream is the sum of two squares, the real and imaginary parts. The quadratic form in the exponent of the multivariate Gaussian, whose contours we just drew, is a sum of squares after whitening. And the sample variance of n repeated measurements is a sum of squared deviations.

Two results answer these questions. A sum of ν squared standard normals has a definite distribution, χ^2_ν, with mean ν and variance 2ν. And the sample variance divides by $n-1$, not n, because estimating the mean uses up exactly one "degree of freedom" in a sense the geometry makes precise.

The questions, in words: *if ν independent standard normal numbers are squared and added, what is the density of the total? And what changes when the numbers are deviations from their own average rather than from the true mean?*

2.13.1 One square

Start with a single square, $Q = Y^2$ with $Y \sim \mathcal{N}(0,1)$. *When is Q small?* For $q > 0$, $Q \le q$ happens exactly when $-\sqrt{q} \le Y \le \sqrt{q}$. So we can get the density of Q by differentiating the probability of that interval:

$$f_1(q) = \frac{\mathrm{d}}{\mathrm{d}q}\,\mathrm{P}(Q \le q) \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}q}\left[\Phi(\sqrt{q}) - \Phi(-\sqrt{q})\right] \overset{(2)}{=} 2\varphi(\sqrt{q})\,\frac{1}{2\sqrt{q}} \overset{(3)}{=} \frac{1}{\sqrt{2\pi q}}\,e^{-q/2}. \tag{2.88}$$

(1) The probability of an interval is the difference of the cumulative distribution at its ends.
(2) Chain rule, $\frac{\mathrm{d}}{\mathrm{d}q}\sqrt{q} = \frac{1}{2\sqrt{q}}$, and the symmetry $\varphi(-y) = \varphi(y)$. The two ends contribute equally: this is the factor two of [Cowan (10.14)], which counts the positive and the negative root.
(3) $\varphi(\sqrt{q}) = e^{-q/2}/\sqrt{2\pi}$.

The density diverges like $q^{-1/2}$ at the origin, because Y is most likely near zero and squaring crowds those values towards $q = 0$. One square is a gamma variable, Gamma$(\frac{1}{2}, 2)$ [CasellaBerger Lemma 5.3.2]. To check, recall the gamma density (2.20): with shape $\alpha = \frac{1}{2}$ and scale $\beta = 2$ it is $q^{-1/2}e^{-q/2}/(\Gamma(\frac{1}{2})\sqrt{2})$, and $\Gamma(\frac{1}{2}) = \sqrt{\pi}$ (2.37) makes this identical to (2.88).

2.13.2 Many squares: two derivations

The geometric route: integrate the joint density over a ball. *The question in words:* what is the probability that $Q_\nu \le q$, whatever the individual values of $Y_1, \ldots, Y_\nu$ happen to be? We know the joint density of all the Y_j, and we do not care about them one by one, only about the one combination Q_ν. So we do what we always do with variables we do not care about

(Section 1.10.2): integrate the joint density over every set of values $y_1, \dots, y_\nu$ that gives $Q_\nu \le q$, and then change variables to Q. It goes in four steps.

Step 1: the joint density. The Y_j are independent, so their joint density is the product of the ν one-dimensional densities. Writing $\boldsymbol{y} = (y_1, \dots, y_\nu)$ and $|\boldsymbol{y}|^2 = y_1^2 + \cdots + y_\nu^2$,

$$f(\boldsymbol{y}) = \prod_{j=1}^{\nu} \frac{e^{-y_j^2/2}}{\sqrt{2\pi}} = \frac{e^{-(y_1^2+\cdots+y_\nu^2)/2}}{(2\pi)^{\nu/2}} = \frac{e^{-|\boldsymbol{y}|^2/2}}{(2\pi)^{\nu/2}}, \tag{2.89}$$

since a product of exponentials is the exponential of the sum. The density depends on $\boldsymbol{y}$ only through its length $r = |\boldsymbol{y}|$: it is the same at every point of a sphere centred on the origin.

Step 2: the event $Q_\nu \le q$ is a ball. $Q_\nu = |\boldsymbol{Y}|^2$ is the squared distance of the random point $\boldsymbol{Y}$ from the origin. So $Q_\nu \le q$ happens exactly when $\boldsymbol{Y}$ lands inside the ball of radius $\sqrt{q}$, and its probability is the joint density integrated over all $\boldsymbol{y}$ in that ball:

$$\mathrm{P}(Q_\nu \le q) = \int_{|\boldsymbol{y}|^2 \le q} \frac{e^{-|\boldsymbol{y}|^2/2}}{(2\pi)^{\nu/2}} \, \mathrm{d}^\nu y.$$

This is the one-square argument of Section 2.13.1 in ν dimensions: there the ball was the interval $[-\sqrt{q}, \sqrt{q}]$.

Step 3: spherical coordinates. Because the integrand depends only on r, we slice the ball into thin spherical shells. A shell of radius r and thickness $\mathrm{d}r$ has volume $S_{\nu-1} r^{\nu-1} \mathrm{d}r$, where $S_{\nu-1}$ is the area of the unit sphere in ν dimensions ($S_1 = 2\pi$, the circumference of the unit circle; $S_2 = 4\pi$). The power $r^{\nu-1}$ is there because a sphere of radius r is the unit sphere stretched by r in each of its $\nu - 1$ directions. Integrating over the angles of each shell leaves a one-dimensional integral,

$$\mathrm{P}(Q_\nu \le q) = \frac{S_{\nu-1}}{(2\pi)^{\nu/2}} \int_0^{\sqrt{q}} r^{\nu-1} e^{-r^2/2} \, \mathrm{d}r. \tag{2.90}$$

We still need $S_{\nu-1}$. The Gaussian integral gives it, by computing one integral in two ways. The integral of $e^{-|\boldsymbol{y}|^2/2}$ over all of $\mathbb{R}^\nu$ factorises into ν one-dimensional Gaussian integrals, each equal to $\sqrt{2\pi}$; in shells it is $S_{\nu-1} \int_0^\infty r^{\nu-1} e^{-r^2/2} \mathrm{d}r$. Setting the two equal,

$$(2\pi)^{\nu/2} \overset{(1)}{=} \int_{\mathbb{R}^\nu} e^{-|\boldsymbol{y}|^2/2} \, \mathrm{d}^\nu y \overset{(2)}{=} S_{\nu-1} \int_0^\infty r^{\nu-1} e^{-r^2/2} \, \mathrm{d}r \overset{(3)}{=} S_{\nu-1} \, 2^{\nu/2-1} \, \Gamma\left(\tfrac{\nu}{2}\right) \quad \Longrightarrow \quad S_{\nu-1} = \frac{2\pi^{\nu/2}}{\Gamma(\nu/2)}. \tag{2.91}$$

(1) Cartesian coordinates: $e^{-|\boldsymbol{y}|^2/2} = \prod_j e^{-y_j^2/2}$, and each $\int_{-\infty}^{\infty} e^{-y_j^2/2} \mathrm{d}y_j = \sqrt{2\pi}$.
(2) Spherical coordinates, as in step 3, with the ball extended to all of space.
(3) Substitute $t = r^2/2$, so $r = \sqrt{2t}$, $\mathrm{d}r = \mathrm{d}t/\sqrt{2t}$ and $r^{\nu-1}\mathrm{d}r = (2t)^{\nu/2-1}\mathrm{d}t$; the t integral is $\int_0^\infty t^{\nu/2-1} e^{-t} \mathrm{d}t = \Gamma(\nu/2)$.

Divide by $2^{\nu/2-1}\Gamma(\nu/2)$ and use $(2\pi)^{\nu/2}/2^{\nu/2-1} = 2\pi^{\nu/2}$. (Check: $\nu = 2$ gives $2\pi/\Gamma(1) = 2\pi$, and $\nu = 3$ gives $2\pi^{3/2}/(\sqrt{\pi}/2) = 4\pi$.)

Step 4: from the radius to Q, and differentiate. In (2.90) change the integration variable from r to $s = r^2$, the value of Q on the shell, and then differentiate with respect to the upper limit:

$$\mathrm{P}(Q_\nu \le q) \overset{(1)}{=} \frac{S_{\nu-1}}{(2\pi)^{\nu/2}} \int_0^q s^{(\nu-1)/2} \, e^{-s/2} \, \frac{\mathrm{d}s}{2\sqrt{s}} \overset{(2)}{=} \frac{1}{2^{\nu/2}\,\Gamma(\nu/2)} \int_0^q s^{\nu/2-1} \, e^{-s/2} \, \mathrm{d}s,$$

$$f_\nu(q) = \frac{\mathrm{d}}{\mathrm{d}q} \mathrm{P}(Q_\nu \le q) \overset{(3)}{=} \frac{q^{\nu/2-1} e^{-q/2}}{2^{\nu/2}\,\Gamma(\nu/2)}, \qquad q > 0, \tag{2.92}$$

(1) $r = \sqrt{s}$, so $r^{\nu-1} = s^{(\nu-1)/2}$ and $\mathrm{d}r = \mathrm{d}s/(2\sqrt{s})$; the limits $r = 0$ and $r = \sqrt{q}$ become $s = 0$ and $s = q$.

(2) Insert $S_{\nu-1}$ from (2.91): $\frac{2\pi^{\nu/2}}{\Gamma(\nu/2)} \cdot \frac{1}{(2\pi)^{\nu/2}} \cdot \frac{1}{2} = \frac{1}{2^{\nu/2}\Gamma(\nu/2)}$, and combine the powers, $s^{(\nu-1)/2} s^{-1/2} = s^{\nu/2-1}$.

(3) The derivative of an integral with respect to its upper limit is the integrand at that limit.

the χ^2 density with ν **degrees of freedom** [Cowan (2.34)], [Wasserman p. 30]. The power $q^{\nu/2-1}$ is pure geometry: the area of a sphere of radius $\sqrt{q}$ in ν dimensions. In high dimensions this factor pushes the probability away from the origin, which is why χ^2_ν peaks near $\nu - 2$ rather than at zero. We use the same shell argument for the Maxwell–Boltzmann speed distribution in Section 2.15.

The characteristic function route. The second route draws no sphere. Characteristic functions turn the sum of squares into a product [Cowan (10.12)–(10.15)]. First transform one square. With $a = 1 - 2ik$,

$$\phi_1(k) = \mathbb{E}\, e^{ikY^2} \overset{(1)}{=} \int_{-\infty}^{\infty} \frac{e^{-y^2/2}}{\sqrt{2\pi}}\, e^{iky^2}\, \mathrm{d}y \overset{(2)}{=} \int_{-\infty}^{\infty} \frac{e^{-ay^2/2}}{\sqrt{2\pi}}\, \mathrm{d}y \overset{(3)}{=} (1 - 2ik)^{-1/2}. \tag{2.93}$$

(1) The expectation of a function of Y is its integral against the density of Y.

(2) Combine the exponents: $-\frac{y^2}{2} + iky^2 = -\frac{(1-2ik)y^2}{2}$.

(3) The Gaussian integral $\int e^{-ay^2/2}\mathrm{d}y = \sqrt{2\pi/a}$, which holds for complex a with positive real part (here $\mathrm{Re}\, a = 1$) with the principal square root, by analytic continuation from real a.

For $Q_\nu = Y_1^2 + \cdots + Y_\nu^2$ with independent Y_j, the product rule (2.47) gives $\phi_\nu(k) = (1 - 2ik)^{-\nu/2}$ [Cowan (10.15)]. Which density has this transform? One square was a gamma variable, so try the gamma density with shape α and scale β:

$$\int_0^\infty e^{ikx}\, \frac{x^{\alpha-1}e^{-x/\beta}}{\Gamma(\alpha)\beta^\alpha}\, \mathrm{d}x \overset{(1)}{=} \frac{1}{\Gamma(\alpha)\beta^\alpha} \int_0^\infty x^{\alpha-1} e^{-x(1-i\beta k)/\beta}\, \mathrm{d}x \overset{(2)}{=} \frac{1}{\Gamma(\alpha)\beta^\alpha}\, \Gamma(\alpha)\Big(\frac{\beta}{1-i\beta k}\Big)^\alpha = (1 - i\beta k)^{-\alpha}, \tag{2.94}$$

(1) Combine the exponentials.

(2) Substitute $t = x(1 - i\beta k)/\beta$; then $\int_0^\infty x^{\alpha-1}e^{-cx}\mathrm{d}x = \Gamma(\alpha)/c^\alpha$, again valid for complex c with positive real part.

so $(1 - 2ik)^{-\nu/2}$ is the characteristic function of Gamma$(\nu/2, 2)$. Since a characteristic function determines its density, $f_\nu(q) = q^{\nu/2-1}e^{-q/2}/(2^{\nu/2}\Gamma(\nu/2))$, which is (2.92) again: the product of ν transforms and the integral over a ball give the same density.

Working definition 2.18 (χ^2 distribution)

$Q \sim \chi^2_\nu$ if $Q = \sum_{j=1}^{\nu} Y_j^2$ with $Y_j \overset{\text{iid}}{\sim} \mathcal{N}(0, 1)$. Equivalently, Q has density (2.92), the Gamma$(\nu/2, 2)$ density, and characteristic function $(1-2ik)^{-\nu/2}$. *Summary numbers:* $\mathbb{E}\, Q = \nu$, $\mathrm{Var}\, Q = 2\nu$, mode $\max(\nu - 2, 0)$. *Additivity:* independent $\chi^2_{\nu_1}$ and $\chi^2_{\nu_2}$ add to $\chi^2_{\nu_1+\nu_2}$ (multiply the characteristic functions). *Recognise it by:* a sum of squares of independent, zero-mean, unit-variance Gaussian quantities, such as residuals divided by their true errors.

Mean and variance. The mean of χ^2_ν is ν and its variance is 2ν. For one square, $\mathbb{E}\, Y^2 = 1$ and $\mathbb{E}\, Y^4 = 3$ (differentiate the Gaussian characteristic function four times, or integrate by parts twice as in (2.38)), so $\mathrm{Var}\, Y^2 = 3 - 1 = 2$. Means and variances of independent terms add, so

$\mathbb{E}\,Q_\nu = \nu$ and $\mathrm{Var}\,Q_\nu = \sum_{i=1}^{\nu} \mathrm{Var}\,Y_i^2 = \sum_{i=1}^{\nu} 2 = 2\nu$ [Cowan (2.36)–(2.37)]. This explains why the variance of χ^2 increases with degrees of freedom as each random variable comes with its own fluctuation and they all add up. The script sums ν squared normals 2×10^5 times and finds mean 5.010 and variance 10.076 for $\nu = 5$, and 9.993 and 19.897 for $\nu = 10$ (Figure 2.36a). For large ν the CLT makes $\chi^2_\nu \approx \mathcal{N}(\nu, 2\nu)$, but slowly: its skewness is $\sqrt{8/\nu}$, still 0.28 at $\nu = 100$ (the skewness of one square, $\sqrt{8}$, shrinks like $1/\sqrt{\nu}$, as in (2.55)).

Example: is $\chi^2 = 14.2$ for ten degrees of freedom a good fit? Yes, it is acceptable. *The question in words:* if the straight line is the right model, how often would a fit come out this bad or worse? With $\nu = 10$, $\mathbb{E}\,\chi^2 = 10$ and the standard deviation is $\sqrt{20} = 4.5$. So 14.2 is less than one standard deviation high. Exactly, $\mathrm{P}(\chi^2_{10} > 14.2) = 0.16$: one fit in six would do this badly even with the right model. The central 90% range of χ^2_{10} is 3.9 to 18.3. A fit with $\chi^2 = 24$ would have tail probability 0.008 and would be suspicious.

The same reduced χ^2/ν can mean different things for different ν. Its standard deviation is $\sqrt{2/\nu}$, which is 0.45 for ten points. So "$\chi^2/\nu = 1.4$" is unremarkable for $\nu = 10$, while for $\nu = 100$ ($\chi^2 = 140$) it has tail probability 0.005. Hypothesis tests built on this are the subject of Chapter 4.

Example: cosmic variance. A CMB band power is a χ^2 variable, and that fixes its scatter. Recall that $\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2$ is the measured power at multipole ℓ, built from the $2\ell+1$ harmonic coefficients $a_{\ell m}$, and C_ℓ is its true value. *How many independent Gaussians go into it?* Exactly $2\ell+1$ real numbers. The $m = 0$ coefficient is real. For $m > 0$ the real and imaginary parts count separately. And $a_{\ell,-m}$ adds nothing new, being fixed by $a_{\ell,-m} = (-1)^m a^*_{\ell m}$. For an isotropic Gaussian sky these $2\ell+1$ numbers are independent Gaussians whose squares add up to $\sum_m |a_{\ell m}|^2$, each with the same share of the variance. So $(2\ell+1)\widehat{C}_\ell/C_\ell \sim \chi^2_{2\ell+1}$, and

$$\mathrm{Var}\,\widehat{C}_\ell \overset{(1)}{=} \left(\frac{C_\ell}{2\ell+1}\right)^2 \mathrm{Var}\,\chi^2_{2\ell+1} \overset{(2)}{=} \frac{C_\ell^2}{(2\ell+1)^2}\,2(2\ell+1) = \frac{2C_\ell^2}{2\ell+1},$$

where (1) scales a random variable by a constant and (2) uses $\mathrm{Var}\,\chi^2_\nu = 2\nu$. This is the cosmic variance that Chapter 7 verifies by simulation. At $\ell = 2$, $\widehat{C}_\ell$ is a χ^2_5 variable divided by five: skewed, with a 1σ scatter of 63%.

2.13.3 Correlated Gaussians: the quadratic form

Correlations do not change the answer, as long as the sum of squares uses the full inverse covariance. If $\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{C})$ in k dimensions, then

$$Q = (\boldsymbol{X}-\boldsymbol{\mu})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{X}-\boldsymbol{\mu}) \;\sim\; \chi^2_k \tag{2.95}$$

[Cowan (2.39)], [Wasserman Thm 2.44(4)]. The proof is one line with the whitening of Section 2.12: with $\mathbf{L}$ the Cholesky factor, $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$, the vector $\boldsymbol{Z} = \mathbf{L}^{-1}(\boldsymbol{X}-\boldsymbol{\mu})$ has independent standard normal components and $\boldsymbol{Z}^{\mathsf{T}}\boldsymbol{Z} = (\boldsymbol{X}-\boldsymbol{\mu})^{\mathsf{T}}(\mathbf{L}\mathbf{L}^{\mathsf{T}})^{-1}(\boldsymbol{X}-\boldsymbol{\mu}) = Q$. This is what justified the ellipse contents in (2.82).

Example: forgetting the correlations. Dropping the off-diagonal elements keeps the right mean but gives the wrong spread. The script takes a correlated three-dimensional Gaussian with covariance

$$\mathbf{C} = \begin{pmatrix} 1 & 0.6 & 0.3 \\ 0.6 & 2 & -0.5 \\ 0.3 & -0.5 & 1.5 \end{pmatrix}$$

and computes Q for 2×10^5 draws: mean 2.999 and variance 5.989, as χ^2_3 requires. It also computes the "naive" sum $\sum_i (x_i - \mu_i)^2 / C_{ii}$, which ignores the off-diagonal elements. Its mean is still 2.997, because each term has expectation 1 whatever the correlations. But its variance is 7.284 instead of 6 (Figure 2.36b), because the terms are correlated and so do not add like independent squares. A goodness-of-fit test that uses only the diagonal errors on correlated data (neighbouring bins of a smoothed spectrum, overlapping band powers) will reject correct models too often, even though its average looks fine.

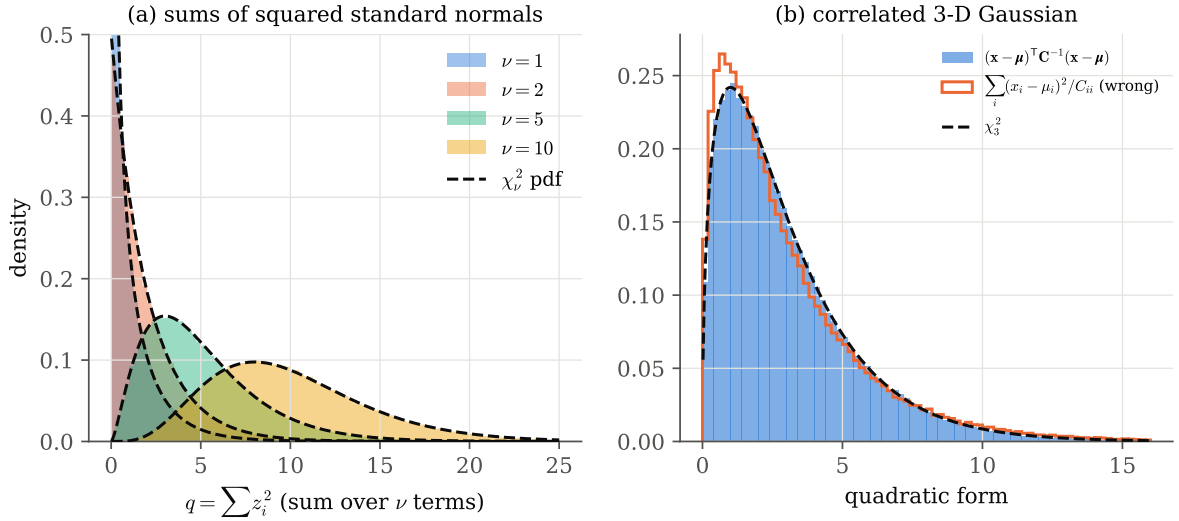

Figure 2.36: (a) Histograms of sums of ν squared standard normals for $\nu = 1, 2, 5, 10$ against the χ^2_ν densities (dashed). For $\nu = 1$ and 2 the density is largest at zero; for larger ν the peak moves out to $\nu - 2$. (b) For a correlated three-dimensional Gaussian, the full quadratic form follows χ^2_3, while the sum that uses only the diagonal variances (orange) has the right mean but the wrong shape: it piles up near zero and has a longer tail, so its variance is larger.

2.13.4 The sample variance and the lost degree of freedom

Five readings of a pendulum period, $x_1, \dots, x_5$, scatter about the unknown true value μ with unknown spread σ. We estimate μ by the sample mean $\bar{x} = \frac{1}{n}\sum x_i$, and σ^2 from the deviations $x_i - \bar{x}$. Why divide the sum of squared deviations by $n - 1$?

The bias. Deviations from $\bar{x}$ are systematically smaller than deviations from the true μ. The reason: the sample mean is the value of a that minimises $\sum_i (x_i - a)^2$ (set the derivative $-2\sum_i (x_i - a)$ to zero), so no other centre, μ included, gives a smaller sum. By how much smaller? Write $x_i - \mu = (x_i - \bar{x}) + (\bar{x} - \mu)$ and expand:

$$\sum_{i=1}^{n} (x_i - \mu)^2 \overset{(1)}{=} \sum_{i=1}^{n} (x_i - \bar{x})^2 + 2(\bar{x} - \mu) \sum_{i=1}^{n} (x_i - \bar{x}) + n(\bar{x} - \mu)^2$$
$$\overset{(2)}{=} \sum_{i=1}^{n} (x_i - \bar{x})^2 + n(\bar{x} - \mu)^2. \tag{2.96}$$

(1) Square the sum of two terms and sum over i; the last term does not depend on i.
(2) $\sum_i (x_i - \bar{x}) = n\bar{x} - n\bar{x} = 0$.

Take expectations for independent x_i with variance σ^2, any distribution. The left side has expectation $n\sigma^2$ and $\mathbb{E}(\bar{x}-\mu)^2 = \operatorname{Var}\bar{x} = \sigma^2/n$, so

$$\mathbb{E}\sum_{i=1}^{n}(x_i-\bar{x})^2 = n\sigma^2 - n\cdot\frac{\sigma^2}{n} = (n-1)\sigma^2. \tag{2.97}$$

Hence $S^2 = \frac{1}{n-1}\sum(x_i-\bar{x})^2$ has $\mathbb{E}\,S^2 = \sigma^2$, while the "natural" $\frac{1}{n}\sum(x_i-\bar{x})^2$ is low on average by the factor $(n-1)/n$. The script, with $n=5$ and $\sigma^2 = 4.0$, finds $\mathbb{E}\,S^2 = 4.0024$ and $\mathbb{E}\big[\frac{1}{n}\sum(x_i-\bar{x})^2\big] = 3.2019$, against the predicted 3.2000. The missing σ^2/n is exactly the variance of $\bar{x}$ around μ: the part of the scatter that the sample mean "absorbs" by following the data.

The distribution: rotate the data. For Gaussian data we can say much more: $(n-1)S^2/\sigma^2$ is exactly χ^2_{n-1}, and it is independent of $\bar{x}$. A rotation of the data shows both. Picture the n readings as one point $\boldsymbol{x}\in\mathbb{R}^n$. The sample mean is about the component of $\boldsymbol{x}$ along the diagonal direction $\boldsymbol{e} = (1,\dots,1)/\sqrt{n}$, since $\boldsymbol{e}^{\mathsf{T}}\boldsymbol{x} = \sqrt{n}\,\bar{x}$. The deviations $x_i-\bar{x}$ are the components of what is left over, $\boldsymbol{x}-\sqrt{n}\,\bar{x}\,\boldsymbol{e}$, which is perpendicular to $\boldsymbol{e}$ and so lives in an $(n-1)$-dimensional subspace (Figure 2.37). Choose an orthonormal basis whose first vector is $\boldsymbol{e}$, collect the basis vectors as the rows of an orthogonal matrix $\mathbf{H}$ (for $n=3$, one choice, the **Helmert** matrix, is shown below), and rotate: $\boldsymbol{y} = \mathbf{H}(\boldsymbol{x}-\mu\mathbf{1})$, where $\mathbf{1} = (1,\dots,1)$. Then:

- $\boldsymbol{x}-\mu\mathbf{1} \sim \mathcal{N}(0,\sigma^2\mathbb{1})$, so by (2.84) $\boldsymbol{y} \sim \mathcal{N}(0,\sigma^2\mathbf{H}\mathbf{H}^{\mathsf{T}}) = \mathcal{N}(0,\sigma^2\mathbb{1})$: the y_j are again independent with variance σ^2. An isotropic Gaussian looks the same in every rotated frame.
- $y_1 = \boldsymbol{e}^{\mathsf{T}}(\boldsymbol{x}-\mu\mathbf{1}) = \sqrt{n}(\bar{x}-\mu)$.
- A rotation preserves length, so $\sum_{j=1}^{n} y_j^2 = \sum_i(x_i-\mu)^2$, and by (2.96), $\sum_{j=2}^{n} y_j^2 = \sum_i(x_i-\mu)^2 - n(\bar{x}-\mu)^2 = \sum_i(x_i-\bar{x})^2$.

The last line says that $(n-1)S^2/\sigma^2 = \sum_{j=2}^{n}(y_j/\sigma)^2$ is a sum of $n-1$ independent squared standard normals, and it involves only $y_2,\dots,y_n$, which are independent of y_1 and hence of $\bar{x}$.

Example: $n=3$, by hand. The rows of

$$\mathbf{H} = \begin{pmatrix} \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} & 0 \\ \frac{1}{\sqrt{6}} & \frac{1}{\sqrt{6}} & -\frac{2}{\sqrt{6}} \end{pmatrix}$$

have unit length and are mutually orthogonal (for example, row $2\cdot$ row $3 = \frac{1}{\sqrt{12}} - \frac{1}{\sqrt{12}} + 0 = 0$). Take the readings $\boldsymbol{x} = (1,2,6)$, so $\bar{x} = 3$ and $\sum(x_i-\bar{x})^2 = 4+1+9 = 14$. The second and third rotated components (the shift by $\mu\mathbf{1}$ drops out of them, because their rows sum to zero) are $y_2 = (1-2)/\sqrt{2}$ and $y_3 = (1+2-12)/\sqrt{6}$, and $y_2^2 + y_3^2 = \frac{1}{2} + \frac{81}{6} = 14$. The first component carries the mean, the other two carry the scatter.

Key idea: Sample mean and sample variance of Gaussian data

If $x_1,\dots,x_n \overset{\text{iid}}{\sim} \mathcal{N}(\mu,\sigma^2)$ [CasellaBerger Thm 5.3.1]: (a) $\bar{x}$ and S^2 are independent; (b) $\bar{x} \sim \mathcal{N}(\mu,\sigma^2/n)$; (c) $(n-1)S^2/\sigma^2 \sim \chi^2_{n-1}$. One degree of freedom is spent on the direction along which $\bar{x}$ is measured; the scatter lives in the remaining $n-1$.

Casella and Berger prove (a) by factorising the joint density after the change of variables $(\bar{x}, x_2 - \bar{x}, \ldots, x_n - \bar{x})$, and (c) by induction, adding one data point at a time with the update $(n-1)S_n^2 = (n-2)S_{n-1}^2 + \frac{n-1}{n}(x_n - \bar{x}_{n-1})^2$ [CasellaBerger (5.3.1)–(5.3.2)]. They also give the fastest check of (a): $\mathrm{Cov}(\bar{x}, x_j - \bar{x}) = \sum_i \frac{1}{n}(\delta_{ij} - \frac{1}{n})\sigma^2 = 0$, and uncorrelated linear functions of independent Gaussians are independent [CasellaBerger Lemma 5.3.3]. The rotation is the same argument seen geometrically.

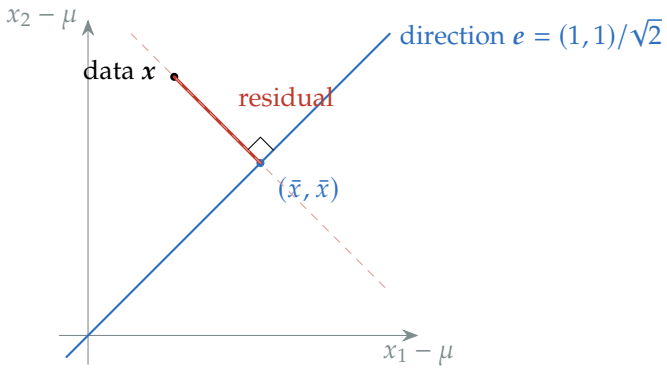

Figure 2.37: Two readings seen as one point x in the plane (origin at the true value). Projecting onto the diagonal gives the sample mean $(\bar{x}, \bar{x})$; the residual, whose length squared is $\sum(x_i - \bar{x})^2$, is perpendicular to the diagonal. All data sets with the same mean lie on the dashed line, so the residual has only $n - 1 = 1$ direction to move in. For an isotropic Gaussian the component along the diagonal and the component across it are independent.

Python: checking the theorem, and seeing it fail. The script draws 200000 samples of $n = 5$ Gaussian readings.

Listing 2.17: The sample variance: $n - 1$ degrees of freedom, and independence from the mean (`code/ch02/25_chi2_sampvar.py`)

```
67 n, sigma, mu = 5, 2.0, 10.0
68 xs = rng.normal(mu, sigma, (NREP, n))
69 xbar = xs.mean(axis=1)
70 S2 = xs.var(axis=1, ddof=1)             # 1/(n-1) estimator
71 S2n = xs.var(axis=1, ddof=0)            # 1/n estimator
72 w = (n - 1) * S2 / sigma ** 2
73
74 # known-mean version: sum (x_i - mu)^2 / sigma^2 has n dof
75 w_known = ((xs - mu) ** 2).sum(axis=1) / sigma ** 2
76
77 # independence of xbar and S^2: Gaussian vs exponential parent
78 xe = rng.exponential(1.0, (NREP, n))
79 corr_gauss = np.corrcoef(xbar, S2)[0, 1]
80 corr_exp = np.corrcoef(xe.mean(axis=1), xe.var(axis=1, ddof=1))[0, 1]
```

Line 70 computes S^2 with `ddof=1`, numpy's name for dividing by $n - 1$ ("delta degrees of freedom"). Line 71 divides by n. Line 72 forms $(n-1)S^2/\sigma^2$, whose simulated mean and variance are 4.002 and 8.022, as χ^2_4 requires (4 and 8). Line 75 forms the same sum with the true mean instead of $\bar{x}$, which follows χ^2_5 instead (Figure 2.38a). Lines 78–80 test independence, and show where it fails. The correlation between $\bar{x}$ and S^2 is +0.0016 for Gaussian readings, but +0.685 for exponential readings. *Why?* For a skewed parent, a sample that happens to contain a large value has both a large mean and a large variance. The independence of $\bar{x}$ and S^2 is special to the Gaussian (it actually characterises it), and so is everything built on it in the next section.

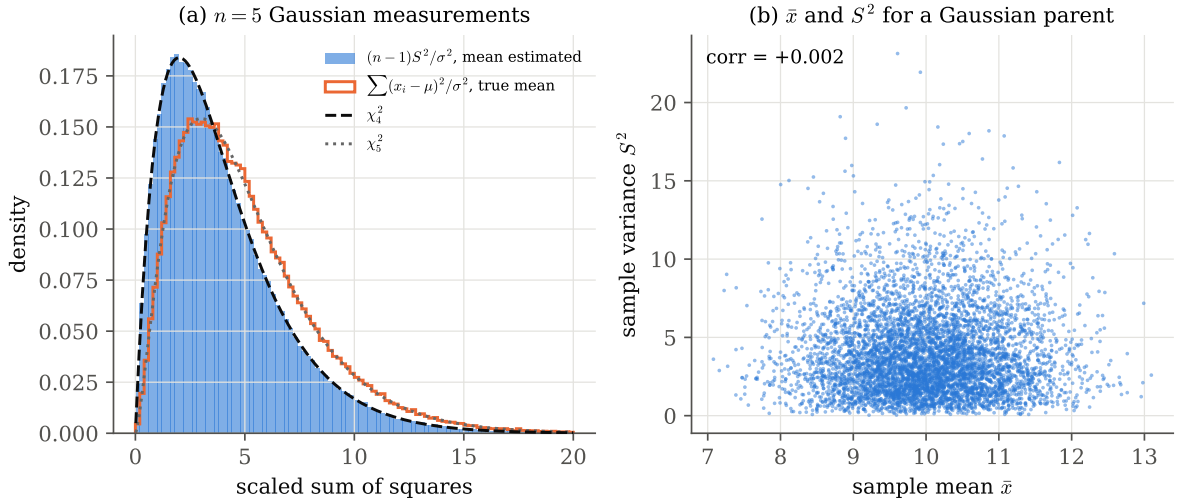

Figure 2.38: (a) For five Gaussian readings, the scaled sum of squared deviations from the sample mean (histogram) follows χ^2_4 (dashed), while deviations from the true mean (outline) follow χ^2_5 (dotted). (b) Sample mean against sample variance for Gaussian readings: no trend at all, as independence requires.

Watch out: Degrees of freedom are dimensions, not data points

The rule "ν = number of data minus number of fitted parameters" is the rotation argument again: each parameter that enters the model *linearly* and is fitted by least squares removes one direction from the residual vector, exactly as $\bar{x}$ did. The rule is exact for linear models with Gaussian errors, approximate for nonlinear ones, and wrong when the data are correlated but treated as independent, or when parameters sit at a physical boundary.

2.14 When the error bar is itself estimated: Student's t and the F ratio

We time five swings of a pendulum, compute g from each, and quote the result as $\bar{x} \pm S/\sqrt{5}$, with S the sample standard deviation. Then, to claim a "two-sigma" discrepancy with the textbook value, we check whether $|\bar{x} - g_0|$ exceeds $1.96\, S/\sqrt{5}$. This is wrong, and not by a little. The rule 1.96 comes from the Gaussian, and it assumes that we know the true σ. We do not. Our error bar is itself a random number, computed from the same five readings, and sometimes it comes out much too small. When it does, the ratio $(\bar{x} - \mu)/(S/\sqrt{n})$ is large, with μ the true value. So the ratio has fatter tails than a Gaussian. W. S. Gosset, who faced exactly this with small samples at the Guinness brewery and published as "Student", derived its distribution [CasellaBerger p. 181].

Gosset's distribution does three jobs. It is the exact distribution of the *studentised* mean for Gaussian data, so small-sample intervals and tests built on it are honest. It is also a Gaussian whose variance is itself random, which makes it the standard robust replacement for a Gaussian likelihood. And the same construction applied to two variances gives the F distribution, the tool for asking whether two detectors, two runs or two models have the same scatter.

The question, in words: *if a Gaussian quantity is divided by an independent, estimated measure of its own spread, how is the ratio distributed, and how different is it from a Gaussian?*

2.14.1 The studentised mean

Why this ratio appears. Let $x_1, \dots, x_n \overset{\text{iid}}{\sim} \mathcal{N}(\mu, \sigma^2)$. If we knew σ, the standardised mean

$$U = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}} \sim \mathcal{N}(0,1)$$

would be all we need. We do not know σ, so we replace it by the sample standard deviation S, with $S^2 = \frac{1}{n-1}\sum_i (x_i - \bar{x})^2$. Write $p = n-1$. The quantity we actually compute is the **studentised mean**, and dividing its top and bottom by $\sigma/\sqrt{n}$ shows what it is made of [CasellaBerger (5.3.5)]:

$$T = \frac{\bar{x} - \mu}{S/\sqrt{n}} \overset{(1)}{=} \frac{(\bar{x} - \mu)/(\sigma/\sqrt{n})}{\sqrt{S^2/\sigma^2}} \overset{(2)}{=} \frac{U}{\sqrt{V/p}}, \qquad V = \frac{(n-1)S^2}{\sigma^2} \sim \chi^2_p. \tag{2.98}$$

(1) Divide numerator and denominator by $\sigma/\sqrt{n}$. The $\sqrt{n}$ cancels in the denominator.
(2) $S^2/\sigma^2 = V/p$ by the definition of V. That V is χ^2_p, and that U and V are independent, are the results on the sample mean and variance of Section 2.13.4.

The unknown σ has cancelled. So the whole problem is: given two independent pieces, $U \sim \mathcal{N}(0,1)$ and $V \sim \chi^2_p$, what is the distribution of $T = U/\sqrt{V/p}$?

The two ingredients and their joint density. The density of U is the standard Gaussian, and the density of V is the χ^2_p density (2.92):

$$f_U(u) = \frac{1}{\sqrt{2\pi}} e^{-u^2/2}, \qquad f_V(v) = \frac{1}{2^{p/2}\Gamma(p/2)} v^{p/2-1} e^{-v/2} \quad (v > 0). \tag{2.99}$$

Because U and V are independent, their joint density is the product, $f_{U,V}(u,v) = f_U(u)\, f_V(v)$.

Change variables from (U,V) to (T,V). We keep V and trade U for T. Solving (2.98) for u gives the map and its Jacobian:

$$u = t\sqrt{\frac{v}{p}}, \quad v = v, \qquad \left|\frac{\partial(u,v)}{\partial(t,v)}\right| \overset{(1)}{=} \begin{vmatrix} \sqrt{v/p} & \dfrac{t}{2\sqrt{pv}} \\ 0 & 1 \end{vmatrix} \overset{(2)}{=} \sqrt{\frac{v}{p}}. \tag{2.100}$$

(1) The four partial derivatives: $\partial u/\partial t = \sqrt{v/p}$, $\partial u/\partial v = t/(2\sqrt{pv})$, $\partial v/\partial t = 0$, $\partial v/\partial v = 1$.
(2) The matrix is triangular, so its determinant is the product of the diagonal entries. The off-diagonal entry never matters.

The joint density of (T,V) is the old joint density, evaluated at the old variables, times this Jacobian (the rule of Eq. (1.38)):

$$\begin{aligned} f_{T,V}(t,v) &\overset{(1)}{=} f_U\!\left(t\sqrt{\tfrac{v}{p}}\right) f_V(v) \sqrt{\frac{v}{p}} \\ &\overset{(2)}{=} \frac{1}{\sqrt{2\pi}} e^{-t^2 v/(2p)} \, \frac{v^{p/2-1} e^{-v/2}}{2^{p/2}\Gamma(p/2)} \sqrt{\frac{v}{p}} \\ &\overset{(3)}{=} \frac{1}{\sqrt{2\pi p}\; 2^{p/2}\Gamma(p/2)} \, v^{(p+1)/2-1} \exp\!\left[-\frac{v}{2}\left(1 + \frac{t^2}{p}\right)\right]. \end{aligned} \tag{2.101}$$

(1) Change of variables, with the joint density of (U,V) factorised by independence.
(2) Substitute the two densities (2.99), with $u^2 = t^2 v/p$.
(3) Collect the powers of v: $v^{p/2-1} \cdot v^{1/2} = v^{(p+1)/2-1}$. Collect the exponentials: $e^{-t^2 v/(2p)}\, e^{-v/2} = e^{-\frac{v}{2}(1+t^2/p)}$. The constants are $1/\sqrt{2\pi}$, $1/\sqrt{p}$ and $1/(2^{p/2}\Gamma(p/2))$.

The question that finishes the job. What is the probability density for $T = t$, regardless of what V happens to be? That is a marginal density: we have the joint density of (T, V), and V is a nuisance we do not care about, so we integrate it out (Section 1.10.2). Write $A = 1 + t^2/p$ to keep the formula short. Then

$$\begin{aligned} f_T(t) &\overset{(1)}{=} \int_0^\infty f_{T,V}(t,v)\,\mathrm{d}v \\ &\overset{(2)}{=} \frac{1}{\sqrt{2\pi p}\,2^{p/2}\Gamma(p/2)} \int_0^\infty v^{(p+1)/2-1}\, e^{-Av/2}\,\mathrm{d}v \\ &\overset{(3)}{=} \frac{1}{\sqrt{2\pi p}\,2^{p/2}\Gamma(p/2)}\,\Gamma\!\Big(\frac{p+1}{2}\Big)\Big(\frac{2}{A}\Big)^{(p+1)/2} \\ &\overset{(4)}{=} \frac{\Gamma\big(\frac{p+1}{2}\big)}{\Gamma\big(\frac{p}{2}\big)\sqrt{p\pi}}\,\Big(1+\frac{t^2}{p}\Big)^{-(p+1)/2}. \end{aligned} \tag{2.102}$$

(1) Marginalisation: the density of T alone is the joint density summed (integrated) over every value V can take.
(2) Insert (2.101). Everything that does not depend on v comes outside the integral.
(3) The gamma integral $\int_0^\infty x^{a-1}e^{-bx}\,\mathrm{d}x = \Gamma(a)/b^a$, with $a = \frac{p+1}{2}$ and $b = \frac{A}{2}$, so $1/b^a = (2/A)^{(p+1)/2}$.
(4) The powers of two cancel, $2^{(p+1)/2}/(2^{p/2}\sqrt{2}) = 1$, leaving $1/\sqrt{\pi p}$; then put back $A = 1 + t^2/p$.

This is Student's t density with p degrees of freedom [CasellaBerger (5.3.6)], [Wasserman p. 30]. The whole construction fits in one line: a standard Gaussian U, divided by the square root of an independent χ^2_p/p, is t_p. The t distribution exists because the fixed σ of a Gaussian standardisation has been replaced by a random estimate, whose square is a scaled χ^2, and that extra randomness fattens the tails.

Working definition 2.19 (Student's t distribution)

$T \sim t_p$ if $T = U/\sqrt{V/p}$ with $U \sim \mathcal{N}(0,1)$ and $V \sim \chi^2_p$ independent; its density is (2.102). For Gaussian data, $(\bar{x} - \mu)/(S/\sqrt{n}) \sim t_{n-1}$ exactly, for every $n \geq 2$. *Equivalent picture:* a Gaussian $\mathcal{N}(0, \sigma^2)$ whose variance is random, $\sigma^2 \sim \text{Inv-Gamma}(p/2, p/2)$ [so the precision $1/\sigma^2$ is a gamma variable with mean one] [Lambert §8.4.7]. *Summary numbers:* $\mathbb{E}\,T = 0$ for $p > 1$, $\operatorname{Var} T = p/(p-2)$ for $p > 2$; only moments of order less than p exist.

The tails, and the moments that do not exist. For large $|t|$, (2.102) falls like $|t|^{-(p+1)}$, a power law. So $\mathbb{E}\,|T|^r$ is finite only for $r < p$ [CasellaBerger (5.3.7)]. With $p = 1$ the density is $\Gamma(1)/(\Gamma(\frac{1}{2})\sqrt{\pi})\,(1+t^2)^{-1} = \frac{1}{\pi(1+t^2)}$, the Cauchy distribution of Section 2.10.5. So the studentised mean of *two* Gaussian measurements has no mean at all. The variance, for $p > 2$, follows from independence:

$$\operatorname{Var} T = \mathbb{E}\,T^2 \overset{(1)}{=} p\;\mathbb{E}(U^2)\;\mathbb{E}\Big(\frac{1}{V}\Big) \overset{(2)}{=} p\int_0^\infty \frac{1}{v}\,\frac{v^{p/2-1}e^{-v/2}}{2^{p/2}\Gamma(p/2)}\,\mathrm{d}v \overset{(3)}{=} p\,\frac{2^{p/2-1}\Gamma(p/2-1)}{2^{p/2}\Gamma(p/2)} \overset{(4)}{=} \frac{p}{p-2}. \tag{2.103}$$

(1) $T^2 = pU^2/V$ with U and V independent, so the expectation factorises; $\mathbb{E}\,T = 0$ by symmetry.
(2) $\mathbb{E}\,U^2 = 1$, and the expectation of $1/V$ is its integral against the χ^2_p density.
(3) The integrand is $v^{(p/2-1)-1}e^{-v/2}$, which integrates to $\Gamma(p/2-1)\,2^{p/2-1}$ provided $p > 2$ (otherwise it diverges at $v = 0$).

(4) $\Gamma(p/2) = (p/2-1)\Gamma(p/2-1)$, so the ratio is $\frac{1}{2(p/2-1)} = \frac{1}{p-2}$.

The variance of T is dominated by the rare samples whose estimated error bar S happens to be tiny. That is what the divergence of step (3) at small v means. As $p \to \infty$, $V/p \to 1$ by the law of large numbers and $(1 + t^2/p)^{-(p+1)/2} \to e^{-t^2/2}$, so $t_\infty = \mathcal{N}(0,1)$ [Wasserman p. 30]. For non-Gaussian data and large n the studentised mean still tends to $\mathcal{N}(0,1)$ (the studentised CLT, [Wasserman Thm 5.10]). What the t distribution adds is the *exact* small-n answer for Gaussian data.

Example: five pendulum readings. Back to the five pendulum values of g from the opening: how often does the Gaussian rule cry "two sigma" when nothing is wrong? The script simulates 400000 experiments of $n = 5$ readings with $\sigma = 0.05\,\mathrm{m\,s^{-2}}$ and computes T for each.

Listing 2.18: The studentised mean of five Gaussian readings (`code/ch02/26_student_t_F.py`)

```
35 n, mu, sigma = 5, 9.81, 0.05                  # five pendulum readings of g, noise 0.05
36 x = rng.normal(mu, sigma, (NREP, n))
37 xbar = x.mean(axis=1)
38 S = x.std(axis=1, ddof=1)
39 T = (xbar - mu) / (S / np.sqrt(n))             # sigma replaced by its estimate
40 Z = (xbar - mu) / (sigma / np.sqrt(n))         # sigma known: exactly N(0,1)
41
42 frac_T_196 = np.mean(np.abs(T) > 1.96)         # "2-sigma" by the Gaussian table
43 frac_Z_196 = np.mean(np.abs(Z) > 1.96)
44 t975 = stats.t.ppf(0.975, n - 1)               # the correct 95% two-sided point
45 frac_T_t975 = np.mean(np.abs(T) > t975)
46 frac_T_3 = np.mean(np.abs(T) > 3.0)
```

Line 38 estimates the error bar from the same five numbers (`ddof=1` is the $n-1$ divisor). Line 39 forms T with the estimated error bar and line 40 forms the same ratio with the true σ, which is exactly $\mathcal{N}(0,1)$. Lines 42–46 count how often each exceeds various thresholds. *With the true* σ, $|Z| > 1.96$ happens in a fraction 0.0497 of experiments, the promised 5%. *With the estimated error bar*, $|T| > 1.96$ happens in 0.1209, against the t_4 prediction 0.1216. So the nominal "2σ discrepancy" occurs more than twice as often as claimed. The correct 95% point is $t_{4,\,0.975} = 2.776$, and $|T|$ exceeds it in a fraction 0.0493. Further out the difference explodes: $|T| > 3$ happens in 0.0396 of experiments (t_4: 0.0399), fifteen times the Gaussian 0.0027 (Figure 2.39a).

Watch out: Do not use Gaussian thresholds with an estimated error bar

With n readings and σ estimated from them, the two-sided 95% multiplier is $t_{n-1,0.975}$: 12.7 for $n = 2$, 4.30 for $n = 3$, 2.78 for $n = 5$, 2.26 for $n = 10$, 2.09 for $n = 20$, and it reaches 1.96 only as $n \to \infty$. For three-sigma or five-sigma claims the Gaussian rule is off by orders of magnitude unless n is large. And the exact t needs Gaussian readings: with a few outliers even t is too optimistic.

Example: a Gaussian with a random width. Integrating V out of (2.101) has a second reading. For a fixed value $V = v$, $T = U\sqrt{p/v}$ is just a Gaussian with variance p/v; integrating over v averages these Gaussians of different widths. So the t distribution is a Gaussian whose width is itself random, and that is also a recipe for modelling data. Lambert's schools example [Lambert §8.4.7] merges the test scores of many schools that share one mean but have different spreads. Each school on its own is Gaussian; the merged population is not. If the school variances are distributed as $\sigma^2 \sim \text{Inv-Gamma}(\nu/2, \nu/2)$, equivalently the precisions $1/\sigma^2$ as $\text{Gamma}(\nu/2, \text{scale } 2/\nu)$, which is χ^2_ν/ν, the merged distribution is exactly t_ν: "its head rises, its shoulders fall, and its tails fatten." The script draws 400000 values both ways for $\nu = 3$: as a

Gaussian with a random precision (lines 51–52), and as $U/\sqrt{V/\nu}$ (line 54). Both histograms follow t_3, with Kolmogorov–Smirnov distances [the largest gap between the empirical and the exact cumulative distribution] of 0.0010 and 0.0013, as small as sampling noise allows at this sample size (Figure 2.39b).

So the t distribution is the workhorse *robust likelihood*. When a few measurements have underestimated errors, when a detector occasionally misbehaves, when the population is heterogeneous, a t_ν likelihood with ν of a few lets outliers exist without dragging the fit. The degrees of freedom need not be an integer: ν is a free, real-valued shape parameter that can itself be fitted [Lambert §8.4.7]. Its multivariate version, a multivariate Gaussian with one random scale factor for the whole covariance, gives joint tails heavy enough to see Lambert's hedge-fund "bankruptcy days" that a multivariate normal fit misses [Lambert §8.4.11].

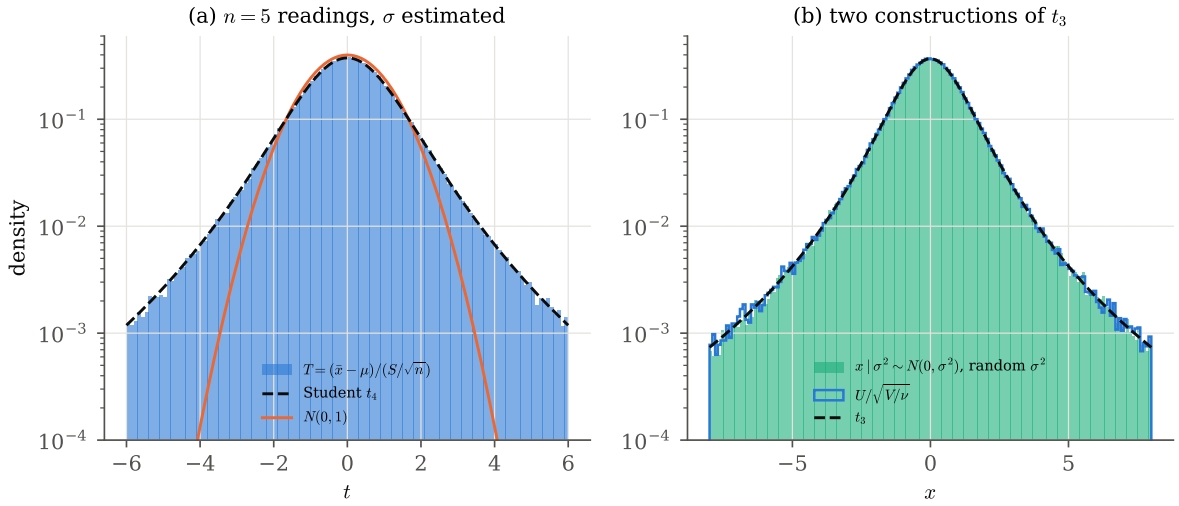

Figure 2.39: (a) The studentised mean of five Gaussian readings (histogram, logarithmic scale) follows Student's t_4 (dashed). The standard normal (solid) is far too thin in the tails. (b) Two constructions of t_3: a Gaussian whose variance is drawn afresh from an inverse-gamma distribution for every value, and the ratio $U/\sqrt{V/\nu}$. They are the same distribution.

2.14.2 Ratios of variances: Snedecor's F

Two calorimeters measure the same electron beam. Calorimeter X gives n_X readings with sample variance S_X^2, calorimeter Y gives n_Y readings with S_Y^2. Is X's resolution really worse, or did the numbers fluctuate? For Gaussian readings each $(n-1)S^2/\sigma^2$ is χ^2_{n-1}, and the two are independent, so [CasellaBerger (5.3.8)]

$$F = \frac{S_X^2/\sigma_X^2}{S_Y^2/\sigma_Y^2} = \frac{V_1/p}{V_2/q}, \qquad V_1 \sim \chi^2_p, \quad V_2 \sim \chi^2_q, \qquad p = n_X - 1, \quad q = n_Y - 1. \tag{2.104}$$

Under the hypothesis $\sigma_X = \sigma_Y$ the unknown widths cancel and $F = S_X^2/S_Y^2$ is computable from the data. Its density comes from the same trick as for t: hold the denominator fixed, then average over it. Fix $V_2 = w$. Then $F = \frac{q}{pw} V_1$, so $V_1 = \frac{pw}{q} x$ and $f_{F\,|\,w}(x) = \frac{pw}{q} f_p\big(\frac{pwx}{q}\big)$. Averaging over w:

$$f_F(x) \overset{(1)}{=} \int_0^\infty f_q(w)\, \frac{pw}{q}\, f_p\Big(\frac{pwx}{q}\Big) \mathrm{d}w$$
$$\overset{(2)}{=} \frac{(p/q)^{p/2}\, x^{p/2-1}}{2^{(p+q)/2}\Gamma(\frac{p}{2})\Gamma(\frac{q}{2})} \int_0^\infty w^{(p+q)/2-1}\, e^{-\frac{w}{2}\left(1+\frac{px}{q}\right)} \mathrm{d}w$$

$$\overset{(3)}{=} \frac{\Gamma\left(\frac{p+q}{2}\right)}{\Gamma\left(\frac{p}{2}\right)\Gamma\left(\frac{q}{2}\right)} \left(\frac{p}{q}\right)^{p/2} \frac{x^{p/2-1}}{\left(1+\frac{p}{q}x\right)^{(p+q)/2}}, \qquad x > 0. \tag{2.105}$$

(1) Law of total probability, with the change-of-variable factor $\frac{\mathrm{d}V_1}{\mathrm{d}x} = \frac{pw}{q}$.

(2) Insert both χ^2 densities (2.92). The powers of w are $1 + (\frac{p}{2} - 1) + (\frac{q}{2} - 1) = \frac{p+q}{2} - 1$; the x-dependence outside the integral is $x^{p/2-1}$ with the constant $(p/q)^{1+p/2-1}$.

(3) The gamma integral with $a = \frac{p+q}{2}$ and $c = \frac{1}{2}(1 + px/q)$; the factor $2^{(p+q)/2}$ cancels.

This is Snedecor's $F_{p,q}$ density [CasellaBerger (5.3.9)]. Its mean is slightly above one. By the same factorisation as (2.103), $\mathbb{E}\,F = \frac{q}{p}\,\mathbb{E}\,V_1\,\mathbb{E}\,\frac{1}{V_2} = \frac{q}{q-2}$ for $q > 2$ [CasellaBerger Ex. 5.3.7]. It exceeds one because $1/V_2$ is convex, so its average exceeds one over the average of V_2.

Three facts connect F to its neighbours [CasellaBerger Thm 5.3.8], and each is visible from the definition (2.104). First, $1/F \sim F_{q,p}$: swap numerator and denominator. Second, if $T \sim t_q$ then $T^2 = U^2/(V/q) = (\chi^2_1/1)/(\chi^2_q/q) \sim F_{1,q}$. Third, $\frac{(p/q)F}{1+(p/q)F} = \frac{V_1}{V_1+V_2} \sim \mathrm{Beta}(p/2, q/2)$, the fraction of a total carried by one gamma variable, which we derive in Section 2.15. Casella and Berger also note Kelker's result: the ratio has an F distribution for any spherically symmetric parent, not only the Gaussian. So the F test is somewhat robust.

Example: two calorimeters. Small samples determine variances poorly. With six and eleven readings, one calorimeter's variance must come out more than three times the other's before we can claim, at the 5% level, that its resolution is worse. The script shows this. It takes $n_X = 6$ readings with $\sigma_X = 1.5$ and $n_Y = 11$ readings with $\sigma_Y = 0.4$ (the true widths differ, but they cancel in (2.104)), so $p = 5$ and $q = 10$. Over 400000 repetitions the mean of F is 1.252, against $q/(q-2) = 1.250$. The 95th percentile of $F_{5,10}$ is 3.326, and it is exceeded in a fraction 0.0502 of repetitions (Figure 2.40a). The script also squares the t_4 values of the pendulum experiment and compares them with $F_{1,4}$: the Kolmogorov–Smirnov distance on 10^5 values is 0.0035 (Figure 2.40b).

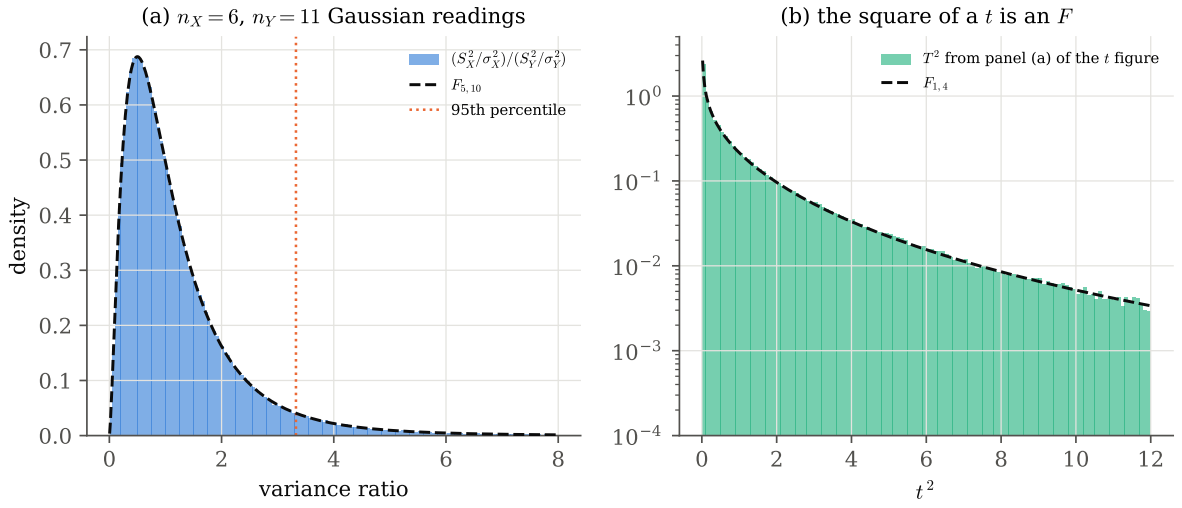

Figure 2.40: (a) The ratio of two scaled sample variances, from six and eleven Gaussian readings, follows $F_{5,10}$ (dashed); the dotted line marks its 95th percentile. (b) The squares of the studentised means of the pendulum experiment follow $F_{1,4}$, on a logarithmic scale that shows the power-law tail.

Where the ratios come back. Every exact small-sample test in classical statistics is built on one pattern: a Gaussian or a χ^2, divided by an independent χ^2 that estimates the unknown scale. Examples are the t test for a mean, the two-sample t test, the F test for the equality of variances, and the F test that compares a model with a nested model having extra parameters by the ratio of χ^2 improvements. These are the subject of Chapter 4. Bayesian inference (Chapter 5) arrives at the same t_{n-1}. Integrating an unknown Gaussian σ out of the posterior for μ, with the prior $p(\sigma) \propto 1/\sigma$, produces it [Sivia p. 56–57, (3.43)–(3.44)]. The fattening of the tails is the price of not knowing the noise level, whichever school of inference pays it.

2.15 The rest of the zoo, each with the machine that makes it

Almost every distribution a physicist meets is produced by a small machine built from the ones we already have: a uniform phase, a sum, a product, a length, a ratio, a sorting. So a table of distributions is not a list of unrelated formulas. Recognising the machine lets us choose the right distribution for a new problem, and it tells us when a distribution will fail. Each remaining common continuous distribution is treated the same way: the machine, the density derived from it, the summary numbers, and a check by running the machine in Python.

The question for every entry, in words: *which physical mechanism produces this distribution, and what does the mechanism predict for its shape, its mean and its spread?*

2.15.1 Uniform: complete ignorance within a range

A charged particle crosses a silicon strip detector whose strips have pitch $w = 50\,\mu\text{m}$, and only the strip that fired is recorded. Where in the strip did the particle pass? With no further information every position is equally likely. The same holds for a phase that has been scrambled, the rounding error of a digitiser, or the position of an event within a time bin. All are **uniform**: $X \sim \mathrm{U}(a, b)$ has density $1/(b-a)$ on $[a, b]$ [CasellaBerger p. 81]. It is the maximum-entropy assignment when only the range is known (Section 2.11.5). Its moments are

$$\begin{aligned} \mathbb{E}\,X &\overset{(1)}{=} \int_a^b \frac{x}{b-a}\,\mathrm{d}x = \frac{b^2-a^2}{2(b-a)} = \frac{a+b}{2}, \\ \operatorname{Var} X &\overset{(2)}{=} \int_a^b \frac{(x-\frac{a+b}{2})^2}{b-a}\,\mathrm{d}x \overset{(3)}{=} \frac{1}{b-a}\int_{-(b-a)/2}^{(b-a)/2} u^2\,\mathrm{d}u = \frac{(b-a)^2}{12}. \end{aligned} \tag{2.106}$$

(1) Definition of the mean, and $b^2 - a^2 = (b-a)(b+a)$.
(2) Definition of the variance about the mean just found.
(3) Substitute $u = x - \frac{a+b}{2}$; then $\int_{-h}^{h} u^2\mathrm{d}u = \frac{2h^3}{3}$ with $h = \frac{b-a}{2}$, which gives $\frac{(b-a)^3}{12}$.

So the strip detector has a position resolution of $w/\sqrt{12} = 14.4\,\mu\text{m}$, the famous "pitch over root twelve", and a digitiser with step Δ adds quantisation noise of variance $\Delta^2/12$.

The uniform distribution is also the parent of all others: any continuous variable can be made from a uniform one, and turned back into one. If X is continuous with cumulative distribution function F, then $U = F(X)$ is uniform on $[0, 1]$, because

$$\mathrm{P}(U \le u) \overset{(1)}{=} \mathrm{P}\big(X \le F^{-1}(u)\big) \overset{(2)}{=} F\big(F^{-1}(u)\big) = u,$$

where (1) uses that F is increasing and (2) is the definition of F. Read backwards, $X = F^{-1}(U)$ turns uniform random numbers into draws from any distribution: this is inverse-transform sampling, the first tool of Chapter 6. Read forwards, it says that a p-value, which is $1 - F$ of the observed statistic under H_0, is uniformly distributed when H_0 is true (Chapter 4).

2.15.2 Exponential, gamma and Weibull: waiting and adding

The exponential and gamma distributions were derived in Section 2.6 from the Poisson process with rate λ: the wait for the first event is $\text{Exp}(\lambda)$, and the wait for the n-th event is $\text{Gamma}(n, 1/\lambda)$, the Erlang density (2.19). The characteristic function (2.94) shows the whole family at once: gamma variables with a common scale add. $\text{Gamma}(\alpha, \beta)$, with shape α and scale β, has $\phi(k) = (1 - i\beta k)^{-\alpha}$, so for independent gamma variables with a common scale

$$\text{Gamma}(\alpha_1, \beta) + \text{Gamma}(\alpha_2, \beta) = \text{Gamma}(\alpha_1 + \alpha_2, \beta), \tag{2.107}$$

since $(1 - i\beta k)^{-\alpha_1}(1 - i\beta k)^{-\alpha_2} = (1 - i\beta k)^{-(\alpha_1+\alpha_2)}$ [CasellaBerger Ex. 4.6.8]. Two special lines of the family we have met: $\text{Exp}(\lambda) = \text{Gamma}(1, 1/\lambda)$, and $\chi^2_\nu = \text{Gamma}(\nu/2, 2)$ [CasellaBerger (3.3.10)–(3.3.11)]. So adding exponential waits and adding squared Gaussians are the same operation seen through different parameters.

The moments follow from a trick called "recognise the kernel" [CasellaBerger (3.3.7)–(3.3.8)]: multiplying by x turns one gamma density into another, whose integral we already know. Since the gamma density integrates to one, $\int_0^\infty x^{\alpha-1}e^{-x/\beta}\mathrm{d}x = \Gamma(\alpha)\beta^\alpha$ for every $\alpha > 0$. Then

$$\mathbb{E}\,X \overset{(1)}{=} \frac{1}{\Gamma(\alpha)\beta^\alpha}\int_0^\infty x^{(\alpha+1)-1}e^{-x/\beta}\,\mathrm{d}x \overset{(2)}{=} \frac{\Gamma(\alpha+1)\beta^{\alpha+1}}{\Gamma(\alpha)\beta^\alpha} \overset{(3)}{=} \alpha\beta, \tag{2.108}$$

(1) Multiply the density by x: the integrand becomes the kernel of a $\text{Gamma}(\alpha + 1, \beta)$ density.
(2) Its integral is the normalisation of that density.
(3) $\Gamma(\alpha + 1) = \alpha\Gamma(\alpha)$.

and in the same way $\mathbb{E}\,X^2 = \alpha(\alpha + 1)\beta^2$, so $\text{Var}\,X = \alpha\beta^2$. For χ^2_ν this gives back ν and 2ν.

A third member of the waiting-time family is the **Weibull** distribution, $Y = X^{1/\gamma}$ with X exponential [CasellaBerger (3.3.12)]. It is the lifetime of a component whose failure rate $h(t)$ is not constant but grows (or falls) like a power of its age, $h(t) \propto t^{\gamma-1}$. So $\gamma > 1$ describes wear-out, $\gamma < 1$ infant mortality, and $\gamma = 1$ the memoryless exponential. The Weibull is also one of the three limiting laws for the *maximum* of many variables, listed in the taxonomy of Section 2.10.6.

As a prior, the gamma distribution is the natural choice for a Poisson rate $\lambda > 0$ [Lambert §8.5.3]. The reason is conjugacy, which Machine 3 of the beta distribution below shows at work.

2.15.3 Log-normal: products of many factors

A photo-electron entering a photomultiplier hits the first dynode and knocks out g_1 secondary electrons. Each of these knocks g_2 out of the next dynode, and so on through ten stages. The gain is a *product*, $G = g_1 g_2 \cdots g_{10}$. A product becomes a sum when we take logarithms: $\ln G = \sum_i \ln g_i$ is a sum of independent terms, so the central limit theorem makes $\ln G$ approximately Gaussian [Cowan p. 34–35]. A quantity whose logarithm is Gaussian is **log-normal**. Whenever an effect acts by multiplication (gains in cascades, fragmentation, growth, the stretching of fluid elements, the luminosity of a galaxy built by many mergers) the log-normal is the default, just as the Gaussian is for additive effects.

If $\ln X = Y \sim \mathcal{N}(\mu, \sigma^2)$, then $X = e^Y$ and $\mathrm{d}y/\mathrm{d}x = 1/x$, so

$$f(x) \overset{(1)}{=} f_Y(\ln x)\left|\frac{\mathrm{d}y}{\mathrm{d}x}\right| \overset{(2)}{=} \frac{1}{\sqrt{2\pi\sigma^2}}\,\frac{1}{x}\,\exp\!\left[-\frac{(\ln x - \mu)^2}{2\sigma^2}\right], \qquad x > 0, \tag{2.109}$$

(1) The one-dimensional change of variables.
(2) Insert the Gaussian density for $Y = \ln x$ [Cowan (2.31)], [CasellaBerger (3.3.21)].

The parameters μ and σ^2 are the mean and variance of $\ln X$, not of X. The moments of X come from the Gaussian moment generating function $\mathbb{E}\,e^{rY}$:

$$\mathbb{E}\,X^r = \mathbb{E}\,e^{rY} \overset{(1)}{=} \int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2}} \exp\!\left[ry - \frac{(y-\mu)^2}{2\sigma^2}\right] \mathrm{d}y$$
$$\overset{(2)}{=} e^{r\mu + r^2\sigma^2/2} \int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2}} \exp\!\left[-\frac{(y-\mu-r\sigma^2)^2}{2\sigma^2}\right] \mathrm{d}y \overset{(3)}{=} e^{r\mu + r^2\sigma^2/2}. \tag{2.110}$$

(1) $X^r = e^{rY}$, integrated against the density of Y.

(2) Complete the square: $ry - \frac{(y-\mu)^2}{2\sigma^2} = -\frac{(y-\mu-r\sigma^2)^2}{2\sigma^2} + r\mu + \frac{r^2\sigma^2}{2}$, as expanding both sides confirms.

(3) The remaining integral is a normalised Gaussian centred at $\mu + r\sigma^2$.

So $\mathbb{E}\,X = e^{\mu+\sigma^2/2}$ and $\operatorname{Var} X = \mathbb{E}\,X^2 - (\mathbb{E}\,X)^2 = e^{2\mu+\sigma^2}(e^{\sigma^2} - 1)$ [Cowan (2.32)–(2.33)]. The median is e^{μ}, because ln is monotonic and the median of Y is μ. So mean > median > mode = $e^{\mu-\sigma^2}$: a long tail to the right.

Example: the gain of a ten-stage photomultiplier. The script gives each of 10 dynodes an independent uniform multiplication factor $g_i \sim \mathrm{U}(3,5)$, draws 4×10^5 gains, and compares with the log-normal predicted by the CLT applied to $\ln G$.

Listing 2.19: The gain of a ten-dynode photomultiplier (`code/ch02/27_zoo_lognormal_maxwell.py`)

```
35 n_dyn = 10
36 g = rng.uniform(3.0, 5.0, (NREP, n_dyn))
37 G = g.prod(axis=1)
38 lnG = np.log(G)
39 # CLT prediction for ln G: sum of n_dyn iid ln g_i
40 # E ln g and Var ln g for g ~ U(3,5), computed by quadrature-free closed form
41 a, b = 3.0, 5.0
42 E_ln = (b * np.log(b) - b - (a * np.log(a) - a)) / (b - a)
43 E_ln2 = (b * (np.log(b) ** 2 - 2 * np.log(b) + 2) - a * (np.log(a) ** 2 - 2 * np.log(a) +
       2)) / (b - a)
44 mu_ln = n_dyn * E_ln
45 s_ln = np.sqrt(n_dyn * (E_ln2 - E_ln ** 2))
46 mean_G_th_ln = np.exp(mu_ln + s_ln ** 2 / 2)       # log-normal mean
47 mean_G_exact = 4.0 ** n_dyn                          # E prod g_i = (E g)^n exactly
48 median_G = np.median(G)
```

Lines 36–38 run the machine: multiply ten factors, take the log. Lines 42–45 compute the CLT prediction exactly. For a uniform g, $\mathbb{E}\ln g$ and $\mathbb{E}(\ln g)^2$ are elementary integrals ($\int \ln g\,\mathrm{d}g = g\ln g - g$ and $\int (\ln g)^2 \mathrm{d}g = g[(\ln g)^2 - 2\ln g + 2]$). The mean and variance of $\ln G$ are ten times those of $\ln g$. The prediction is $\mu = 13.757$, $\sigma = 0.4633$; the simulated $\ln G$ has mean 13.758 and standard deviation 0.4629.

The gain itself is strongly skewed: its skewness is 1.333, while $\ln G$ has -0.054. Its median is 0.948×10^6 against $e^{\mu} = 0.943 \times 10^6$, and its mean is 1.050×10^6, matching the log-normal $e^{\mu+\sigma^2/2} = 1.050 \times 10^6$ and the exact $\mathbb{E}\,G = (\mathbb{E}\,g)^{10} = 4^{10} = 1.049 \times 10^6$ (Figure 2.41).

Watch out: Averaging logarithms gives the median, not the mean

For a log-normal quantity, $\exp(\overline{\ln x})$ estimates the median e^{μ}, which is smaller than the mean by the factor $e^{\sigma^2/2}$ (11% for the photomultiplier). Fitting a straight line to $\ln x$ and exponentiating the prediction has the same bias. Decide which of the two you need, and correct by $e^{\sigma^2/2}$ if it is the mean.

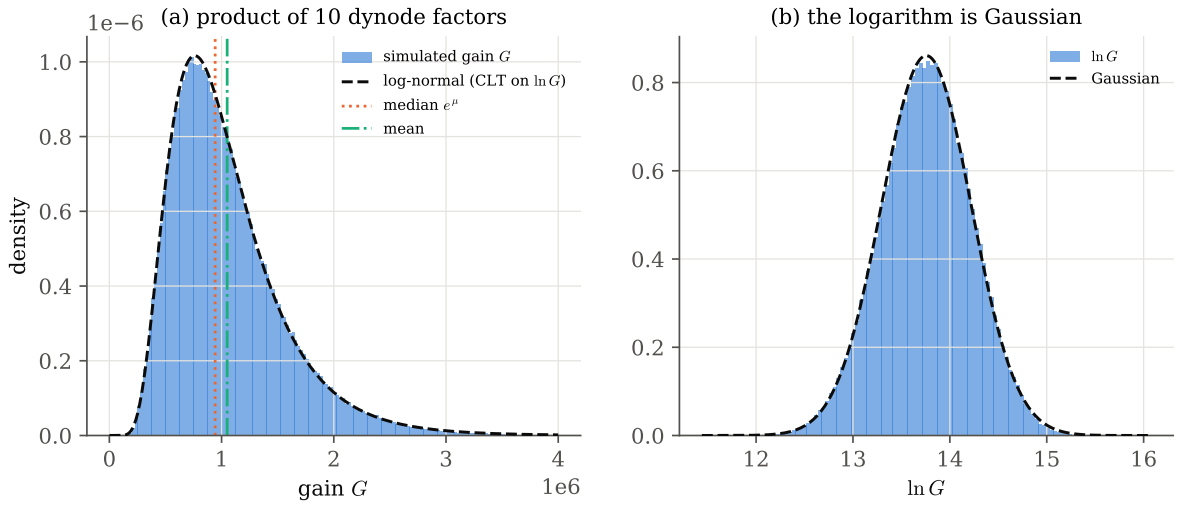

Figure 2.41: (a) The simulated gain of a ten-stage photomultiplier (histogram) and the log-normal predicted by applying the central limit theorem to $\ln G$ (dashed). The median e^{μ} (dotted) lies well below the mean (dash-dotted). (b) The same gains on a logarithmic axis: a symmetric Gaussian.

2.15.4 Rayleigh and Maxwell–Boltzmann: the length of a Gaussian vector

The velocity components (v_x, v_y, v_z) of an argon atom in a gas at temperature T are independent Gaussians with mean zero and variance $s^2 = k_B T/m$ (this is the MaxEnt result of Section 2.11.5, or the Boltzmann factor $e^{-mv^2/2k_BT}$). The *speed* $v = |\boldsymbol{v}|$ is the length of a three-dimensional Gaussian vector. We derived its distribution in all but name in the geometric route to χ^2: the density of $\boldsymbol{v}$ is $(2\pi s^2)^{-3/2} e^{-v^2/2s^2}$, and the volume of the shell at radius v is $S_2 v^2 \mathrm{d}v = 4\pi v^2 \mathrm{d}v$. Hence

$$f(v) \overset{(1)}{=} 4\pi v^2 \frac{e^{-v^2/2s^2}}{(2\pi s^2)^{3/2}} \overset{(2)}{=} \sqrt{\frac{2}{\pi}} \frac{v^2}{s^3} e^{-v^2/2s^2}, \qquad v > 0, \tag{2.111}$$

(1) The shell argument of (2.91) with $\nu = 3$.
(2) $4\pi/(2\pi)^{3/2} = \sqrt{2/\pi}$.

This is the Maxwell–Boltzmann speed distribution. Equivalently, $v^2/s^2 \sim \chi^2_3$. Its three landmark speeds, the most probable, the rms and the mean, are

$$v_{\text{mode}} \overset{(1)}{=} \sqrt{2}\, s = \sqrt{\frac{2k_BT}{m}}, \qquad v_{\text{rms}} \overset{(2)}{=} \sqrt{3}\, s,$$
$$\mathbb{E}\, v \overset{(3)}{=} \sqrt{\frac{2}{\pi}} \frac{1}{s^3} \int_0^\infty v^3 e^{-v^2/2s^2} \mathrm{d}v \overset{(4)}{=} \sqrt{\frac{8}{\pi}}\, s = \sqrt{\frac{8k_BT}{\pi m}}. \tag{2.112}$$

(1) $\frac{\mathrm{d}}{\mathrm{d}v}\left(v^2 e^{-v^2/2s^2}\right) = \left(2v - v^3/s^2\right) e^{-v^2/2s^2} = 0$ at $v^2 = 2s^2$.
(2) $\mathbb{E}\, v^2 = s^2\ \mathbb{E}\, \chi^2_3 = 3s^2$: equipartition, $\frac{1}{2} m\, \mathbb{E}\, v^2 = \frac{3}{2} k_B T$.
(3) Definition of the mean.
(4) With $t = v^2/2s^2$, $\int_0^\infty v^3 e^{-v^2/2s^2} \mathrm{d}v = 2s^4 \int_0^\infty t e^{-t} \mathrm{d}t = 2s^4$, and $\sqrt{2/\pi} \cdot 2s = \sqrt{8/\pi}\, s$.

For argon at 300 K the script finds $s = 249.9$ m/s, and from 4×10^5 simulated atoms a mean speed of 398.9 m/s (theory 398.7), with the mode at 353.4 and the rms speed at 432.8 (theory 432.8) (Figure 2.42b).

In two dimensions the shell has circumference $2\pi r$, and the same argument gives the

Rayleigh distribution

$$f(r) = \frac{r}{s^2}\, e^{-r^2/2s^2}, \qquad \mathbb{E}\, r = s\sqrt{\pi/2}, \qquad r^2 \sim s^2 \chi^2_2, \tag{2.113}$$

and the squared length r^2 is *exponential* with mean $2s^2$, since $\chi^2_2 = \text{Gamma}(1, 2)$. Of all the cases in this book, this one reaches furthest. A complex Gaussian mode $z = x + iy$, with independent real and imaginary parts of equal variance, has a Rayleigh amplitude $|z|$, a uniform phase, and an exponential power $|z|^2$. That describes a Fourier mode $\tilde{\delta}(\boldsymbol{k})$ of a Gaussian random field (Chapter 7), each $a_{\ell m}$ with $m \neq 0$ on the CMB sky, and each frequency bin of Gaussian detector noise in a gravitational-wave periodogram.

What follows for the scatter of a measured power? The exponential has standard deviation equal to its mean. So a raw periodogram fluctuates by 100% in every bin, however long the data stream. Only averaging reduces the scatter: over bins or segments (Welch's method), or over the $2\ell + 1$ values of m, which gives the cosmic variance of Section 2.13.2. The script checks the unit-variance case: $\mathbb{E}\,|z| = 1.2531$ against $\sqrt{\pi/2} = 1.2533$, and $|z|^2$ has mean 1.9986 and standard deviation 2.0012, both 2 for an exponential (Figure 2.42a).

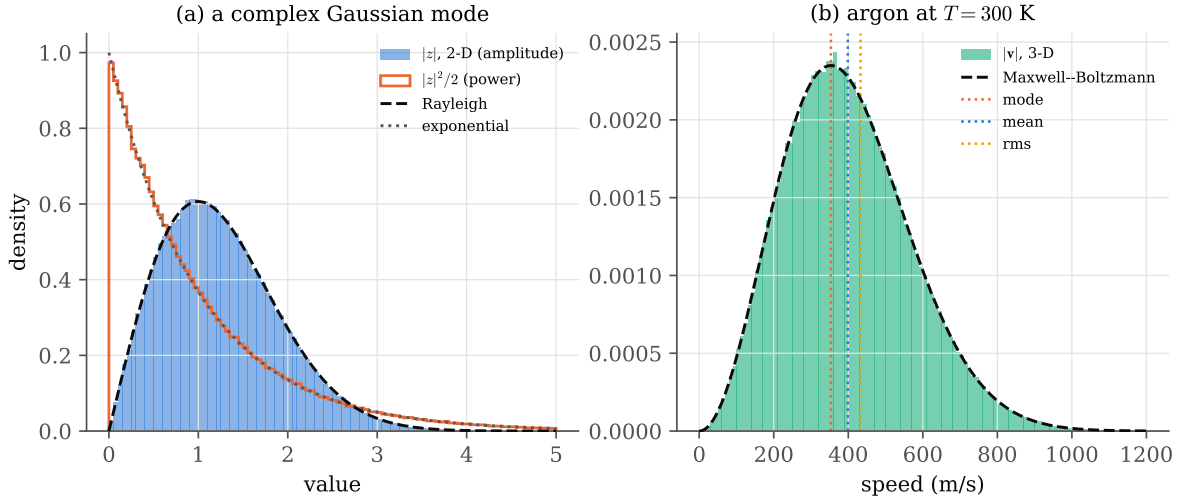

Figure 2.42: (a) The amplitude of a complex Gaussian mode follows the Rayleigh density, and half its squared amplitude, the power, follows a unit exponential. (b) Speeds of simulated argon atoms at 300 K against the Maxwell–Boltzmann law, with the mode, the mean and the rms speed marked in that order.

2.15.5 Beta: probabilities of probabilities

The distributions so far describe data. The beta distribution usually describes a *probability*: the efficiency of a trigger, the bias of a coin, the fraction of events that are signal. It lives on $[0, 1]$ and has density [CasellaBerger (3.3.16)], [Kruschke (6.3)]

$$f(\theta \,|\, a, b) = \frac{\theta^{a-1}(1-\theta)^{b-1}}{B(a,b)}, \qquad B(a,b) = \int_0^1 \theta^{a-1}(1-\theta)^{b-1} \mathrm{d}\theta = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}. \tag{2.114}$$

It is produced by three different machines, and each explains something.

Machine 1: sorting uniform numbers. Draw n independent uniform numbers on $[0, 1]$ and let $U_{(k)}$ be the k-th smallest, the k-th **order statistic**. For $U_{(k)}$ to lie in $[u, u + \mathrm{d}u]$, one of the n

numbers must fall in that interval, $k-1$ of them below u and $n-k$ above it. The number of ways to choose which is which is the multinomial coefficient $\frac{n!}{(k-1)!\,1!\,(n-k)!}$ of Section 2.3, and the probabilities of the three cells are u, $\mathrm{d}u$ and $1-u$. So

$$f_{U_{(k)}}(u)\,\mathrm{d}u = \frac{n!}{(k-1)!\,(n-k)!}\,u^{k-1}(1-u)^{n-k}\,\mathrm{d}u, \tag{2.115}$$

which is Beta$(k, n-k+1)$, with $B(k, n-k+1) = \frac{(k-1)!(n-k)!}{n!}$ [CasellaBerger Ex. 5.4.5]. For a general continuous parent with cumulative distribution F and density f, the same count gives $\frac{n!}{(k-1)!(n-k)!}F(x)^{k-1}[1-F(x)]^{n-k}f(x)$ [CasellaBerger Thm 5.4.4]. Casella and Berger prove it by differentiating the binomial probability that at least k of the n values lie below x. The same counting gives the joint density of two order statistics, and from it the distribution of the range $U_{(n)} - U_{(1)} \sim$ Beta$(n-1, 2)$ [CasellaBerger Thm 5.4.6, Ex. 5.4.7].

Order statistics describe the median, quantiles, the fastest of n photon arrival times (which sets the timing of a scintillator), and the largest of n noise fluctuations (the look-elsewhere effect of Chapter 4). With $n = 10$ and $k = 3$ the script finds the mean and variance of $U_{(3)}$ to be 0.2728 and 0.01659, against $\frac{k}{n+1} = 0.2727$ and $\frac{k(n-k+1)}{(n+1)^2(n+2)} = 0.01653$ (Figure 2.44a).

Machine 2: the share of a total. Let $X \sim \text{Gamma}(a, 1)$ and $Y \sim \text{Gamma}(b, 1)$ be independent. They could be the waiting times for the a-th and the b-th events of two independent unit-rate processes, or two χ^2 variables. What is the distribution of the share $U = X/(X+Y)$? Change variables to $S = X + Y$ and U, so $X = SU$, $Y = S(1-U)$, with Jacobian $\left|\partial(x,y)/\partial(s,u)\right| = s$:

$$\begin{aligned} f(u,s) &\overset{(1)}{=} s\,\frac{(su)^{a-1}e^{-su}}{\Gamma(a)}\,\frac{(s(1-u))^{b-1}e^{-s(1-u)}}{\Gamma(b)} \\ &\overset{(2)}{=} \underbrace{\frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)}\,u^{a-1}(1-u)^{b-1}}_{\text{Beta}(a,b)} \times \underbrace{\frac{s^{a+b-1}e^{-s}}{\Gamma(a+b)}}_{\text{Gamma}(a+b,1)}. \end{aligned} \tag{2.116}$$

(1) The joint density of independent X and Y at $x = su$, $y = s(1-u)$, times the Jacobian. The determinant of $\begin{pmatrix} u & s \\ 1-u & -s \end{pmatrix}$ is $-us - s(1-u) = -s$.

(2) Collect powers: $s \cdot s^{a-1}s^{b-1} = s^{a+b-1}$, and $e^{-su}e^{-s(1-u)} = e^{-s}$. Multiply and divide by $\Gamma(a+b)$.

The density factorises, so the share U is Beta(a, b) and is *independent* of the total S. As a by-product, the second factor integrates to one, so the first must too, which proves $B(a,b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$ [CasellaBerger (3.3.17)]. With $a = 2.5$, $b = 4$ the script finds $\mathbb{E}\,U = 0.3846$ against $a/(a+b) = 0.3846$ (Figure 2.44b). The relation of F to the beta distribution in Section 2.14.2 is this machine applied to two χ^2 variables.

Summary numbers and shapes. Recognising kernels again, $\mathbb{E}\,\theta^r = B(a+r, b)/B(a,b)$ [CasellaBerger (3.3.18)], so

$$\mathbb{E}\,\theta = \frac{a}{a+b}, \qquad \text{Var}\,\theta = \frac{ab}{(a+b)^2(a+b+1)}, \qquad \text{mode} = \frac{a-1}{a+b-2}\ \ (a,b>1). \tag{2.117}$$

The two shape parameters make the family flexible (Figure 2.43). It is uniform for $a = b = 1$, U-shaped for $a, b < 1$, J-shaped when one of them is below one, and single-peaked for $a, b > 1$. It is symmetric when $a = b$, with variance $1/[4(2a+1)]$.

How do we choose a and b? Kruschke's advice [Kruschke p. 128–131] is to think of a and b as "previously seen" successes and failures. The concentration $\kappa = a + b$ measures how much prior data that is, and

$$a = \mu\kappa, \quad b = (1-\mu)\kappa \qquad \text{or} \qquad a = \omega(\kappa-2)+1, \quad b = (1-\omega)(\kappa-2)+1$$

set the mean μ or the mode ω [Kruschke (6.5)–(6.6)]. A prior with mode 0.8 and concentration 12 is Beta(9, 3). From a desired mean and standard deviation, $a = \mu\nu$ and $b = (1-\mu)\nu$ with $\nu = \mu(1-\mu)/\sigma^2 - 1$ [Kruschke (6.7)]: mean 0.5 and standard deviation 0.1 give Beta(12, 12). The standard deviation must be below $1/\sqrt{12} = 0.289$, that of the uniform, or the formula returns a U-shaped (or impossible) answer.

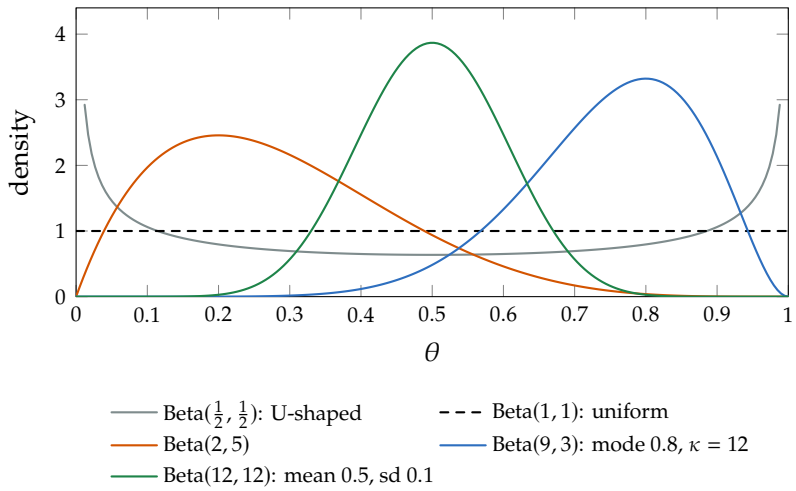

Figure 2.43: Members of the beta family. With both parameters below one the density piles up at the ends; with both equal to one it is flat; above one it has a single peak whose position is set by the ratio of the parameters and whose width shrinks as their sum grows. The blue and green curves are Kruschke's two worked prior specifications.

Working definition 2.20 (beta distribution)

$\theta \sim \text{Beta}(a, b)$, $a, b > 0$, has density (2.114) on $[0, 1]$ and moments (2.117). *Recognise it by:* a probability or a fraction that is itself uncertain. It is the k-th smallest of n uniform numbers (Beta$(k, n-k+1)$), the share $X/(X+Y)$ of two independent gamma variables with a common scale (Beta(a, b)), and, as shown next, the updated belief about a success probability after $a-1$ successes and $b-1$ failures observed from a flat start [with prior Beta(a_0, b_0) and h successes in N trials the result is Beta(a_0+h, b_0+N-h)].

Machine 3: keep the runs that match. The third machine is inference itself. A coin has unknown bias θ. Before flipping it, our belief about θ is Beta(2, 2): probably near a half, but anything is possible. *The event.* We flip it $N = 10$ times and see $h = 7$ heads. *The question.* Which values of θ could have produced seven heads, and how strongly should we now believe in each? Let the computer answer by brute force, with no formula at all. Draw θ from the prior; flip a coin with that θ ten times; keep θ if and only if the run produced exactly seven heads; repeat.

Listing 2.20: Keep the runs that match: a posterior by rejection (`code/ch02/28_beta_dirichlet.py`)

```
# ------------------------------------------------------------- (3) rejection "posterior"
a0, b0, N, h = 2.0, 2.0, 10, 7
```

```
46 theta = rng.beta(a0, b0, size=2_000_000)
47 heads = rng.binomial(N, theta)
48 kept = theta[heads == h]
49 acc = kept.size / theta.size
50 evidence_th = special.comb(N, h) * special.beta(a0 + h, b0 + N - h) / special.beta(a0, b0)
```

Line 46 draws two million values of θ from the prior. Line 47 runs the *forward* model, the prediction direction of Chapter 1: for each θ, simulate the experiment. Line 48 keeps only those θ that reproduced the data, which is conditioning on the observation, the inference direction. The histogram of the kept values is the answer (Figure 2.44c). *What is it analytically?* Take the candidate values of θ one at a time. A given θ is kept with the binomial probability of the data, $\binom{10}{7}\theta^7(1-\theta)^3$. It was drawn in the first place with the prior density. So the kept values have density proportional to the product of the two,

$$\underbrace{\theta(1-\theta)}_{\text{Beta(2,2) kernel}} \times \underbrace{\theta^7(1-\theta)^3}_{\text{probability of the data}} = \theta^8(1-\theta)^4,$$

the kernel of Beta$(9, 5)$. In general, prior Beta(a_0, b_0) and binomial data give Beta(a_0+h, b_0+N-h). The family is **conjugate** to the binomial: prior and posterior belong to the same family. And "a and b are previous successes and failures" is literally true. The script's kept values have mean 0.6428 and standard deviation 0.1240, against $\frac{9}{14} = 0.6429$ and 0.1237.

The acceptance fraction has a meaning too. It is 0.1123, the probability of seeing seven heads averaged over the prior, $\binom{10}{7}B(9,5)/B(2,2) = 0.1119$. That is the *evidence*, the denominator of Bayes' theorem. So this little machine is the whole of Chapter 5 in miniature. Rejection wastes 89% of the draws here. It would waste nearly all of them for a continuous observation or many parameters, which is why Chapter 9 replaces it by Markov chain Monte Carlo. The same logic makes the gamma distribution conjugate to the Poisson rate: a Gamma(α, β) prior times the Poisson likelihood $\lambda^n e^{-\lambda}$ is again a gamma kernel.

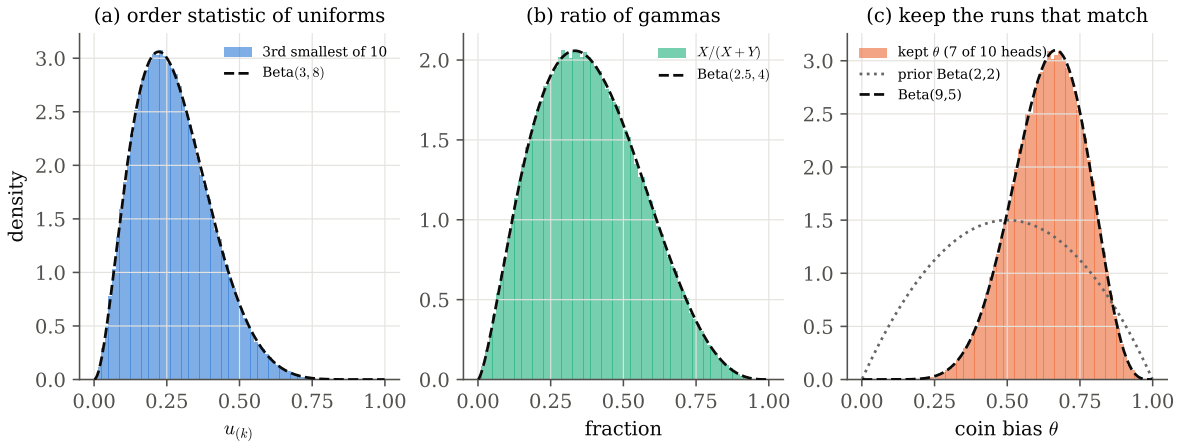

Figure 2.44: Three machines that make a beta distribution. (a) The third smallest of ten uniform numbers. (b) The share $X/(X+Y)$ of two independent gamma variables. (c) Coin biases drawn from a Beta$(2, 2)$ prior (dotted) and kept only when their simulated ten flips gave seven heads: the survivors follow Beta$(9, 5)$.

2.15.6 Dirichlet: several probabilities that sum to one

A histogram with K bins has bin probabilities $p_1, \ldots, p_K$ with $\sum_j p_j = 1$; an election has vote shares; a decay has branching ratios. The distribution for such a vector is the **Dirichlet**, and

the gamma machine of (2.116) (Machine 2, the share of a total) builds it. Draw independent $G_j \sim \text{Gamma}(\alpha_j, 1)$, $j = 1, \dots, K$, and normalise, $p_j = G_j / \sum_l G_l$. The same change of variables, now with K variables, gives the density on the simplex [the set of vectors with all $p_j \geq 0$ and $\sum_j p_j = 1$, a triangle for $K = 3$]

$$f(p_1, \dots, p_K) = \frac{\Gamma(\alpha_0)}{\prod_j \Gamma(\alpha_j)} \prod_{j=1}^{K} p_j^{\alpha_j - 1}, \qquad \alpha_0 = \sum_j \alpha_j, \tag{2.118}$$

which reduces to the beta for $K = 2$. Its properties follow from the machine without any integration. *Marginals.* One component is $p_1 = G_1/(G_1 + R)$ with $R = \sum_{j \geq 2} G_j \sim \text{Gamma}(\alpha_0 - \alpha_1, 1)$ by (2.107), so by machine 2 each marginal is a beta,

$$p_j \sim \text{Beta}(\alpha_j, \alpha_0 - \alpha_j), \qquad \mathbb{E}\, p_j = \frac{\alpha_j}{\alpha_0}, \qquad \text{Var}\, p_j = \frac{\alpha_j(\alpha_0 - \alpha_j)}{\alpha_0^2(\alpha_0 + 1)}.$$

Covariances. These follow from the constraint $\sum_j p_j = 1$. For $K = 3$, $p_1 + p_2 = 1 - p_3$, so

$$\begin{aligned} 2\,\text{Cov}(p_1, p_2) &\overset{(1)}{=} \text{Var}\, p_3 - \text{Var}\, p_1 - \text{Var}\, p_2 \\ &\overset{(2)}{=} \frac{\alpha_3(\alpha_0 - \alpha_3) - \alpha_1(\alpha_0 - \alpha_1) - \alpha_2(\alpha_0 - \alpha_2)}{\alpha_0^2(\alpha_0 + 1)} \overset{(3)}{=} \frac{-2\alpha_1\alpha_2}{\alpha_0^2(\alpha_0 + 1)}. \end{aligned} \tag{2.119}$$

(1) $\text{Var}(p_1 + p_2) = \text{Var}(1 - p_3) = \text{Var}\, p_3$, and $\text{Var}(p_1 + p_2) = \text{Var}\, p_1 + \text{Var}\, p_2 + 2\,\text{Cov}(p_1, p_2)$.
(2) Insert the beta variances.
(3) Write $s = \alpha_1 + \alpha_2$, so $\alpha_3 = \alpha_0 - s$. The numerator is $(\alpha_0 - s)s - \alpha_1(\alpha_0 - \alpha_1) - \alpha_2(\alpha_0 - \alpha_2) = -s^2 + \alpha_1^2 + \alpha_2^2 = -2\alpha_1\alpha_2$.

So $\text{Cov}(p_i, p_j) = -\alpha_i\alpha_j/[\alpha_0^2(\alpha_0 + 1)]$ for $i \neq j$ (for $K > 3$ lump the other components into one, which is again gamma), the same negative-correlation pattern as the multinomial counts of (2.9): if one share grows, the others must shrink.

For Lambert's three-party election with Dirichlet(4, 2, 2) [Lambert §8.5.1], the script finds $\mathbb{E}\, p_1 = 0.4999$ (0.5000), $\text{Var}\, p_1 = 0.02767$ (0.02778) and $\text{Cov}(p_1, p_2) = -0.01386$ (-0.01389) (Figure 2.45). Two facts decide when to use it. It is conjugate to the multinomial, exactly as the beta is to the binomial: prior Dirichlet($\boldsymbol{\alpha}$) and bin counts $\boldsymbol{n}$ give Dirichlet($\boldsymbol{\alpha} + \boldsymbol{n}$). And, as Lambert warns, its correlations are all fixed by the α's, so it cannot express a belief such as "if party 2 does well, so does party 3"; logistic-normal priors are used when that matters.

2.15.7 Two relatives from earlier sections

Two more distributions complete the zoo, and both have appeared already. The **Laplace** or double-exponential density $\frac{1}{2\sigma} e^{-|x-\mu|/\sigma}$, with Var $= 2\sigma^2$ [CasellaBerger (3.3.22)–(3.3.23)], was the MaxEnt answer for a known mean absolute deviation. Its machine is the difference of two independent exponential waits with the same mean σ. To check, multiply the characteristic functions: $(1 - i\sigma k)^{-1}(1 + i\sigma k)^{-1} = (1 + \sigma^2 k^2)^{-1}$, which is the transform of the Laplace density. It has a cusp at the centre and exponential tails, fatter than Gaussian but with all moments finite. The **Cauchy** (Breit–Wigner) distribution of Section 2.10.5 has three machines: the line shape of an unstable state, the ratio of two independent standard normals [CasellaBerger p. 89], and Student's t_1. Its location parameter is the median, even though it has no mean [CasellaBerger (3.3.19)–(3.3.20)].

One family tree. Stepping back, nearly everything in this part hangs from two roots. From the *Gaussian*: squares give χ^2, lengths give Rayleigh and Maxwell, ratios give t, F and Cauchy,

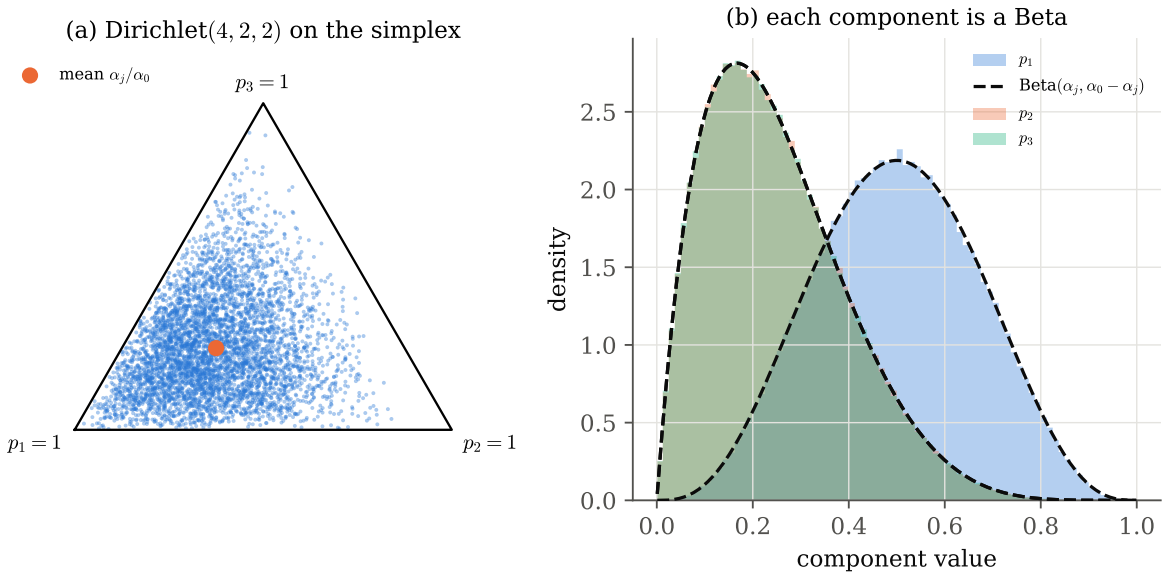

Figure 2.45: (a) Draws from Dirichlet$(4, 2, 2)$ on the triangle of possible vote shares: each corner is one party winning everything, and the cloud sits nearer the corner of the party with the largest α. (b) Each share on its own follows a beta distribution (dashed curves).

exponentials give the log-normal, linear maps give the multivariate normal. From the *exponential* (the waiting time of a Poisson process): sums give the gamma, shares of sums give the beta and the Dirichlet, powers give the Weibull, differences give the Laplace. The two trees meet at $\chi^2_\nu = \text{Gamma}(\nu/2, 2)$, and χ^2_2 is itself an exponential. Section 2.16 collects them into one table.

2.16 Which distribution when

A new set of numbers arrives: the invariant masses of a few thousand dielectron events, the output of a matched filter running over a month of detector noise, the χ^2 of a fit that took a week to set up. Someone asks what distribution the numbers follow. The tempting answer is to make a histogram and pick whichever curve from the zoo looks closest. The better order is the opposite one. Every distribution of this chapter came out of a machine, and the machine is what we can know before seeing a single number. So the question "which distribution?" becomes "which machine made these numbers?". The histogram comes afterwards, to check the answer where the check is most demanding: in the tails.

Choosing by machine is a procedure, and it can be written down. The machines fit into one family tree and one table. The procedure works on all three kinds of data the book keeps returning to: collider counts, detector noise and fitted spectra. And it has one firm warning attached: two distributions that agree in mean and variance can disagree by factors of thousands where discoveries are claimed.

2.16.1 Reading the mechanism

Before fitting any curve, we answer four questions about how the number was made.

1. *Is it a count or a continuous measurement?* Counts go to the counting machines of Section 2.1 to Section 2.8, whose table ends the previous part. Continuous measurements go to this part.

2. *Which operation produced it?* Adding many small pieces, multiplying many factors, squaring and adding, taking the length of a vector, dividing one random quantity by another, waiting for an event, taking a share of a total, or sorting.
3. *Are the ingredients independent, and do they have a finite variance?* If the answer is no, the limit theorems that manufacture Gaussians and χ^2's are switched off, and a Cauchy or a Landau law (Sections 2.10.5 and 2.10.6) may be what arrives.
4. *Which part of the distribution will the conclusion rest on?* An average and its error bar use the centre, where almost any sensible model agrees. A p-value, a discovery claim or a false-alarm rate uses the tail, where models disagree most.

Lambert draws the same procedure as a decision tree for choosing a likelihood [Lambert §8.6, Fig. 8.33], and adds the practical advice to err on the side of robustness [Lambert §8.8]: when unsure, prefer the model with heavier tails (the negative binomial over the Poisson, Student's t over the Gaussian).

Most continuous distributions descend from just two parents, the Gaussian and the exponential. Figure 2.46 arranges the machines as two trees [Lambert §8.3, Fig. 8.1]. Each box names a distribution and, underneath, the operation that makes it from its parent. The Gaussian tree is the world of sums, the exponential tree the world of waiting. The dashed line is the one place where they are literally the same distribution: $\chi^2_\nu = \text{Gamma}(\nu/2, 2)$, so a sum of ν squared Gaussians is the wait for the $(\nu/2)$-th event of a Poisson stream of rate $\frac{1}{2}$. Above both sits the uniform distribution, which by the inverse-transform rule of Section 2.15.1 can be turned into any of them.

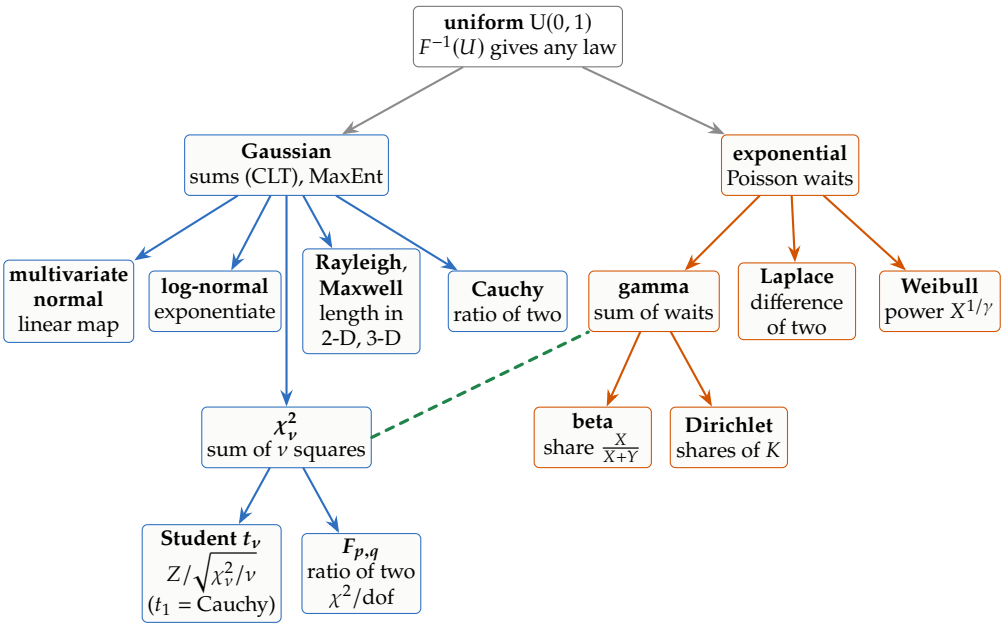

Figure 2.46: Two family trees hold most of the continuous zoo. Blue: everything built from Gaussians, with the building operation written under each name. Orange: everything built from the exponential waiting time of a Poisson process. The green dashed line joins χ^2_ν and the gamma family, which are the same distribution. The uniform at the top feeds both trees, since any law is F^{-1} of a uniform number.

The table collects the continuous machines with their summary numbers and the places they turn up in physics. Every mean and variance in it was derived earlier in the chapter, and the section that derived it also gives the density.

One row of the table is new, the Voigt profile. It is the first of three recognition problems, and it shows how two rows combine.

Taxonomy: which continuous distribution, when

mechanism	distribution	mean; variance	physics examples
sum of many small independent pieces with finite variance; or only mean and variance known	$\mathcal{N}(\mu, \sigma^2)$	μ; σ^2	measurement and thermal noise, large-λ counts, real and imaginary part of a noise Fourier bin
linear map $A\boldsymbol{Z} + \boldsymbol{\mu}$ of independent standard normals	$\mathcal{N}(\boldsymbol{\mu}, \mathbf{C})$	$\boldsymbol{\mu}$; $\mathbf{C} = AA^{\mathsf{T}}$	correlated parameters, pixels of a Gaussian field, Fisher forecasts
only a range known; $F(X)$ of any continuous X	$\mathrm{U}(a, b)$	$\frac{a+b}{2}$; $\frac{(b-a)^2}{12}$	strip pitch/$\sqrt{12}$, rounding, random phase, p-values under H_0
wait for the first event of a constant-rate stream; power of a complex Gaussian mode	$\mathrm{Exp}(\lambda)$	$\frac{1}{\lambda}$; $\frac{1}{\lambda^2}$	decay times, arrival gaps, periodogram power, $\lvert a_{\ell m}\rvert^2$
sum of α waits; χ^2 with a scale	$\mathrm{Gamma}(\alpha, \beta)$	$\alpha\beta$; $\alpha\beta^2$	time to the n-th photon, prior on a Poisson rate
failure rate a power of age	Weibull, $Y = X^{1/\gamma}$, $X \sim \mathrm{Exp}(1)$	$\Gamma(1 + \frac{1}{\gamma})$; $\Gamma(1 + \frac{2}{\gamma}) - \Gamma(1 + \frac{1}{\gamma})^2$	lifetimes of tubes and electronics, extremes
product of many positive independent factors	log-normal, $\ln X \sim \mathcal{N}(\mu, \sigma^2)$	$e^{\mu+\sigma^2/2}$; $e^{2\mu+\sigma^2}(e^{\sigma^2} - 1)$	photomultiplier gain, log-normal density-field models
sum of ν squared independent standard normals	χ^2_ν	ν; 2ν	goodness of fit, $(n-1)S^2/\sigma^2$, $\widehat{C}_\ell$ and cosmic variance
length of a 2-D / 3-D Gaussian vector (scale s)	Rayleigh / Maxwell	$s\sqrt{\pi/2}$; $(2 - \frac{\pi}{2})s^2$ / $s\sqrt{8/\pi}$; $(3 - \frac{8}{\pi})s^2$	Fourier amplitudes, matched-filter SNR in noise / molecular speeds
Gaussian over an independently estimated scale	Student t_ν	0 $(\nu > 1)$; $\frac{\nu}{\nu-2}$ $(\nu > 2)$	mean with an estimated error bar, likelihood robust to outliers
ratio of two independent χ^2/dof	$F_{p,q}$	$\frac{q}{q-2}$ $(q > 2)$	comparing two resolutions, nested fits
resonance line shape; ratio of two normals	Cauchy (Breit–Wigner)	none; none (median M, half-width γ)	unstable-particle mass, natural line width
resonance seen with Gaussian resolution	Voigt	none; none	measured mass peaks, pressure-broadened lines
energy lost in a thin layer	Landau	none; none	$\mathrm{d}E/\mathrm{d}x$ in silicon and gas
uncertain probability; k-th of n uniforms; share of two gammas	$\mathrm{Beta}(a, b)$	$\frac{a}{a+b}$; $\frac{ab}{(a+b)^2(a+b+1)}$	efficiencies, branching fractions, prior on a success probability
uncertain probability vector	$\mathrm{Dirichlet}(\boldsymbol{\alpha})$	$\frac{\alpha_j}{\alpha_0}$; $\frac{\alpha_j(\alpha_0-\alpha_j)}{\alpha_0^2(\alpha_0+1)}$	bin probabilities of a histogram, branching ratios
difference of two equal exponentials; known mean absolute deviation	$\mathrm{Laplace}(\mu, \sigma)$	μ; $2\sigma^2$	least-absolute-deviation fits

2.16.2 Three recognitions

Example: a Z peak seen through a detector. In Section 2.10.5 the Z line shape was the Breit–Wigner (2.58), with detector resolution ignored. A real calorimeter adds to each true mass B an independent Gaussian error $G \sim \mathcal{N}(0, \sigma^2)$, with $\sigma = 2.0\,\text{GeV}$ for our example. The measured mass is $m = B + G$. *The question:* does the smearing turn the peak into a Gaussian, and what happens to the tails? *Reading the mechanism:* a *sum* of two independent pieces, so the characteristic function is a product:

$$\phi_m(k) \overset{(1)}{=} \mathbb{E}\big(e^{ikB}\big)\;\mathbb{E}\big(e^{ikG}\big) \overset{(2)}{=} e^{iMk-\gamma|k|}\;e^{-\sigma^2k^2/2}, \qquad \gamma = \Gamma/2. \tag{2.120}$$

(1) $e^{ik(B+G)} = e^{ikB}e^{ikG}$, and the expectation of a product of independent factors is the product of expectations, (2.47).
(2) The Cauchy transform (2.59) with centre M and half-width γ, and the Gaussian transform (2.50) with mean zero.

The inverse transform of (2.120) is the **Voigt profile**, the convolution of the two densities. It has no closed form, but the characteristic function already answers the question: no, the Cauchy tail survives. First, ϕ_m still has the kink $|k|$ at $k = 0$, so it is not differentiable there and m still has no mean: Gaussian smearing cannot cure a Cauchy tail. Second, the tail itself survives unchanged. For $|m - M|$ much larger than both σ and γ,

$$\begin{aligned} p_m(m) &\overset{(1)}{=} \int_{-\infty}^{\infty} p_B(m-g)\,p_G(g)\,\mathrm{d}g \overset{(2)}{=} p_B(m)\int_{-\infty}^{\infty} p_G(g)\,\mathrm{d}g\,\big[1 + O(\sigma^2/(m-M)^2)\big] \\ &\overset{(3)}{=} \frac{1}{\pi}\,\frac{\gamma}{(m-M)^2+\gamma^2}\,\big[1+\ldots\big] \overset{(4)}{=} \frac{\gamma}{\pi\,(m-M)^2}\,\big[1+\ldots\big]. \end{aligned} \tag{2.121}$$

(1) The density of a sum of independent variables is the convolution of their densities: to reach m, the Gaussian must supply g and the resonance $m - g$.
(2) p_G is non-negligible only for $|g| \lesssim 3\sigma$, and over that range the Breit–Wigner, far out in its tail, changes little. Expanding $p_B(m-g)$ to second order in g, the linear term averages to zero because $\mathbb{E}\,G = 0$, and the quadratic term is smaller by a factor of order $\sigma^2/(m-M)^2$.
(3) p_G integrates to one, and (2.58) written with $\gamma = \Gamma/2$.
(4) $(m-M)^2 \gg \gamma^2$.

So the fraction of events more than Δ from the peak is, for $\Delta \gg \sigma, \gamma$,

$$\mathrm{P}(|m-M| > \Delta) \overset{(1)}{=} 2\int_{\Delta}^{\infty} \frac{\gamma}{\pi u^2}\,\mathrm{d}u \overset{(2)}{=} \frac{2\gamma}{\pi\Delta}, \tag{2.122}$$

(1) The symmetry of the two tails and the approximation (2.121) with $u = |m - M|$.
(2) $\int_{\Delta}^{\infty} u^{-2}\mathrm{d}u = 1/\Delta$.

For $\gamma = 1.2476\,\text{GeV}$ and $\Delta = 10\,\text{GeV}$ this gives 0.0794.

Listing 2.21: A Breit–Wigner resonance smeared by Gaussian resolution (`code/ch02/29_which_distribution.py`)

```
M, Gam, sig = 91.1876, 2.4952, 2.0          # GeV: Z mass, full width, detector resolution
gam = Gam / 2                               # Cauchy half-width
m = M + gam * rng.standard_cauchy(NREP) + rng.normal(0.0, sig, NREP)
Delta = 10.0
out_sim = np.mean(np.abs(m - M) > Delta)
uu = np.linspace(-Delta, Delta, 200_001)
core = np.trapezoid(voigt_profile(uu, sig, gam), uu)
out_voigt = 1.0 - core
```

```
45 out_tail = 2 * gam / (np.pi * Delta)          # Cauchy tail estimate, valid for Delta >>
       sigma, gamma
46 # FWHM of the Voigt density, found numerically, and the Gaussian with the same FWHM
47 grid = np.linspace(0, 10, 200_001)
48 vp = voigt_profile(grid, sig, gam)
49 fwhm = 2 * grid[np.argmin(np.abs(vp - vp[0] / 2))]
50 sig_eq = fwhm / (2 * np.sqrt(2 * np.log(2)))
51 out_gauss = 2 * stats.norm.sf(Delta / sig_eq)
```

The script builds the machine literally, and the Gaussian fails by a factor of several hundred in the wings. Line 39 adds a Cauchy draw of half-width γ and a Gaussian draw of width σ to the Z mass, for each of 2×10^5 events. Line 41 counts the fraction of events beyond Δ. Lines 42–44 integrate the exact Voigt density (`scipy.special.voigt_profile`, whose arguments are the Gaussian σ and the Cauchy half-width γ) over the core. Lines 47–51 find the full width at half maximum of the Voigt profile and build the Gaussian with the same width, the curve one would get by fitting a Gaussian to the peak by eye.

The three estimates of the tail agree: the simulated fraction beyond 10 GeV is 0.0820, the exact Voigt value is 0.0825, and the tail estimate (2.122) is 0.0794. The Voigt peak has a full width at half maximum of 6.18 GeV, and a Gaussian with that width ($\sigma_{\text{eq}} = 2.63$ GeV) puts only 1.4×10^{-4} of its probability beyond 10 GeV. On a linear plot the two curves are hard to tell apart. On the logarithmic plot of Figure 2.47b the difference is a factor of several hundred. An analysis that modelled the peak as a Gaussian would find about 8% of the Z events in its "background" sidebands.

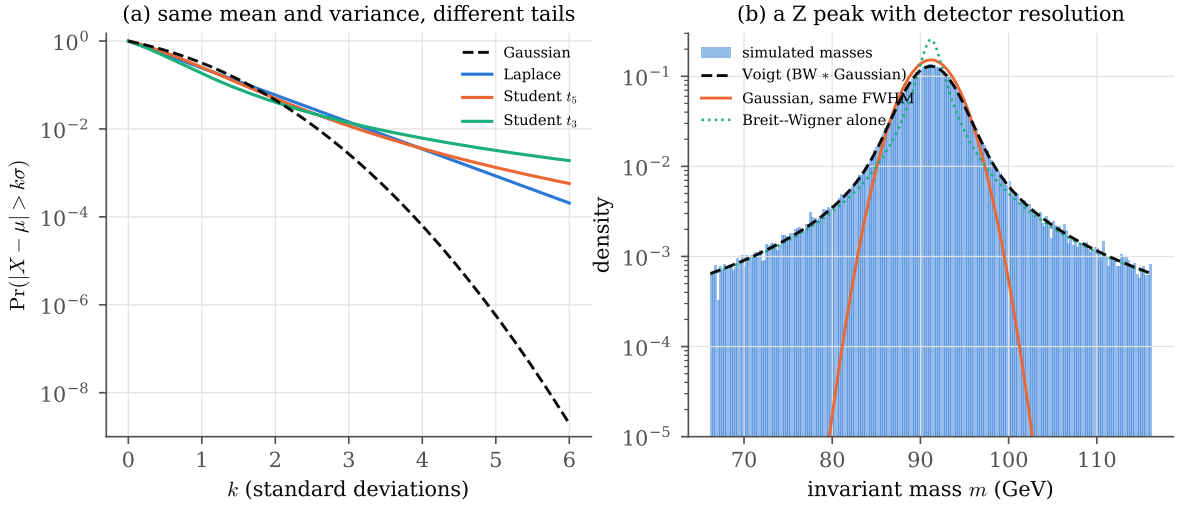

Figure 2.47: (a) Two-sided tail probability against distance from the mean, in units of the standard deviation, for four symmetric distributions scaled to the same mean and variance. They agree within a factor of two out to about two standard deviations and then separate by orders of magnitude. (b) Simulated Z masses with a Breit–Wigner width and Gaussian detector resolution, on a logarithmic scale. The Voigt density (dashed) follows them into the wings; the Gaussian with the same half-maximum width (solid) matches only the core; far from the peak the Voigt rejoins the pure Breit–Wigner (dotted).

Example: false alarms in a gravitational-wave search. A matched filter correlates the detector output with a template waveform whose phase is unknown. It returns two numbers at each time, the correlation with the cosine-phase and with the sine-phase template, normalised so that in pure Gaussian noise each is a standard normal and the two are independent. The signal-to-noise ratio is $\rho = \sqrt{x^2 + y^2}$, with x and y the two correlations. *The question:* how often

does noise alone push ρ above a threshold? *Reading the mechanism: the length of a two-dimensional Gaussian vector*. So ρ is Rayleigh with $s = 1$, and ρ^2 is χ^2_2, the exponential with mean 2 (Section 2.15.4). The chance that noise alone crosses a threshold ρ_* is

$$\mathrm{P}(\rho > \rho_*) \overset{(1)}{=} \mathrm{P}(\rho^2 > \rho_*^2) \overset{(2)}{=} \int_{\rho_*^2}^{\infty} \tfrac{1}{2} e^{-u/2}\,\mathrm{d}u \overset{(3)}{=} e^{-\rho_*^2/2}. \tag{2.123}$$

(1) $\rho \geq 0$, and squaring is increasing on $[0, \infty)$.
(2) The χ^2_ν density (2.92) with $\nu = 2$ is $u^0 e^{-u/2}/(2\,\Gamma(1)) = \frac{1}{2}e^{-u/2}$.
(3) $\int_a^\infty \frac{1}{2}e^{-u/2}\mathrm{d}u = e^{-a/2}$.

The script checks the formula at $\rho_* = 3$: the fraction of 2×10^5 noise draws above threshold is 0.0112, against $e^{-9/2} = 0.0111$ (script lines 54–59). At the conventional detection threshold $\rho_* = 8$ the formula gives 1.27×10^{-14} per independent template and time sample. That looks reassuringly small. But a search examines very many templates at every sample of months of data, so the answer depends on the χ^2_2 law holding fourteen decades down its tail. Real detector noise contains short non-Gaussian bursts ("glitches"), which is exactly the kind of fat tail of Figure 2.47a.

So searches do not trust (2.123) for their final significance. They measure the background empirically. They shift one detector's data in time against another's, by more than the light travel time, and count how often noise alone produces a coincident trigger. The formula *verifies* the pipeline on simulated Gaussian noise; the time slides are the research instrument on real data. The same Rayleigh and exponential laws describe the amplitude and the power of a noise frequency bin, which returns in the gravitational-wave Fisher forecasts of Chapter 10, where the noise enters through its power spectral density.

Example: is $\chi^2 = 130$ for 100 degrees of freedom a bad fit? It is suspicious but not damning, and the Gaussian shortcut gets its tail wrong by 40%. A fit of a model with P adjustable parameters to N Gaussian measurements returns a minimum χ^2. For a model linear in its parameters, the minimum is a quadratic form in the residuals with $N-P$ independent directions left over (the argument of Sections 2.13.3 and 2.13.4, made precise in Chapter 3). Reading the mechanism: *a sum of $\nu = N - P$ squared standard normals*, so $\chi^2_{\min} \sim \chi^2_\nu$. *The question:* how often would a correct model give $\chi^2 \geq 130$? With $\nu = 100$ it is tempting to use the central limit theorem, since χ^2_{100} is a sum of 100 independent χ^2_1 variables, and write $\chi^2 \approx \mathcal{N}(\nu, 2\nu)$:

$$z = \frac{\chi^2 - \nu}{\sqrt{2\nu}} = \frac{130 - 100}{\sqrt{200}} = 2.12, \qquad \mathrm{P}(Z > z) = 0.0169.$$

The exact tail, from `scipy.stats.chi2.sf(130, 100)`, is 0.0235, about 40% larger. *Why?* The parent χ^2_1 is skewed, and the CLT removes skewness only slowly (Section 2.10.3). To measure it, we need the cumulants κ_n (the Taylor coefficients of $\ln\phi$). The cumulants of χ^2_1 follow from its characteristic function $(1-2ik)^{-1/2}$ (2.93): $\ln\phi = -\frac{1}{2}\ln(1-2ik) = \sum_{n\geq 1}\frac{(2ik)^n}{2n}$, and matching with $\ln\phi = \sum_n \kappa_n (ik)^n/n!$ gives $\kappa_n = 2^{n-1}(n-1)!$, so $\kappa_2 = 2$ and $\kappa_3 = 8$. Then

$$\gamma_1\big(\chi^2_\nu\big) \overset{(1)}{=} \frac{\kappa_3(\chi^2_\nu)}{\kappa_2(\chi^2_\nu)^{3/2}} \overset{(2)}{=} \frac{\nu\,\kappa_3(\chi^2_1)}{\big[\nu\,\kappa_2(\chi^2_1)\big]^{3/2}} \overset{(3)}{=} \frac{8\nu}{(2\nu)^{3/2}} = \sqrt{\frac{8}{\nu}}. \tag{2.124}$$

(1) Skewness is the third cumulant in units of the standard deviation cubed, with the cumulants of (2.54).
(2) Cumulants of independent variables add, and χ^2_ν is the sum of ν independent χ^2_1.
(3) $\kappa_3(\chi^2_1) = 8$ and $\kappa_2(\chi^2_1) = 2$.

At $\nu = 100$ the skewness is still 0.28. So the right tail is longer than the Gaussian's, and the Gaussian approximation underestimates how often a correct model gives a large χ^2. The verdict itself is mild. A correct model would give $\chi^2 \geq 130$ in about 2% of repetitions, so the fit is suspicious but not damning, and Chapter 4 turns this reasoning into a test. The practical rule is simpler: never use $\mathcal{N}(\nu, 2\nu)$ for a tail probability when the exact χ^2_ν survival function is one line of code.

2.16.3 The tails decide

The three examples share a lesson: the core of each distribution was well described by a Gaussian, and the question was about the tail. Figure 2.47a puts numbers on it. It shows four symmetric distributions, each scaled to mean zero and variance one: the Gaussian, the Laplace, and Student's t_5 and t_3 (for t_ν with scale c the variance is $c^2\nu/(\nu-2)$ by (2.103), so $c^2 = 3/5$ and $1/3$). They are indistinguishable at one standard deviation and cross near two. At three standard deviations the two-sided tail probabilities are 0.0027 for the Gaussian but 0.0144 (Laplace), 0.0117 (t_5) and 0.0138 (t_3), four to five times more. At five standard deviations the Gaussian gives 5.7×10^{-7} and t_3 gives 3.2×10^{-3}, a ratio of 5650.

Key idea: Choose by mechanism, check in the tails

A distribution is chosen by recognising the machine that made the numbers (sum, product, squares, length, ratio, wait, share). Its mean and variance are then fixed by the machine, but agreement in mean and variance says almost nothing beyond about two standard deviations. Any conclusion that uses a tail probability must justify the tail separately, by the mechanism or by an empirical measurement of the background.

The physics of the tails is usually different from the physics of the core. Cowan makes the point for the two distributions with divergent moments, the Breit–Wigner and the Landau. A real resonance mass is bounded by the masses of its decay products and by the collision energy, and a real energy loss by the energy of the incoming particle, so "the models break down in the tails of the distributions" [Cowan pp. 38–39]. Near the peak the idealised machine is accurate; far from it, other mechanisms take over (kinematic limits, radiation, pile-up, detector glitches, non-Gaussian foregrounds).

So particle physicists quote a "5σ" discovery as a tail probability of 2.9×10^{-7} computed from the *distribution of the test statistic*, obtained by simulation or by an asymptotic theorem (Chapter 4), and never from a Gaussian assumption about the data alone. The same caution applies to a posterior interval far from the peak of a posterior (Chapter 5), and to the Fisher forecast of Chapter 10, which is Gaussian by construction and must be checked against a sampled posterior in the tails (Chapter 9).

Watch out: A good fit to the peak is not a test of the tails

A histogram with most of its entries within $\pm 2\sigma$ fits a Gaussian, a Laplace or a t_5 almost equally well: the χ^2 of the fit is dominated by the populated bins, and the tail bins hold too few entries to discriminate. The choice between them must come from the mechanism, or from a dedicated sample that populates the tails (a control region, a time slide, a large simulation).

With a mechanism in hand, the summary numbers of the table give a first check that costs nothing: compare the sample mean and variance with the predicted ones, the Fano factor for counts (Section 2.8), and, when enough data exist, the sample skewness with the predicted γ_1. A mismatch in these moments rules the mechanism out; a match leaves the tails still to be

checked.

Recap: Part summary: continuous distributions

- **Gaussian, three ways.** (i) The binomial near its peak, by Stirling's formula and a second-order expansion of $\ln p_k$ (de Moivre–Laplace), with error $O(1/n)$ at the peak. (ii) The central limit theorem: the characteristic function of a standardised sum tends to $e^{-k^2/2}$ whenever the parent has finite variance, with error $O(n^{-1/2})$ set by the skewness (Berry–Esseen). (iii) Maximum entropy: the least committal density with a given mean and variance.
- **When the CLT fails or is slow.** Cauchy (Breit–Wigner): no mean, and the average of n draws is as wide as one draw. Landau: finite range in reality, but so skewed that the mean of 25 layers is still far from Gaussian.
- **Multivariate normal.** $\boldsymbol{X} = \boldsymbol{\mu} + A\boldsymbol{Z}$ with $\mathbf{C} = AA^{\mathsf{T}}$; contours are ellipses, and the region $\Delta\chi^2 \le 2.30$ (two parameters) holds 68.3%; marginals drop rows and columns of $\mathbf{C}$; conditionals shift the mean by $\mathbf{C}_{ba}\mathbf{C}_{aa}^{-1}(\boldsymbol{x}_a - \boldsymbol{\mu}_a)$ and shrink the covariance to the Schur complement.
- χ^2_ν**.** Sum of ν squared standard normals, $\chi^2_\nu = \text{Gamma}(\nu/2, 2)$, mean ν, variance 2ν; $(\boldsymbol{X}-\boldsymbol{\mu})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{X}-\boldsymbol{\mu}) \sim \chi^2_k$; $(n-1)S^2/\sigma^2 \sim \chi^2_{n-1}$, independent of $\bar{X}$, because estimating the mean uses up one direction.
- t **and** F**.** Student $t_\nu = Z/\sqrt{\chi^2_\nu/\nu}$: the studentised mean, heavier tails, variance $\nu/(\nu-2)$, a scale mixture of Gaussians; $F_{p,q}$ is a ratio of two scaled χ^2 and $t_q^2 = F_{1,q}$.
- **The zoo.** Uniform (only a range; parent of all through F^{-1}), gamma and Weibull (waits), log-normal (products), Rayleigh and Maxwell (lengths of Gaussian vectors; a complex Gaussian mode has exponential power), beta and Dirichlet (uncertain probabilities, conjugate to binomial and multinomial counts), Laplace (differences of waits).
- **Which one when.** Recognise the mechanism first, then check moments, and check tails separately: laws with equal variance can differ by factors of thousands at 5σ.

Chapter summary

Every common probability distribution comes from a machine that generates it. Counting machines give the discrete laws: one trial, many trials, histogram bins, rare events, a random stream in time, the waits between its events, and the ways real detectors break these assumptions. Measuring machines give the continuous laws: the Gaussian three times over, then the multivariate normal, the χ^2, Student's t and the F ratio built from it, and the rest of the continuous zoo built from the Gaussian and the exponential. All of it runs in the direction of *prediction*: fix a hypothesis and ask what data it produces and how often. On the pipeline of Chapter 0, that is the step which says how a statistic S scatters given the parameters θ, $P(S \mid \theta)$, for the simplest statistics (counts, sums, sample means and variances, χ^2's, power-spectrum estimates). Every later chapter either reads such a $P(S \mid \theta)$ backwards as a likelihood or builds a new one by simulation. The two tables list each concept, what it means operationally (how to compute, recognise or test it), and where it is used next.

Counting distributions (first part)

concept	operational meaning	used later in
distribution as a mechanism	state the machine and its assumptions, derive the law, then simulate the machine (not the formula) and compare histograms	every chapter
Bernoulli	one yes/no trial, $p^x(1-p)^{1-x}$; N trials give $p^z(1-p)^{N-z}$, depending only on the number of successes	Chapters 3 and 5
binomial	successes in n independent trials with the same p: count the $\binom{n}{k}$ paths; mean np, variance $np(1-p)$	Chapters 3 to 5
multinomial	a histogram with a fixed total: binomial marginals, covariance $-Np_ip_j$ between bins	Chapters 3 and 4
Poisson	$n \to \infty$, $np = \lambda$ limit of the binomial; mean = variance = λ; closed under sums and thinning	Chapters 3 to 6
Poisson process	constant rate, no memory; $\mathrm{d}P_n/\mathrm{d}t = \lambda(P_{n-1} - P_n)$; with a Poisson total, histogram bins become independent Poisson counts	Chapters 3 and 6
exponential, gamma (Erlang)	wait for the first / n-th event; memoryless; means $1/\lambda$, n/λ	Chapters 5 and 6
geometric, negative binomial	trials to the first / r-th success; also a Poisson with gamma-distributed rate (overdispersion)	Chapters 3 and 5
Fano factor	variance over mean of counts; ≈ 1 Poisson, > 1 fluctuating rate or clumping, < 1 dead time; judge against $\sqrt{2/(k-1)}$	Chapters 4 and 8
dead time	recorded rate $n/(1+n\tau)$ or $ne^{-n\tau}$; correcting it removes bias but inflates the variance by $1 + n\tau$	Chapter 6
large-count limit	all Poisson cumulants equal λ, skewness $1/\sqrt{\lambda}$: Gaussian near the peak, exact Poisson in the tails	Chapters 3 and 4

Continuous distributions (second part)

concept	operational meaning	used later in
Gaussian $\mathcal{N}(\mu, \sigma^2)$	μ the centre, σ the width; probabilities from Φ; 68.3/95.4/99.7% within $1/2/3\sigma$	every chapter
Stirling, Laplace's method	expand the logarithm of a peaked integrand to second order about its maximum	Chapters 5 and 10
de Moivre–Laplace	binomial near its peak $\approx$ Gaussian with mean np, variance $np(1-p)$; error largest in the tails	Chapters 3 and 4
characteristic function	$\mathbb{E}\, e^{ikX}$, always exists; sums multiply it; cumulants are the Taylor coefficients of its logarithm	Chapters 6 and 7
central limit theorem	standardised sums of finite-variance variables tend to $\mathcal{N}(0,1)$; error $\sim \gamma_1/\sqrt{n}$ (Berry–Esseen); check by simulation	Chapters 3, 4 and 6
Cauchy, Landau	no mean: averaging does not narrow a Cauchy; use the median or a truncated mean; Landau sums converge very slowly	Chapters 3 and 6
maximum entropy	least committal distribution given constraints: $p \propto e^{-\sum_j \lambda_j f_j}$; mean $\to$ exponential, variance $\to$ Gaussian	Chapter 5
multivariate normal	$\boldsymbol{\mu} + A\boldsymbol{Z}$ with $\mathbf{C} = AA^{\mathsf{T}}$ (Cholesky); ellipses with $\Delta\chi^2 = 2.30, 6.18$ in 2-D; marginal = delete rows and columns; conditional = Schur complement	Chapters 7, 9 and 10
χ^2_ν	sum of ν squared standard normals; mean ν, variance 2ν; quadratic forms $\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$; exact tail by `chi2.sf`	Chapters 3, 4, 7 and 8
sample variance, $n-1$	$(n-1)S^2/\sigma^2 \sim \chi^2_{n-1}$, independent of $\bar{X}$ for Gaussian data; one direction is used by the mean	Chapters 3 and 4
Student t	mean over an estimated error bar; heavier tails, $t_\nu \to \mathcal{N}$ as $\nu \to \infty$; robust likelihood	Chapters 4 and 5
F ratio	ratio of two independent scaled χ^2; compare variances or nested fits; $t^2 = F_{1,q}$	Chapter 4
uniform, inverse transform	$F(X)$ is uniform; $F^{-1}(U)$ samples any law; p-values are uniform under H_0	Chapters 4 and 6
log-normal	products of positive factors; mean $e^{\mu+\sigma^2/2}$ above the median e^{μ}	Chapters 5 and 7
Rayleigh, Maxwell, exponential power	length of a 2-D / 3-D Gaussian vector; a complex Gaussian mode has Rayleigh amplitude, uniform phase, exponential power	Chapters 7, 8 and 10
beta, Dirichlet	uncertain probability (vector); conjugate to binomial (multinomial) counts; "keep the runs that match" gives the posterior	Chapters 5 and 9
which distribution when	recognise the mechanism, check the moments, justify the tails separately	Chapters 4, 10 and 12

Reading the literature

- **Main line.** [Wasserman §§2.3–2.4, 2.10, 5.4] gives the discrete and continuous families, the multivariate normal with its marginals and conditionals, and the central limit theorem with the Berry–Esseen bound, compactly and with short examples; the MGF proof of the CLT is in [Wasserman §5.7.2].
- **The clearest first reading.** [Kruschke Ch. 6]: the beta distribution as a description of belief about a probability, its parameters as previous successes and failures, and how to set them from a mean and a spread.

- **The physicist's version.** [Cowan Ch. 2] for each distribution with a physics setting (including the Breit–Wigner and Landau laws and their divergent moments), and [Cowan Ch. 10] for characteristic functions, the limits binomial → Poisson → Gaussian, the χ^2 from squares, and the practical validity of the CLT.
- **Careful derivations.** [CasellaBerger §§3.2–3.3, 4.5–4.6, 5.3–5.4]: the families with full proofs of their moments, the bivariate and multivariate normal, the independence of $\bar{X}$ and S^2, the t and F densities by Jacobians, and order statistics.
- **Maximum entropy.** [Sivia Ch. 5]: the monkey argument for the entropy, the loaded die, the kangaroo problem, and the exponential, Gaussian, Laplace and Poisson as MaxEnt assignments.
- **Choosing a likelihood and a prior.** [Lambert Ch. 8]: a catalogue of sampling and prior distributions with a story for each, their interrelations, the robust versions (negative binomial, Student t), and a decision tree for choosing a likelihood.
- **Pictures.** [SeeingTheory pp. 38–39]: an interactive demonstration of the central limit theorem.
- **Going further.** The Gaussian approximation to the $\widehat{C}_\ell$ likelihood and its failure at low ℓ, where the $\chi^2_{2\ell+1}$ skewness matters, is treated in [16]; Chapters 7 and 8 build on it.

Chapter 3

Estimators, Error Propagation and the Likelihood

Where this chapter is going

Every measurement ends with a number and an error bar. The number is easy to get: we average, we fit, we read off a peak. The error bar is the hard part, and it is where statistics lives. It answers one question: *"if nature let us run this experiment again, how different would our number be?"*

The book's pipeline (Chapter 0) runs from a theory to its data, from the data to a statistic S that compresses them, from S to how S scatters, $P(S \mid \theta)$, and from that scatter to the physics. The error bar lives on the two middle arrows: building S, and working out how it scatters.

The key step is to treat a summary of the data as a **random variable** in its own right. If we imagine repeating the experiment many times, the summary takes a different value each time, so it has a distribution. That distribution has a centre (does it sit on the true value, or is it biased?), a width (the standard error) and correlations with other summaries. From this one step come the answers to several practical questions: why widths shrink like $1/\sqrt{N}$ (the law of large numbers and the central limit theorem), why the sample variance divides by $N - 1$, how noisy a covariance matrix estimated from simulations is, how errors pass through a formula, and how to combine measurements of different quality. The same probability of the data, read *backwards* as a function of the parameters, is the likelihood, the subject of the second half of the chapter.

3.1 One number from many readings: estimators and their sampling distribution

A student times a pendulum of length $L = 1\,\mathrm{m}$ ten times and converts each period into a value of the gravitational acceleration. The ten numbers are

$$9.79,\ 9.83,\ 9.86,\ 9.80,\ 9.77,\ 9.84,\ 9.81,\ 9.78,\ 9.85,\ 9.82\ \ \mathrm{m\,s^{-2}}.$$

No two agree. What is "the answer"? The average, 9.815? The middle value? The first reading? And whatever we choose, how far from the true g can it be? A particle physicist faces the same question with twenty muon decay times and the lifetime τ_μ, and a cosmologist with one CMB map and the amplitude of fluctuations.

The way forward is to stop asking for "the answer" and choose a *recipe* instead: a fixed rule that turns any list of readings into one number. A rule can be applied to data we did not get.

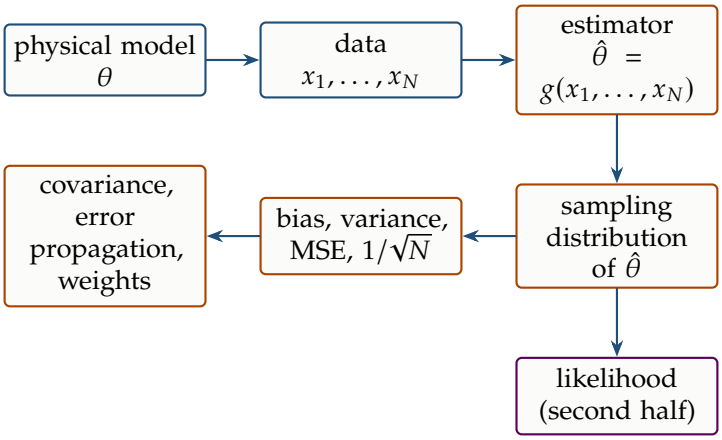

Figure 3.1: The route through the ideas. A model with true parameter θ produces data. A recipe (the estimator) turns data into a number. Imagining many repetitions of the experiment turns that number into a random variable with a sampling distribution (orange boxes). Its centre and width give the error bar, and the same machinery propagates and combines error bars. The last box, the likelihood, reads the probability of the data as a function of θ and is the subject of the second part.

So we can ask how its output would scatter if the experiment were repeated. That scatter is the error bar.

The shape of every problem that follows. In each of these examples there is a quantity we care about and can never look at directly: the true g, the muon lifetime, an amplitude of the early Universe. Call it s. What we hold instead are readings $x_1, \ldots, x_N$, and each of them carries some information about s mixed with things we do not want: noise, a contaminating signal, a calibration offset. Schematically,

$$x_i = (\text{a piece that responds to } s) + (\text{everything else}), \qquad \hat{s} = F(x_1, \ldots, x_N). \tag{3.1}$$

The recipe is the function F. Choosing it, given what we know about how each reading responds to s and about the size and structure of everything else, is the whole subject of estimation. This chapter first learns to judge a given F by the scatter of its output; its second half, the likelihood, and Chapter 5, the posterior, are two systematic ways of choosing F in the first place.

The experiment as a random number generator. Think of the whole experiment, ten readings and all, as one throw of a very complicated die. Nature fixes the true g and the noise level. Each throw produces a new list of ten numbers, and our recipe turns each list into one number. Throw the die many times and those numbers form a histogram. This imagined histogram plays the role of the *ensemble* of statistical mechanics. We only ever see one microstate, our one data set. The error bars we quote, however, are properties of the whole ensemble.

Before any symbol.

1. What did we observe? A list of numbers $x_1, \ldots, x_N$.
2. What could have produced it? A family of probability distributions, labelled by the unknown quantity we care about (the *statistical model*).
3. What recipe turns the list into one number? (The *estimator*.)
4. If nature reran the experiment with the same true value, how would the recipe's output be distributed? (The *sampling distribution*.)

5. What does that distribution say about our one number? Its centre tells us whether the recipe aims at the right place. Its width is the error bar.

Step 4 is a *prediction* in the sense of Chapter 0: we start from a hypothesised truth and ask what outcomes it produces. Every error bar built from a sampling distribution runs in this forward direction, from truth to data. The reverse question, from the data we saw back to the truths that could have produced them, is the likelihood of the second half of the chapter and the Bayesian inference of Chapter 5.

3.1.1 Statistical models: the list of possible truths

Statistical inference is "using data to infer the distribution that generated the data" [Wasserman p. 87]. So before inferring anything, we must write down which distributions could have generated it.

Working definition 3.1 (statistical model)

A **statistical model** $\mathfrak{F}$ is a set of probability distributions [the candidate explanations of how the data were produced]. It is **parametric** if its members can be labelled by finitely many numbers,

$$\mathfrak{F} = \{ f(x;\theta) \ : \ \theta \in \Theta \}, \tag{3.2}$$

where θ is the **parameter** [a fixed but unknown number, or vector, that picks one member] and Θ the **parameter space** [all values θ is allowed to take]. If $\theta = (\theta_1, \theta_2)$ and we only care about θ_1, then θ_2 is a **nuisance parameter** [needed to describe the data, not wanted in the answer]. A model that cannot be labelled by finitely many numbers is **nonparametric**.

The Gaussian model for the pendulum is the two-parameter family

$$\mathfrak{F} = \left\{ f(x;\mu,\sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\!\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \ : \ \mu \in \mathbb{R},\ \sigma > 0 \right\}. \tag{3.3}$$

Here μ is the centre of the readings and σ their noise level. The semicolon in $f(x;\mu,\sigma)$ separates the value of the random variable, x, from the labels of the distribution, μ and σ. If all we want is $g = \mu$, then σ is a nuisance parameter: we need it to describe the scatter, but it is not part of the answer.

A coin flip (or "did this muon decay inside the detector?") is the one-parameter Bernoulli model $f(x;p) = p^x(1-p)^{1-x}$, $x \in \{0,1\}$, where p is the probability of a 1 (see Chapter 2).

The set of *all* distribution functions, $\mathfrak{F}_{\text{ALL}}$, is nonparametric: no finite list of numbers labels its members. Even there we can ask about single numbers computed from the distribution function F, such as the mean $T(F) = \int x \, \mathrm{d}F(x)$, the variance $T(F) = \int x^2 \mathrm{d}F(x) - \left(\int x \, \mathrm{d}F(x)\right)^2$ or the median $T(F) = F^{-1}(1/2)$. Any such function of the whole distribution is called a **statistical functional** [Wasserman p. 89]. Estimating a whole density f is harder: it needs a smoothness assumption, for instance $\int (f'')^2 \mathrm{d}x < \infty$, which says the candidate densities are "not too wiggly". Density estimation comes back with histograms and kernels.

Data = model + noise. A very common model has the form

$$Y = r(X) + \epsilon, \qquad \mathbb{E}(\epsilon) = 0, \tag{3.4}$$

where X is the setting we control (a pendulum length, a frequency), Y the reading we get, and $r(x) = \mathbb{E}(Y \mid X = x)$ the **regression function**, the average reading at setting x. Every

measurement written as "the model prediction plus noise" has this form. The condition $\mathbb{E}(\epsilon) = 0$ costs nothing: we can always *define* the noise as the gap between the reading and its average, $\epsilon := Y - r(X)$, and then its mean is zero automatically:

$$\begin{aligned}\mathbb{E}(\epsilon) &\overset{(1)}{=} \mathbb{E}\big[\mathbb{E}(\epsilon \mid X)\big] \\ &\overset{(2)}{=} \mathbb{E}\big[\mathbb{E}(Y - r(X) \mid X)\big] \\ &\overset{(3)}{=} \mathbb{E}\big[\mathbb{E}(Y \mid X) - r(X)\big] \\ &\overset{(4)}{=} \mathbb{E}\big[r(X) - r(X)\big] = 0. \end{aligned} \tag{3.5}$$

(1) Law of total expectation: average first over Y at fixed X, then over X.
(2) Insert the definition of ϵ.
(3) Once X is fixed, $r(X)$ is a constant and comes out of the conditional average.
(4) By definition $r(X) = \mathbb{E}(Y \mid X)$.

So "zero-mean noise" is not an extra assumption. What *is* an assumption is the *shape* of the noise distribution (Gaussian, Poisson, ...), and that assumption is what the likelihood in the second half of this chapter is built from.

3.1.2 Statistic, estimator, estimate

Lab talk uses three words loosely that we must keep apart: the recipe, the random number it will produce before the data are in, and the value it produces once they are.

Working definition 3.2 (statistic, estimator, estimate)

Let $X_1, \dots, X_N$ be a **sample** [N independent readings, each drawn from the same $f(x;\theta)$]. A **statistic** is any function of the sample that contains no unknown quantity. An **estimator** of θ is a statistic used to guess θ,

$$\hat{\theta}_N = g(X_1, \dots, X_N). \tag{3.6}$$

The **estimate** is the number $g(x_1, \dots, x_N)$ obtained by feeding in the particular data we observed.

The distinction matters. The estimator is a fixed *function*, like "add them up and divide by N". Because its inputs are random, its output is a random variable. The estimate is one realisation of that random variable, the one our universe happened to give us. For the pendulum, the sample mean is an estimator of g, and $9.815\,\mathrm{m\,s^{-2}}$ is an estimate [Cowan §5.1, p. 64].

The readings are independent and identically distributed (iid): each comes from the same $f(x;\theta)$, and none influences another. Independence means the joint density of the whole list is the product of the single densities,

$$f_{\text{sample}}(x_1, \dots, x_N; \theta) = f(x_1;\theta)\, f(x_2;\theta) \cdots f(x_N;\theta) = \prod_{i=1}^{N} f(x_i;\theta), \tag{3.7}$$

so the entire experiment is a single draw of one N-dimensional random vector $(X_1, \dots, X_N)$ [Cowan (5.1)].

3.1.3 The sampling distribution and the standard error

An estimator is a random variable, so it has a distribution. The width of that distribution is the error bar.

Working definition 3.3 (sampling distribution, standard error)

The **sampling distribution** of $\hat{\theta}_N$ is its probability distribution over imagined repetitions of the whole experiment [each repetition draws a fresh sample of size N from the same $f(x;\theta)$, with θ held fixed]. Its standard deviation is the **standard error**,

$$\mathrm{se}(\hat{\theta}_N) = \sqrt{\mathrm{Var}_\theta(\hat{\theta}_N)}. \tag{3.8}$$

Usually se depends on the unknown truth. Replacing the truth by estimates gives the **estimated standard error** $\widehat{\mathrm{se}}$, the number we actually quote.

The subscript in $\mathbb{E}_\theta$, Var_θ, P_θ means "computed with the density $f(x;\theta)$ at this one fixed θ". It does *not* mean an average over values of θ [Wasserman p. 89]. Written out, the mean of the sampling distribution can be computed in two ways [Cowan (5.3)]: as a one-dimensional integral over the values of $\hat{\theta}$, or as an N-dimensional integral over all possible data sets:

$$\mathbb{E}_\theta[\hat{\theta}] = \int \hat{\theta}\; g(\hat{\theta};\theta)\,\mathrm{d}\hat{\theta} = \int\cdots\int \hat{\theta}(x_1,\ldots,x_N)\, f(x_1;\theta)\cdots f(x_N;\theta)\,\mathrm{d}x_1\cdots\mathrm{d}x_N, \tag{3.9}$$

where $g(\hat{\theta};\theta)$ is the sampling density. The second form is often the easier one, because it never needs g. It needs only the recipe $\hat{\theta}(x_1,\ldots,x_N)$ and the model density f.

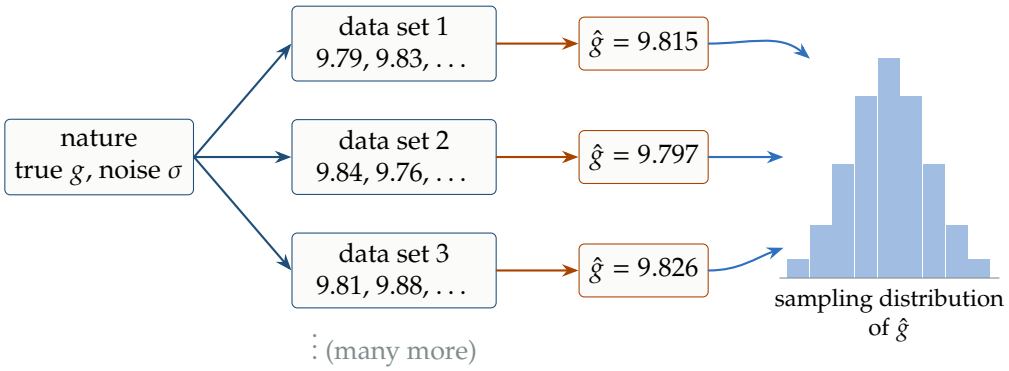

Figure 3.2: Imagined repetitions. Nature, with its true value held fixed, produces a fresh data set on each run of the experiment. The same recipe turns each data set into an estimate, and the estimates pile up into a histogram, the sampling distribution. We observe only one data set, but the error bar is the width of this histogram.

Example: The fraction of successes. Let $X_1,\ldots,X_N$ be Bernoulli(p): $X_i = 1$ if, say, the i-th muon decays inside the fiducial volume. Take $\hat{p} = N^{-1}\sum_i X_i$. We need $\mathbb{E}\,X_i = 1\cdot p + 0\cdot(1-p) = p$ and $\mathrm{Var}\,X_i = \mathbb{E}\,X_i^2 - p^2 = p - p^2 = p(1-p)$ (because $X_i^2 = X_i$). Then

$$\mathbb{E}_p(\hat{p}) \overset{(1)}{=} \frac{1}{N}\sum_{i=1}^{N}\mathbb{E}_p(X_i) \overset{(2)}{=} \frac{1}{N}\,Np = p,$$

$$\mathrm{Var}_p(\hat{p}) \overset{(3)}{=} \frac{1}{N^2}\,\mathrm{Var}_p\Big(\sum_{i=1}^{N}X_i\Big) \overset{(4)}{=} \frac{1}{N^2}\sum_{i=1}^{N}\mathrm{Var}_p(X_i) \overset{(5)}{=} \frac{p(1-p)}{N}.$$

(1) Expectation is linear: $\mathbb{E}(aU + bV) = a\,\mathbb{E}\,U + b\,\mathbb{E}\,V$, for any random variables.
(2) Each of the N terms equals p.
(3) $\mathrm{Var}(cU) = c^2\,\mathrm{Var}\,U$ for a constant c.
(4) For independent variables the covariances vanish, so the variance of a sum is the sum of the variances (derived in Eq. (3.20) below).
(5) Each term equals $p(1-p)$.

So $\hat{p}$ is centred on the truth, and $\mathrm{se} = \sqrt{p(1-p)/N}$. We do not know p, so we quote $\widehat{\mathrm{se}} = \sqrt{\hat{p}(1-\hat{p})/N}$ [Wasserman p. 91, Ex. 6.8]. With $N = 400$ and $\hat{p} = 0.30$ this is $\sqrt{0.3 \times 0.7/400} = 0.023$.

Example: Estimating π with darts. Throw darts uniformly at a square of side L with an inscribed circle. A dart lands in the circle with probability $p = \pi(L/2)^2/L^2 = \pi/4$ [SeeingTheory pp. 16–17]. With $X_i = 1$ for a hit, $\hat{\pi} = 4\hat{p}$ is an estimator of π. From Section 3.1.3,

$$\mathbb{E}(\hat{\pi}) \overset{(1)}{=} 4\,\mathbb{E}(\hat{p}) = 4 \cdot \frac{\pi}{4} = \pi,$$
$$\mathrm{se}(\hat{\pi}) \overset{(2)}{=} 4\sqrt{\frac{p(1-p)}{n}} \overset{(3)}{=} 4\sqrt{\frac{(\pi/4)(1-\pi/4)}{n}} = \frac{1.642}{\sqrt{n}}.$$

(1) Linearity, and $\mathbb{E}\,\hat{p} = p = \pi/4$.
(2) $\mathrm{Var}(4\hat{p}) = 16\,\mathrm{Var}\,\hat{p}$, so the standard deviation is multiplied by 4.
(3) Insert $p = \pi/4$: $(\pi/4)(1-\pi/4) = 0.7854 \times 0.2146 = 0.1685$, and $4\sqrt{0.1685} = 1.642$.

With $n = 100$ darts the simulation in Section 3.1.4 gives a mean of 3.142 and a spread of 0.1642 over 200 000 repetitions, against the derived 0.1642. A hundred darts pin π down only to about ± 0.16. This is our first sighting of the Monte Carlo error $\propto 1/\sqrt{n}$ of Chapter 6.

Example: The muon lifetime from twenty decays. Decay times of a muon at rest are exponential, $f(t;\tau) = \tau^{-1}e^{-t/\tau}$, with $\mathbb{E}\,t = \tau$ and $\mathrm{Var}\,t = \tau^2$ (Chapter 2). The estimator $\hat{\tau} = N^{-1}\sum_i t_i$ has, exactly as in Section 3.1.3, $\mathbb{E}\,\hat{\tau} = \tau$ and $\mathrm{Var}\,\hat{\tau} = \tau^2/N$. But here we can do better than the mean and variance: we know the whole sampling distribution. A sum of N independent exponentials of mean τ is a Gamma (Erlang) variable with shape N and scale τ (Chapter 2). Dividing by N divides the scale by N:

$$g(\hat{\tau};\tau) = \frac{\hat{\tau}^{\,N-1}e^{-N\hat{\tau}/\tau}}{\Gamma(N)\,(\tau/N)^N}, \qquad \hat{\tau} > 0. \tag{3.10}$$

This density is skewed to the right: its skewness is $2/\sqrt{N}$, i.e. 0.4472 for $N = 20$ (the simulation gives 0.4475). So the error bar $\tau/\sqrt{N}$ does not tell the whole story, because a skewed distribution treats the two sides differently. For $N = 20$, integrating (3.10) shows that $\hat{\tau}$ falls below the true τ slightly more often than above it (53% against 47%), but large upward excursions are the more common ones: $\hat{\tau}$ exceeds τ by two standard errors with probability 3.3%, and falls short by two standard errors with probability only 1.0%.

3.1.4 Seeing it in Python

Listing 3.1: Four recipes applied to the same simulated experiments (code/ch03/01_sampling_distribution.py)

```
rng = rng_for("ch03", "01_sampling_distribution")
setup()
M = 200_000                    # number of imagined repetitions of the experiment
```

```python

# ---------- (A) ten Gaussian readings of g ----------
g_true, sigma, N = 9.81, 0.05, 10
x = g_true + sigma * rng.standard_normal((M, N))      # each row = one experiment
est = {
    "sample mean": x.mean(axis=1),
    "sample median": np.median(x, axis=1),
    "mid-range": 0.5 * (x.min(axis=1) + x.max(axis=1)),
    "first reading": x[:, 0],
}
sd = {k: v.std(ddof=1) for k, v in est.items()}
```

The script creates a matrix `x` of shape $(M, N) = (200\,000, 10)$: each row is one complete pendulum experiment with true $g = 9.81$ and $\sigma = 0.05\,\mathrm{m\,s^{-2}}$. The dictionary `est` applies four different recipes to every row: the sample mean, the sample median, the mid-range $(\min + \max)/2$, and the lazy "first reading only". The last line measures the spread of each recipe over the M repetitions. That spread *is* the standard error, obtained without any formula.

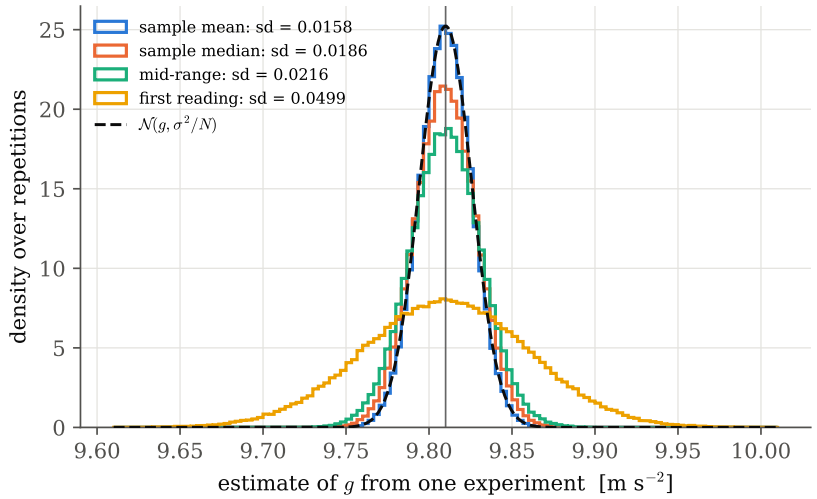

Figure 3.3: Sampling distributions of four estimators of g, each built from the same 200 000 simulated ten-reading experiments. All four are centred on the true value (vertical line). The sample mean is the narrowest and sits on the derived curve $\mathcal{N}(g, \sigma^2/N)$. Using only the first reading gives a distribution as wide as the noise itself.

The numbers: the sample mean scatters by 0.01583 against the derived $\sigma/\sqrt{N} = 0.01581$; the median by 0.01859 (its variance is 1.379 times larger, tending to $\pi/2 \approx 1.57$ for large N with Gaussian noise); the mid-range by 0.02155; the first reading by $0.04993 \approx \sigma$. All four recipes are "right on average". They differ in how much they scatter, and that is what makes one of them better. Section 3.2 makes "better" precise.

The simulated mean and spread of $\hat{\tau}$ are 2.198 and 0.4914 μs, against the derived $\tau = 2.197$ and $\tau/\sqrt{20} = 0.491$ μs.

What this bought us. An estimator is a recipe, so it has a sampling distribution. The standard error is the width of that distribution, not the width of the data: with ten readings of noise σ the sample mean scatters by $\sigma/\sqrt{10}$, a single reading by σ.

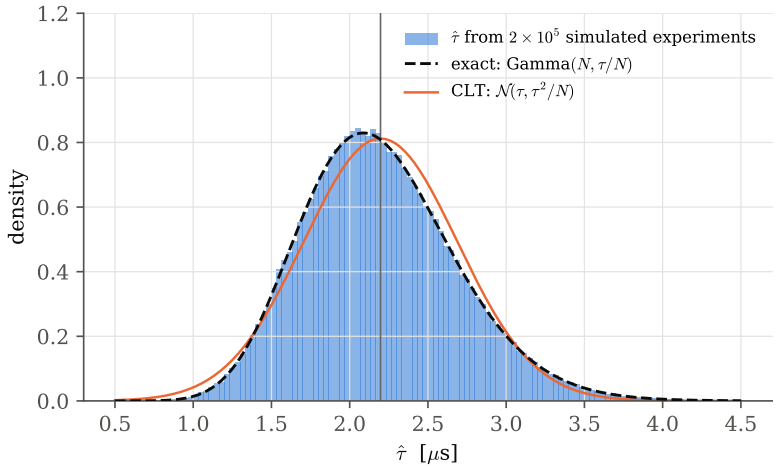

Figure 3.4: Sampling distribution of the lifetime estimate from twenty decays. The histogram of simulated $\hat{\tau}$ follows the exact Gamma density (3.10) (dashed), including its longer right tail. The Gaussian with the same mean and width (solid) is close but visibly too symmetric.

word	what it is	pendulum example
parameter θ	fixed, unknown number labelling the true distribution	the true g
statistic	any function of the data with no unknowns	$\max_i x_i$, $\sum x_i^2$
estimator $\hat{\theta}$	a statistic used to guess θ; a random variable	$\bar{X} = N^{-1} \sum X_i$
estimate	the estimator evaluated on our data; one number	9.815
standard error	width of the estimator's sampling distribution	$\sigma/\sqrt{N} = 0.016$

Watch out: What is random and what is fixed

In the frequentist picture, θ is fixed and $\hat{\theta}$ is random. A statement such as "$g = 9.815 \pm 0.016$" is shorthand for a statement about the *recipe*: applied to repeated experiments, it lands within 0.016 of the truth about two times in three. It is not a probability distribution for g. Probability distributions *for* parameters are the Bayesian answer of Chapter 5, and the precise meaning of an interval is the subject of Chapter 4.

A first look at intervals and tests. The sampling distribution also gives the two other basic tools of statistics, intervals and tests. Suppose $\hat{\theta}_N$ is approximately Gaussian with estimated standard error $\widehat{\text{se}}$ (the central limit theorem of Section 3.3 explains why this is so common). Then the interval $C_N = (\hat{\theta}_N - z_{\alpha/2}\widehat{\text{se}},\ \hat{\theta}_N + z_{\alpha/2}\widehat{\text{se}})$ with $z_{\alpha/2} = \Phi^{-1}(1 - \alpha/2)$ (Φ is the standard normal distribution function) traps the fixed θ in a fraction $1 - \alpha$ of repetitions as $N \to \infty$ [Wasserman p. 94, Thm 6.16]. For $\alpha = 0.05$, $z_{\alpha/2} = 1.96 \approx 2$: "estimate $\pm$ two standard errors". For the Bernoulli case the interval is $\hat{p} \pm z_{\alpha/2}\sqrt{\hat{p}(1-\hat{p})/N}$ [Wasserman Ex. 6.17].

A **hypothesis test** uses the same sampling distribution the other way round. We start from a default hypothesis, such as "the coin is fair", $p = 1/2$. Under it we know how $T = |\hat{p} - 1/2|$ is distributed. If the observed T is larger than the default would usually produce, we reject the default [Wasserman p. 95, Ex. 6.18]. Both ideas are developed properly in Chapter 4.

Verification and research. Here the Monte Carlo *verifies* a result we can derive, $\text{se}(\bar{X}) = \sigma/\sqrt{N}$. The same few lines, "simulate the experiment many times, apply the recipe, histogram the output", are the *research instrument* when no formula exists. The sampling distribution of a CMB power spectrum estimated from a masked, noisy, beam-smoothed map (Chapter 8), or of

a topological summary of a field such as its Euler characteristic (Chapter 12), is obtained in exactly this way, with a simulator of the sky in place of `rng.standard_normal`.

3.2 Aiming and scattering: bias, variance and mean squared error

Charged particles cross a silicon strip detector and leave hits whose positions along one strip are uniformly spread between 0 and the strip's unknown active length θ. We record $n = 10$ hit positions. Three colleagues propose three recipes. The first doubles the average position (the average of a uniform variable sits in the middle). The second takes the largest position seen (no hit can be beyond the end). The third takes the largest position and nudges it up a little, because the largest of ten hits is almost never exactly at the end.

Which recipe should we use? Each one is a guess at θ, and each guess misses by some amount that changes from experiment to experiment. The fair comparison is the average squared miss, the mean squared error. It splits into two parts every experimentalist already knows: a systematic offset and a statistical scatter.

Darts at a target. Picture the sampling distribution of Section 3.1 as a cluster of darts around a bull's-eye at the true value. Two things can go wrong. The cluster can be centred in the wrong place (a thrower with a consistent pull to the left), or it can be wide (a shaky hand). The first is *bias*, the second is *variance*. A good estimator needs both to be small, and it may be worth accepting a little of one to remove a lot of the other.

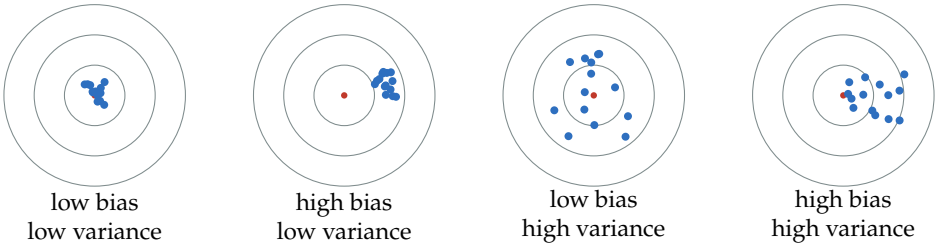

Figure 3.5: Four throwers, fourteen darts each. The red dot is the true value of the parameter and every blue dot is the estimate from one repetition of the experiment. Moving the whole cluster off the centre is bias. Spreading it out is variance. The mean squared error is the average squared distance of the darts from the red dot, and it grows with both.

The questions, in words.

1. Over many repetitions, where is the recipe's output centred? Is that the true value? (Bias.)
2. How widely does the output scatter about its own centre? (Variance, or its square root, the standard error.)
3. On average, how far is the output from the *truth*, counting both effects? (Mean squared error.)
4. As we take more data, does the output settle down on the truth? (Consistency.)

3.2.1 Bias, variance and their sum

Two things can be wrong with an estimator: its centre can be off, and its spread can be large. Each has a name, and the two combine into one measure of total error.

Working definition 3.4 (bias, unbiased, mean squared error)

The **bias** of an estimator $\hat{\theta}_n$ is

$$\text{bias}(\hat{\theta}_n) = \mathbb{E}_\theta(\hat{\theta}_n) - \theta \tag{3.11}$$

[the offset of the centre of the sampling distribution from the truth, at this fixed θ]. The estimator is **unbiased** if the bias is zero for *every* θ in Θ. The **mean squared error** is

$$\text{MSE}(\hat{\theta}_n) = \mathbb{E}_\theta\left[(\hat{\theta}_n - \theta)^2\right] \tag{3.12}$$

[the average over repetitions of the squared miss distance].

Both are functions of the unknown θ, because the average is taken with $f(x;\theta)$. The two ideas fit together exactly: the MSE is the variance plus the squared bias. To show it, call the centre of the sampling distribution $\bar{\theta}_n := \mathbb{E}_\theta(\hat{\theta}_n)$. It is a fixed number, not a random variable. Then

$$\begin{aligned}
\text{MSE}(\hat{\theta}_n) &\overset{(1)}{=} \mathbb{E}_\theta\left[(\hat{\theta}_n - \bar{\theta}_n + \bar{\theta}_n - \theta)^2\right] \\
&\overset{(2)}{=} \mathbb{E}_\theta\left[(\hat{\theta}_n - \bar{\theta}_n)^2\right] + 2(\bar{\theta}_n - \theta)\,\mathbb{E}_\theta\left[\hat{\theta}_n - \bar{\theta}_n\right] + (\bar{\theta}_n - \theta)^2 \\
&\overset{(3)}{=} \mathbb{E}_\theta\left[(\hat{\theta}_n - \bar{\theta}_n)^2\right] + (\bar{\theta}_n - \theta)^2 \\
&\overset{(4)}{=} \text{Var}_\theta(\hat{\theta}_n) + \text{bias}^2(\hat{\theta}_n).
\end{aligned} \tag{3.13}$$

(1) Add and subtract the constant $\bar{\theta}_n$ inside the square.
(2) Expand $(a+b)^2 = a^2 + 2ab + b^2$ with $a = \hat{\theta}_n - \bar{\theta}_n$ (random) and $b = \bar{\theta}_n - \theta$ (constant). Constants come out of the expectation, and $\mathbb{E}(b^2) = b^2$.
(3) $\mathbb{E}_\theta[\hat{\theta}_n - \bar{\theta}_n] = \bar{\theta}_n - \bar{\theta}_n = 0$ by the definition of $\bar{\theta}_n$, so the cross term vanishes.
(4) The first term is the variance by definition. The second is the squared bias (3.11).

Key idea: MSE = bias^2 + variance

The mean squared error of any estimator is the square of its systematic offset plus the square of its statistical scatter, MSE = bias^2 + se^2. For an unbiased estimator the MSE is just the variance.

Why is the result true, beyond the algebra? It is Pythagoras. The miss $\hat{\theta}_n - \theta$ is a fixed offset b (the bias) plus a random part a whose average is zero. Squaring gives $a^2 + 2ab + b^2$. The cross term averages to zero, because b is a constant and a averages to zero. So the two parts add in square, like the two perpendicular sides of a right triangle. The same identity is the parallel-axis theorem of mechanics: the moment of inertia about the true value equals the moment about the centre of mass plus the total mass times the squared distance between the two.

Statistics and the laboratory.

statistics	laboratory
bias	systematic error (a miscalibrated scale)
standard error	statistical error (shrinks with more data)
MSE = bias^2 + se^2	"add the errors in quadrature"
unbiased estimator	a method with no systematic offset, for every true value
consistent estimator	a method that homes in on the truth as data accumulate

The variance of the estimator is the *statistical* error. A bias, or a mistake in the model, is a *systematic* error, and more data do not remove it [Cowan §5.1, (5.5)]. One caution about the quadrature row. Physicists add a systematic in quadrature because they treat its unknown size as random, drawn from an ensemble of possible miscalibrations. The bias in (3.13) is not random. It is a definite, if unknown, number, and it enters squared for a purely algebraic reason: the cross term vanished.

3.2.2 Three recipes for the strip length

Back to the silicon strip from the start of this section. A strip of unknown active length θ records $n = 10$ hits, and each hit position X_i is equally likely to be anywhere along it, $X_i \sim \text{Uniform}(0, \theta)$, with density $1/\theta$ on $[0, \theta]$. The three colleagues each proposed a way of turning the ten positions into one number for θ, that is, an estimator $\hat{\theta} = g(X_1, \ldots, X_n)$ in the sense of Section 3.1.2. It is customary to call a candidate estimator T (for a statistic of the data), and we number the three candidates in the order the colleagues proposed them. Two ingredients appear in them: the sample mean $\bar{X} = \frac{1}{n}\sum_{i=1}^{n} X_i$, and the largest of the ten positions, written $X_{(n)} = \max_i X_i$ (the subscript in parentheses means "the n-th in order of size"). The moments of a single hit we need are (from Chapter 2)

$$\mathbb{E}\, X_i = \frac{\theta}{2}, \qquad \mathbb{E}\, X_i^2 = \int_0^\theta \frac{x^2}{\theta}\mathrm{d}x = \frac{\theta^2}{3}, \qquad \operatorname{Var} X_i = \frac{\theta^2}{3} - \frac{\theta^2}{4} = \frac{\theta^2}{12}. \tag{3.14}$$

The three recipes, written as formulas, are

$T_1 = 2\bar{X}$	double the average position (a uniform hit sits at $\theta/2$ on average),
$T_2 = X_{(n)}$	take the largest position (no hit can lie beyond the end),
$T_3 = \frac{n+1}{n} X_{(n)}$	nudge the largest position up (it almost never reaches the end).

For each recipe we ask the questions listed above: where is it centred, how widely does it scatter, and what is its total error?

Example: Doubling the mean.

$$\mathbb{E}\, T_1 \overset{(1)}{=} 2 \cdot \frac{1}{n}\sum_{i=1}^{n} \mathbb{E}\, X_i \overset{(2)}{=} 2 \cdot \frac{\theta}{2} = \theta,$$

$$\operatorname{Var} T_1 \overset{(3)}{=} 4 \operatorname{Var} \bar{X} \overset{(4)}{=} 4 \cdot \frac{\theta^2}{12\,n} = \frac{\theta^2}{3n}.$$

(1) Linearity of expectation.
(2) Each $\mathbb{E}\, X_i = \theta/2$ by (3.14).
(3) $\operatorname{Var}(cU) = c^2 \operatorname{Var} U$ with $c = 2$.
(4) $\operatorname{Var} \bar{X} = \operatorname{Var} X_i / n$ for independent readings (the same steps as in Section 3.1.3, and derived generally in (3.20)).

So T_1 is unbiased and $\mathrm{MSE}(T_1) = \theta^2/(3n)$. For $n = 10$ and $\theta = 1$ this is 0.0333.

Example: The largest hit. We first need the sampling distribution of the maximum. The maximum is below t exactly when *every* hit is below t. For $0 \le t \le \theta$,

$$\mathrm{P}(X_{(n)} \le t) \overset{(1)}{=} \mathrm{P}(X_1 \le t,\ X_2 \le t,\ \ldots,\ X_n \le t) \overset{(2)}{=} \prod_{i=1}^{n} \mathrm{P}(X_i \le t) \overset{(3)}{=} \left(\frac{t}{\theta}\right)^n.$$

(1) "The largest is at most t" is the same event as "all are at most t".
(2) The hits are independent, so the joint probability factorises.
(3) For a uniform variable $\mathrm{P}(X_i \le t) = t/\theta$.

Differentiating, the density is $g(t) = n\,t^{n-1}/\theta^n$ on $[0, \theta]$. It piles up near the end of the strip, as the picture of ten hits suggests. Its moments are

$$\begin{aligned}
\mathbb{E}\,X_{(n)} &\overset{(1)}{=} \int_0^\theta t \cdot \frac{n\,t^{n-1}}{\theta^n}\mathrm{d}t \overset{(2)}{=} \frac{n}{\theta^n}\,\frac{\theta^{n+1}}{n+1} = \frac{n}{n+1}\,\theta, \\
\mathbb{E}\,X_{(n)}^2 &\overset{(3)}{=} \frac{n}{\theta^n}\,\frac{\theta^{n+2}}{n+2} = \frac{n}{n+2}\,\theta^2, \\
\operatorname{Var} X_{(n)} &\overset{(4)}{=} \frac{n}{n+2}\,\theta^2 - \frac{n^2}{(n+1)^2}\,\theta^2 \overset{(5)}{=} \frac{n\,\theta^2}{(n+1)^2(n+2)}.
\end{aligned}$$

(1) Definition of the mean of a continuous variable with density g.
(2) $\int_0^\theta t^n \mathrm{d}t = \theta^{n+1}/(n+1)$.
(3) The same integral with one more power of t: $\int_0^\theta t^{n+1}\mathrm{d}t = \theta^{n+2}/(n+2)$.
(4) $\operatorname{Var} = \mathbb{E}\,X^2 - (\mathbb{E}\,X)^2$.
(5) Common denominator: $n(n+1)^2 - n^2(n+2) = n\big[(n+1)^2 - n(n+2)\big] = n$.

So $\operatorname{bias}(T_2) = \frac{n}{n+1}\theta - \theta = -\frac{\theta}{n+1}$: the largest hit always falls short of the end. By (3.13),

$$\operatorname{MSE}(T_2) \overset{(1)}{=} \frac{\theta^2}{(n+1)^2} + \frac{n\,\theta^2}{(n+1)^2(n+2)} \overset{(2)}{=} \frac{\theta^2\,\big[(n+2)+n\big]}{(n+1)^2(n+2)} = \frac{2\,\theta^2}{(n+1)(n+2)}.$$

(1) Squared bias plus variance.
(2) Put both terms over the denominator $(n+1)^2(n+2)$. Then $2n+2 = 2(n+1)$ cancels one factor of $n+1$.

For $n = 10$: bias $= -1/11 = -0.09091$ and MSE $= 2/132 = 0.01515$ (with $\theta = 1$). Even though it is biased, T_2 has less than half the MSE of the unbiased T_1.

Example: Correcting the bias. The bias of T_2 is known exactly, as a fraction of θ, so we can divide it out:

$$\begin{aligned}
\mathbb{E}\,T_3 &\overset{(1)}{=} \frac{n+1}{n}\,\mathbb{E}\,X_{(n)} \overset{(2)}{=} \frac{n+1}{n}\cdot\frac{n}{n+1}\,\theta = \theta, \\
\operatorname{Var} T_3 &\overset{(3)}{=} \frac{(n+1)^2}{n^2}\cdot\frac{n\,\theta^2}{(n+1)^2(n+2)} = \frac{\theta^2}{n(n+2)}.
\end{aligned}$$

(1) Linearity, with the constant $(n+1)/n$.
(2) The mean of the maximum from Section 3.2.2.
(3) $\operatorname{Var}(cU) = c^2 \operatorname{Var} U$ with $c = (n+1)/n$, and the variance of the maximum.

Now $\operatorname{MSE}(T_3) = \theta^2/(n(n+2)) = 1/120 = 0.008333$ for $n = 10$: unbiased *and* four times better than T_1. For large n, $\operatorname{MSE}(T_1) \propto 1/n$ while $\operatorname{MSE}(T_3) \propto 1/n^2$. The maximum uses the one feature of the data (the sharp edge) that carries the most information about θ. The mean washes that edge out.

Seeing it in Python. Listing 3.2 simulates $M = 200\,000$ experiments of ten hits and applies all three recipes to each.

Listing 3.2: The three recipes and their derived bias and variance (code/ch03/02_bias_variance_uniform.py)

```
def estimators(x):
    n = x.shape[1]
    mx = x.max(axis=1)
    return {"T1": 2 * x.mean(axis=1), "T2": mx, "T3": (n + 1) / n * mx}

def theory(n):
    """bias, variance, MSE of T1, T2, T3 (derived in the text), theta = 1."""
    return {
        "T1": (0.0, theta**2 / (3 * n)),
        "T2": (-theta / (n + 1), n * theta**2 / ((n + 1) ** 2 * (n + 2))),
        "T3": (0.0, theta**2 / (n * (n + 2))),
    }
```

The function `estimators` takes a matrix whose rows are experiments and returns the three estimates for each row. The function `theory` encodes the formulas just derived, so the script can put the two side by side. The simulated biases are 2.896×10^{-4}, -0.09081 and 1.080×10^{-4} (derived: 0, -0.09091, 0). The simulated MSEs are 0.03342, 0.01517 and 0.008373 (derived: 0.03333, 0.01515, 0.008333). Agreement to the third digit is what $M = 200\,000$ repetitions buy.

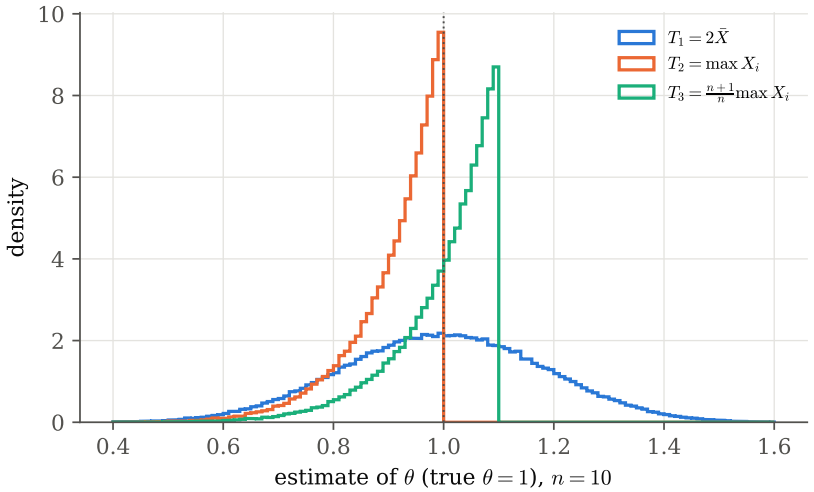

Figure 3.6: Sampling distributions of the three strip-length recipes with ten hits each. Doubling the mean gives a broad, symmetric bump centred on the truth. The largest hit gives a sharp distribution that ends exactly at the truth and so sits entirely to its left. Stretching it by 11/10 moves it onto the truth and keeps it narrow.

3.2.3 The MSE depends on the truth

For the strip, T_3 beat T_1 at every θ. That is unusual. The MSE is a function of the unknown truth, so one recipe can win for some true values and lose for others. The simplest case shows how.

Example: Shrinking the mean towards zero. Let $X_1, \dots, X_n \sim \mathcal{N}(\mu, \sigma^2)$ and consider the family of recipes $T_c = c\,\bar{X}$ with a constant $0 < c \le 1$. Then

$$\mathrm{MSE}(T_c) \overset{(1)}{=} \left(\mathbb{E}\,T_c - \mu\right)^2 + \mathrm{Var}\,T_c \overset{(2)}{=} (c-1)^2\mu^2 + c^2\,\frac{\sigma^2}{n}.$$

(1) The decomposition (3.13).

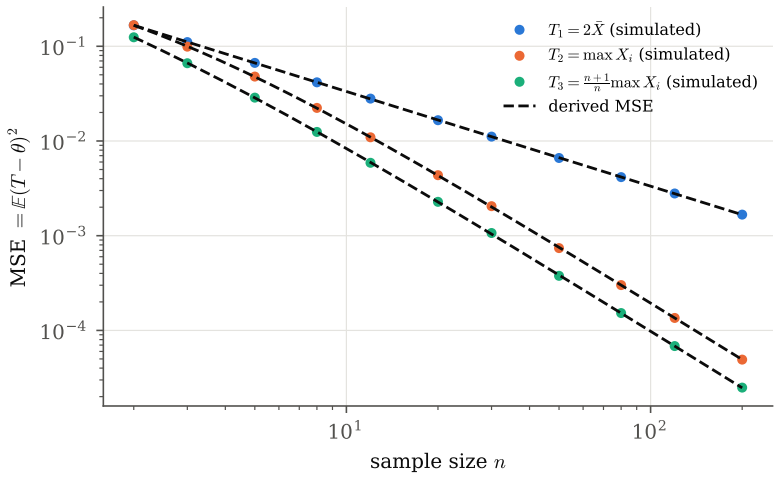

Figure 3.7: Mean squared error against the number of hits, on log–log axes. The points are simulations and the dashed curves the derived formulas. Doubling the mean falls with slope -1. Both recipes built on the largest hit fall with slope -2, and the corrected one stays below the uncorrected one at every n.

(2) $\mathbb{E}\,T_c = c\mu$ and $\operatorname{Var} T_c = c^2 \operatorname{Var} \bar{X} = c^2\sigma^2/n$.

Setting the derivative with respect to c to zero, $2(c-1)\mu^2 + 2c\,\sigma^2/n = 0$, gives the best constant $c^* = \mu^2/(\mu^2 + \sigma^2/n)$. It depends on the unknown μ, so it is not a recipe we can use. Fix $c < 1$ instead and compare with $\bar{X}$, which is T_1 here and has MSE σ^2/n. Shrinking lowers the variance term by the factor c^2 but adds the bias term $(c-1)^2\mu^2$, which grows with μ. So shrinking wins when μ is near zero and loses when μ is far from zero (Figure 3.8). With $\sigma^2/n = 1$ and $c = 0.8$ the curves cross where $0.04\,\mu^2 + 0.64 = 1$, i.e. at $|\mu| = 3$.

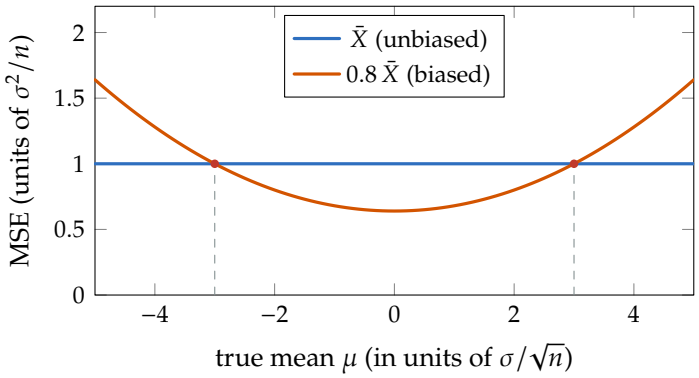

Figure 3.8: Mean squared error of two recipes for a Gaussian mean, as a function of the true value. The sample mean has the same MSE everywhere. The shrunken recipe wins inside $|\mu| < 3$ and loses outside, and the two curves meet at the red dots. Neither is better for every possible truth.

There is usually no "best" estimator. Because the MSE is a function of θ, two estimators are usually not ordered: one wins for some true values and loses for others. The simplest way to get a meaningful comparison is to restrict the class, for instance to unbiased estimators, and look for the smallest variance inside it. That programme leads to the Cramér–Rao bound and the Fisher information (second half of Chapter 3 and Chapter 10).

Watch out: Unbiased is not the same as good

An unbiased estimator can be much worse than a biased one. T_1 in the strip example is unbiased and has four times the MSE of T_3 and twice that of the biased T_2. Conversely, a biased estimator is not "wrong": Wasserman notes that unbiasedness "used to receive much attention but these days is considered less important" [Wasserman p. 90]. What matters is the size of the total error, and that it shrinks as data accumulate.

Example: Poisson counts. A counter records $X_1, \dots, X_n \sim \text{Poisson}(\lambda)$ events in n equal time bins, and we estimate the rate by $\hat{\lambda} = \bar{X}$. From Chapter 2, $\mathbb{E}\,X_i = \text{Var}\,X_i = \lambda$. Then

$$\text{bias}(\hat{\lambda}) \overset{(1)}{=} \frac{1}{n}\sum_i \mathbb{E}\,X_i - \lambda = 0,$$

$$\text{se}(\hat{\lambda}) \overset{(2)}{=} \sqrt{\frac{\text{Var}\,X_i}{n}} = \sqrt{\frac{\lambda}{n}},$$

$$\text{MSE}(\hat{\lambda}) \overset{(3)}{=} 0^2 + \frac{\lambda}{n} = \frac{\lambda}{n}.$$

(1) Linearity and $\mathbb{E}\,X_i = \lambda$.
(2) Variance of a mean of independent readings, and $\text{Var}\,X_i = \lambda$ for a Poisson variable.
(3) Decomposition (3.13) with zero bias.

The estimated standard error is $\sqrt{\hat{\lambda}/n}$. For $n = 1$ this is the familiar "$\sqrt{N}$ error on N counts" [Wasserman Exercise 6.1].

3.2.4 Consistency: does the recipe home in on the truth?

A minimal demand on any recipe is that more data make it better, eventually without limit. To say this precisely we must say what it means for a sequence of random numbers to approach a constant. One random number can still land anywhere, so "approach" has to be a statement about probabilities. The simplest version is below (the other versions are in Section 3.3.2).

Convergence in probability and consistency. A sequence of random variables Y_n **converges in probability** to a constant c, written $Y_n \xrightarrow{P} c$, if for every $\epsilon > 0$

$$\text{P}\big(|Y_n - c| > \epsilon\big) \longrightarrow 0 \qquad (n \to \infty) \tag{3.15}$$

[any band around c, however narrow, eventually contains Y_n in almost all repetitions]. An estimator is **consistent** if $\hat{\theta}_n \xrightarrow{P} \theta$ for every $\theta \in \Theta$.

To prove consistency we need a bound on the probability of a large miss. One elementary inequality supplies it.

Markov and Chebyshev inequalities. If $Y \geq 0$ and $t > 0$, then $\text{P}(Y \geq t) \leq \mathbb{E}\,Y/t$ (Markov). Applied to $Y = (U - a)^2$ with $t = \epsilon^2$ it gives, for any random variable U and any constant a,

$$\text{P}\big(|U - a| \geq \epsilon\big) \leq \frac{\mathbb{E}\big[(U-a)^2\big]}{\epsilon^2}. \tag{3.16}$$

With $a = \mathbb{E}\,U$ the numerator is $\text{Var}\,U$ (Chebyshev).

Markov's inequality is true for a reason we can see: a non-negative quantity cannot have a big chunk of probability at large values without dragging its average up. Written out, with $\mathbb{1}\{\cdot\}$ the indicator that is 1 when the condition holds and 0 otherwise,

$$\mathbb{E}\,Y \overset{(1)}{\geq} \mathbb{E}\big[Y\,\mathbb{1}\{Y \geq t\}\big] \overset{(2)}{\geq} \mathbb{E}\big[t\,\mathbb{1}\{Y \geq t\}\big] \overset{(3)}{=} t\;\mathrm{P}(Y \geq t). \tag{3.17}$$

(1) $Y \geq 0$, so throwing away the part of the average where $Y < t$ cannot increase it.
(2) Where the indicator is 1, $Y \geq t$. Where it is 0, both sides are 0.
(3) The average of an indicator is the probability of its event.

Dividing by t gives Markov. Now take $U = \hat{\theta}_n$ and $a = \theta$ in (3.16): the numerator is exactly the MSE, so

$$\mathrm{P}\big(|\hat{\theta}_n - \theta| \geq \epsilon\big) \leq \frac{\mathrm{MSE}(\hat{\theta}_n)}{\epsilon^2} = \frac{\mathrm{bias}^2(\hat{\theta}_n) + \mathrm{se}^2(\hat{\theta}_n)}{\epsilon^2}. \tag{3.18}$$

A sufficient condition for consistency. If $\mathrm{bias}(\hat{\theta}_n) \to 0$ and $\mathrm{se}(\hat{\theta}_n) \to 0$ as $n \to \infty$, then $\hat{\theta}_n$ is consistent. The reason is (3.18): its right side then goes to zero for every fixed ϵ, and it bounds the probability of a miss larger than ϵ.

Example: Which recipes are consistent?

- $\hat{p} = \bar{X}$ for coin flips: bias 0, se $= \sqrt{p(1-p)/n} \to 0$. Consistent [Wasserman Ex. 6.11].
- $T_2 = X_{(n)}$ for the strip: bias $-\theta/(n+1) \to 0$, variance $\sim \theta^2/n^2 \to 0$. *Biased but consistent.*
- "Use the first reading only" for the pendulum: bias 0 but se $= \sigma$ for every n. The inequality tells us nothing, and indeed $\mathrm{P}(|X_1 - g| > \epsilon)$ is the same fixed number for all n. *Unbiased but not consistent.*

Bias and consistency are therefore independent properties. One is about the centre of the sampling distribution at fixed n, the other about the whole distribution as $n \to \infty$.

Try it. Show that $T_c = c_n \bar{X}$ with $c_n = n/(n+1)$ is biased for every finite n and yet consistent for a Gaussian mean. (Compute its bias and variance and let $n \to \infty$.)

What this bought us. Choose recipes by their total error, MSE = bias^2 + se^2. Bias alone is a poor guide. A recipe whose bias and standard error both vanish as the data grow is consistent, by Chebyshev's inequality.

Verification and research. For the strip we could derive every number, and the simulation only checked the algebra. In real analyses the recipe is often a long chain (a fit inside a selection inside a reconstruction) and the bias has no formula. The standard remedy is the same simulation used as an instrument: inject a known truth into simulated data, run the full chain many times, and measure the bias and scatter of the output. This "injection–recovery" test is how the bias of a CMB power spectrum estimator on a masked sky is found and removed (Chapter 8).

3.3 Why error bars shrink like $1/\sqrt{N}$: the law of large numbers and the central limit theorem

Every accelerator physicist knows the rule of thumb: to halve the error on a cross-section, collect four times the luminosity. A Monte Carlo integration that gives two correct digits with 10^4 samples needs 10^6 for three. The rule has exceptions that bite. The average of energies drawn from a Breit–Wigner resonance does not improve at all as we add events.

Two theorems account for the rule and for its exceptions. The law of large numbers says that an average settles on the true mean. The central limit theorem says how it is distributed on the way: as a Gaussian of width $\sigma/\sqrt{N}$, provided the readings have a finite variance σ^2. The Breit–Wigner has none, and that is why it escapes the rule.

A random walk, rescaled. The sum of N independent readings is a random walk of N steps. Its distance from the expected position grows like $\sqrt{N}$, the familiar result from diffusion ($\langle x^2\rangle \propto t$). The mean is the sum divided by N, so its scatter is $\sqrt{N}/N = 1/\sqrt{N}$. And the shape of a diffusing cloud forgets the shape of the individual step: after many steps it is a Gaussian, whatever the kick distribution was. That is the central limit theorem, the same statement as the approach of a diffusion kernel to a heat-equation Gaussian.

What we want to know.

1. How does the scatter of an average depend on the number of readings, and on correlations between them?
2. In what sense does a random average "tend to" the true mean? (There are several inequivalent senses.)
3. What does the histogram of averages look like for large N, and how large is large?
4. What breaks, and why, when the parent has no finite variance?

3.3.1 The variance of a sum and of a mean

The $1/\sqrt{N}$ comes from one identity: the variance of a sum is the sum of all the variances and covariances of its terms. Let $X_1, \dots, X_N$ have means μ_i, variances σ_i^2 and covariances $\operatorname{Cov}(X_i, X_j) = \mathbb{E}[(X_i - \mu_i)(X_j - \mu_j)]$, with $\operatorname{Cov}(X_i, X_i) = \sigma_i^2$. For the sum,

$$\operatorname{Var}\Big(\sum_{i=1}^{N} X_i\Big) \overset{(1)}{=} \mathbb{E}\Big[\Big(\sum_{i=1}^{N}(X_i-\mu_i)\Big)^2\Big] \overset{(2)}{=} \mathbb{E}\Big[\sum_{i=1}^{N}\sum_{j=1}^{N}(X_i-\mu_i)(X_j-\mu_j)\Big]$$
$$\overset{(3)}{=} \sum_{i=1}^{N}\sum_{j=1}^{N}\operatorname{Cov}(X_i,X_j) \overset{(4)}{=} \sum_{i=1}^{N}\sigma_i^2 + \sum_{i\neq j}\operatorname{Cov}(X_i,X_j). \tag{3.19}$$

(1) By linearity the mean of the sum is $\sum \mu_i$. The variance is the mean squared deviation from it.
(2) The square of a sum is the double sum of all products.
(3) Linearity of expectation, term by term, and the definition of covariance.
(4) Split the double sum into the diagonal $i = j$ and the rest.

If the readings are independent, every covariance with $i \neq j$ vanishes. If they also share one variance σ^2, the mean $\bar{X} = N^{-1}\sum X_i$ has

$$\mathbb{E}\,\bar{X} = \mu, \qquad \operatorname{Var}\bar{X} = \frac{1}{N^2}\,N\sigma^2 = \frac{\sigma^2}{N}, \qquad \operatorname{se}(\bar{X}) = \frac{\sigma}{\sqrt{N}} \tag{3.20}$$

[Wasserman p. 52, Thm. 3.17], [Cowan (5.8), (5.13)]. This is the $1/\sqrt{N}$. It needs nothing about the parent except a finite σ.

Example: Averaging a die. For a fair die, $\mathbb{E}\,X = 3.5$ and $\mathbb{E}\,X^2 = (1{+}4{+}9{+}16{+}25{+}36)/6 = 91/6$, so $\operatorname{Var} X = 91/6 - 49/4 = 35/12 = 2.917$. The average of 50 rolls therefore has $\operatorname{Var}\bar{X} = 2.917/50 = 0.0583$ and se $= 0.24$ [SeeingTheory pp. 38–39]. The individual rolls scatter over 1–6, their average over roughly 3.26–3.74 (two thirds of the time).

Example: Correlated readings do not average away. Suppose every pair of readings has the same correlation ρ, so $\operatorname{Cov}(X_i, X_j) = \rho\sigma^2$ for $i \neq j$. This happens when a common drift, such as a temperature change in the pendulum lab, moves all readings together. There are $N(N-1)$ ordered pairs with $i \neq j$, so from (3.19)

$$\operatorname{Var}\bar{X} \overset{(1)}{=} \frac{1}{N^2}\Big[N\sigma^2 + N(N-1)\rho\sigma^2\Big] \overset{(2)}{=} \frac{\sigma^2}{N}\big[1 + (N-1)\rho\big] \xrightarrow{N\to\infty} \rho\,\sigma^2.$$

(1) Divide the variance of the sum by N^2. Diagonal terms give $N\sigma^2$, off-diagonal ones $N(N-1)\rho\sigma^2$.
(2) Factor out σ^2/N.

With $\rho = 0.1$ the error of the mean can never fall below $\sqrt{0.1}\,\sigma = 0.32\,\sigma$, however many readings we take. The ratio $N_{\text{eff}} = \sigma^2/\operatorname{Var}\bar{X} = N/[1 + (N-1)\rho]$ is the number of *effectively independent* readings. The same quantity decides how useful a correlated Markov chain is (Chapter 9).

3.3.2 What "tends to" means for random variables

For numbers, $a_n \to a$ has one meaning. For random variables there are several. A random variable is not one number: it is a rule that assigns a value to every outcome of the experiment, and that rule has a distribution. A sequence can approach its limit value by value, or only in its distribution, and these are different things. Two simple sequences show the difference [Wasserman p. 71]. If $X_n \sim \mathcal{N}(0,1)$ for every n, independently, the X_n never settle anywhere, yet every one has the same distribution. If $X_n \sim \mathcal{N}(0, 1/n)$, the distributions squeeze onto 0 (Figure 3.9), and we would like to say $X_n \to 0$.

Working definition 3.5 (three modes of convergence)

Let X_n be random variables with distribution functions F_n, and X a random variable with distribution function F.

- $X_n \xrightarrow{P} X$ (**in probability**) if $\mathrm{P}(|X_n - X| > \epsilon) \to 0$ for every $\epsilon > 0$ [the chance of a miss bigger than ϵ dies out].
- $X_n \rightsquigarrow X$ (**in distribution**) if $F_n(t) \to F(t)$ at every t where F is continuous [only the histograms converge, not the values themselves].
- $X_n \xrightarrow{\text{qm}} X$ (**in quadratic mean**) if $\mathbb{E}(X_n - X)^2 \to 0$ [the mean squared miss dies out].

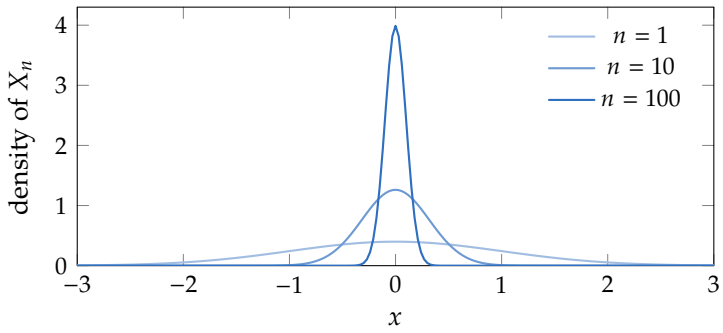

Figure 3.9: The densities of $X_n \sim \mathcal{N}(0, 1/n)$ for $n = 1, 10, 100$. The area stays one while the width shrinks like $1/\sqrt{n}$, so all the probability crowds onto the point 0. This is the picture behind every mode of convergence to a constant.

Example: $X_n \sim \mathcal{N}(0, 1/n)$ converges to 0 in every sense. In quadratic mean, $\mathbb{E}\, X_n^2 = \operatorname{Var} X_n = 1/n \to 0$. In probability, by Chebyshev (3.16), $\mathrm{P}(|X_n| > \epsilon) \le 1/(n\epsilon^2) \to 0$. In distribution, write $Z = \sqrt{n} X_n \sim \mathcal{N}(0, 1)$ with distribution function Φ:

$$F_n(t) = \mathrm{P}(X_n \le t) \overset{(1)}{=} \mathrm{P}(\sqrt{n} X_n \le \sqrt{n}\, t) \overset{(2)}{=} \Phi(\sqrt{n}\, t) \xrightarrow{n\to\infty} \begin{cases} 0, & t < 0, \\ 1/2, & t = 0, \\ 1, & t > 0. \end{cases}$$

(1) Multiply both sides of the inequality by $\sqrt{n} > 0$.
(2) $\sqrt{n} X_n$ is standard normal.

The limit $X = 0$ (a point mass) has $F(t) = 0$ for $t < 0$ and $F(t) = 1$ for $t \ge 0$. The two agree everywhere except at $t = 0$, where $F_n(0) = 1/2 \ne F(0) = 1$. That one disagreement is not a failure of X_n to approach 0. At $t = 0$ the limit F jumps from 0 to 1, and each X_n, being symmetric about 0, keeps exactly half its probability below the jump. This is why the definition asks for convergence only where F is continuous: the jump points of F are ignored [Wasserman Ex. 5.3].

How the modes are related. Quadratic mean implies in probability, which implies in distribution. The converse implications fail in general. There is one important partial converse: convergence in distribution *to a constant* implies convergence in probability to that constant [Wasserman Thm. 5.4].

$$X_n \xrightarrow{\text{qm}} X \quad \Longrightarrow \quad X_n \xrightarrow{P} X \quad \Longrightarrow \quad X_n \rightsquigarrow X$$

Figure 3.10: Implications between the modes of convergence. The solid arrows always hold. The dashed red arrows, pointing back, fail in general. The dashed arrow from distribution back to probability does hold in one case: when the limit is a single number, which is the case for consistency.

Why each arrow holds, and why the reverse ones fail:

- *qm* $\Rightarrow$ *P.* Chebyshev with $U = X_n$, $a = X$: $\mathrm{P}(|X_n - X| > \epsilon) \le \mathbb{E}(X_n - X)^2/\epsilon^2 \to 0$. This is the argument of (3.18).
- *P* $\not\Rightarrow$ *qm.* Let $U \sim \text{Uniform}(0, 1)$ and $X_n = \sqrt{n}$ if $U < 1/n$, else 0. Then $\mathrm{P}(|X_n| > \epsilon) = 1/n \to 0$, but $\mathbb{E}\, X_n^2 = n \cdot (1/n) = 1$ for every n. A rare but large value keeps the mean square alive. The same device with $X_n = n^2$ on probability $1/n$ gives $X_n \xrightarrow{P} 0$ while $\mathbb{E}\, X_n = n \to \infty$: convergence in probability says nothing about averages [Wasserman p. 75].

- $P \Rightarrow D$. If X_n is very probably within ϵ of X, then $\mathrm{P}(X_n \le t)$ is squeezed between $\mathrm{P}(X \le t - \epsilon)$ and $\mathrm{P}(X \le t + \epsilon)$ up to a vanishing error. At a continuity point both bounds tend to $F(t)$ as $\epsilon \to 0$.
- $D \not\Rightarrow P$. Let $X \sim \mathcal{N}(0,1)$ and $X_n = -X$. Every X_n has the distribution $\mathcal{N}(0,1)$, so $X_n \rightsquigarrow X$ trivially, but $|X_n - X| = 2|X|$ never shrinks.

Convergence in probability and in distribution survive the usual operations [Wasserman Thm. 5.5]: if $X_n \xrightarrow{P} X$ and $Y_n \xrightarrow{P} Y$ then $X_n + Y_n \xrightarrow{P} X + Y$, $X_n Y_n \xrightarrow{P} XY$, and $h(X_n) \xrightarrow{P} h(X)$ for continuous h. For convergence in distribution the analogous rule is **Slutsky's theorem**: if $X_n \rightsquigarrow X$ and $Y_n \rightsquigarrow c$, a *constant*, then $X_n + Y_n \rightsquigarrow X + c$ and $X_n Y_n \rightsquigarrow cX$. (Without the constant it fails: X_n and Y_n could each be $\mathcal{N}(0,1)$ but perfectly anticorrelated, so that $X_n + Y_n = 0$.)

There are two further modes: *almost sure* convergence, $\mathrm{P}(X_n \to X) = 1$, which asks for convergence along each single sequence of outcomes, and convergence in mean, $\mathbb{E}\,|X_n - X| \to 0$. Only the first is needed, once, for the strong law below.

3.3.3 The law of large numbers

Weak law of large numbers. If $X_1, X_2, \ldots$ are iid with mean μ, then $\bar{X}_N \xrightarrow{P} \mu$. The distribution of the sample mean piles up on the true mean.

With a finite variance the proof is one line of Chebyshev (3.16) with $U = \bar{X}_N$, $a = \mu$:

$$\mathrm{P}\big(|\bar{X}_N - \mu| > \epsilon\big) \overset{(1)}{\le} \frac{\operatorname{Var} \bar{X}_N}{\epsilon^2} \overset{(2)}{=} \frac{\sigma^2}{N\epsilon^2} \xrightarrow{N\to\infty} 0. \tag{3.21}$$

(1) Chebyshev's inequality, with $\mathbb{E}\,\bar{X}_N = \mu$ so that the numerator is the variance.
(2) Variance of the mean (3.20).

The theorem holds even without a finite variance, provided $\mathbb{E}\,|X| < \infty$ [Wasserman Thm. 5.6]. The *strong* law says more: with probability one, the running average of a single infinite sequence of readings converges to μ [Wasserman Thm. 5.18]. That is the version that justifies computing an average along one long Monte Carlo run or one long Markov chain.

The law of large numbers is also a statement about the meaning of probability. Let $X_i = \mathbb{1}\{\text{event } A \text{ on trial } i\}$. Then $\bar{X}_N$ is the relative frequency of A and $\mu = \mathrm{P}(A)$, so relative frequencies converge to probabilities. The "frequentist" reading of probability rests on this.

Example: How many tosses? Chebyshev against the truth. For a fair coin, how large must n be so that $\mathrm{P}(0.4 \le \bar{X}_n \le 0.6) \ge 0.7$? With $\mu = 1/2$ and $\operatorname{Var} \bar{X}_n = p(1-p)/n = 1/(4n)$,

$$\mathrm{P}(0.4 \le \bar{X}_n \le 0.6) \overset{(1)}{=} 1 - \mathrm{P}\big(|\bar{X}_n - \tfrac{1}{2}| > 0.1\big) \overset{(2)}{\ge} 1 - \frac{1}{4n\,(0.1)^2} = 1 - \frac{25}{n}.$$

(1) The complement of "within 0.1 of 1/2".
(2) Chebyshev with $\operatorname{Var} \bar{X}_n = 1/(4n)$ and $\epsilon = 0.1$.

The bound exceeds 0.7 once $25/n \le 0.3$, i.e. $n \ge 84$ [Wasserman Ex. 5.7]. Chebyshev is a guarantee for *every* distribution with this variance, so it is pessimistic for any particular one. The exact binomial probability at $n = 84$ is 0.937. Using the Gaussian approximation of the next subsection, $\mathrm{P}(|\bar{X}_n - \tfrac{1}{2}| \le 0.1) \approx 2\Phi(0.1\sqrt{n}/0.5) - 1 \ge 0.7$ requires $0.2\sqrt{n} \ge z_{0.85} = 1.036$, i.e. $n \ge 27$, where the exact probability is 0.7522.

A sharper guarantee, and a first interval. Chebyshev uses only the variance, so it must hold for every distribution. For Bernoulli readings (each X_i is 0 or 1, with $\mathrm{P}(X_i = 1) = p$) we know more, and **Hoeffding's inequality** uses it: $\mathrm{P}(|\bar{X}_n - p| > \epsilon) \le 2e^{-2n\epsilon^2}$ [Wasserman Thm. 4.5, (4.4)]. This bound falls exponentially in n, not as $1/n$. With $n = 100$ and $\epsilon = 0.2$ it gives $2e^{-8} = 0.00067$, where Chebyshev gives only $1/(4 \cdot 100 \cdot 0.04) = 0.0625$ [Wasserman Ex. 4.6]. (For the moderate $\epsilon = 0.1$ of the coin example, Chebyshev happens to be the stronger of the two.)

The bound also gives an interval. Set the right side equal to a small probability α and solve for ϵ: $\epsilon_n = \sqrt{\ln(2/\alpha)/(2n)}$. Then the interval $\hat{p} \pm \epsilon_n$ contains the true p with probability at least $1 - \alpha$, for *every* p and every n, with no large-n approximation [Wasserman Ex. 6.15]. For $\alpha = 0.05$ and $n = 100$, $\epsilon_n = \sqrt{3.689/200} = 0.136$.

What does "with probability at least $1 - \alpha$" refer to? Not to p, which is fixed. It refers to the interval recipe, applied over repeated experiments. A striking case makes the point: Wasserman's Ex. 6.14 builds a legitimate 75% interval that, on some data sets, is known with certainty to contain θ. So the sentence "with probability 0.95, p is contained in the interval", said of $\bar{X} \pm 1.96\, S/\sqrt{n}$ [SeeingTheory p. 42], is loose: the 0.95 belongs to the recipe, not to p. The full story of intervals is in Chapter 4.

3.3.4 The central limit theorem

The law of large numbers says where the sample mean goes. It does not say how $\bar{X}_N$ is distributed on the way, which is what we need for error bars. The central limit theorem does.

Key idea: Central limit theorem

Let $X_1, \dots, X_N$ be iid with mean μ and finite variance σ^2. Then

$$Z_N := \frac{\bar{X}_N - \mu}{\sqrt{\mathrm{Var}\,\bar{X}_N}} = \frac{\sqrt{N}(\bar{X}_N - \mu)}{\sigma} \rightsquigarrow \mathcal{N}(0,1), \tag{3.22}$$

that is, $\mathrm{P}(Z_N \le z) \to \Phi(z)$ for every z. Informally, $\bar{X}_N \approx \mathcal{N}(\mu, \sigma^2/N)$ whatever the parent distribution.

The theorem approximates probabilities, not values: "it's the probability statements that we are approximating, not the random variable itself" [Wasserman p. 77]. No single $\bar{X}_N$ becomes a Gaussian number; what becomes Gaussian is the chance that $\bar{X}_N$ falls in a given range.

In practice we do not know σ. The theorem still holds with σ replaced by the sample standard deviation S_N of Section 3.4. The reason: $S_N \xrightarrow{P} \sigma$, and Slutsky's theorem lets us swap a factor that tends to a constant [Wasserman Thm. 5.10]. For random vectors, $\sqrt{N}(\bar{\boldsymbol{X}}_N - \boldsymbol{\mu}) \rightsquigarrow \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$ with $\boldsymbol{\Sigma}$ the covariance matrix of one reading [Wasserman Thm. 5.12].

Why it is true: cumulants add. The cleanest physicist's argument uses the **cumulant generating function** $K_Y(t) = \ln \mathbb{E}\, e^{tY} = \sum_{k \ge 1} \kappa_k t^k / k!$, the logarithm of the moment generating function. Its Taylor coefficients κ_k are the **cumulants** [κ_1 is the mean, κ_2 the variance, $\kappa_3/\kappa_2^{3/2}$ the skewness]. For independent U, V, $\mathbb{E}\, e^{t(U+V)} = \mathbb{E}\, e^{tU}\ \mathbb{E}\, e^{tV}$, so $K_{U+V} = K_U + K_V$: cumulants of independent variables add, like free energies of independent subsystems. Let $Y_i = (X_i - \mu)/\sigma$, which has $\kappa_1 = 0$, $\kappa_2 = 1$, and write $Z_N = N^{-1/2} \sum_i Y_i$. Then

$$K_{Z_N}(t) \overset{(1)}{=} \sum_{i=1}^{N} K_Y\big(t/\sqrt{N}\big) \overset{(2)}{=} N \sum_{k \ge 2} \frac{\kappa_k}{k!} \frac{t^k}{N^{k/2}}$$

$$\overset{(3)}{=} \frac{t^2}{2} + \frac{\kappa_3}{6\sqrt{N}}\,t^3 + \frac{\kappa_4}{24\,N}\,t^4 + \cdots \xrightarrow{N\to\infty} \frac{t^2}{2}. \tag{3.23}$$

(1) Cumulants of independent variables add, and scaling $Y \to cY$ turns $K_Y(t)$ into $K_Y(ct)$, here with $c = 1/\sqrt{N}$.
(2) Insert the series. The $k = 1$ term is absent because $\kappa_1 = 0$.
(3) The $k = 2$ term is $N \cdot \frac{1}{2}t^2/N$. The k-th term carries $N^{1-k/2}$, which vanishes for every $k \geq 3$.

The limit $t^2/2$ is the cumulant generating function of $\mathcal{N}(0,1)$, whose only nonzero cumulant is the variance. Every other cumulant of the standardised mean dies, the skewness fastest, like $\kappa_3/\sqrt{N}$. For an exponential parent $\kappa_3 = 2$, so the skewness of the mean is $2/\sqrt{N}$, exactly the value we met for the muon lifetime in Section 3.1.3. (The rigorous proof uses the characteristic function $\mathbb{E}\,e^{itY}$, which exists for every distribution, and the same expansion to second order [Wasserman Lemma 5.20].)

How large is large? The expansion shows that the error of the Gaussian approximation is controlled by the skewness divided by $\sqrt{N}$. The **Berry–Esseen inequality** makes this quantitative [Wasserman Thm. 5.11, (5.4)]:

$$\sup_z \left|\mathrm{P}(Z_N \leq z) - \Phi(z)\right| \leq \frac{C\;\mathbb{E}\,|X_1 - \mu|^3}{\sqrt{N}\,\sigma^3}, \tag{3.24}$$

with $C = 33/4$ in Wasserman. (That constant is very generous. Much smaller values, below one half, have since been proved.) Symmetric parents converge fast. Skewed ones, like exponential lifetimes or Poisson counts with small means, need more readings.

Example: Pile-up in a collider. The number of proton–proton interactions per bunch crossing is Poisson with mean $\lambda = 5$. Over $n = 125$ crossings, what is the probability that the average number of interactions is below 5.5? With $\mu = \sigma^2 = \lambda = 5$,

$$\mathrm{P}(\bar{X}_n < 5.5) \overset{(1)}{=} \mathrm{P}\Big(\frac{\sqrt{n}(\bar{X}_n - \mu)}{\sigma} < \frac{\sqrt{n}(5.5-\mu)}{\sigma}\Big) \overset{(2)}{=} \mathrm{P}\Big(Z < \frac{\sqrt{125}\times 0.5}{\sqrt{5}}\Big) \approx \Phi(2.5) = 0.9938.$$

(1) Subtract μ, multiply by $\sqrt{n}/\sigma > 0$: the event is unchanged.
(2) $\sqrt{125}/\sqrt{5} = \sqrt{25} = 5$, times 0.5 is 2.5. By the CLT the left side is approximately standard normal.

(The same numbers describe a count of errors in computer programs [Wasserman Ex. 5.9].)

Example: When there is no variance: the Breit–Wigner. A resonance of mass m and width Γ has the Breit–Wigner (Cauchy) line shape, which in units $x = (E-m)/(\Gamma/2)$ is $f(x) = 1/[\pi(1+x^2)]$. Its tails fall like x^{-2}, so $\int |x| f\,\mathrm{d}x$ diverges: it has no mean and no variance [Cowan §2.8, §5.2]. Its characteristic function is $\phi(t) = \mathbb{E}\,e^{itX} = e^{-|t|}$. For the average of N independent draws,

$$\mathbb{E}\;e^{it\bar{X}_N} \overset{(1)}{=} \prod_{i=1}^{N} \mathbb{E}\;e^{i(t/N)X_i} \overset{(2)}{=} \left(e^{-|t|/N}\right)^N = e^{-|t|}.$$

(1) The exponential of a sum is a product, and independence lets the average factorise.
(2) Each factor is the characteristic function at t/N.

The average of N Cauchy variables has *exactly* the same distribution as one of them. Averaging does not help at all. The half-width of the central 50% of $\bar{X}_N$ is 1 (the quartiles of the Cauchy are ± 1) for every N. The fix is to use a different estimator. The sample median of Cauchy data *is* consistent. For large N its standard error is $1/(2f(0)\sqrt{N})$, the general large-N result for a median at a point where the density is $f(0)$; with $f(0) = 1/\pi$ this is $\pi/(2\sqrt{N})$.

3.3.5 Seeing it in Python

Listing 3.3: Variance of the sample mean for three parents, and the Cauchy exception (code/ch03/03_one_over_sqrtN.py)

```
parents = {
    "Uniform(0,1)": (lambda s: rng.uniform(0, 1, s), 1 / 12),
    "Exponential(1)": (lambda s: rng.exponential(1.0, s), 1.0),
    "Poisson(3)": (lambda s: rng.poisson(3.0, s).astype(float), 3.0),
}
var_of_mean = {k: [] for k in parents}
iqr = {"Exponential(1)": [], "Cauchy": []}
for N in Ns:
    for k, (draw, _) in parents.items():
        m = draw((M, N)).mean(axis=1)
        var_of_mean[k].append(m.var(ddof=1))
        if k == "Exponential(1)":
            q = np.percentile(m, [25, 75]); iqr[k].append(0.5 * (q[1] - q[0]))
    mc = rng.standard_cauchy((M, N)).mean(axis=1)
    q = np.percentile(mc, [25, 75]); iqr["Cauchy"].append(0.5 * (q[1] - q[0]))

slopes = {k: np.polyfit(np.log(Ns), np.log(v), 1)[0] for k, v in var_of_mean.items()}
```

For each $N = 1, 2, 4, \ldots, 1024$ the script draws $M = 20\,000$ experiments of N readings from a uniform, an exponential and a Poisson parent, averages each row, and records the variance of the M averages. It also records the half-width of the central 50% of the averages for exponential and Cauchy parents (a width that exists even when the variance does not). The fitted log–log slopes of $\mathrm{Var}\,\bar{X}_N$ against N are -1.001, -0.9973 and -1.002 (derived: -1). The Cauchy half-width is 1.011 at $N = 1$ and 0.9998 at $N = 1024$ (derived: 1 for all N).

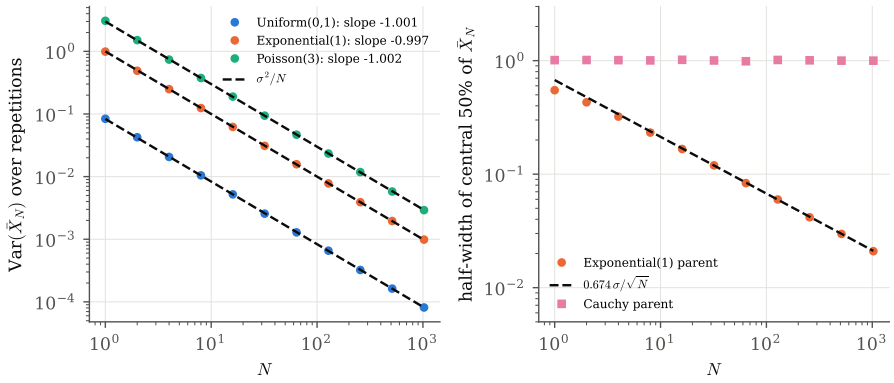

Figure 3.11: Left: the variance of the sample mean falls as σ^2/N (dashed lines) for three very different parents, a straight line of slope -1 on log–log axes. Right: the width of the distribution of the mean falls as $1/\sqrt{N}$ for exponential readings but stays flat for Cauchy readings, where averaging a thousand values is no better than taking one.

Asymptotically normal. An estimator is **asymptotically normal** if $(\hat{\theta}_N - \theta)/\mathrm{se} \rightsquigarrow \mathcal{N}(0,1)$ [for large N its sampling distribution is a Gaussian centred on the truth with width equal to

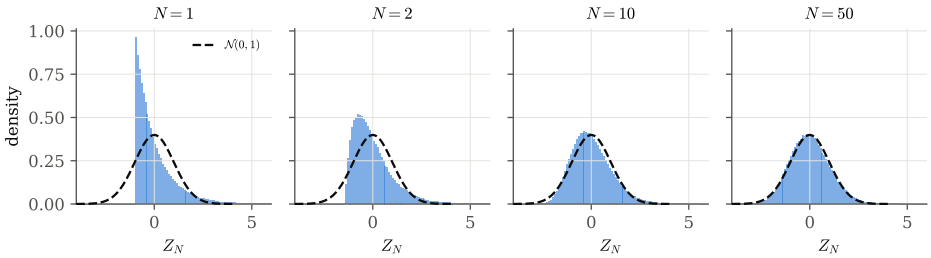

Figure 3.12: The central limit theorem at work on exponential decay times. Each panel is the histogram of the standardised mean Z_N of N exponential readings, over 200 000 repetitions, with the standard normal curve dashed. At $N = 1$ it is the exponential itself, cut off at $Z = -1$. By $N = 10$ it is close to Gaussian with a visible right skew, and by $N = 50$ the residual skewness $2/\sqrt{50} = 0.28$ is hard to see.

the standard error] [Wasserman (6.8)].

Most estimators we will meet are asymptotically normal: sample means by the CLT, smooth functions of means by the delta method of Section 3.6, and maximum-likelihood estimators by the argument of the second half of Chapter 3. That is why "estimate ± standard error" means roughly a 68% interval so often.

Watch out: The CLT is about the mean, not about the data

The CLT does not make the readings Gaussian, and it does not make every statistic Gaussian. The histogram of individual muon decay times stays exponential forever. It is the histogram of their *average* that becomes Gaussian. And it needs a finite variance: for Cauchy-like tails (a resonance, a ratio of noisy quantities, Section 3.6.4) it fails completely.

What this bought us. Independent errors add like the steps of a random walk, so the scatter of a mean is $\sigma/\sqrt{N}$ and its distribution approaches a Gaussian, with a residual skewness that falls like $1/\sqrt{N}$. Correlations put a floor under the error, and a parent without a variance defeats averaging altogether.

Verification and research. The log–log plot verifies σ^2/N where we know σ. In a Monte Carlo computation (Chapter 6) we run the same check backwards: the slope of the measured variance against N tells us whether the samples are really independent (slope -1) or correlated (a flatter slope, as for an MCMC chain in Chapter 9), and the plateau of a correlated run measures its N_{eff}.

3.4 Estimating the scatter itself: the sample variance and its error

The pendulum error bar $\sigma/\sqrt{N}$ contains the noise level σ, which nobody told us. We must estimate it from the same ten readings. A cosmologist faces the same task at every multipole: the angular power spectrum C_ℓ *is* a variance, the variance of the $2\ell + 1$ spherical-harmonic coefficients $a_{\ell m}$, and estimating it from one sky is estimating a variance from a finite sample. So is quoting the error bar of a Monte Carlo average (Chapter 6).

Two facts come out of this. The estimator of a variance that is right on average divides by $N - 1$, not by N. And that estimate has its own uncertainty, the "error on the error", of which the cosmic-variance formula is a special case.

Equipartition with the centre of mass removed. We cannot measure the spread of the readings about the unknown truth μ, only about their own average $\bar{X}$. Deviations from $\bar{X}$ are systematically a little smaller than deviations from μ, because the average sits in the middle of the data by construction. How much smaller? Think of N particles of a gas, each velocity component carrying energy $\frac{1}{2}kT$ on average. If we measure velocities relative to the centre of mass, one degree of freedom is gone and the total relative kinetic energy is $(N-1)\frac{1}{2}kT$. In the same way, the N deviations $X_i - \bar{X}$ sum to zero, only $N-1$ of them are free, and each carries σ^2 on average.

What we want to know.

1. What is the average of $\sum_i (X_i - \bar{X})^2$ over repetitions?
2. What divisor makes the estimate of σ^2 right on average, and is that the best divisor?
3. How much does the estimate of σ^2 itself scatter?
4. What changes when the true mean is known, as for the $a_{\ell m}$ of the CMB?

3.4.1 The $N-1$

Let $X_1, \dots, X_N$ be iid with mean μ and variance σ^2. The question is the average, over repetitions, of the **sum of squared deviations** $\mathrm{SS} = \sum_i (X_i - \bar{X})^2$. We know the average of the squared deviations from μ; it is σ^2 each. So we first relate the two sums. Write $X_i - \mu = (X_i - \bar{X}) + (\bar{X} - \mu)$ and square:

$$\sum_{i=1}^{N} (X_i - \mu)^2 \overset{(1)}{=} \sum_i (X_i - \bar{X})^2 + 2(\bar{X} - \mu) \sum_i (X_i - \bar{X}) + N(\bar{X} - \mu)^2$$
$$\overset{(2)}{=} \mathrm{SS} + N(\bar{X} - \mu)^2. \tag{3.25}$$

(1) Expand the square. The factor $\bar{X} - \mu$ does not depend on i and comes out of the sum.
(2) $\sum_i (X_i - \bar{X}) = N\bar{X} - N\bar{X} = 0$: deviations from the average sum to zero.

This is again the parallel-axis theorem: spread about the truth equals spread about the centre plus N times the squared offset of the centre. Now average over repetitions:

$$\mathbb{E}\,\mathrm{SS} \overset{(1)}{=} \sum_{i=1}^{N} \mathbb{E}(X_i - \mu)^2 - N\,\mathbb{E}(\bar{X} - \mu)^2 \overset{(2)}{=} N\sigma^2 - N \cdot \frac{\sigma^2}{N} = (N-1)\,\sigma^2. \tag{3.26}$$

(1) Rearrange (3.25) and use linearity of expectation.
(2) $\mathbb{E}(X_i - \mu)^2 = \sigma^2$ for each i, and $\mathbb{E}(\bar{X} - \mu)^2 = \mathrm{Var}\,\bar{X} = \sigma^2/N$ from (3.20).

The missing σ^2 is exactly the variance of the average: the data are spread about $\bar{X}$, and $\bar{X}$ is itself off from μ by about $\sigma/\sqrt{N}$.

Working definition 3.6 (sample variance)

The **sample variance** is

$$S^2 = \frac{1}{N-1} \sum_{i=1}^{N} (X_i - \bar{X})^2, \tag{3.27}$$

and by (3.26) it is unbiased, $\mathbb{E}\,S^2 = \sigma^2$ [Wasserman p. 52, Thm. 3.17]. The divisor $N-1$ is the

number of **degrees of freedom** [independent directions left in the data after one direction was used to fix $\bar{X}$]. If the true mean μ is *known*, the estimator $S_0^2 = N^{-1}\sum_i (X_i - \mu)^2$ is unbiased with divisor N, since then nothing was used up [Cowan (5.9)–(5.10)].

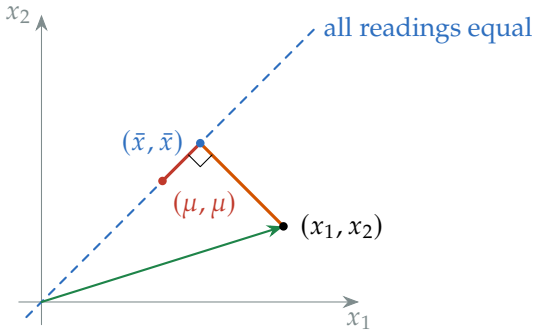

Figure 3.13: Two readings as one point in the plane. The dashed diagonal holds the data sets in which both readings are equal. The average $(\bar{x}, \bar{x})$ is the foot of the perpendicular from the data point onto the diagonal. The orange residual, of squared length SS, lives in the one direction perpendicular to the diagonal. The red segment is the offset of the average from the truth. The right angle is the identity (3.25): distance^2 to the truth = orange^2 + red^2.

The geometry in Figure 3.13 holds for any N. The data are a vector in $\mathbb{R}^N$. The average is its projection on the line spanned by $(1, 1, \ldots, 1)$, and the residual vector $(X_i - \bar{X})_i$ lives in the $(N-1)$-dimensional subspace perpendicular to it. If the noise is isotropic (independent, equal variance), each of those $N-1$ directions carries variance σ^2, which is (3.26) without algebra. For a Gaussian parent we get the whole distribution, not just the average. Rotate to a new orthonormal basis whose first axis is the diagonal. Independent Gaussian noise of equal variance looks the same in every such basis, so the new coordinates are again independent Gaussians of variance σ^2. The first carries $\bar{X}$; the other $N-1$ carry the residual. So SS/σ^2 is a sum of $N-1$ squares of independent standard normals, that is

$$\frac{(N-1)S^2}{\sigma^2} \sim \chi^2_{N-1}, \tag{3.28}$$

independently of $\bar{X}$ (the χ^2 distribution is in Chapter 2).

Example: The pendulum's noise level. For the ten readings of Section 3.1, $\bar{x} = 9.815$ and the deviations are $-0.025, 0.015, 0.045, -0.015, -0.045, 0.025, -0.005, -0.035, 0.035, 0.005$. Their squares sum to $2(0.025^2 + 0.015^2 + 0.045^2 + 0.035^2 + 0.005^2) = 2 \times 0.004125 = 0.00825$. Hence

$$s^2 \overset{(1)}{=} \frac{0.00825}{9} = 9.17 \times 10^{-4}, \qquad s = 0.0303, \qquad \widehat{\mathrm{se}}(\bar{x}) \overset{(2)}{=} \frac{s}{\sqrt{10}} = 0.0096\ \mathrm{m\,s^{-2}}.$$

(1) Divide the sum of squared deviations by $N - 1 = 9$.
(2) The estimated standard error of the mean replaces σ by s in (3.20).

The result is $g = 9.815 \pm 0.010\ \mathrm{m\,s^{-2}}$. How much should we trust the "±0.010"? That is the question of Section 3.4.3.

Example: S^2 is consistent. Expanding the square in (3.27), $\sum_i (X_i - \bar{X})^2 = \sum_i X_i^2 - N\bar{X}^2$, so

$$S^2 \overset{(1)}{=} \frac{N}{N-1}\Big[\frac{1}{N}\sum_{i=1}^{N} X_i^2 - \bar{X}^2\Big] \xrightarrow{P} 1 \cdot \big[\mathbb{E}\,X^2 - \mu^2\big] \overset{(2)}{=} \sigma^2.$$

(1) Factor out $N/(N-1)$. Inside the bracket, the first term is the mean of the iid variables X_i^2, which tends in probability to $\mathbb{E}\,X^2$ by the WLLN. $\bar{X} \xrightarrow{P} \mu$ and squaring is continuous, so $\bar{X}^2 \xrightarrow{P} \mu^2$. Sums and products of sequences that converge in probability converge to the sums and products of the limits, and $N/(N-1) \to 1$.
(2) $\mathbb{E}\,X^2 - \mu^2 = \sigma^2$.

[CasellaBerger Ex. 5.5.3]; [Wasserman Exercise 5.1]. The same argument applied with the continuous map $\sqrt{\cdot}$ gives $S \xrightarrow{P} \sigma$.

Watch out: S is a biased estimator of σ

Unbiasedness does not survive nonlinear maps. Because $\operatorname{Var} S = \mathbb{E}\,S^2 - (\mathbb{E}\,S)^2 \geq 0$, we have $(\mathbb{E}\,S)^2 \leq \mathbb{E}\,S^2 = \sigma^2$, so $\mathbb{E}\,S \leq \sigma$, with equality only if S never fluctuates (this is Jensen's inequality for the concave square root). For Gaussian data, $\mathbb{E}\,S = c_4(N)\,\sigma$ with $c_4(N) = \sqrt{2/(N-1)}\;\Gamma(N/2)/\Gamma\big((N-1)/2\big)$, which follows from the mean of the square root of a χ^2_{N-1} variable. For $N = 5$, $c_4 = 0.94$; the simulation gives $\mathbb{E}\,S/\sigma = 0.94$. S is biased for every finite N but consistent [CasellaBerger Ex. 5.5.5].

3.4.2 Is $N-1$ the best divisor?

Unbiased is not the same as best (Section 3.2). For Gaussian data we can compute the MSE of $W_d = \mathrm{SS}/d$ for any divisor d, because by (3.28) $\mathrm{SS} = \sigma^2\chi^2_{N-1}$ and a χ^2_ν variable has mean ν and variance 2ν.

Example: The divisor that minimises the MSE.

$$\mathrm{MSE}(W_d) \overset{(1)}{=} \left(\frac{(N-1)\sigma^2}{d} - \sigma^2\right)^2 + \frac{2(N-1)\sigma^4}{d^2} \overset{(2)}{=} \sigma^4\Big[\big((N-1)u - 1\big)^2 + 2(N-1)u^2\Big], \quad u = \frac{1}{d}.$$

(1) Squared bias plus variance (3.13), with $\mathbb{E}\,W_d = (N-1)\sigma^2/d$ and $\operatorname{Var} W_d = 2(N-1)\sigma^4/d^2$.
(2) Factor out σ^4 and write $u = 1/d$.

Setting the u-derivative to zero, $2(N-1)\big[(N-1)u - 1\big] + 4(N-1)u = 0$, i.e. $(N+1)u = 1$. The minimum is at $d = N+1$. For $N = 10$ the three candidates give

$$d = N-1:\ \tfrac{2}{9} = 0.222, \qquad d = N:\ 0.01 + 0.18 = 0.190, \qquad d = N+1:\ \tfrac{4}{121} + \tfrac{18}{121} = 0.182$$

(in units of σ^4). The simulation gives 0.2229, 0.1907 and 0.1826.

So the unbiased S^2 does not have the smallest MSE. Even $d = N$ beats it [CasellaBerger Exs. 7.3.3–7.3.4]: the biased maximum-likelihood estimator $\hat{\sigma}^2 = \mathrm{SS}/N$ has MSE $(2N-1)\sigma^4/N^2$, smaller than the $2\sigma^4/(N-1)$ of S^2. A larger divisor shrinks the estimate towards zero, trading a small downward bias for a reduction in variance.

Why, then, do we usually quote S^2? For two reasons. First, estimates are often *averaged* later, and when they are, biases add up while scatter averages away; an unbiased estimate is then what we want. Second, the optimal divisor depends on the parent: $N+1$ is special to Gaussian data.

3.4.3 The variance of the variance

How much does S^2 scatter? The answer involves the fourth central moment $\mu_4 = \mathbb{E}(X-\mu)^4$. Without loss of generality set $\mu = 0$ (shifting every reading by a constant changes neither S^2 nor

the central moments). Using $\sum_i (X_i - \bar{X})^2 = \sum_i X_i^2 - \frac{1}{N}\sum_{i,j} X_i X_j$, split S^2 into a "diagonal" and an "off-diagonal" part:

$$S^2 = \underbrace{\frac{1}{N}\sum_i X_i^2}_{A} - \underbrace{\frac{1}{N(N-1)}\sum_{i\neq j} X_i X_j}_{B}. \tag{3.29}$$

(The coefficient of X_i^2 is $\frac{1}{N-1}(1-\frac{1}{N}) = \frac{1}{N}$, and that of X_iX_j, $i \neq j$, is $\frac{1}{N-1}\cdot\frac{1}{N}$.) The variance of a difference is $\operatorname{Var}(A-B) = \operatorname{Var}A + \operatorname{Var}B - 2\operatorname{Cov}(A,B)$, so we need three pieces.

$$\operatorname{Var}A \overset{(1)}{=} \frac{1}{N^2}\, N\, \operatorname{Var}(X^2) \overset{(2)}{=} \frac{\mu_4 - \sigma^4}{N}, \tag{3.30}$$

$$\mathbb{E}\,B^2 \overset{(3)}{=} \frac{1}{N^2(N-1)^2}\sum_{i\neq j}\sum_{k\neq l}\mathbb{E}[X_iX_jX_kX_l] \overset{(4)}{=} \frac{2N(N-1)\sigma^4}{N^2(N-1)^2} = \frac{2\sigma^4}{N(N-1)}, \tag{3.31}$$

$$\operatorname{Cov}(A,B) \overset{(5)}{=} \frac{1}{N^2(N-1)}\sum_k\sum_{i\neq j}\mathbb{E}[X_k^2X_iX_j] \overset{(6)}{=} 0. \tag{3.32}$$

(1) The X_i^2 are independent, so the variance of their sum is the sum of their variances.
(2) $\operatorname{Var}(X^2) = \mathbb{E}\,X^4 - (\mathbb{E}\,X^2)^2 = \mu_4 - \sigma^4$ (recall $\mu = 0$).
(3) $\mathbb{E}\,B = 0$ because each term has $\mathbb{E}\,X_iX_j = \mathbb{E}\,X_i\;\mathbb{E}\,X_j = 0$. So $\operatorname{Var}B = \mathbb{E}\,B^2$, which is the double sum over pairs of pairs.
(4) A product $X_iX_jX_kX_l$ with $i \neq j$ has zero mean unless every index appears at least twice, which forces $\{k,l\} = \{i,j\}$. There are two such choices, $(k,l) = (i,j)$ or (j,i), each giving $\mathbb{E}\,X_i^2X_j^2 = \sigma^4$. There are $N(N-1)$ ordered pairs (i,j).
(5) $\mathbb{E}\,B = 0$, so $\operatorname{Cov}(A,B) = \mathbb{E}[AB]$. Multiply out the two sums.
(6) Since $i \neq j$, at least one of i, j differs from k and from the other index, so it appears once and its factor $\mathbb{E}\,X = 0$ kills the term.

Putting the pieces together,

$$\begin{aligned}\operatorname{Var}S^2 &\overset{(1)}{=} \operatorname{Var}A + \operatorname{Var}B - 2\operatorname{Cov}(A,B) \overset{(2)}{=} \frac{\mu_4-\sigma^4}{N} + \frac{2\sigma^4}{N(N-1)} \\ &\overset{(3)}{=} \frac{1}{N}\left[\mu_4 - \frac{N-3}{N-1}\,\sigma^4\right].\end{aligned} \tag{3.33}$$

(1) Variance of a difference.
(2) Insert (3.30)–(3.32).
(3) $-\sigma^4 + \frac{2\sigma^4}{N-1} = -\sigma^4\,\frac{N-1-2}{N-1}$.

This is [Cowan (5.14)]. For a Gaussian parent, $\mu_4 = 3\sigma^4$ (from Isserlis' theorem, or by direct integration: $\mathbb{E}\,Z^4 = 3$ for a standard normal), and

$$\operatorname{Var}S^2\big|_{\text{Gauss}} = \frac{\sigma^4}{N}\,\frac{3(N-1)-(N-3)}{N-1} = \frac{2\sigma^4}{N-1}, \tag{3.34}$$

in agreement with $\operatorname{Var}\chi^2_{N-1} = 2(N-1)$ in (3.28).

The error on the error. For Gaussian data the relative error of S^2 is $\sqrt{2/(N-1)}$, and that of S is half as large (a relative error halves under a square root; this is the propagation rule of Section 3.6):

$$\frac{\operatorname{se}(S)}{\sigma} \approx \frac{1}{\sqrt{2(N-1)}}. \tag{3.35}$$

With ten readings an error bar is itself uncertain by about 24%. With a hundred, by 7%. Quoting an error bar to three significant figures from ten points is meaningless.

For a heavy-tailed parent the variance of S^2 is larger, because μ_4 weights the tails heavily. An exponential parent of mean τ has $\sigma = \tau$ and $\mu_4 = 9\tau^4 = 9\sigma^4$, three times the Gaussian value. To quote the uncertainty of S^2 from data, replace μ_4 by the sample moment $m_4 = \frac{1}{N}\sum_i (X_i - \bar{X})^4$ [Cowan (5.15)].

Example: Cosmic variance. In a statistically isotropic Gaussian sky, the $2\ell+1$ coefficients $a_{\ell m}$ at multipole ℓ behave (for this count) like $2\ell+1$ independent real Gaussian variables of mean zero and variance C_ℓ (the precise complex bookkeeping is in Chapter 7). The natural estimator $\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2$ is the known-mean estimator S_0^2 with $N = 2\ell+1$. With known mean zero, $\sum_m a_{\ell m}^2 / C_\ell$ is a sum of $2\ell+1$ squared standard normals, i.e. $\chi^2_{2\ell+1}$, so

$$\mathbb{E}\,\widehat{C}_\ell \overset{(1)}{=} \frac{C_\ell}{2\ell+1}(2\ell+1) = C_\ell, \qquad \operatorname{Var}\widehat{C}_\ell \overset{(2)}{=} \frac{C_\ell^2}{(2\ell+1)^2}\cdot 2(2\ell+1) = \frac{2C_\ell^2}{2\ell+1}.$$

(1) A χ^2_ν variable has mean ν.
(2) It has variance 2ν, and $\operatorname{Var}(cU) = c^2 \operatorname{Var} U$ with $c = C_\ell/(2\ell+1)$.

This is **cosmic variance**: the relative error $\sqrt{2/(2\ell+1)}$ is 63% at the quadrupole $\ell = 2$ and cannot be reduced, because we have only one sky. It is the known-mean version of (3.34), with N in place of $N-1$ because no degree of freedom is spent on estimating a mean.

3.4.4 Seeing it in Python

Listing 3.4: The two divisors and the scatter of S^2 (`code/ch03/04_sample_variance.py`)

```
mse = {"N-1": [], "N": [], "N+1": []}
for N in Ns:
    x = rng.standard_normal((M, N))                  # sigma = 1
    ss = ((x - x.mean(axis=1, keepdims=True)) ** 2).sum(axis=1)
    mean_biased.append((ss / N).mean())
    mean_unbiased.append((ss / (N - 1)).mean())
    var_S2_gauss.append((ss / (N - 1)).var(ddof=1))
    for lab, d in (("N-1", N - 1), ("N", N), ("N+1", N + 1)):
        mse[lab].append(np.mean((ss / d - 1.0) ** 2))
    y = rng.exponential(1.0, (M, N))                 # sigma = 1, mu_4 = 9
    ssy = ((y - y.mean(axis=1, keepdims=True)) ** 2).sum(axis=1)
```

Each row of `x` is one experiment of N standard normal readings ($\sigma = 1$). The script forms SS row by row, divides by N and by $N-1$, and averages over the $M = 100\,000$ rows. It also records the variance of S^2 across rows and the MSE of the three divisors. The last three lines repeat the variance measurement for an exponential parent. For $N = 5$ the average of SS/N is 0.796 (derived: $4/5 = 0.8$) and of SS/$(N-1)$ is 0.995 (derived: 1). At $N = 10$, $\operatorname{Var} S^2 = 0.2229$ for Gaussian readings (derived 0.2222) and 0.8255 for exponential ones (derived from (3.33) with $\mu_4 = 9$: 0.8222).

What this bought us. Divide by $N-1$ because one degree of freedom went into $\bar{X}$. The resulting S^2 is unbiased but has its own scatter, $\operatorname{Var} S^2 = \frac{1}{N}[\mu_4 - \frac{N-3}{N-1}\sigma^4]$, which for Gaussian data means a relative error of $1/\sqrt{2(N-1)}$ on S. With a known mean the divisor is N, and the Gaussian scatter $2\sigma^4/N$ is cosmic variance.

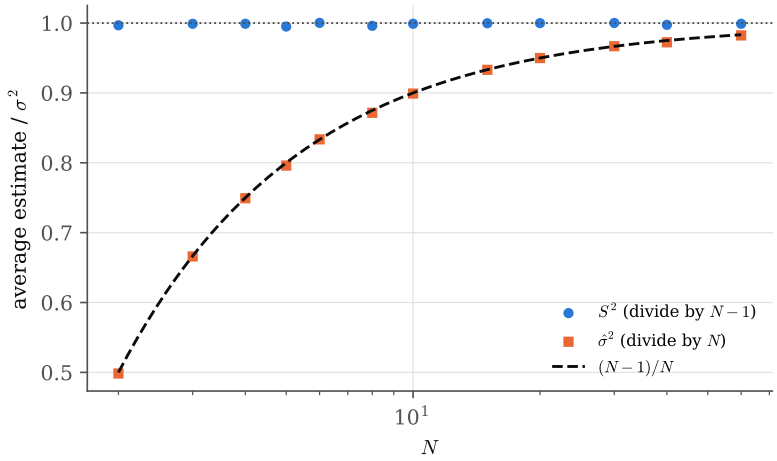

Figure 3.14: Average of two variance estimators over 100 000 Gaussian experiments, as a function of the number of readings. Dividing by $N-1$ is right on average at every N. Dividing by N falls short by the factor $(N-1)/N$ (dashed), badly for $N=2$ and negligibly beyond a few tens.

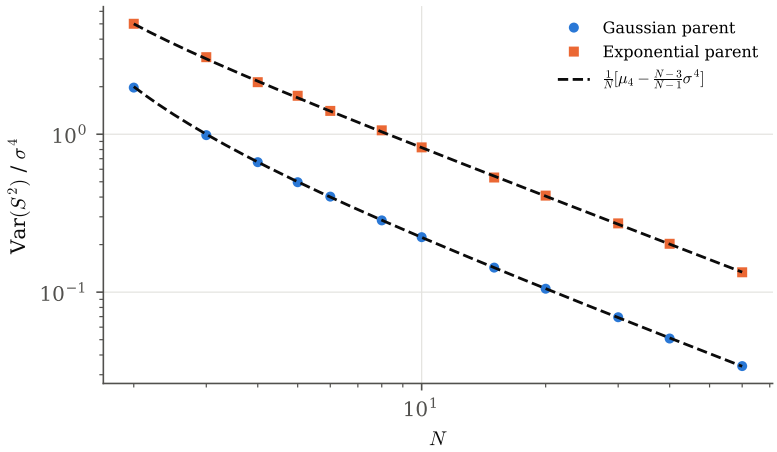

Figure 3.15: Scatter of the sample variance over repetitions. Both parents follow the derived formula (3.33) (dashed), falling roughly as $1/N$. The exponential parent, with its long tail, has a variance of the variance about four times larger than the Gaussian at the same N.

Verification and research. Here the simulation verifies (3.33). The formula is needed later as an instrument: the error bar of any Monte Carlo estimate of a variance, and hence of every simulated covariance matrix (Section 3.5), is set by it. For a masked sky the $a_{\ell m}$ are no longer independent, the effective number of modes drops below $2\ell+1$, often to roughly $f_{\mathrm{sky}}(2\ell+1)$, and the true variance of the power spectrum estimate is found by simulation (Chapter 8).

3.5 Estimating covariance and correlation matrices, and how noisy they are

A CMB or galaxy-survey analysis compresses a map into $p = 20$ band powers and compares them with theory through a $\chi^2 = (\boldsymbol{d}-\boldsymbol{m})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{d}-\boldsymbol{m})$. The covariance matrix $\mathbf{C}$ of the band powers has no formula once masks and noise enter, so we run n simulations and estimate it from the scatter of the simulated band powers. Supercomputer time limits us to, say, $n = 50$. The resulting matrix shows correlations between bins that are not there, and its inverse is too

large. In the same way a detector with twenty readout channels shows "cross-talk" between channels that is just noise.

The sample variance, extended to a matrix, tells us how noisy each element is, and so how large the false correlations can be. A change of variable gives a reliable error bar for a real correlation. And a single factor removes the bias of the inverse.

A tilted cloud, seen through few points. A correlation coefficient measures the tilt of a cloud of points in a scatter plot. With a thousand points the tilt is obvious. With ten points drawn from a perfectly round cloud, the ten happen to line up a little by chance, and a tilt appears. A 20×20 correlation matrix has 190 tilts to get wrong, so some of them will be large by chance. It is the same reason why a few stars in the sky seem to form constellations.

The questions, in words.

1. How do we estimate, without bias, the covariance of two quantities from paired readings?
2. If two quantities are truly unrelated, how large a sample correlation can chance produce?
3. For a real correlation, what is the sampling distribution of its estimate, and how do we put an error bar on it?
4. What happens when we invert a noisy covariance matrix?

3.5.1 The sample covariance matrix

Recall from Chapter 2 the covariance $\Sigma_{ab} = \mathrm{Cov}(X_a, X_b) = \mathbb{E}[(X_a - \mu_a)(X_b - \mu_b)]$ of two components of a random vector $\boldsymbol{X} = (X_1, \dots, X_p)$, and the correlation $\rho_{ab} = \Sigma_{ab}/\sqrt{\Sigma_{aa}\Sigma_{bb}}$, which lies in $[-1, 1]$.

Working definition 3.7 (sample covariance and correlation)

Given n independent readings $\boldsymbol{x}_1, \dots, \boldsymbol{x}_n$ of a p-component vector [each $\boldsymbol{x}_j$ is one simulation, or one event, giving all p numbers at once], with average $\bar{\boldsymbol{x}} = n^{-1}\sum_j \boldsymbol{x}_j$, the **sample covariance matrix** is

$$\hat{\mathbf{C}} = \frac{1}{n-1}\sum_{j=1}^{n}(\boldsymbol{x}_j - \bar{\boldsymbol{x}})(\boldsymbol{x}_j - \bar{\boldsymbol{x}})^{\mathsf{T}}, \qquad \hat{C}_{ab} = \frac{1}{n-1}\sum_{j=1}^{n}(x_{aj} - \bar{x}_a)(x_{bj} - \bar{x}_b), \tag{3.36}$$

and the **sample correlation** is

$$r_{ab} = \frac{\hat{C}_{ab}}{\sqrt{\hat{C}_{aa}\hat{C}_{bb}}} = \frac{\sum_j (x_{aj} - \bar{x}_a)(x_{bj} - \bar{x}_b)}{\sqrt{\sum_j (x_{aj} - \bar{x}_a)^2 \, \sum_j (x_{bj} - \bar{x}_b)^2}}. \tag{3.37}$$

In (3.37) the factors $1/(n-1)$ cancel between numerator and denominator, which gives the second form; by the Cauchy–Schwarz inequality it always satisfies $|r| \le 1$. The printed formula [Wasserman (14.6)] drops the $1/(n-1)$ from the numerator only, which would let $|r|$ exceed 1. The form above is the correct one and agrees with [Cowan (5.12)].

The diagonal of $\hat{\mathbf{C}}$ holds the sample variances of Section 3.4. The off-diagonal elements are unbiased by the same argument. Write $\boldsymbol{y}_j = \boldsymbol{x}_j - \boldsymbol{\mu}$, so that $\boldsymbol{x}_j - \bar{\boldsymbol{x}} = \boldsymbol{y}_j - \bar{\boldsymbol{y}}$, and use

$\sum_j (\boldsymbol{y}_j - \bar{\boldsymbol{y}})(\boldsymbol{y}_j - \bar{\boldsymbol{y}})^{\mathsf{T}} = \sum_j \boldsymbol{y}_j \boldsymbol{y}_j^{\mathsf{T}} - n\, \bar{\boldsymbol{y}}\bar{\boldsymbol{y}}^{\mathsf{T}}$ (the matrix version of (3.25)):

$$\mathbb{E}\Big[\sum_j (\boldsymbol{x}_j - \bar{\boldsymbol{x}})(\boldsymbol{x}_j - \bar{\boldsymbol{x}})^{\mathsf{T}}\Big] \overset{(1)}{=} \sum_j \mathbb{E}[\boldsymbol{y}_j \boldsymbol{y}_j^{\mathsf{T}}] - n\, \mathbb{E}[\bar{\boldsymbol{y}}\bar{\boldsymbol{y}}^{\mathsf{T}}] \overset{(2)}{=} n\boldsymbol{\Sigma} - n \cdot \frac{\boldsymbol{\Sigma}}{n} = (n-1)\,\boldsymbol{\Sigma}. \tag{3.38}$$

(1) Linearity of expectation applied element by element.
(2) $\mathbb{E}[\boldsymbol{y}_j \boldsymbol{y}_j^{\mathsf{T}}] = \boldsymbol{\Sigma}$ by definition. For the mean, $\mathbb{E}[\bar{y}_a \bar{y}_b] = n^{-2} \sum_{j,k} \mathbb{E}[y_{aj} y_{bk}] = n^{-2} \cdot n\, \Sigma_{ab}$, because readings $j \neq k$ are independent with zero mean.

So $\mathbb{E}\,\hat{\mathbf{C}} = \boldsymbol{\Sigma}$ [Wasserman p. 233, (14.4)]. A handy form for computing is $\hat{C}_{ab} = \frac{n}{n-1}\big(\overline{x_a x_b} - \bar{x}_a \bar{x}_b\big)$, where the bar means the average over readings [Cowan (5.11)].

Example: A 2×2 covariance by hand. Four paired readings $(x, y) = (1,2), (2,1), (3,4), (4,3)$. Both averages are 2.5. The deviations are $\delta x = (-1.5, -0.5, 0.5, 1.5)$ and $\delta y = (-0.5, -1.5, 1.5, 0.5)$. Then

$$\hat{C}_{xx} \overset{(1)}{=} \tfrac{1}{3}(2.25 + 0.25 + 0.25 + 2.25) = \tfrac{5}{3}, \qquad \hat{C}_{yy} \overset{(2)}{=} \tfrac{5}{3},$$
$$\hat{C}_{xy} \overset{(3)}{=} \tfrac{1}{3}(0.75 + 0.75 + 0.75 + 0.75) = 1, \qquad r \overset{(4)}{=} \frac{1}{\sqrt{(5/3)(5/3)}} = 0.6.$$

(1) Squares of the x deviations, divided by $n - 1 = 3$.
(2) The y deviations are a permutation of the x ones, so the same sum.
(3) Products $(-1.5)(-0.5)$, $(-0.5)(-1.5)$, $(0.5)(1.5)$, $(1.5)(0.5)$, each 0.75.
(4) Definition (3.37).

Four points already give a respectable-looking $r = 0.6$. Is it real? To answer, we need to know how large r gets when there is no correlation at all.

3.5.2 Correlations from pure noise

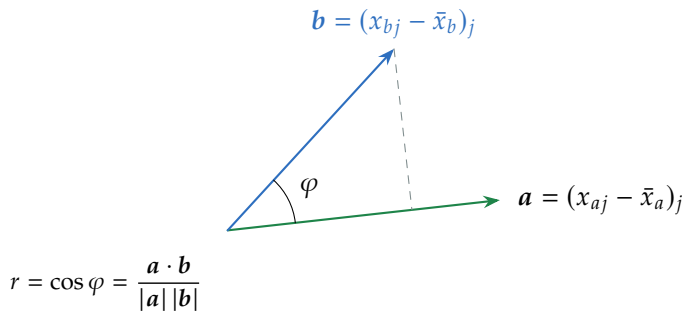

Figure 3.16: The sample correlation as an angle. The deviations of the n readings of each quantity form two vectors in $\mathbb{R}^n$, both perpendicular to $(1, \ldots, 1)$ and so living in an $(n-1)$-dimensional space. The sample correlation is the cosine of the angle between them. Uncorrelated noise points $\boldsymbol{b}$ in a random direction relative to $\boldsymbol{a}$.

Formula (3.37) is a dot product divided by two lengths, so it is the cosine of the angle between the two deviation vectors in Figure 3.16. This picture gives the spread of r for unrelated quantities without any integrals.

Example: The scatter of r when $\rho = 0$. Let the two quantities be independent Gaussians. As in Figure 3.13, the deviation vectors live in the $(m = n - 1)$-dimensional subspace perpendicular

to $(1, \dots, 1)$, and in it the Gaussian noise vector $\boldsymbol{b}$ is isotropic: its direction $\boldsymbol{u} = \boldsymbol{b}/|\boldsymbol{b}|$ is uniformly distributed on the unit sphere, independently of $\boldsymbol{a}$. Rotate coordinates so that $\boldsymbol{a}$ points along the first axis. Then $r = u_1$ and

$$\mathbb{E}\, r \overset{(1)}{=} 0, \qquad \mathbb{E}\, r^2 = \mathbb{E}\, u_1^2 \overset{(2)}{=} \frac{1}{m} \sum_{k=1}^{m} \mathbb{E}\, u_k^2 \overset{(3)}{=} \frac{1}{m}\, \mathbb{E}\Big[\sum_{k=1}^{m} u_k^2\Big] \overset{(4)}{=} \frac{1}{m} = \frac{1}{n-1}.$$

(1) $\boldsymbol{u}$ and $-\boldsymbol{u}$ are equally likely.
(2) By symmetry every component of a uniform unit vector has the same mean square.
(3) Linearity of expectation.
(4) A unit vector has $\sum_k u_k^2 = 1$ exactly.

So for unrelated quantities r scatters about zero with standard deviation $1/\sqrt{n-1}$, and for large n it is close to Gaussian. With $n = 4$ as in Section 3.5.1, $1/\sqrt{3} = 0.58$: our $r = 0.6$ is one standard deviation from zero and means nothing.

Key idea: Spurious correlations

If p quantities are truly independent, each of the $p(p-1)/2$ off-diagonal sample correlations scatters about zero with standard deviation about $1/\sqrt{n-1}$. Among many pairs, roughly 5% exceed $1.96/\sqrt{n-1}$ in magnitude by chance alone.

With $p = 20$ and $n = 50$ there are 190 pairs. The prediction is a spread of $1/\sqrt{49} = 0.1429$ and about ten pairs beyond $|r| = 0.28$. The simulation (Figure 3.17) gives a spread of 0.1484 in one realisation and a largest $|r|$ of 0.4416. Searching a large matrix for the most correlated pair and then quoting its significance as if it were the only pair examined is the *look-elsewhere effect* of Chapter 4.

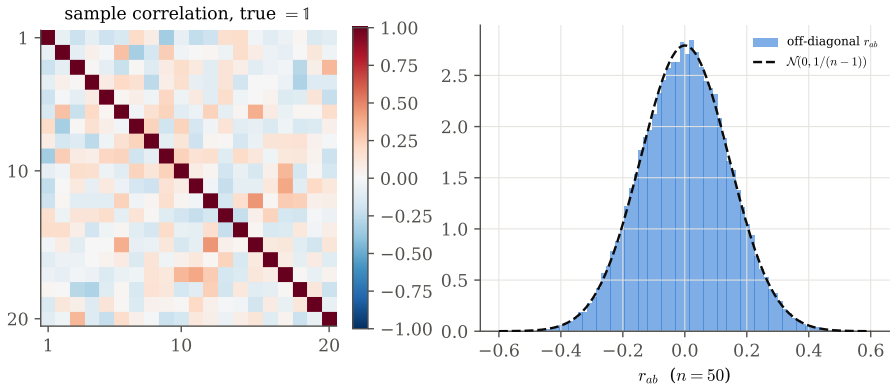

Figure 3.17: Left: the sample correlation matrix of twenty independent quantities from fifty readings. The true matrix is the identity. Every coloured off-diagonal square is noise, and some reach ±0.4. Right: the off-diagonal elements from 400 such matrices, with the Gaussian of standard deviation $1/\sqrt{n-1}$ (dashed).

3.5.3 A real correlation, its error bar, and Fisher's z

For a bivariate Gaussian with correlation $\rho \neq 0$, the sample correlation is biased and skewed, with, to leading order in $1/n$ [Cowan (5.16)–(5.17)],

$$\mathbb{E}\, r \approx \rho - \frac{\rho(1-\rho^2)}{2n}, \qquad \operatorname{Var} r \approx \frac{(1-\rho^2)^2}{n}. \tag{3.39}$$

The variance shrinks as $|\rho| \to 1$, because r cannot exceed 1: the sampling distribution is squashed against the wall and develops a long tail towards zero. An error bar $r \pm \sqrt{\operatorname{Var} r}$ is then misleading, since it depends on the unknown ρ and may poke above 1.

Fisher's remedy is a change of variable that makes the width independent of ρ. We look for $z = h(r)$ with $\operatorname{Var} z$ constant. To first order in the fluctuation (the propagation rule derived in Section 3.6), $\operatorname{Var} h(r) \approx h'(\rho)^2 \operatorname{Var} r$, so we need $h'(\rho) \propto 1/(1-\rho^2)$:

$$h(\rho) \overset{(1)}{=} \int_0^\rho \frac{\mathrm{d}s}{1-s^2} \overset{(2)}{=} \frac{1}{2}\int_0^\rho \Big(\frac{1}{1+s} + \frac{1}{1-s}\Big)\mathrm{d}s \overset{(3)}{=} \frac{1}{2}\ln\frac{1+\rho}{1-\rho} = \operatorname{artanh}\rho. \tag{3.40}$$

(1) Choose the integration constant so that $h(0) = 0$.
(2) Partial fractions: $\frac{1}{1-s^2} = \frac{1}{2}\big(\frac{1}{1+s} + \frac{1}{1-s}\big)$.
(3) Integrate: $\ln(1+s) - \ln(1-s)$, evaluated from 0 to ρ.

Then $\operatorname{Var} z \approx (1-\rho^2)^{-2}(1-\rho^2)^2/n = 1/n$. A finer calculation replaces n by $n-3$, and z is very nearly Gaussian even for small n:

$$z = \operatorname{artanh} r \approx \mathcal{N}\Big(\operatorname{artanh}\rho,\ \frac{1}{n-3}\Big). \tag{3.41}$$

The inverse map is $\rho = \tanh z = (e^{2z}-1)/(e^{2z}+1)$. The map stretches the region near ± 1, which pulls the squashed tail back into a symmetric shape.

Example: An interval for a correlation. We observe $r = 0.6$ from $n = 20$ pairs. A 95% interval is built in z and mapped back [Wasserman p. 234]:

$$\hat z \overset{(1)}{=} \operatorname{artanh} 0.6 = \tfrac{1}{2}\ln 4 = 0.693, \qquad \frac{1.96}{\sqrt{n-3}} \overset{(2)}{=} \frac{1.96}{\sqrt{17}} = 0.475,$$

$$(a, b) \overset{(3)}{=} (0.218,\ 1.169), \qquad (\tanh a, \tanh b) \overset{(4)}{=} (0.214,\ 0.824).$$

(1) $\frac{1}{2}\ln\frac{1.6}{0.4} = \frac{1}{2}\ln 4$.
(2) The standard deviation of z from (3.41), times 1.96.
(3) $\hat z \mp 0.475$.
(4) Map each end back with tanh, which is increasing, so the order is kept.

The interval $(0.21, 0.82)$ is asymmetric about 0.6, longer on the side away from the wall at 1, exactly as the skewed sampling distribution demands.

Listing 3.5: Simulating the sample correlation for $\rho = 0.6$, $n = 20$ (`code/ch03/05_covariance_noise.py`)

```
rho, n2, M = 0.6, 20, 100_000
L = np.linalg.cholesky(np.array([[1, rho], [rho, 1]]))
Z = rng.standard_normal((M, n2, 2)) @ L.T
a = Z[..., 0] - Z[..., 0].mean(axis=1, keepdims=True)
b = Z[..., 1] - Z[..., 1].mean(axis=1, keepdims=True)
r = (a * b).sum(1) / np.sqrt((a * a).sum(1) * (b * b).sum(1))
z = np.arctanh(r)
```

The script makes correlated pairs by multiplying independent standard normals by the Cholesky factor L of the target 2×2 correlation matrix ($LL^{\mathsf T}$ equals that matrix, so $L\epsilon$ has exactly that covariance, Chapter 2). It removes the mean of each column within every experiment and applies (3.37) row by row. Over 100 000 experiments the mean of r is 0.5902 (from (3.39): 0.5904), its spread 0.1544 (leading order: 0.1431, an underestimate at this small n) and its skewness -0.8008. For z, the spread is 0.2416 against $1/\sqrt{17} = 0.2425$, and the skewness -8.926×10^{-4}: Fisher's transformation has removed it.

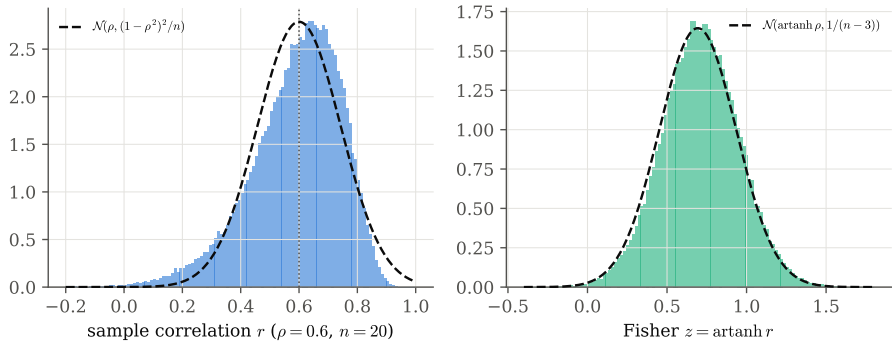

Figure 3.18: Left: the sample correlation from twenty pairs with true correlation 0.6 (dotted). It is skewed, with a long tail towards zero, and the leading-order Gaussian (dashed) is too narrow on that side. Right: the same experiments after Fisher's transformation $z = \operatorname{artanh} r$. The histogram now sits on a symmetric Gaussian of width $1/\sqrt{n-3}$.

3.5.4 How noisy is every element, and what inversion does

For Gaussian readings there is a clean formula for the scatter of each element of $\hat{\mathbf{C}}$. The rotation argument of Section 3.4.1, applied to each component, turns the n centred readings into $n-1$ independent vectors $z_k \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$, with $(n-1)\hat{\mathbf{C}} = \sum_{k=1}^{n-1} z_k z_k^{\mathsf{T}}$. We need one fact about Gaussian fourth moments, familiar to physicists as Wick's theorem.

Isserlis (Wick) theorem. For a zero-mean Gaussian vector, $\mathbb{E}[z_a z_b z_c z_d] = \Sigma_{ab}\Sigma_{cd} + \Sigma_{ac}\Sigma_{bd} + \Sigma_{ad}\Sigma_{bc}$: the sum over all ways of pairing the four factors, each pair replaced by its covariance. (With $a = b = c = d$ it gives $\mathbb{E}\, z^4 = 3\sigma^4$.)

$$\operatorname{Var}\hat{C}_{ab} \overset{(1)}{=} \frac{1}{(n-1)^2}\sum_{k=1}^{n-1}\operatorname{Var}(z_{ak}z_{bk}) \overset{(2)}{=} \frac{1}{n-1}\Big(\mathbb{E}[z_a z_b z_a z_b] - \Sigma_{ab}^2\Big)$$
$$\overset{(3)}{=} \frac{1}{n-1}\Big(\Sigma_{aa}\Sigma_{bb} + 2\Sigma_{ab}^2 - \Sigma_{ab}^2\Big) = \frac{\Sigma_{aa}\Sigma_{bb} + \Sigma_{ab}^2}{n-1}. \tag{3.42}$$

(1) $\hat{C}_{ab}$ is $1/(n-1)$ times a sum of $n-1$ independent terms, so variances add.
(2) All $n-1$ terms have the same distribution, and $\operatorname{Var}(U) = \mathbb{E}\,U^2 - (\mathbb{E}\,U)^2$ with $\mathbb{E}[z_a z_b] = \Sigma_{ab}$.
(3) Isserlis with indices (a, b, a, b): the pairings give $\Sigma_{ab}\Sigma_{ab}$, $\Sigma_{aa}\Sigma_{bb}$ and $\Sigma_{ab}\Sigma_{ba}$.

For $a = b$ this is $2\Sigma_{aa}^2/(n-1)$, the Gaussian variance of S^2 in (3.34). For $\Sigma = \mathbb{1}$ and $a \neq b$ it is $1/(n-1)$, the scatter of spurious correlations found above. Each element of a covariance matrix estimated from $n = 50$ simulations is uncertain by about $1/\sqrt{49} = 14\%$ of the typical diagonal size.

Inverting a noisy matrix. The χ^2 needs $\mathbf{C}^{-1}$, and here noise does more than add scatter: it biases the result. The reason is that $1/x$ is a convex function. For a single number, Jensen's inequality gives $\mathbb{E}[1/\hat{\sigma}^2] > 1/\mathbb{E}[\hat{\sigma}^2]$: a fluctuation of $\hat{\sigma}^2$ towards zero raises $1/\hat{\sigma}^2$ by more than an equal fluctuation upwards lowers it. For a matrix, the noise spreads the eigenvalues of $\hat{\mathbf{C}}$ apart. The smallest ones come out too small, and inverting turns them into eigenvalues of $\hat{\mathbf{C}}^{-1}$ that are too large. For Gaussian readings and $n > p + 2$ the exact result is

$$\mathbb{E}\big[\hat{\mathbf{C}}^{-1}\big] = \frac{n-1}{n-p-2}\,\mathbf{C}^{-1}, \tag{3.43}$$

a property of the inverse-Wishart distribution. The unbiased estimate of the inverse covariance is therefore $\widehat{\mathbf{C}^{-1}} = \frac{n-p-2}{n-1}\hat{\mathbf{C}}^{-1}$, the **Hartlap factor** [6]. As p approaches n the bias explodes, and at $p \geq n$ the matrix $\hat{\mathbf{C}}$ is singular (its rank is at most $n-1$).

Example: How many simulations? With $n = 30$ simulations and $p = 10$ bins, $(n-1)/(n-p-2) = 29/18 = 1.611$: without the correction, every χ^2 is too large by 61%, and parameter error bars come out too small by a factor of about $\sqrt{1.61} = 1.27$. The simulation gives 1.616. To keep the bias below 10% we need $(n-1)/(n-p-2) \leq 1.1$. From $n - 1 \leq 1.1(n-p-2)$ we get $0.1\,n \geq 1.1p + 1.2$, i.e. $n \geq 11p + 12$: about 120 simulations for 10 bins. Even then, the *noise* in the inverse (not just its bias) widens the parameter constraints, a further effect that has to be propagated.

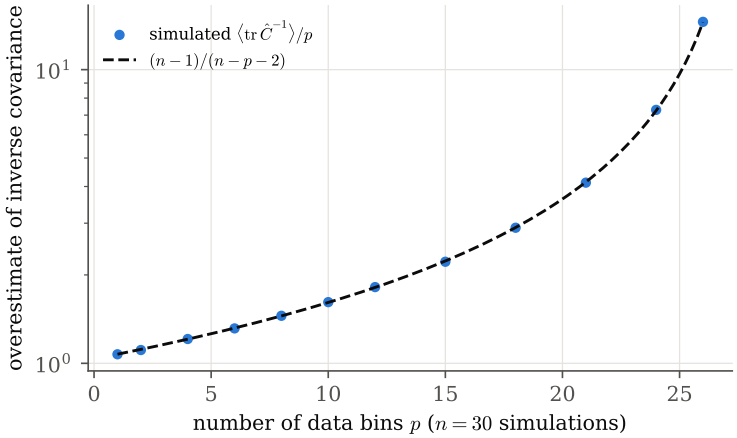

Figure 3.19: How much the inverse of a sample covariance matrix overestimates the true inverse, for thirty simulations and a growing number of bins (logarithmic vertical axis). The simulated overestimate follows $(n-1)/(n-p-2)$ (dashed): small for a few bins, a factor of two by $p \approx 14$, and diverging as p approaches $n-2$.

Watch out: Selected and misread correlations

A correlation coefficient estimated from the same data that were used to choose which pair to look at is not distributed as (3.41). Nor is a correlation evidence of a causal link, and a zero correlation does not mean independence (the correlation only sees the linear part of a relation, Chapter 2).

What this bought us. A covariance matrix estimated from n samples has element-wise noise of relative size $\sim 1/\sqrt{n-1}$, which shows up as spurious correlations of that size. Put error bars on a correlation in the variable $z = \operatorname{artanh} r$, where the width is $1/\sqrt{n-3}$. Before inverting an estimated covariance, multiply the inverse by the Hartlap factor $(n-p-2)/(n-1)$, and choose n well above p.

Verification and research. Everything above was verified against formulas valid for Gaussian readings. For band powers from masked skies or non-Gaussian fields, neither (3.42) nor (3.43) is exact, and the number of simulations needed for a stable χ^2 is itself found by simulation: rerun the covariance estimate with independent sets of simulations and watch how the parameter constraints move (Chapter 8).

3.6 Propagating errors through a formula

The pendulum student now measures the length, $L = 1.000 \pm 0.002\,\mathrm{m}$, and the period, $T = 2.006 \pm 0.004\,\mathrm{s}$, and computes $g = 4\pi^2 L/T^2$. What is the error on g? A particle physicist asks the same about a branching ratio $N_{\mathrm{signal}}/N_{\mathrm{norm}}$, a cosmologist about H_0 derived from a measured angle and a sound horizon. And sometimes the textbook answer is badly wrong: a ratio whose denominator is poorly measured has a distribution with tails that no Gaussian error bar describes.

Faced with a formula and a few uncertain inputs, the tempting non-answer is the one in Figure 3.20: we are not sure how big the error on each point is, so we give the error bar an error bar of its own, and that one an error bar too. It never ends in a number. The way out is to notice that the uncertainty of g is not a new, separate unknown. It is the uncertainty of L and T, carried once through the formula $g = 4\pi^2 L/T^2$. The rest of this section shows how.

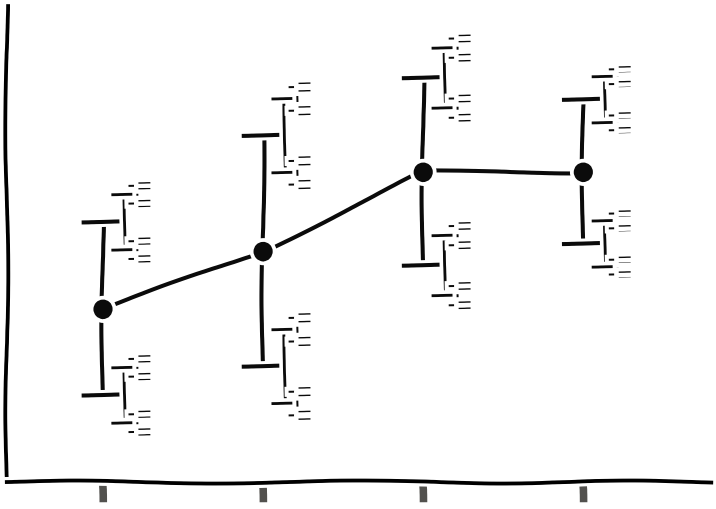

Figure 3.20: What not propagating an error looks like: every error bar gets error bars of its own, three levels deep, and the picture never settles to one number per point.

The standard answer replaces the formula by its tangent, which gives the output covariance as a "Jacobian sandwich" $A\mathbf{C}A^{\mathsf{T}}$ and shows exactly where correlations between the inputs enter. The answer is exact for linear formulas, and right for large samples (the delta method). Where it fails, a Monte Carlo propagation still works.

Every smooth function is linear up close. Zoom in on a smooth curve and it looks like its tangent line. If the cloud of possible input values is small compared with the scale on which the function bends, then over that cloud the function is effectively linear, and a linear map sends a Gaussian to a Gaussian, stretched by the slope. When the cloud is wide enough to feel the curvature, the output is skewed and its centre shifts. Near a pole, like $1/x$ at $x = 0$, all bets are off.

What we want to know.

1. Given the means and covariance of the inputs, what are the mean and covariance of the outputs, to the first order in the fluctuations?

2. When is that answer exact, and when is it an approximation?

3. How do correlations between inputs change the result?
4. How can we tell that the approximation has failed, and what then?

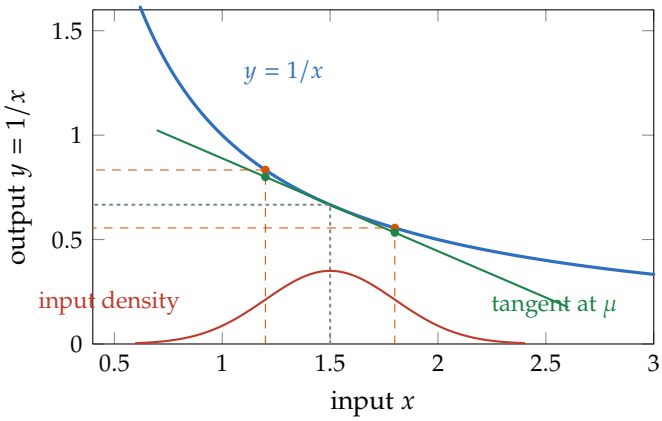

Figure 3.21: Linear propagation through $y = 1/x$ with input $\mu = 1.5$, $\sigma = 0.3$. The red curve is the input density. Orange dots: the true images of $\mu \pm \sigma$, at 0.556 and 0.833, lie asymmetrically about the image 0.667 of the mean (dotted). Green dots: the tangent line puts them symmetrically at 0.533 and 0.800. The curvature makes the output skewed towards large y, which is what the Monte Carlo shows later.

3.6.1 The first-order formula

Let the inputs $\boldsymbol{x} = (x_1, \dots, x_n)$ have means $\boldsymbol{\mu}$ and covariance matrix $V_{ij} = \operatorname{Cov}(x_i, x_j)$, and let $y(\boldsymbol{x})$ be a smooth function. Expand about the means,

$$y(\boldsymbol{x}) = y(\boldsymbol{\mu}) + \sum_{i=1}^{n} \left.\frac{\partial y}{\partial x_i}\right|_{\boldsymbol{\mu}} (x_i - \mu_i) + \frac{1}{2} \sum_{i,j} \left.\frac{\partial^2 y}{\partial x_i \partial x_j}\right|_{\boldsymbol{\mu}} (x_i - \mu_i)(x_j - \mu_j) + \cdots , \tag{3.44}$$

If the inputs scatter only a little about their means, the quadratic and higher terms are small, so we keep only the linear term. Write $g_i = \partial y / \partial x_i$ at $\boldsymbol{\mu}$. Then, to this order,

$$\mathbb{E}\, y \overset{(1)}{=} y(\boldsymbol{\mu}) + \sum_i g_i \, \mathbb{E}(x_i - \mu_i) \overset{(2)}{=} y(\boldsymbol{\mu}), \tag{3.45}$$

$$\sigma_y^2 = \mathbb{E}\big[(y - \mathbb{E}\, y)^2\big] \overset{(3)}{=} \mathbb{E}\Big[\Big(\sum_i g_i (x_i - \mu_i)\Big)^2\Big] \overset{(4)}{=} \sum_{i,j} g_i g_j \, \mathbb{E}\big[(x_i - \mu_i)(x_j - \mu_j)\big] \overset{(5)}{=} \sum_{i,j} g_i \, V_{ij} \, g_j . \tag{3.46}$$

(1) Take the expectation of the linearised (3.44). The g_i are constants.
(2) Each $\mathbb{E}(x_i - \mu_i) = 0$.
(3) Subtract (3.45) from the linearised y.
(4) Square of a sum is a double sum, then linearity.
(5) Definition of the covariance.

For several outputs $y_1, \dots, y_m$, the same steps with two different outputs y_k, y_l give the covariance matrix of the outputs,

$$U_{kl} = \operatorname{Cov}(y_k, y_l) \approx \sum_{i,j} \frac{\partial y_k}{\partial x_i} \frac{\partial y_l}{\partial x_j} V_{ij}, \qquad U = A\, V A^{\mathsf{T}}, \qquad A_{ki} = \left.\frac{\partial y_k}{\partial x_i}\right|_{\boldsymbol{\mu}}, \tag{3.47}$$

where A is the $m \times n$ **Jacobian** matrix [Cowan (1.53)–(1.56)].

Working definition 3.8 (linear error propagation)

Linear (first-order) **error propagation** replaces each function by its tangent plane at the input means [the first two terms of the Taylor series, valid when the inputs scatter over a region where the second derivatives hardly matter], so that the output covariance is $U = AVA^{\mathsf{T}}$ with A the Jacobian at the means. If the inputs are uncorrelated, V is diagonal and $\sigma_y^2 = \sum_i (\partial y/\partial x_i)^2 \sigma_i^2$ [Cowan (1.57)].

Four rules everybody uses. With two inputs and $V_{12} = \rho\sigma_1\sigma_2$, (3.46) gives [Cowan (1.59)–(1.60)]:

$$y = x_1 \pm x_2: \quad \sigma_y^2 = \sigma_1^2 + \sigma_2^2 \pm 2\rho\sigma_1\sigma_2, \tag{3.48}$$

$$y = x_1 x_2 \text{ or } x_1/x_2: \quad \frac{\sigma_y^2}{y^2} = \frac{\sigma_1^2}{x_1^2} + \frac{\sigma_2^2}{x_2^2} \pm \frac{2\rho\sigma_1\sigma_2}{x_1 x_2}, \tag{3.49}$$

$$y = x^k: \quad \frac{\sigma_y}{|y|} = |k|\,\frac{\sigma_x}{|x|}, \tag{3.50}$$

$$y = \ln x: \quad \sigma_y = \frac{\sigma_x}{x}. \tag{3.51}$$

(For the product take +, for the ratio −. The derivatives are $\partial(x_1x_2)/\partial x_1 = x_2$, $\partial(x_1/x_2)/\partial x_2 = -x_1/x_2^2$, and dividing by y^2 turns them into relative errors.) Absolute errors add in quadrature for sums, relative errors for products and ratios.

Example: The pendulum. $g = 4\pi^2 L T^{-2}$ is a product of powers, so relative errors add in quadrature with weights $|k|$:

$$\frac{\sigma_g^2}{g^2} \overset{(1)}{=} \left(\frac{\sigma_L}{L}\right)^2 + \left(2\,\frac{\sigma_T}{T}\right)^2 \overset{(2)}{=} (0.002)^2 + \left(\frac{2\times 0.004}{2.006}\right)^2 = 4.0\times10^{-6} + 1.59\times10^{-5},$$

$$g \overset{(3)}{=} \frac{4\pi^2 \times 1.000}{2.006^2} = 9.811\ \mathrm{m\,s^{-2}}, \qquad \sigma_g = 9.811 \times \sqrt{1.99\times10^{-5}} = 0.04377\ \mathrm{m\,s^{-2}}.$$

(1) (3.49) and (3.50) with $k = 1$ for L and $k = -2$ for T. L and T are measured independently, so $\rho = 0$.
(2) Insert the numbers.
(3) The central value is the function at the input means (3.45).

The period dominates. Its relative error (0.20%) is the same as that of L, but it enters squared, so it contributes four times the variance. To improve g, time more swings.

Example: A common calibration: correlated errors. Two energies E_1, E_2 are measured with the same calorimeter. Each has an independent statistical error σ_s and they share one calibration error σ_c: $E_i = E_i^{\text{true}} + \epsilon_i + \delta$, where the ϵ_i are independent with mean 0 and variance σ_s^2, and the common shift δ, independent of both, has mean 0 and variance σ_c^2. Then $V_{11} = V_{22} = \sigma_s^2 + \sigma_c^2$ and $V_{12} = \mathrm{Cov}(\epsilon_1 + \delta, \epsilon_2 + \delta) = \sigma_c^2$. For the difference and the sum, (3.48) gives

$$\mathrm{Var}(E_1 - E_2) \overset{(1)}{=} 2(\sigma_s^2 + \sigma_c^2) - 2\sigma_c^2 = 2\sigma_s^2, \qquad \mathrm{Var}(E_1 + E_2) \overset{(2)}{=} 2(\sigma_s^2 + \sigma_c^2) + 2\sigma_c^2 = 2\sigma_s^2 + 4\sigma_c^2.$$

(1) Minus sign: the common shift δ cancels in a difference.
(2) Plus sign: it adds coherently in a sum, so its standard deviation doubles.

Ignoring the correlation would overstate the error of a mass difference and understate the error of a total energy. This is why experiments publish full covariance matrices, not just error bars.

3.6.2 Linear maps are exact, and every covariance can be diagonalised

If $\boldsymbol{y} = A\boldsymbol{x}$ exactly (a linear map, as in a change of basis, a rebinning, or a sum of channels), there is no Taylor remainder, and

$$U_{kl} = \operatorname{Cov}(y_k, y_l) \overset{(1)}{=} \mathbb{E}\Big[\sum_i A_{ki}(x_i - \mu_i) \sum_j A_{lj}(x_j - \mu_j)\Big] \overset{(2)}{=} \sum_{i,j} A_{ki} V_{ij} A_{lj} = (AVA^{\mathsf{T}})_{kl} \tag{3.52}$$

(1) $y_k - \mathbb{E}\, y_k = \sum_i A_{ki}(x_i - \mu_i)$ by linearity, with no approximation.
(2) Multiply out and use linearity of expectation.

holds exactly [Cowan (1.62)]. A linear map of a Gaussian vector is Gaussian, so for Gaussian inputs the whole distribution of $\boldsymbol{y}$ is $\mathcal{N}(A\boldsymbol{\mu}, AVA^{\mathsf{T}})$.

Exactness has a useful consequence: a well-chosen linear map removes all correlations. V is real and symmetric, so it has n orthonormal eigenvectors $\boldsymbol{r}^{(k)}$ with $V\boldsymbol{r}^{(k)} = \lambda_k \boldsymbol{r}^{(k)}$ and $\boldsymbol{r}^{(k)} \cdot \boldsymbol{r}^{(l)} = \delta_{kl}$. Take the rows of A to be these eigenvectors, $A_{ki} = r_i^{(k)}$. Then

$$U_{kl} \overset{(1)}{=} \sum_{i,j} r_i^{(k)} V_{ij} r_j^{(l)} \overset{(2)}{=} \sum_i r_i^{(k)} \lambda_l \, r_i^{(l)} \overset{(3)}{=} \lambda_l \, \delta_{kl}. \tag{3.53}$$

(1) (3.52) with $A_{ki} = r_i^{(k)}$.
(2) $\sum_j V_{ij} r_j^{(l)} = \lambda_l r_i^{(l)}$, the eigenvalue equation.
(3) Orthonormality of the eigenvectors.

The new variables $y_k = \boldsymbol{r}^{(k)} \cdot \boldsymbol{x}$ are uncorrelated, with variances equal to the eigenvalues of V [Cowan (1.63)–(1.65)]. This is the statistics version of finding normal modes of coupled oscillators, and of the principal axes of an inertia tensor.

Example: Decorrelating two measurements. For $V = \sigma^2 \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$ the eigenvectors are $(1,1)/\sqrt{2}$ and $(1,-1)/\sqrt{2}$ with eigenvalues $\sigma^2(1 \pm \rho)$ (check: $V(1,1)^{\mathsf{T}} = \sigma^2(1+\rho)(1,1)^{\mathsf{T}}$). The combinations $(x_1 + x_2)/\sqrt{2}$ and $(x_1 - x_2)/\sqrt{2}$ are uncorrelated, and with ρ close to 1 the difference is much better measured than either input. The calibration example above is this with $\rho = \sigma_c^2/(\sigma_s^2 + \sigma_c^2)$.

3.6.3 The delta method: why the first-order formula is right for large samples

Linear propagation is an approximation, so when can we trust it? When the inputs are themselves estimators built from n readings. Their scatter then shrinks like $1/\sqrt{n}$, the cloud of inputs shrinks onto the tangent, and the curvature terms become negligible. The delta method makes this precise.

The delta method. If $\sqrt{n}(Y_n - \mu) \rightsquigarrow \mathcal{N}(0, \sigma^2)$ and g is differentiable with $g'(\mu) \neq 0$, then

$$\sqrt{n}\big(g(Y_n) - g(\mu)\big) \rightsquigarrow \mathcal{N}\big(0,\ g'(\mu)^2\sigma^2\big), \qquad \text{i.e.} \qquad g(Y_n) \approx \mathcal{N}\Big(g(\mu),\ \frac{g'(\mu)^2\sigma^2}{n}\Big). \tag{3.54}$$

For a vector, $\sqrt{n}\big(g(\boldsymbol{Y}_n) - g(\boldsymbol{\mu})\big) \rightsquigarrow \mathcal{N}\big(0, \nabla g^{\mathsf{T}} \boldsymbol{\Sigma} \nabla g\big)$ [Wasserman Thms. 5.13, 5.15].

Why it is true: expand $g(Y_n) = g(\mu) + g'(\mu)(Y_n - \mu) + R_n$ with a remainder R_n of order $(Y_n - \mu)^2$. Multiply by $\sqrt{n}$. The linear term $g'(\mu)\sqrt{n}(Y_n - \mu)$ tends in distribution to $\mathcal{N}(0, g'(\mu)^2\sigma^2)$. The remainder is $\sqrt{n}\, R_n \sim \sqrt{n}\,(Y_n - \mu)^2 = [\sqrt{n}(Y_n - \mu)]^2/\sqrt{n}$, a quantity of fixed size divided by $\sqrt{n}$, so it tends to zero in probability, and Slutsky's theorem lets us drop it. The curvature does not disappear. It becomes negligible compared with the shrinking linear scatter.

Example: A function of one mean, and the product of two. In both cases the inputs are sample means, so by the central limit theorem $\sqrt{n}(\bar{X}_n - \mu) \rightsquigarrow \mathcal{N}(0, \sigma^2)$ and the delta method applies. (a) For $W_n = e^{\bar{X}_n}$, $g(s) = e^s$ has $g'(\mu) = e^\mu$, so $W_n \approx \mathcal{N}(e^\mu, e^{2\mu}\sigma^2/n)$ [Wasserman Ex. 5.14]. (b) For the product of two means, $Y = \bar{X}_1\bar{X}_2$ from n paired readings with covariance matrix $\boldsymbol{\Sigma} = (\sigma_{ab})$, the gradient of $g(s_1, s_2) = s_1 s_2$ at $\boldsymbol{\mu}$ is (μ_2, μ_1) and

$$\nabla g^{\mathsf{T}} \boldsymbol{\Sigma} \nabla g \overset{(1)}{=} \begin{pmatrix} \mu_2 & \mu_1 \end{pmatrix} \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{12} & \sigma_{22} \end{pmatrix} \begin{pmatrix} \mu_2 \\ \mu_1 \end{pmatrix} \overset{(2)}{=} \mu_2^2\sigma_{11} + 2\mu_1\mu_2\sigma_{12} + \mu_1^2\sigma_{22},$$

(1) $\partial(s_1 s_2)/\partial s_1 = s_2$ and $\partial(s_1 s_2)/\partial s_2 = s_1$, at the means.
(2) Multiply out the quadratic form.

so $\sqrt{n}(\bar{X}_1\bar{X}_2 - \mu_1\mu_2) \rightsquigarrow \mathcal{N}(0, \mu_2^2\sigma_{11} + 2\mu_1\mu_2\sigma_{12} + \mu_1^2\sigma_{22})$ [Wasserman Ex. 5.16]. Dividing by $(\mu_1\mu_2)^2$ this is the product rule (3.49).

When the slope vanishes. If $g'(\mu) = 0$, the first-order formula says $\sigma_y = 0$, which is absurd. The second-order term takes over [CasellaBerger Thm. 5.5.26]: with $g(Y_n) - g(\mu) \approx \frac{1}{2}g''(\mu)(Y_n - \mu)^2$ and $n(Y_n - \mu)^2/\sigma^2 \rightsquigarrow \chi^2_1$,

$$n\big(g(Y_n) - g(\mu)\big) \rightsquigarrow \frac{\sigma^2 g''(\mu)}{2}\,\chi^2_1. \tag{3.55}$$

Estimating a power $|A|^2$ when the true amplitude A is zero is exactly this case. With $g(s) = s^2$ we have $g'(0) = 0$ and $g'' = 2$, so the estimate is $\sigma^2\chi^2_1/n$: never negative, and biased upward by σ^2/n (the mean of χ^2_1 is 1).

The second-order bias. Keeping the quadratic term of (3.44) in the mean gives $\mathbb{E}\,y \approx y(\boldsymbol{\mu}) + \frac{1}{2}\sum_{ij}\partial_i\partial_j y\, V_{ij}$. For $y = 1/x$ this is $\mathbb{E}(1/x) \approx \frac{1}{\mu}\big(1 + \sigma^2/\mu^2\big)$, always above $1/\mu$, as Figure 3.21 suggests. For the ratio of means $\bar{X}/\bar{Y}$ Casella and Berger derive in the same way [CasellaBerger Ex. 5.5.27]

$$\mathbb{E}\,\frac{\bar{X}}{\bar{Y}} \approx \frac{\mu_X}{\mu_Y}, \qquad \operatorname{Var}\frac{\bar{X}}{\bar{Y}} \approx \frac{1}{n}\,\frac{\mu_X^2}{\mu_Y^2}\Big(\frac{\sigma_X^2}{\mu_X^2} + \frac{\sigma_Y^2}{\mu_Y^2} - \frac{2\sigma_{XY}}{\mu_X\mu_Y}\Big),$$

the ratio rule (3.49) with $\sigma^2 \to \sigma^2/n$, and they warn that it can be far off when μ_Y is near zero.

3.6.4 When linear propagation fails: the ratio of Gaussians

Let $x_1 \sim \mathcal{N}(\mu_1, \sigma_1^2)$ and $x_2 \sim \mathcal{N}(\mu_2, \sigma_2^2)$ be independent and $y = x_1/x_2$. The linear rule gives a Gaussian of width $\sigma_y = |y_0|\sqrt{(\sigma_1/\mu_1)^2 + (\sigma_2/\mu_2)^2}$ around $y_0 = \mu_1/\mu_2$. But the denominator has a nonzero density at $x_2 = 0$, where y diverges, so y has no mean and no variance at all, however small σ_2/μ_2 is. The extreme case, both means zero, shows where the heavy tails come from.

Example: The ratio of two zero-mean Gaussians is a Breit–Wigner. Let $x_1, x_2 \sim \mathcal{N}(0, 1)$ independently. The pair (x_2, x_1) is an isotropic Gaussian in the plane, so its polar angle Θ is uniformly distributed, and $y = x_1/x_2 = \tan\Theta$. Since tan has period π, we can take Θ uniform on $(-\pi/2, \pi/2)$. Then

$$\mathrm{P}(y \le t) \overset{(1)}{=} \mathrm{P}(\Theta \le \arctan t) \overset{(2)}{=} \frac{\arctan t + \pi/2}{\pi}, \qquad f(t) \overset{(3)}{=} \frac{1}{\pi(1 + t^2)}.$$

(1) tan is increasing on $(-\pi/2, \pi/2)$.

(2) Uniform distribution on an interval of length π.
(3) Differentiate: $\frac{\mathrm{d}}{\mathrm{d}t}\arctan t = 1/(1+t^2)$.

This is the Cauchy (Breit–Wigner) distribution of Section 3.3.4 [CasellaBerger §5.5]. For $\mu_2 \neq 0$ the ratio keeps a Cauchy-like $1/y^2$ tail. Its weight is set by how much probability x_2 has near zero.

Listing 3.6: Monte Carlo propagation for a ratio of Gaussians (`code/ch03/06_error_propagation.py`)

```
# ---------- (ii) ratio of Gaussians ----------
mu1, s1, s2 = 10.0, 1.0, 1.0
fig, axs = plt.subplots(1, 3, figsize=(8.0, 2.7))
out = {}
for ax, mu2, c, tag in zip(axs, [10.0, 3.0, 1.0], SERIES, ["A", "B", "C"]):
    x1 = mu1 + s1 * rng.standard_normal(M)
    x2 = mu2 + s2 * rng.standard_normal(M)
    y = x1 / x2
    y0 = mu1 / mu2
    sy = abs(y0) * np.sqrt((s1 / mu1) ** 2 + (s2 / mu2) ** 2)
    lo, med, hi = np.percentile(y, [15.865, 50, 84.135])
    out[tag] = dict(y0=y0, sy=sy, med=med, half=0.5 * (hi - lo),
                    neg=np.mean(y < 0), far=np.mean(np.abs(y - y0) > 5 * sy))
```

The script takes $\mu_1 = 10$, $\sigma_1 = \sigma_2 = 1$ and three denominators, $\mu_2 = 10, 3, 1$ (relative error 0.1, 0.33, 1). For each it draws 10^6 pairs, forms the ratio, and compares the Monte Carlo distribution with the linear prediction. Because the variance may not exist, it measures the width by the half-distance between the 15.9 and 84.1 percentiles (which is σ for a Gaussian), and it counts negative ratios and "5σ" outliers.

	$\sigma_2/\mu_2 = 0.1$	0.33	1
linear prediction $y_0 \pm \sigma_y$	1 ± 0.1414	3.33 ± 1.16	10 ± 10.05
Monte Carlo median	0.9999	3.329	7.083
Monte Carlo central-68% half-width	0.1425	1.294	11.49
fraction with $y < 0$	0	0.001363	0.1589
fraction beyond $5\sigma_y$ (Gaussian: 5.7×10^{-7})	1.600×10^{-4}	0.02883	0.0961

Table 3.1: Linear propagation against Monte Carlo for $y = x_1/x_2$.

At 10% relative error the linear rule is fine in the core (width 0.1425 against 0.1414) but already has 300 times too many 5σ outliers. At 33% the core is 12% wider than predicted and 3% of ratios are beyond "5σ". At 100% the linear answer is meaningless: the median is 7.083, not 10, and 0.1589 of the ratios are negative although both means are positive.

For the pendulum, by contrast, the Monte Carlo spread of g is 0.04375 against the linear 0.04377, and the mean is 9.811 (Figure 3.23).

Taxonomy: Which propagation to use

situation	method
linear function ($\boldsymbol{y} = A\boldsymbol{x}$)	$U = AVA^{\mathsf{T}}$, exact
small relative errors, smooth y	first-order formula; check one case by Monte Carlo
y depends on a quantity whose error is not small (ratio, $1/x$, $\ln x$ near 0)	Monte Carlo propagation: sample inputs, apply y, histogram; quote median and percentiles
$g'(\mu) = 0$ at the input means	second-order delta method, χ^2_1 shape
inputs from an MCMC chain	apply y to every sample of the chain (Chapter 9)

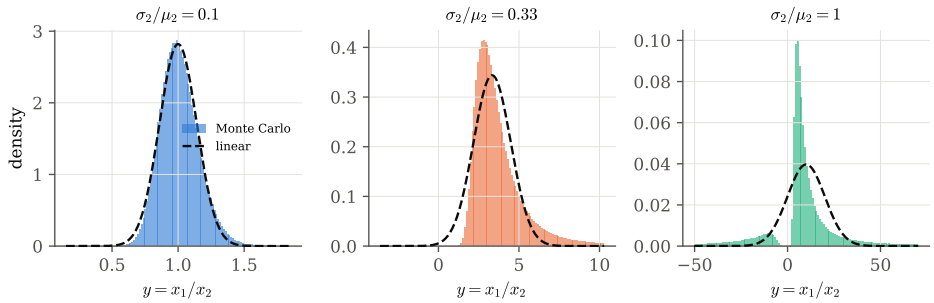

Figure 3.22: The ratio of two Gaussian quantities, simulated (histograms) and by linear propagation (dashed), as the denominator's relative error grows from left to right. At 10% the two agree. At 33% the true distribution is skewed, with a long right tail. At 100% it has a spike near zero, negative values and heavy tails, and bears no resemblance to the Gaussian.

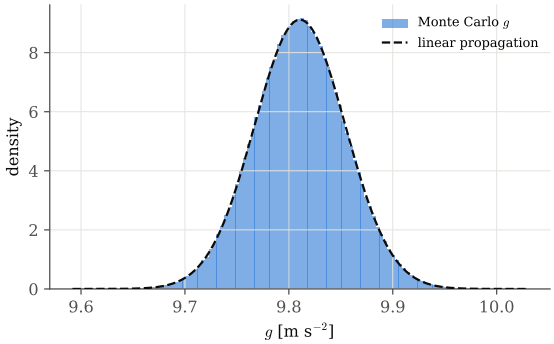

Figure 3.23: Monte Carlo propagation for the pendulum. A million pairs (L, T) drawn from their Gaussian errors give the histogram of g. The linear-propagation Gaussian (dashed) lies on top of it, because the relative errors of 0.2% are tiny compared with the scale on which L/T^2 bends.

Symmetric error bars on a ratio. An efficiency, a branching ratio or a signal-to-background ratio with a poorly known denominator should not be quoted as "central ± symmetric error". The median is shifted, the errors are asymmetric, and the tails are long. Quote percentiles from a Monte Carlo propagation or, better, build a likelihood for the ratio directly (second half of Chapter 3), as Cowan recommends [Cowan p. 22].

What this bought us. To first order, covariances propagate as $U = AVA^{\mathsf{T}}$ with the Jacobian A: absolute errors add in quadrature for sums, relative errors for products, and correlations add $\pm 2\rho\sigma_1\sigma_2$ terms. The rule is exact for linear maps and asymptotically right for smooth functions of estimators (delta method). It fails when the input scatter reaches a region of strong curvature or a pole, and then Monte Carlo propagation is the answer.

How this is used in real research: Verification and research

For the pendulum, Monte Carlo propagation merely verifies the linear formula. For a derived cosmological parameter (the age of the Universe from H_0, Ω_m and Ω_Λ; $S_8 = \sigma_8\sqrt{\Omega_m/0.3}$), the same idea is the working tool: take every sample of a posterior chain, compute the derived quantity, and histogram it. No Jacobian is needed, and correlations and nonlinearity are handled automatically (Chapter 9).

3.7 Combining measurements of different quality: the weighted mean

Eight laboratories have measured the same quantity μ: a particle mass, a lifetime, the Hubble constant. Their error bars range from 0.5 to 3 in some unit. A reviewer asks for one number. The plain average treats the best laboratory and the worst on an equal footing, and that feels wrong. A measurement with a small error bar should count for more. But how much more, and how small is the error of the combination?

One idea settles both questions with the tools we already have. The combination is again an estimator, a recipe applied to the data, so it has a sampling distribution, a bias and a variance (Sections 3.1 and 3.2). Among all unbiased linear recipes we look for the one with the smallest variance. The answer is the **inverse-variance weighted mean**, and the same answer drops out of the Gaussian likelihood, which is our first glimpse of the second half of the chapter. The questions, in order, are these.

1. Which weights w_i make $\sum_i w_i x_i$ unbiased with the smallest variance, and what is that variance?
2. How can we check that the measurements agree well enough for the combination to mean something?
3. What changes when the measurements are correlated, for example because they share a systematic error?
4. What if the readings also contain something we do not want, which enters each of them differently? How do we remove it?

When the readings carry more than the signal. The laboratories differ only in how noisy they are. Readings can also differ in what they contain. At the start of the chapter we wrote every reading as a piece that responds to what we want, plus everything else (3.1). So far, "everything else" has been noise of a known kind: it scatters around zero with a spread we can describe, and it is different in every reading. For that we already have good tools. We average, the noise partly cancels, and the error bar shrinks like $1/\sqrt{N}$.

Sometimes they carry something more than noise. Picture yourself at a noisy party with two microphones, trying to record a friend. She stands between them, so both pick up her voice equally loudly. A loudspeaker plays music, and it stands closer to the second microphone, so there the music is twice as loud. Averaging the two recordings does not help, because the music is not random noise that averages away: it is the same song in both, only louder in one. Yet there is a trick. Double the first recording and subtract the second. The music, twice in each, cancels. The voice, twice minus once, survives. Noise-cancelling headphones work on exactly this principle.

The sky does the same thing to an astronomer. The microwave background has the same brightness at two observing frequencies, while the dust of our own Galaxy is much brighter at the higher one. A calibration drift, a contaminating source, a foreground: whenever the unwanted part has a pattern of its own across the readings, different from the pattern of what we want, we can weight the readings so that the unwanted pattern cancels and the wanted one survives. Each reading gets its own weight, $F = \sum_i w_i x_i$, and the question is which weights to use.

The party in symbols. Call the voice (or the sky signal) s and the music (or the dust) f. It is twice as strong in the second reading, and each reading has its own noise. Combine them with

two numbers w_1, w_2:

$$x_1 = s + f + n_1, \qquad x_2 = s + 2f + n_2,$$
$$w_1 x_1 + w_2 x_2 \overset{(1)}{=} (w_1 + w_2)\, s + (w_1 + 2w_2)\, f + (w_1 n_1 + w_2 n_2). \tag{3.56}$$

(1) Multiply out and collect the terms in s, in f and in the noise.

Each bracket is a dial. The first sets the *normalisation*: unless $w_1 + w_2 = 1$ we are estimating a rescaled signal. The plain difference $x_2 - x_1 = f + n_2 - n_1$ shows how badly this can go: its weights sum to zero, so the signal cancels completely and what is left measures the foreground. The second bracket sets the *contamination*: $w_1 + 2w_2 = 0$ removes f whatever its value. Both conditions together fix the weights, $w_1 = 2$, $w_2 = -1$, and

$$2x_1 - x_2 \overset{(1)}{=} s + (2n_1 - n_2), \qquad \mathrm{Var}(2x_1 - x_2) \overset{(2)}{=} 4\sigma_1^2 + \sigma_2^2. \tag{3.57}$$

(1) (3.56) with $w_1 + w_2 = 1$ and $w_1 + 2w_2 = 0$.
(2) Independent noises: variances add, each weighted by w_i^2 (3.19).

The foreground is gone exactly, the signal keeps its unit normalisation, and the price is noise: with $\sigma_1 = \sigma_2 = \sigma$ the clean combination has variance $5\sigma^2$, ten times the $\sigma^2/2$ of the plain average $(x_1 + x_2)/2$, which in exchange keeps $1.5f$ of foreground. Weights that cancel unwanted pieces are easy to find; weights that also keep the noise small are a trade-off. Lesson: a linear combination can switch off anything whose response across the readings differs from that of s, while one constraint, $\sum_i w_i = 1$ for a signal that enters every reading equally, keeps s itself intact; the rest is the choice of the least noisy weights among those allowed.

A picture: weights point in a direction. Write the two readings as one list, $\boldsymbol{x} = (x_1, x_2)^\mathsf{T}$. The signal enters both readings equally, with the pattern $\boldsymbol{a} = (1, 1)^\mathsf{T}$; the dust enters with the pattern $\boldsymbol{c} = (1, 2)^\mathsf{T}$. The weights are a third list, $\boldsymbol{w} = (w_1, w_2)^\mathsf{T}$, and a weighted sum multiplies matching entries and adds them up. That is a dot product, so the readings and the two dials become

$$\boldsymbol{x} = \boldsymbol{a}\, s + \boldsymbol{c}\, f + \boldsymbol{n} \qquad \Longrightarrow \qquad \boldsymbol{w}^\mathsf{T}\boldsymbol{x} \overset{(1)}{=} (\boldsymbol{w}^\mathsf{T}\boldsymbol{a})\, s + (\boldsymbol{w}^\mathsf{T}\boldsymbol{c})\, f + \boldsymbol{w}^\mathsf{T}\boldsymbol{n}. \tag{3.58}$$

(1) Multiply each term by $\boldsymbol{w}^\mathsf{T}$; a number in front of a list comes out of the dot product.

For the weights $\boldsymbol{w} = (2, -1)^\mathsf{T}$ the signal gives $2 \cdot 1 - 1 \cdot 1 = 1$ and survives; the dust gives $2 \cdot 1 - 1 \cdot 2 = 0$ and vanishes. In the language of geometry, $\boldsymbol{w}$ points at right angles to the dust's pattern, so it is blind to the dust however bright it is.

Figure 3.24 shows what the weighted sum does to a point. Lay a ruler along $\boldsymbol{w}$, marked so that it reads $\boldsymbol{w}^\mathsf{T}\boldsymbol{x}$, and drop the data straight down onto it, at right angles. Where the point lands is the reading. Because the ruler stands at right angles to everything else, sliding the point in that direction does not move its shadow: the data and the signal alone land on the same mark. Only the signal moves the shadow along the ruler.

So $\boldsymbol{w}$ is a filter. It asks one question of the data: how much of the pattern we want is here, ignoring everything else? Notice that it does not point along the signal. It points where it must to be blind to everything else, so its direction is set as much by what we ignore as by what we want; only when the rest is plain noise does it line up with the signal itself. Choosing weights is choosing a direction: one that sees what we want and is blind to what we do not. With more readings there is room to be blind to more unwanted patterns at once, and finding the weights is a small set of linear equations. When the unwanted patterns are not known exactly, or the noise matters as much as they do, we look instead for the direction along which the combination scatters least, and that search is the rest of this section.

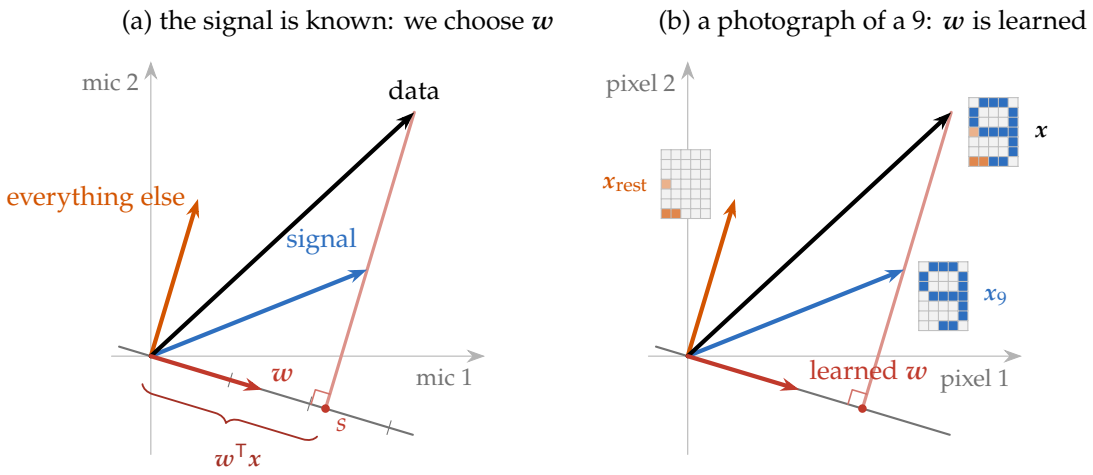

Figure 3.24: Choosing w when the signal is known, and learning it when it is not. (a) The data are the signal plus everything else. The weights w point along a ruler at right angles to everything else, and the reading $w^\top x$ is where the data fall when dropped straight onto it; the tip of the signal lies on the same drop line, so the data and the signal alone give the same reading. The two patterns are drawn further apart than at the party, so that the angles are easy to see. (b) The same split for a photograph of a 9. A picture is a long list of pixel values, so it is a vector too, drawn here in two of its many directions: the pixels of the written 9 are the signal, the paper, a smudge and uneven light are everything else, and the photograph is their sum, as in the first row of Figure 3.25. A network is not told this split; training finds weights whose reading keeps the 9 and ignores the rest, and so decides what counts as the signal.

The universal principle. The two microphones did one thing: each recording was the voice plus everything else, and the weights kept the voice and dropped the rest. Every weighted sum in this section does the same, and so, it turns out, does almost every analysis in the book. What makes it possible is a **feature**: a property that the part we want has and the rest does not. At the party it is how loud each source is in each microphone: the voice equally loud in both, the music twice as loud in one. Building a quantity that keeps the wanted feature and drops the others is **feature extraction**, and the weighted sum is its simplest form. The principle has one hard limit: without a feature there is no separation. Put the loudspeaker right next to your friend, and voice and music arrive equally loud in both microphones; no weights can pull them apart, because weights can use a difference the data contain but cannot invent one.

The principle does not stop at simple problems; even an artificial neural network runs on it. Suppose someone has written the digit 9 on a sheet of paper, we photograph it, and a network must tell from the photograph which digit was written. The photograph is a grid of pixel values: the pixels of the written 9, plus the paper, a smudge, uneven light. A grid of numbers is a long list of numbers, so the photograph is a vector, and this split is the same as the microphones' (Figure 3.24b). A first layer of weighted sums extracts the feature we want, the pixels that belong to the number. Those pixels are in turn a few shapes, a loop and a stroke running down from it, plus details that do not matter, such as the size of the loop; the next layer extracts the shapes. The last layers turn the shapes into the answer: one loop alone is a 0, two loops stacked are an 8, a loop on top with a tail below is a 9. Each layer is a set of weighted sums, each bent by a fixed curve, and each takes what the layer before it kept as its new data. The only real difference from our two microphones is where the weights come from: a network learns them from many labelled examples, while we work ours out from what we know about the patterns and the noise. So even the most complicated network is a long chain of the step we have just taken: isolate one feature, then the next. Figure 3.25 writes it with the same bookkeeping as the party, $x = a\,s + c\,f + n$: at each step the data are split into the part we

want plus the rest, and weights keep the part we want.

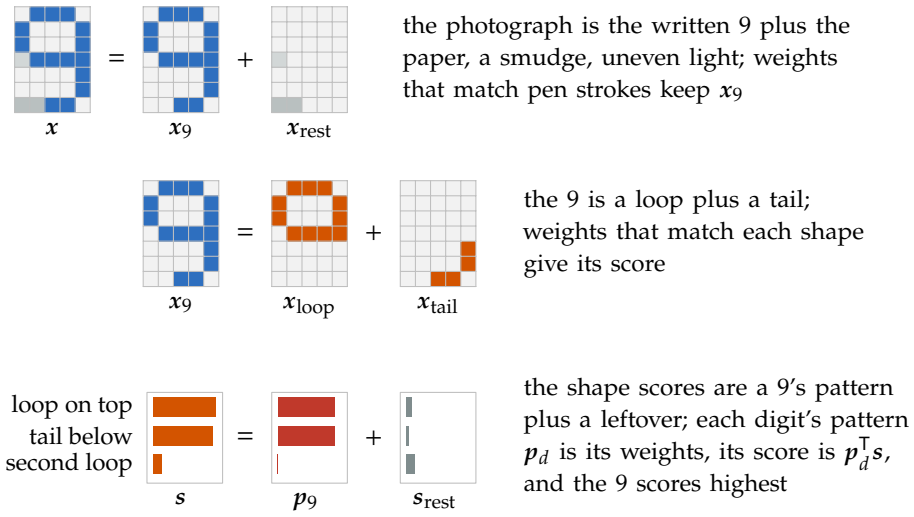

Figure 3.25: Reading a handwritten 9 with the idea of the two microphones, used again and again. Each row has the form *data = what we want + the rest*, exactly like $\boldsymbol{x} = \boldsymbol{a}\,s + \boldsymbol{c}\,f + \boldsymbol{n}$, and a set of weights keeps what we want: a weighted sum $\boldsymbol{w}^{\mathsf{T}}\boldsymbol{x}$ whose weights match the wanted pattern, bent by a fixed curve such as $\max(0, z)$. What one row keeps is the data of the next; in the last row the data are the shape scores, and each digit's weights are its own pattern of shapes. A neural network is this chain with many rows, and with weights learned from labelled examples.

The loop and the tail in the figure are our names, chosen so that the steps are easy to follow. A trained network need not split the 9 this way. Training fixes its weights, and the weights fix the split: at every layer, whatever the weights read becomes that layer's signal, and whatever they are blind to becomes its everything else, just as in Figure 3.24b. The pieces a real network ends up reading are often not shapes we would name. What carries over is the principle. Every layer splits its input into a part it keeps and a part it ignores, and it keeps that part with a weighted sum, the dot product of the two microphones, repeated many times and chained. Readings, patterns and weights are all lists of numbers, so the natural language for all of it is linear algebra.

We start with the simplest case: readings of different quality, no contaminant, and weights chosen so the combination scatters as little as possible. Section 3.7.4 then lets the unwanted pieces be shared between readings, and the same formula becomes the method used to separate the microwave background from the Galaxy.

3.7.1 The best linear combination

Let the measurements $x_1, \ldots, x_N$ be independent, each unbiased, $\mathbb{E}\,x_i = \mu$, with known standard deviations σ_i that differ from one measurement to the next. We try a *linear* recipe $\hat{\mu} = \sum_i w_i x_i$ with numbers w_i still to be chosen. Two properties follow at once:

$$\mathbb{E}\,\hat{\mu} \overset{(1)}{=} \sum_i w_i\,\mathbb{E}\,x_i \overset{(2)}{=} \mu \sum_i w_i, \tag{3.59}$$

$$\operatorname{Var}\hat{\mu} \overset{(3)}{=} \sum_i w_i^2\,\operatorname{Var}x_i \overset{(4)}{=} \sum_i w_i^2\sigma_i^2. \tag{3.60}$$

(1) Linearity of expectation.
(2) Every measurement is unbiased, $\mathbb{E}\,x_i = \mu$.

(3) Variance of a sum (3.19): the covariances vanish because the x_i are independent, and a constant factor comes out squared, $\operatorname{Var}(wx) = w^2 \operatorname{Var} x$.
(4) $\operatorname{Var} x_i = \sigma_i^2$.

So $\hat{\mu}$ is unbiased for every value of μ exactly when the weights sum to one, $\sum_i w_i = 1$. Its mean squared error is then just its variance (3.13), and we want the weights that make $\sum_i w_i^2 \sigma_i^2$ as small as possible under that one constraint.

Minimising with a Lagrange multiplier. Recall the method from mechanics: to minimise $f(\boldsymbol{w})$ subject to $g(\boldsymbol{w}) = 0$, look for points where the gradient of f is parallel to the gradient of g, that is, where the gradient of $f - \lambda g$ vanishes for some number λ (the multiplier). Here $f = \sum_i w_i^2 \sigma_i^2$ and $g = \sum_i w_i - 1$:

$$
\begin{aligned}
0 &\overset{(1)}{=} \frac{\partial}{\partial w_k}\Big[\sum_i w_i^2\sigma_i^2 - \lambda\Big(\sum_i w_i - 1\Big)\Big] \overset{(2)}{=} 2w_k\sigma_k^2 - \lambda \quad\Longrightarrow\quad w_k = \frac{\lambda}{2\sigma_k^2}, \\
1 &\overset{(3)}{=} \sum_k w_k = \frac{\lambda}{2}\sum_k \frac{1}{\sigma_k^2} \quad\Longrightarrow\quad \frac{\lambda}{2} = \frac{1}{W}, \qquad W \equiv \sum_{k=1}^{N} \frac{1}{\sigma_k^2}, \\
w_k &\overset{(4)}{=} \frac{1/\sigma_k^2}{W}, \qquad \operatorname{Var}\hat{\mu} \overset{(5)}{=} \sum_k \frac{1}{\sigma_k^4 W^2}\,\sigma_k^2 = \frac{1}{W^2}\sum_k \frac{1}{\sigma_k^2} = \frac{1}{W}.
\end{aligned}
\tag{3.61}
$$

(1) Stationarity of $f - \lambda g$ in each w_k.
(2) Only the $i = k$ terms depend on w_k: $\partial(w_k^2\sigma_k^2)/\partial w_k = 2w_k\sigma_k^2$ and $\partial w_k/\partial w_k = 1$.
(3) Impose the constraint $\sum_k w_k = 1$ to fix λ.
(4) Insert $\lambda/2 = 1/W$ into $w_k = \lambda/(2\sigma_k^2)$.
(5) Insert these weights into (3.60).

A stationary point need not be a minimum. One inequality settles it: no other unbiased linear recipe does better. For any weights with $\sum_i w_i = 1$, the Cauchy–Schwarz inequality $(\sum_i a_i b_i)^2 \le \sum_i a_i^2 \sum_i b_i^2$ with $a_i = w_i\sigma_i$ and $b_i = 1/\sigma_i$ gives

$$
1 \overset{(1)}{=} \Big(\sum_i w_i\Big)^2 \overset{(2)}{=} \Big(\sum_i w_i\sigma_i \cdot \frac{1}{\sigma_i}\Big)^2 \overset{(3)}{\le} \sum_i w_i^2\sigma_i^2 \sum_i \frac{1}{\sigma_i^2} \overset{(4)}{=} \operatorname{Var}\hat{\mu}\cdot W. \tag{3.62}
$$

(1) The weights sum to one.
(2) Multiply and divide each term by σ_i.
(3) Cauchy–Schwarz. Equality holds only when $a_i \propto b_i$, that is $w_i\sigma_i \propto 1/\sigma_i$, or $w_i \propto 1/\sigma_i^2$.
(4) (3.60) and the definition of W.

So $\operatorname{Var}\hat{\mu} \ge 1/W$ for every unbiased linear combination, and the inverse-variance weights are the only ones that reach the bound.

Working definition 3.9 (inverse-variance weighted mean)

For independent unbiased measurements x_i of one quantity, with standard deviations σ_i,

$$
\hat{\mu} = \frac{\sum_i x_i/\sigma_i^2}{\sum_i 1/\sigma_i^2}, \qquad \sigma_{\hat{\mu}} = \Big(\sum_i \frac{1}{\sigma_i^2}\Big)^{-1/2}.
$$

Each measurement is weighted by its inverse variance $1/\sigma_i^2$ [a measurement twice as precise counts four times as much]. This is the unbiased linear combination with the smallest variance [Cowan (7.26)–(7.27)], [Sivia (2.30)–(2.31)].

What the formula says. Three consequences are worth reading off. First, since $W \geq 1/\sigma_k^2$ for every single k, the combined variance $1/W$ is never larger than the smallest individual variance: adding a measurement, however poor, never hurts [Cowan p. 107]. Second, if one measurement is much more precise than the rest, it dominates both W and the weighted sum, and the combination is essentially that measurement. Third, if all errors are equal, $\sigma_i = \sigma$, the weights are all $1/N$ and $\operatorname{Var}\hat{\mu} = \sigma^2/N$, the familiar variance of the sample mean (3.20).

Two pictures from physics make the formula feel familiar. Inverse variances add like the conductances of resistors in parallel, $1/R = \sum_i 1/R_i$: the combined "resistance to knowing μ" is smaller than the smallest single one. And $\hat{\mu}$ is the centre of mass of the points x_i with masses $1/\sigma_i^2$; a precise measurement is a heavy mass that drags the centre towards itself. Later we will call $1/\sigma^2$ the **information** carried by a measurement, and the statement "the information of independent measurements adds" becomes the additivity of Fisher matrices (Chapter 10).

The same answer from least squares and the likelihood. Suppose, in addition, that each x_i is Gaussian, $x_i \sim \mathcal{N}(\mu, \sigma_i^2)$. The probability density of the whole data set, read as a function of μ, is $\prod_i (2\pi\sigma_i^2)^{-1/2} \exp[-(x_i-\mu)^2/2\sigma_i^2]$, so its logarithm is a constant minus $\frac{1}{2}\chi^2(\mu)$ with

$$\chi^2(\mu) = \sum_{i=1}^{N} \frac{(x_i - \mu)^2}{\sigma_i^2} \tag{3.63}$$

[Cowan (7.25)]. Making the density as large as possible means making χ^2 as small as possible. We complete the square in μ:

$$\begin{aligned}
\chi^2(\mu) &\overset{(1)}{=} \sum_i \frac{x_i^2}{\sigma_i^2} - 2\mu \sum_i \frac{x_i}{\sigma_i^2} + \mu^2 \sum_i \frac{1}{\sigma_i^2} \\
&\overset{(2)}{=} \sum_i \frac{x_i^2}{\sigma_i^2} - 2\mu W\hat{\mu} + \mu^2 W \\
&\overset{(3)}{=} W(\mu - \hat{\mu})^2 + \left[\sum_i \frac{x_i^2}{\sigma_i^2} - W\hat{\mu}^2\right] \overset{(4)}{=} W(\mu - \hat{\mu})^2 + \chi^2_{\min}.
\end{aligned} \tag{3.64}$$

(1) Expand $(x_i - \mu)^2 = x_i^2 - 2\mu x_i + \mu^2$ and sum term by term.
(2) $\sum_i x_i/\sigma_i^2 = W\hat{\mu}$ by the definition of the weighted mean, and $\sum_i 1/\sigma_i^2 = W$.
(3) Add and subtract $W\hat{\mu}^2$: $\mu^2 W - 2\mu W\hat{\mu} + W\hat{\mu}^2 = W(\mu - \hat{\mu})^2$.
(4) The bracket does not depend on μ. It is the value of χ^2 at $\mu = \hat{\mu}$, which we call $\chi^2_{\min}$.

So χ^2 is a parabola in μ with its minimum exactly at the weighted mean [Cowan (7.26)]. Its curvature is $\mathrm{d}^2\chi^2/\mathrm{d}\mu^2 = 2W$, and the density of the data, as a function of μ, is proportional to $\exp[-W(\mu - \hat{\mu})^2/2]$: a Gaussian bump of width $W^{-1/2} = \sigma_{\hat{\mu}}$. So the width of the bump is exactly the error bar we derived from the sampling distribution.

Two more facts can be read off the parabola, and both return in the second half of the chapter. First, the variance is "two over the curvature of χ^2": $\sigma^2_{\hat{\mu}} = 1/W = 2/(2W)$ [Cowan (7.27)], [Sivia (2.31)]. Second, moving μ one standard error away from $\hat{\mu}$ raises χ^2 by exactly 1, because $W\sigma^2_{\hat{\mu}} = 1$. The same formulas also appear as the peak and width of a Bayesian posterior with a flat prior [Sivia pp. 30–31]. For Gaussian data and a flat prior the two readings coincide.

Key idea: Inverse-variance weighting

To combine independent unbiased measurements, weight each by $1/\sigma_i^2$. Inverse variances add: $1/\sigma_{\hat\mu}^2 = \sum_i 1/\sigma_i^2$. For correlated measurements with covariance V, the weights become $\boldsymbol{w} = V^{-1}\mathbf{1}/(\mathbf{1}^{\mathsf T}V^{-1}\mathbf{1})$ and $1/\sigma_{\hat\mu}^2 = \mathbf{1}^{\mathsf T}V^{-1}\mathbf{1}$ (Section 3.7.4).

Example: two measurements of a mass. Two experiments report $x_1 = 10.0 \pm 0.3$ and $x_2 = 10.8 \pm 0.4$ (in GeV). The weights and the combination are

$$\frac{1}{\sigma_1^2} = \frac{1}{0.09} = 11.11, \qquad \frac{1}{\sigma_2^2} = \frac{1}{0.16} = 6.25, \qquad W \overset{(1)}{=} 17.36,$$
$$\hat\mu \overset{(2)}{=} \frac{11.11\times 10.0 + 6.25\times 10.8}{17.36} = \frac{111.1 + 67.5}{17.36} = 10.29, \qquad \sigma_{\hat\mu} \overset{(3)}{=} \frac{1}{\sqrt{17.36}} = 0.24.$$

(1) W is the sum of the inverse variances.
(2) Weighted mean. The first measurement carries weight $11.11/17.36 = 0.64$.
(3) $\sigma_{\hat\mu} = W^{-1/2}$.

The result, 10.29 ± 0.24, is closer to the more precise measurement and is more precise than either. The plain average 10.4 would have the error $\frac{1}{2}\sqrt{0.09 + 0.16} = 0.25$, slightly worse, and would be pulled towards the poorer measurement.

Example: equal errors and one outstanding measurement. Take $N - 1$ measurements with error σ and one with error σ/k. Then $W = (N-1)/\sigma^2 + k^2/\sigma^2$, and the precise measurement carries the weight

$$w_{\text{best}} \overset{(1)}{=} \frac{k^2/\sigma^2}{(N - 1 + k^2)/\sigma^2} = \frac{k^2}{N - 1 + k^2}, \qquad \sigma_{\hat\mu} \overset{(2)}{=} \frac{\sigma}{\sqrt{N - 1 + k^2}}.$$

(1) (3.61), with the common factor $1/\sigma^2$ cancelled.
(2) $\sigma_{\hat\mu} = W^{-1/2}$.

One measurement ten times more precise ($k = 10$) is worth $k^2 = 100$ ordinary ones: with $N - 1 = 9$ ordinary measurements it carries $100/109 = 92\%$ of the weight. Precision is worth its square.

3.7.2 Do the measurements agree? The χ^2 of the residuals

The error $\sigma_{\hat\mu} = W^{-1/2}$ uses only the quoted σ_i, never the spread of the x_i themselves. Two measurements 10.0 ± 0.3 and 10.8 ± 0.4 give the same $\sigma_{\hat\mu}$ as 10.0 ± 0.3 and 15.0 ± 0.4, although the second pair plainly contradicts itself. The value of χ^2 at its minimum is the missing check: it measures how far the data scatter about $\hat\mu$ in units of their own error bars.

What value should we expect? Write $z_i = (x_i - \mu)/\sigma_i$ for the standardised errors: they are independent with mean 0 and variance 1. Then

$$\chi^2_{\min} \overset{(1)}{=} \sum_i \frac{\big[(x_i - \mu) - (\hat\mu - \mu)\big]^2}{\sigma_i^2}$$
$$\overset{(2)}{=} \sum_i z_i^2 - 2(\hat\mu - \mu)\sum_i \frac{x_i - \mu}{\sigma_i^2} + (\hat\mu - \mu)^2 W$$

$$\overset{(3)}{=} \sum_i z_i^2 - 2(\hat\mu-\mu)^2 W + (\hat\mu-\mu)^2 W = \sum_i z_i^2 - W(\hat\mu-\mu)^2,$$

$$\mathbb{E}\,\chi^2_{\min} \overset{(4)}{=} N - W\cdot\frac{1}{W} = N-1. \tag{3.65}$$

(1) Add and subtract the true μ inside $x_i-\hat\mu$.
(2) Expand the square. The first term is z_i^2, and $\sum_i 1/\sigma_i^2 = W$.
(3) $\sum_i (x_i-\mu)/\sigma_i^2 = \sum_i x_i/\sigma_i^2 - \mu W = W(\hat\mu-\mu)$.
(4) $\mathbb{E}\,z_i^2 = 1$ for each of the N terms, and $\mathbb{E}(\hat\mu-\mu)^2 = \operatorname{Var}\hat\mu = 1/W$ because $\hat\mu$ is unbiased.

This is the weighted twin of the $N-1$ in the sample variance (Section 3.4.1): fitting one parameter to the data uses up one of the N independent directions of scatter. For Gaussian measurements the geometry of Section 3.4.1 goes through unchanged in the rescaled coordinates z_i. The noise vector $(z_1,\dots,z_N)$ is isotropic, the fit removes its component along the single direction $(1/\sigma_1,\dots,1/\sigma_N)$, and the remaining $N-1$ perpendicular components are independent standard normals. Hence

$$\chi^2_{\min} \sim \chi^2_{N-1}, \qquad \mathbb{E}\,\chi^2_{\min} = N-1, \qquad \operatorname{Var}\chi^2_{\min} = 2(N-1), \tag{3.66}$$

with the χ^2 distribution of Chapter 2. A value of $\chi^2_{\min}/(N-1)$ near 1 says the scatter matches the error bars. A value far above 1 says it does not.

Example: the two masses again. For two measurements, $\chi^2_{\min}$ depends only on their difference. With $w_1 = W^{-1}/\sigma_1^2$ and $w_2 = 1-w_1$,

$$\chi^2_{\min} \overset{(1)}{=} \frac{(x_1-\hat\mu)^2}{\sigma_1^2} + \frac{(x_2-\hat\mu)^2}{\sigma_2^2} \overset{(2)}{=} (x_1-x_2)^2\Big[\frac{w_2^2}{\sigma_1^2} + \frac{w_1^2}{\sigma_2^2}\Big] \overset{(3)}{=} \frac{(x_1-x_2)^2}{\sigma_1^2+\sigma_2^2},$$
$$\overset{(4)}{=} \frac{(10.0-10.8)^2}{0.09+0.16} = \frac{0.64}{0.25} = 2.56.$$

(1) Definition (3.63) at $\mu=\hat\mu$.
(2) $x_1-\hat\mu = x_1 - w_1x_1 - w_2x_2 = w_2(x_1-x_2)$, and likewise $x_2-\hat\mu = -w_1(x_1-x_2)$.
(3) $w_1 = \sigma_2^2/(\sigma_1^2+\sigma_2^2)$ and $w_2 = \sigma_1^2/(\sigma_1^2+\sigma_2^2)$ (multiply numerator and denominator of w_1 by $\sigma_1^2\sigma_2^2$). The bracket becomes $\big[\sigma_1^4/\sigma_1^2 + \sigma_2^4/\sigma_2^2\big]/(\sigma_1^2+\sigma_2^2)^2 = 1/(\sigma_1^2+\sigma_2^2)$.
(4) Insert the numbers.

The result is natural: x_1-x_2 has mean zero if both measure the same μ and variance $\sigma_1^2+\sigma_2^2$ (3.48), so $\chi^2_{\min}$ is the squared number of standard deviations by which the two disagree, here 1.6. For one degree of freedom, a value of 2.56 or more occurs in 11% of repetitions when both measurements are right, so the pair is acceptable. (This is a first p-value; Chapter 4 develops them properly.) The contradictory pair 10.0 ± 0.3 and 15.0 ± 0.4 gives $\chi^2_{\min} = 25/0.25 = 100$, a ten-standard-deviation disagreement.

What to do when they disagree. A large $\chi^2_{\min}$ means that at least one error bar is underestimated, or that the measurements do not in fact measure the same thing. There is no purely statistical cure. A common convention, used for example in particle-physics averages, is to inflate the combined error by the factor $\sqrt{\chi^2_{\min}/(N-1)}$ when that factor exceeds one. This is equivalent to assuming that every quoted σ_i is too small by the same unknown factor, and it is only as good as that assumption.

Watch out: A tiny error bar from inconsistent data

The formula $\sigma_{\hat{\mu}} = W^{-1/2}$ never looks at the data, so it happily returns a small error for measurements that contradict each other. Always report $\chi^2_{\min}$ and $N-1$ with a weighted mean. When two precise determinations disagree by several standard deviations (as early- and late-Universe measurements of H_0 do in the Hubble tension of Section T2.12.3), their weighted mean is a number that neither experiment supports, and its error bar is meaningless.

3.7.3 Eight laboratories in Python

A simulation checks every claim. The eight laboratories have $\sigma_i = 0.5, 0.7, 1.0, 1.2, 1.5, 2.0, 2.5$ and 3.0, and the true value is $\mu = 0$. We repeat the whole campaign of eight measurements 200 000 times and compute, in each repetition, the plain average, the weighted mean and $\chi^2_{\min}$.

Listing 3.7: Eight laboratories, many times over (`code/ch03/07_weighted_mean.py`)

```
# ---------- (i) eight labs ----------
mu = 0.0
sig = np.array([0.5, 0.7, 1.0, 1.2, 1.5, 2.0, 2.5, 3.0])
N = len(sig)
x = mu + sig * rng.standard_normal((M, N))
w = 1 / sig**2
xw = (x * w).sum(1) / w.sum()
xu = x.mean(1)
chi2 = (((x - xw[:, None]) / sig) ** 2).sum(1)
sd_w_th = 1 / np.sqrt(w.sum())
sd_u_th = np.sqrt((sig**2).sum()) / N
```

The array `x` has one row per repetition and one column per laboratory; multiplying standard normals by the row vector `sig` gives each column its own error bar (numpy broadcasting). The weights `w` are the inverse variances. The weighted mean of each row is the weighted sum divided by `w.sum()`, which is W. In the line for `chi2`, `xw[:, None]` turns the vector of weighted means into a column, so that each row's own $\hat{\mu}$ is subtracted from that row's eight measurements. The last two lines are the predictions, $W^{-1/2}$ for the weighted mean and $\sqrt{\sum_i \sigma_i^2}/N$ for the plain average (the variance of a sum of independent terms divided by N^2).

The weighted mean scatters with standard deviation 0.3391, against the prediction $W^{-1/2} = 0.339$. The plain average scatters with 0.6228, against the prediction $\sqrt{24.68}/8 = 0.621$. The plain average is not merely worse than the weighted mean: it is worse than the best laboratory on its own, whose error is 0.5. Averaging in poor measurements with equal weight destroys information. The simulated $\chi^2_{\min}$ has mean 6.998 and variance 14.05, against $N-1 = 7$ and $2(N-1) = 14$ from (3.66), and Figure 3.26 shows that its whole histogram is χ^2_7.

3.7.4 Correlated measurements

Measurements are often correlated. Two analyses may use the same data in part, the same luminosity, the same energy calibration (Section 3.6.1) or the same theory input. Let the measurements $\boldsymbol{x} = (x_1, \ldots, x_N)^{\mathsf{T}}$ be unbiased, $\mathbb{E}\, x_i = \mu$, with a known covariance matrix V, and write $\mathbf{1} = (1, \ldots, 1)^{\mathsf{T}}$ for the column of ones. The linear combination $\hat{\mu} = \boldsymbol{w}^{\mathsf{T}}\boldsymbol{x}$ is still unbiased exactly when $\mathbf{1}^{\mathsf{T}}\boldsymbol{w} = \sum_i w_i = 1$ [Cowan (7.31)–(7.32)], since the derivation of (3.59) never used independence. Its variance is the error-propagation formula (3.47) with the $1 \times N$ Jacobian

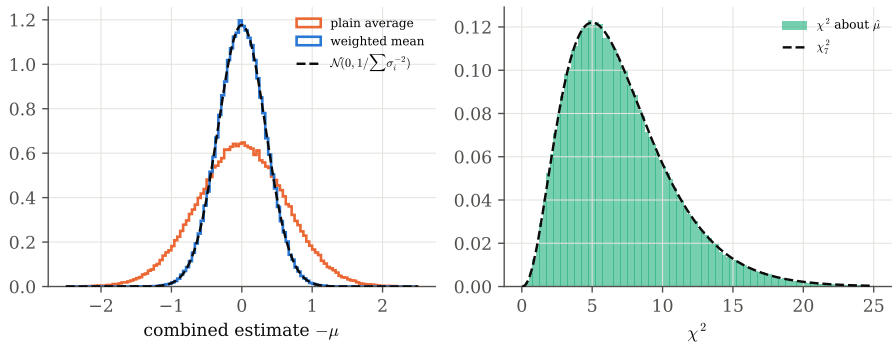

Figure 3.26: Left: over many repetitions of the eight-laboratory campaign, the weighted mean (blue) is a narrow Gaussian of width $W^{-1/2}$ (dashed), while the plain average (orange) is almost twice as wide. Right: the histogram of $\chi^2_{\min}$ about the weighted mean lies on the χ^2 curve with $7 = N - 1$ degrees of freedom, not 8.

$A = \boldsymbol{w}^{\mathsf{T}}$, and this is exact because the map is linear (Section 3.6.2):

$$\operatorname{Var}\hat{\mu} = \sum_{i,j} w_i V_{ij} w_j = \boldsymbol{w}^{\mathsf{T}} V \boldsymbol{w} \tag{3.67}$$

[Cowan (7.33)]. We minimise it with a multiplier as before (Cowan eliminates w_N instead; a multiplier is quicker):

$$\begin{aligned} \mathbf{0} &\overset{(1)}{=} \nabla_{\boldsymbol{w}} \left[\boldsymbol{w}^{\mathsf{T}} V \boldsymbol{w} - \lambda(\mathbf{1}^{\mathsf{T}}\boldsymbol{w} - 1) \right] \overset{(2)}{=} 2V\boldsymbol{w} - \lambda\mathbf{1} \quad \Longrightarrow \quad \boldsymbol{w} = \frac{\lambda}{2} V^{-1}\mathbf{1}, \\ 1 &\overset{(3)}{=} \mathbf{1}^{\mathsf{T}}\boldsymbol{w} = \frac{\lambda}{2}\,\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1} \quad \Longrightarrow \quad \boldsymbol{w} = \frac{V^{-1}\mathbf{1}}{\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1}}, \\ \operatorname{Var}\hat{\mu} &\overset{(4)}{=} \frac{\mathbf{1}^{\mathsf{T}}V^{-1}\,V\,V^{-1}\mathbf{1}}{(\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1})^2} = \frac{1}{\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1}}. \end{aligned} \tag{3.68}$$

(1) Stationarity in all w_k at once.
(2) $\partial(\boldsymbol{w}^{\mathsf{T}}V\boldsymbol{w})/\partial w_k = \sum_j (V_{kj} + V_{jk}) w_j = 2(V\boldsymbol{w})_k$, because V is symmetric.
(3) Impose the constraint to fix λ.
(4) Insert $\boldsymbol{w}$ into (3.67). V^{-1} is symmetric, so $\boldsymbol{w}^{\mathsf{T}} = \mathbf{1}^{\mathsf{T}}V^{-1}/(\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1})$, and $V^{-1}VV^{-1} = V^{-1}$.

In components, $w_i = \sum_j (V^{-1})_{ij} \,/\, \sum_{k,l} (V^{-1})_{kl}$ [Cowan (7.30)]. For uncorrelated measurements $(V^{-1})_{ij} = \delta_{ij}/\sigma_i^2$ and we are back at (3.61). The same weights minimise the generalised $\chi^2(\mu) = (\boldsymbol{x} - \mu\mathbf{1})^{\mathsf{T}} V^{-1} (\boldsymbol{x} - \mu\mathbf{1})$ [Cowan (7.28)], whose derivative $-2\mathbf{1}^{\mathsf{T}}V^{-1}(\boldsymbol{x} - \mu\mathbf{1})$ vanishes at $\mu = \mathbf{1}^{\mathsf{T}}V^{-1}\boldsymbol{x}/\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1}$. That this least-squares combination is also the minimum-variance unbiased linear one is an instance of the Gauss–Markov theorem [Cowan p. 108].

Two correlated measurements. Two measurements already show every new effect of correlation. With correlation coefficient ρ,

$$V = \begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix}, \qquad V^{-1} = \frac{1}{1-\rho^2} \begin{pmatrix} \dfrac{1}{\sigma_1^2} & \dfrac{-\rho}{\sigma_1\sigma_2} \\ \dfrac{-\rho}{\sigma_1\sigma_2} & \dfrac{1}{\sigma_2^2} \end{pmatrix} \tag{3.69}$$

[Cowan (7.34)–(7.35)]. (Check: the inverse of $\left(\begin{smallmatrix} a & b \\ b & d \end{smallmatrix}\right)$ is $\left(\begin{smallmatrix} d & -b \\ -b & a \end{smallmatrix}\right)/(ad - b^2)$, and here $ad - b^2 = \sigma_1^2\sigma_2^2(1-\rho^2)$.) Then

$$\mathbf{1}^{\mathsf{T}} V^{-1}\mathbf{1} \overset{(1)}{=} \frac{1}{1-\rho^2}\Big[\frac{1}{\sigma_1^2} + \frac{1}{\sigma_2^2} - \frac{2\rho}{\sigma_1\sigma_2}\Big] \overset{(2)}{=} \frac{\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2}{(1-\rho^2)\sigma_1^2\sigma_2^2}, \tag{3.70}$$

$$w \equiv w_1 \overset{(3)}{=} \frac{\big[1/\sigma_1^2 - \rho/(\sigma_1\sigma_2)\big]/(1-\rho^2)}{\mathbf{1}^{\mathsf{T}} V^{-1}\mathbf{1}} \overset{(4)}{=} \frac{\sigma_2^2 - \rho\sigma_1\sigma_2}{\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2}, \qquad w_2 = 1 - w, \tag{3.71}$$

$$\operatorname{Var}\hat{\mu} \overset{(5)}{=} \frac{(1-\rho^2)\sigma_1^2\sigma_2^2}{\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2} \tag{3.72}$$

[Cowan (7.36)–(7.39)].

(1) The sum of all four entries of V^{-1}.
(2) Common denominator $\sigma_1^2\sigma_2^2$.
(3) $(V^{-1}\mathbf{1})_1$ is the sum of the first row of V^{-1}.
(4) Multiply numerator and denominator by $(1-\rho^2)\sigma_1^2\sigma_2^2$.
(5) $\operatorname{Var}\hat{\mu} = 1/(\mathbf{1}^{\mathsf{T}} V^{-1}\mathbf{1})$ from (3.68) and (3.70).

How much does the second measurement help? Subtract the information of the first alone:

$$\frac{1}{\operatorname{Var}\hat{\mu}} - \frac{1}{\sigma_1^2} \overset{(1)}{=} \frac{1}{1-\rho^2}\Big[\frac{1}{\sigma_1^2} + \frac{1}{\sigma_2^2} - \frac{2\rho}{\sigma_1\sigma_2} - \frac{1-\rho^2}{\sigma_1^2}\Big] \overset{(2)}{=} \frac{1}{1-\rho^2}\Big[\frac{\rho^2}{\sigma_1^2} - \frac{2\rho}{\sigma_1\sigma_2} + \frac{1}{\sigma_2^2}\Big] \overset{(3)}{=} \frac{1}{1-\rho^2}\Big(\frac{\rho}{\sigma_1} - \frac{1}{\sigma_2}\Big)^2. \tag{3.73}$$

(1) (3.70), with $1/\sigma_1^2$ written over the same denominator $1-\rho^2$.
(2) $1/\sigma_1^2 - (1-\rho^2)/\sigma_1^2 = \rho^2/\sigma_1^2$.
(3) The bracket is a perfect square.

This is never negative [Cowan (7.40)]: a second measurement never hurts, even a correlated one. The gain is zero exactly when $\rho = \sigma_1/\sigma_2$, which includes the trivial case of the same measurement entered twice ($\rho = 1$, $\sigma_1 = \sigma_2$). And for $\rho > \sigma_1/\sigma_2$ the weight w of (3.71) exceeds one, so the worse measurement gets a *negative* weight and $\hat{\mu} = wx_1 + (1-w)x_2$ lies outside the interval between x_1 and x_2 [Cowan p. 109].

This is not a paradox. With a strong positive correlation, both measurements are likely to err in the same direction. If the noisier one reads higher than the precise one, it is telling us that the common error pushed both up, the precise one too, so the true value probably lies *below* both. The optimal combination extrapolates. As $\rho \to 1$ the variance (3.72) goes to zero (for $\sigma_1 \neq \sigma_2$): the difference $x_1 - x_2$ then measures the common error exactly, and it can be subtracted.

The same formula cleans the microwave sky. A CMB experiment observes the sky in several frequency channels. In the temperature units used for the CMB, the CMB itself has the same amplitude in every channel, while the Galactic dust, synchrotron and free–free emission change strongly with frequency, and every channel has its own noise. So each channel map is exactly a reading of the form (3.1), $x_\nu = s + (\text{foregrounds} + \text{noise})_\nu$, at every pixel. Take as V the covariance of the channel maps measured from the maps themselves, foregrounds included, and apply (3.68): the weights $\boldsymbol{w} = V^{-1}\mathbf{1}/(\mathbf{1}^{\mathsf{T}} V^{-1}\mathbf{1})$ keep the CMB at unit normalisation, since $\mathbf{1}^{\mathsf{T}}\boldsymbol{w} = 1$, and minimise everything else together, which is possible because the foregrounds are strongly correlated between channels, the large-ρ regime just described, with negative weights doing the subtracting. This is the **internal linear combination** (ILC) [17]. The foregrounds dominate on some angular scales and in some parts of the sky and not in others, so a single set

of weights for the whole map is a compromise. The needlet ILC, NILC [18], splits the maps into pieces localised both in scale and on the sky (needlets) and computes a separate V, hence separate weights, in each piece. It is one of the four methods behind the Planck maps that Chapters 12 and 13 analyse [19]. One caveat comes straight from the derivation: the weights are computed from the same data they are applied to, so the chance correlation between CMB and foregrounds in a finite patch is partly subtracted too, which biases the cleaned map slightly low (the ILC bias); it is small when each piece contains many pixels.

The same thing in Python. The second half of `07_weighted_mean.py` takes $\sigma_1 = 1$, $\sigma_2 = 2$, evaluates (3.71) and (3.72) on a grid of ρ, and, at seven values of ρ, draws 200 000 correlated pairs with `rng.multivariate_normal`, forms $wx_1 + (1-w)x_2$ and measures its variance. Figure 3.27 shows the result. At $\rho = 0.9$ the simulation gives 0.5453 against the formula's 0.5429, well below the better measurement's own variance $\sigma_1^2 = 1$.

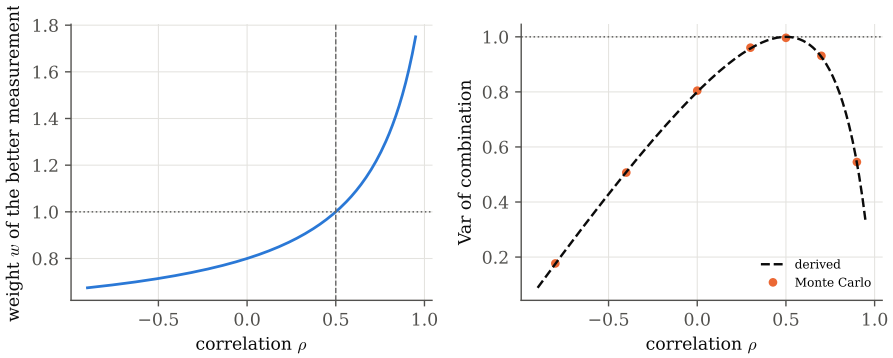

Figure 3.27: Combining two measurements with $\sigma_1 = 1$ and $\sigma_2 = 2$ as their correlation ρ varies. Left: the weight of the better measurement passes 1 at $\rho = \sigma_1/\sigma_2 = 0.5$ (dashed vertical line), and beyond it the poorer measurement is subtracted. Right: the variance of the optimal combination (dashed curve, formula; dots, simulation) touches the better measurement's variance 1 only at $\rho = 0.5$ and falls towards zero as $\rho \to 1$.

Example: two rulers and one thermometer. Cowan's example makes the negative weight concrete [Cowan §7.6.1]. We measure a length λ with two rulers of different materials, calibrated at temperature T_0, with thermal expansion coefficients c_1 and c_2. Each reading L_i is corrected with the measured temperature T,

$$y_i = L_i + c_i(T - T_0), \tag{3.74}$$

[Cowan (7.41)]. The readings have independent errors σ_L, and the one thermometer reading T has error σ_T and enters both corrections. Linear propagation, exact here, gives

$$\sigma_i^2 \overset{(1)}{=} \sigma_L^2 + c_i^2\sigma_T^2, \qquad V_{12} \overset{(2)}{=} c_1c_2\sigma_T^2, \qquad \rho \overset{(3)}{=} \frac{c_1c_2\sigma_T^2}{\sqrt{(\sigma_L^2 + c_1^2\sigma_T^2)(\sigma_L^2 + c_2^2\sigma_T^2)}}$$

[Cowan (7.42)–(7.44)].

(1) Variance of a sum of independent terms, with $\mathrm{Var}[c_i(T - T_0)] = c_i^2\sigma_T^2$.
(2) The only error the two corrected lengths share is the temperature error, as in Section 3.6.1: $\mathrm{Cov}(c_1T, c_2T) = c_1c_2\sigma_T^2$.
(3) $\rho = V_{12}/(\sigma_1\sigma_2)$.

Take $c_1 = 0.02$ and $c_2 = 0.05\,\mathrm{mm\,K^{-1}}$, $\sigma_L = 0.01\,\mathrm{mm}$ and $\sigma_T = 2\,\mathrm{K}$, and suppose the room is really at 22°C, two degrees above $T_0 = 20°\mathrm{C}$, for a true length of 1000.00 mm; the thermometer reads 25°C. The corrected lengths come out as $y_1 = 1000.06$ and $y_2 = 1000.15\,\mathrm{mm}$. The numbers are

$$\sigma_1^2 = 10^{-4} + 4\times10^{-4}\times 4 = 0.0017, \qquad \sigma_2^2 = 10^{-4} + 25\times10^{-4}\times 4 = 0.0101, \qquad V_{12} = 0.004,$$

$$\rho = \frac{0.004}{\sqrt{0.0017\times 0.0101}} = 0.965 \;>\; \frac{\sigma_1}{\sigma_2} = 0.410,$$

$$w \overset{(1)}{=} \frac{\sigma_2^2 - V_{12}}{\sigma_1^2 + \sigma_2^2 - 2V_{12}} = \frac{0.0061}{0.0038} = 1.605,$$

$$\hat\lambda \overset{(2)}{=} 1000 + 1.605\times 0.06 - 0.605\times 0.15 = 1000.006\,\mathrm{mm}, \qquad \sigma_{\hat\lambda} \overset{(3)}{=} \sqrt{\frac{\sigma_1^2\sigma_2^2 - V_{12}^2}{0.0038}} = 0.018\,\mathrm{mm}.$$

(1) (3.71) with $\rho\sigma_1\sigma_2 = V_{12}$.
(2) $\hat\lambda = wy_1 + (1-w)y_2$, written relative to 1000 mm.
(3) (3.72), again with $\rho\sigma_1\sigma_2 = V_{12}$, so that $(1-\rho^2)\sigma_1^2\sigma_2^2 = \sigma_1^2\sigma_2^2 - V_{12}^2$.

The combination 1000.006 ± 0.018 mm lies *outside* the interval [1000.06, 1000.15] and is right, whereas the naive weighted mean that ignores the correlation gives 1000.073 ± 0.038 mm, too high by twice its own error.

Why is a value outside both readings right? Figure 3.28 shows it. Each corrected length is a straight line in the unknown true temperature. Both rulers measure the same length, so they must agree at the true temperature. The estimate is therefore pulled towards the point where the two lines cross [Cowan Fig. 7.7]. The same fit returns an estimate of the temperature itself, $\hat T = 22.2°\mathrm{C}$, from [Cowan (7.47)]: the disagreement between the rulers has been used to correct the thermometer. In the limit $\sigma_L \to 0$ ($\rho \to 1$) the two lines give $\hat\lambda = (c_2y_1 - c_1y_2)/(c_2 - c_1)$ with zero variance.[1]

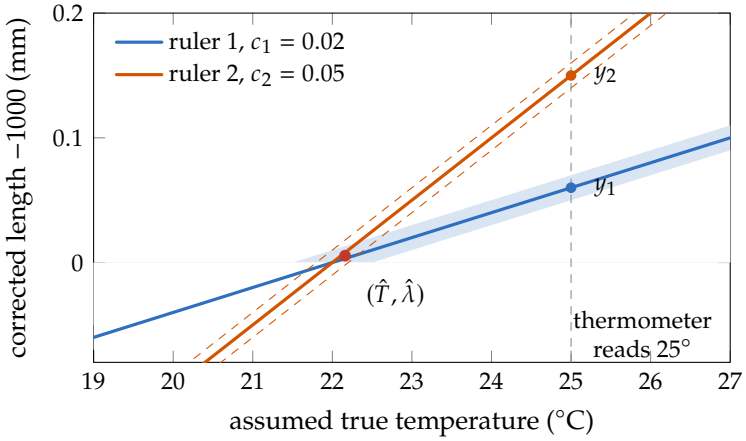

Figure 3.28: Two rulers read at a thermometer reading of 25°C give the corrected lengths y_1 and y_2 (dots on the dashed vertical line). If the temperature were different, each corrected length would slide along its own line, whose slope is the ruler's expansion coefficient; the shaded strip and the thin dashed lines show the $\pm\sigma_L$ reading error. Both rulers measure one length, so the truth sits where the lines cross. The correlated weighted mean (red dot) lands there, below both y_1 and y_2, and at a temperature near 22°C.

[1] This follows from (3.74) with exact readings: then $y_i = \lambda + c_i(T - T_{\mathrm{true}})$, and eliminating $T - T_{\mathrm{true}}$ between $i = 1, 2$ gives $c_2y_1 - c_1y_2 = (c_2 - c_1)\lambda$. Cowan's (7.46) has c_1 and c_2 interchanged in the numerators; the check $c_1 = 0$ (a ruler that does not expand, so $\lambda = y_1$) confirms the version given here.

How research uses it. Every world average of a particle mass or lifetime is an inverse-variance weighted mean, quoted with its $\chi^2_{\min}$ and, when needed, the inflation factor of Section 3.7.2. When several experiments share systematic errors, the correlated formula (3.68) is used under the name "best linear unbiased estimate" (the original discussion is by Lyons and collaborators, [Cowan p. 109]). The hard part is not the algebra but the off-diagonal elements of V, which must be estimated.

Here our Monte Carlo only *verifies* formulas we derived. In research the covariance of the inputs is itself often taken from simulations, and then its noise (Section 3.5.4) passes into the weights.

In cosmology the same algebra appears in a more general form. Combining independent probes with Gaussian likelihoods multiplies the likelihoods, and multiplying Gaussians adds their inverse covariances. For one parameter that is exactly $1/\sigma^2 = \sum_i 1/\sigma_i^2$; for many parameters it is the statement that Fisher matrices add (Chapter 10).

Where this leaves us. Every error bar so far came from one idea: treat a summary of the data as a random variable over imagined repetitions, and ask for its centre and width. The weighted mean showed a second way of seeing the same numbers. The density of the data, read as a function of the unknown μ, peaked at the estimator and had a width equal to its standard error. That reading of the density is the likelihood, the subject of the second half of the chapter. Maximising it gives estimators, and its curvature gives their error bars.

Recap: Part 3a in one page

- An estimator $\hat{\theta} = g(x_1, \ldots, x_N)$ is a random variable. Its sampling distribution over imagined repetitions gives the error bar (the standard error). Simulate it when in doubt.
- MSE = bias^2 + variance. Consistency: $\hat{\theta} \to \theta$ in probability, guaranteed when bias and variance both go to zero.
- Var $\bar{x} = \sigma^2/N$: errors shrink like $1/\sqrt{N}$ (law of large numbers via Chebyshev). The central limit theorem makes the sampling distribution of a mean Gaussian.
- S^2 divides by $N-1$ to be unbiased. Its own error is Var $S^2 = 2\sigma^4/(N-1)$ for Gaussian data (cosmic variance is the same fact).
- Sample covariance and correlation matrices are noisy: sample correlations of independent variables scatter by $\sim 1/\sqrt{N}$, and inverting a simulated covariance needs the Hartlap factor.
- Error propagation: $U = AVA^{\mathsf{T}}$ with the Jacobian A, exact for linear maps. It fails near poles and for noisy denominators; use Monte Carlo propagation there.
- Combining measurements: weight by $1/\sigma_i^2$, so $1/\sigma_{\hat{\mu}}^2 = \sum_i 1/\sigma_i^2$. Check $\chi^2_{\min} \sim \chi^2_{N-1}$. With correlations, $\boldsymbol{w} = V^{-1}\mathbf{1}/(\mathbf{1}^{\mathsf{T}}V^{-1}\mathbf{1})$, and weights can be negative.

3.8 The likelihood: data are the model plus noise

We measure a voltage, count photons in a detector, record the arrival times of decays, or estimate a power spectrum from a map of the sky. In every case we also have a theory with a knob on it: a resistance, a cross-section, a lifetime, a cosmological parameter. Set the knob to a value θ

and the theory predicts what the apparatus should have shown. Call that prediction $d(\theta)$. The apparatus never shows exactly $d(\theta)$. It shows the prediction plus whatever the noise happened to be on that day. Until now the question has run one way: *given* the truth, how does a summary of the data scatter when the experiment is repeated? Now the data are in, and we ask the opposite question: which values of the knob could have produced the data we actually have?

The tool for this backward question is the **likelihood**. It is not a new probability distribution. It is the old one, the distribution of the data, read in the other direction. To understand it we need answers to four questions.

1. How does a model of the noise turn into a number attached to each value of θ?
2. What happens with many measurements?
3. Why is that number *not* a probability distribution for θ, even though it is built from one?
4. Where does it sit in Bayes' theorem, and what information in the data does it keep?

The pipeline of Chapter 0 ends with an arrow from how a statistic S scatters, $P(S \mid \theta)$, to what the observed value of S says about the physics. The likelihood is that arrow. It is the sampling distribution of the data (or of a summary S of them), evaluated at the data we observed and read as a function of the physics θ.

3.8.1 One measurement: from the noise to the likelihood

Start with the simplest experiment there is. The model predicts a number $d(\theta)$, and the measurement adds noise:

$$D = d(\theta) + \epsilon, \qquad \epsilon \sim \mathcal{N}(0, \sigma^2), \tag{3.75}$$

with σ known from calibrating the instrument. The noise ϵ [the random amount by which this particular reading differs from the ideal, noiseless one] has density $\phi_\sigma(\epsilon) = (2\pi\sigma^2)^{-1/2}\exp(-\epsilon^2/2\sigma^2)$. What is the density of the reading D itself? Fix θ and ask for the probability that D lands in a small window $[D_0, D_0 + \mathrm{d}D]$:

$$\begin{aligned} \mathrm{P}\big(D_0 \le D \le D_0 + \mathrm{d}D \mid \theta\big) &\overset{(1)}{=} \mathrm{P}\big(D_0 - d(\theta) \le \epsilon \le D_0 - d(\theta) + \mathrm{d}D\big) \\ &\overset{(2)}{=} \phi_\sigma\big(D_0 - d(\theta)\big)\,\mathrm{d}D \\ &\overset{(3)}{=} \frac{1}{\sqrt{2\pi\sigma^2}}\exp\left[-\frac{\big(D_0 - d(\theta)\big)^2}{2\sigma^2}\right]\mathrm{d}D. \end{aligned} \tag{3.76}$$

(1) At fixed θ the prediction $d(\theta)$ is just a number, so $D = d(\theta) + \epsilon$ lies in the window exactly when ϵ lies in the same window shifted down by $d(\theta)$.
(2) For a small window, probability is density times width. A shift does not stretch the window, so the width is still $\mathrm{d}D$.
(3) Insert the Gaussian density of the noise.

So $D \sim \mathcal{N}(d(\theta), \sigma^2)$: the reading is Gaussian, centred on the prediction, with the width of the noise. Nothing new so far. This is the *forward* or *prediction* direction: fix the physics, ask how the data would scatter.

Now the data are in. We hold $D = D_0$ fixed at the value on the lab book and let θ vary instead. The same expression becomes a function of θ,

$$\mathcal{L}(\theta) \equiv p(D_0 \mid \theta) = \frac{1}{\sqrt{2\pi\sigma^2}}\exp\left[-\frac{\big(D_0 - d(\theta)\big)^2}{2\sigma^2}\right] = \phi_\sigma\big(\underbrace{D_0 - d(\theta)}_{\text{required noise}}\big). \tag{3.77}$$

The last form says what the likelihood measures. Take a trial value θ. The model predicts $d(\theta)$. To turn that prediction into the reading we actually got, the noise must have been exactly $\epsilon = D_0 - d(\theta)$. The likelihood is the probability density of *that* noise value. So for each trial θ it answers one question: how probable is the noise that this θ needs in order to explain our reading?

Key idea: what the likelihood measures

Pick a trial value θ. The model then says what the reading should have been, $d(\theta)$, and the gap $D_0 - d(\theta)$ is the noise that nature would have had to add to turn that prediction into the reading we actually got. The likelihood of θ is how probable this particular piece of noise is. In symbols it is nothing more than the distribution of the data: if $D = d(\theta) + \epsilon$ with $\epsilon \sim \mathcal{N}(0, 1)$, then $D \sim \mathcal{N}(d(\theta), 1)$, and this density, with D held at the observed value and θ left free, is the likelihood function. For noise of width σ, as in (3.77), the 1 becomes σ^2.

A value of θ whose prediction sits close to the data needs only a small, ordinary fluctuation and gets a high likelihood. A value whose prediction sits five noise widths away needs a five-sigma fluctuation and gets a likelihood smaller by a factor $e^{-25/2} \approx 4 \times 10^{-6}$. Figure 3.29 draws exactly this for several data points and two trial models.

In the language of the backward question, each trial value of θ is a candidate explanation, the reading D_0 is what we saw, and the likelihood ranks the candidates by how easily each one would have produced that reading. Parameter estimation in Chapter 5 is built on exactly this.

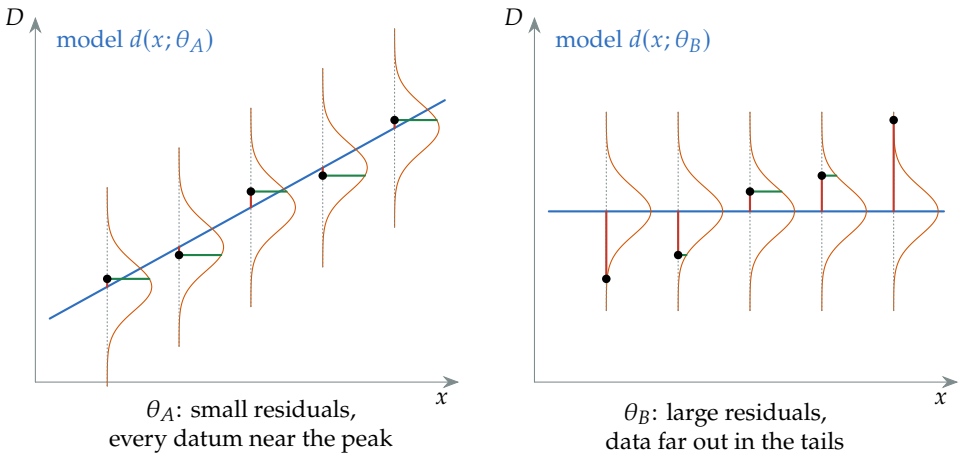

Figure 3.29: The likelihood of two trial parameter values. Black dots are the same five measurements in both panels. The blue line is the model prediction for the trial value, and the orange curve on its side at each x is the noise density $\mathcal{N}(d, \sigma^2)$ centred on the prediction. The red segment is the fluctuation the noise would have had to produce, and the length of the green tick is the height of the noise density at the datum. The likelihood is the product of the five green lengths. On the left they are all long. On the right two of them are almost zero, so θ_B needs an implausible noise realisation.

Working definition 3.10 (likelihood)

For data $\boldsymbol{d}$ and a model that gives the data a probability (or density) $p(\boldsymbol{d} \mid \boldsymbol{\theta})$ for each parameter value, the **likelihood** is that same function with the data held fixed at their observed values and the parameters varied,

$$\mathcal{L}(\boldsymbol{\theta}) \equiv p(\boldsymbol{d}_{\text{obs}} \mid \boldsymbol{\theta}).$$

Operationally: write down the noise model that turns a prediction $d(\boldsymbol{\theta})$ into data [for

example "add independent Gaussian noise of known width"], compute the probability of the observed data under it, and treat the answer as a function of $\boldsymbol{\theta}$ alone. The **log-likelihood** is $\ell(\boldsymbol{\theta}) = \ln \mathcal{L}(\boldsymbol{\theta})$.

Example: one reading of a resistance. We pass a known current $I = 2\,\mathrm{A}$ through a resistor and read the voltage with a voltmeter whose noise is $\sigma = 0.2\,\mathrm{V}$. The model is Ohm's law, $d(R) = IR$, and the reading is $D_0 = 10.4\,\mathrm{V}$. Then

$$\mathcal{L}(R) \overset{(1)}{=} \frac{1}{\sqrt{2\pi}\,(0.2\,\mathrm{V})} \exp\left[-\frac{(10.4\,\mathrm{V} - 2\,\mathrm{A}\cdot R)^2}{2(0.2\,\mathrm{V})^2}\right] \overset{(2)}{=} \frac{1}{\sqrt{2\pi}\,(0.2\,\mathrm{V})} \exp\left[-\frac{(R - 5.2\,\Omega)^2}{2(0.1\,\Omega)^2}\right].$$

(1) (3.77) with $d(R) = IR$.
(2) Factor I^2 out of the square: $(D_0 - IR)^2 = I^2(R - D_0/I)^2$, and $\sigma^2/I^2 = (0.1\,\Omega)^2$.

As a function of R the likelihood is a Gaussian bump centred at $5.2\,\Omega$ with width $0.1\,\Omega$. The peak is at the resistance whose prediction needs zero noise: $IR = D_0$ gives $R = 10.4\,\mathrm{V}/2\,\mathrm{A} = 5.2\,\Omega$. The width is the noise width divided by the slope $\mathrm{d}d/\mathrm{d}R = I$, because a change δR moves the prediction by $I\,\delta R$. The prefactor carries units of V^{-1}, because it is a density in the *voltage*, not in R. That is the first sign that the likelihood is not a probability density for R (Section 3.8.3).

3.8.2 Many measurements: the product and the logarithm

Real experiments have many data points $D_1, \ldots, D_N$, taken at settings $x_1, \ldots, x_N$, with predictions $d_i(\theta) = d(x_i; \theta)$. If the noise in different readings is independent, the joint density factorises, because independence means precisely that the joint density is the product of the single ones [Sivia p. 65, (3.62)]:

$$\mathcal{L}(\theta) \overset{(1)}{=} p(D_1, \ldots, D_N \mid \theta) \overset{(2)}{=} \prod_{i=1}^{N} p(D_i \mid \theta) \overset{(3)}{=} \prod_{i=1}^{N} \frac{1}{\sqrt{2\pi\sigma_i^2}} \exp\left[-\frac{\big(D_i - d_i(\theta)\big)^2}{2\sigma_i^2}\right], \tag{3.78}$$

$$\ell(\theta) \overset{(4)}{=} -\frac{1}{2}\sum_{i=1}^{N} \frac{\big(D_i - d_i(\theta)\big)^2}{\sigma_i^2} \; - \; \sum_{i=1}^{N} \ln\sqrt{2\pi\sigma_i^2}. \tag{3.79}$$

(1) Definition of the likelihood for the whole data vector.
(2) Independent noise: the probability of the joint noise realisation is the product of the probabilities of the individual ones.
(3) Insert (3.76) for each reading, with its own noise width σ_i.
(4) The logarithm of a product is the sum of the logarithms, and $\ln e^u = u$.

The first sum in (3.79) is $\chi^2(\theta)$: each residual $D_i - d_i(\theta)$ is divided by its error bar σ_i, squared, and the squares are added. The second sum does not depend on θ at all. So, for Gaussian noise, $\ell(\theta) = -\tfrac{1}{2}\chi^2(\theta) + \text{const}$. This is why least squares works (Section 3.10).

For identically distributed data, $x_1, \ldots, x_n$ drawn independently from one density $f(x;\theta)$, the same steps give Wasserman's definition [Wasserman p. 122, Def. 9.7],

$$\mathcal{L}_n(\theta) = \prod_{i=1}^{n} f(x_i;\theta), \qquad \ell_n(\theta) = \sum_{i=1}^{n} \ln f(x_i;\theta). \tag{3.80}$$

Three practical remarks follow from the product structure.

(i) *Work with logarithms.* A product of a thousand densities of size 0.1 is 10^{-1000} and underflows every computer. Its logarithm, -2303, is harmless. Sums are also what we differentiate most easily.

(ii) *Constants do not matter.* Multiplying $\mathcal{L}$ by any positive number c that does not depend on θ changes nothing we will do with it: the location of the maximum, the shape, and ratios $\mathcal{L}(\theta_1)/\mathcal{L}(\theta_2)$ are all unchanged [Wasserman p. 123, Remark 9.9]. We drop such constants freely and write $\mathcal{L} \propto \ldots$.

(iii) *Only ratios carry meaning.* Since the overall constant is arbitrary, the statement "$\mathcal{L}(\theta_1) = 0.03$" means nothing. The statement "$\mathcal{L}(\theta_1)/\mathcal{L}(\theta_2) = 20$" means that the data are twenty times more probable under θ_1 than under θ_2. The cosmology literature often reports $-2\ln[\mathcal{L}(\theta)/\mathcal{L}_{\max}]$ [Padilla (26)], which is a $\Delta\chi^2$ for Gaussian noise.

Example: a coin, or any yes/no detector. A detector fires ($x_i = 1$) or not ($x_i = 0$) with unknown probability p. Each trial is Bernoulli, $f(x;p) = p^x(1-p)^{1-x}$. In $n = 20$ trials it fires $S = \sum_i x_i = 12$ times [Wasserman p. 123, Ex. 9.10]. Then

$$\mathcal{L}(p) \overset{(1)}{=} \prod_{i=1}^{n} p^{x_i}(1-p)^{1-x_i} \overset{(2)}{=} p^{\sum_i x_i}(1-p)^{n-\sum_i x_i} = p^{12}(1-p)^{8}.$$

(1) (3.80) with the Bernoulli probability.
(2) Collect the powers: $\prod_i p^{x_i} = p^{\sum_i x_i}$ and likewise for $1-p$.

The left panel of Figure 3.30 shows it. It is a smooth bump with its peak at $p = S/n = 0.6$. The individual zeros and ones have disappeared: only their sum S enters.

Example: a uniform distribution with an unknown end point. Let $x_i \sim \text{Uniform}(0, \theta)$, with density $1/\theta$ on $[0, \theta]$ and zero outside [Wasserman p. 124, Ex. 9.12]. Each factor of the product is $1/\theta$ if $x_i \le \theta$ and zero if $x_i > \theta$. The product is nonzero only if *every* $x_i \le \theta$, that is, if $\theta \ge x_{(n)} \equiv \max_i x_i$:

$$\mathcal{L}(\theta) = \begin{cases} \theta^{-n}, & \theta \ge x_{(n)}, \\ 0, & \theta < x_{(n)}. \end{cases}$$

A value θ smaller than the largest observation is not merely implausible, it is impossible: no noise realisation can put a point above the end of the box. For ten simulated points with largest value $x_{(10)} = 0.9072$, the middle panel of Figure 3.30 shows a cliff at $x_{(10)}$ followed by a decay as θ^{-10}. It has no smooth peak. Because of that cliff, this model breaks rules that smooth likelihoods obey: the maximum is not found by setting a derivative to zero (Section 3.9.1), and the Cramér–Rao bound does not apply (Section 3.13.3).

3.8.3 The likelihood is not a probability density for θ

The likelihood is not the probability density of θ. The temptation is real: it is built from a density, and in the resistor example it even looked like a Gaussian in R. Two facts show that it is not a density for θ. Its area over θ is arbitrary, and it does not change the way a density must when we rename the parameter.

The area under the likelihood is arbitrary. Integrate the resistor likelihood over R:

$$\int_{-\infty}^{\infty} \mathcal{L}(R)\,\mathrm{d}R \overset{(1)}{=} \frac{1}{\sqrt{2\pi}\,\sigma}\int_{-\infty}^{\infty} \exp\!\left[-\frac{(R-D_0/I)^2}{2(\sigma/I)^2}\right]\mathrm{d}R \overset{(2)}{=} \frac{1}{\sqrt{2\pi}\,\sigma}\sqrt{2\pi}\,\frac{\sigma}{I} = \frac{1}{I} = 0.5\,\mathrm{A}^{-1}.$$

(1) The form found in the resistor example, with $\sigma = 0.2\,\mathrm{V}$.

(2) The Gaussian integral $\int e^{-(u-u_0)^2/2s^2}\mathrm{d}u = \sqrt{2\pi}\,s$ with $s = \sigma/I$.

If $\mathcal{L}(R)$ were a probability density for R, this area would be 1. It is 0.5, and it is not even a pure number: it has units of inverse amperes. Change the current to 1 A and the area becomes 1. Measure the current in milliamperes and it changes again. The reason is that the likelihood is a density in the *data*: it integrates to one over D, by construction, and its units are those of $1/D$. Nothing fixes its integral over θ.

The same happens in every example. For the detector,

$$\int_0^1 \mathcal{L}(p)\,\mathrm{d}p \overset{(1)}{=} \int_0^1 p^S(1-p)^{n-S}\,\mathrm{d}p \overset{(2)}{=} B(S+1, n-S+1) \overset{(3)}{=} \frac{S!\,(n-S)!}{(n+1)!} = \frac{12!\,8!}{21!} = 3.780\times10^{-7},$$

(1) The Bernoulli likelihood of the example above.

(2) The Beta integral $\int_0^1 p^{a-1}(1-p)^{b-1}\mathrm{d}p = B(a,b)$, the normalising constant of the Beta distribution (Chapter 2), with $a = S+1$, $b = n-S+1$.

(3) $B(a,b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$ and $\Gamma(m+1) = m!$.

and the numerical integral in `08_likelihood_shapes.py` gives the same number, 3.780×10^{-7}. The peak value is $\mathcal{L}(0.6) = 1.427\times10^{-6}$, so the area is only 0.265 times the peak height (in units of p). Nothing about it is one.

Renaming the parameter changes the area but not the values. The second fact goes deeper. When we change the name of the parameter, a density picks up a Jacobian factor and the likelihood does not. To see it, take $k = 5$ decay times with total $T = \sum_i t_i = 10.51$ (in units of the true lifetime), and describe the decay either by the mean life τ or by the rate $\lambda = 1/\tau$. With $f(t;\tau) = \tau^{-1}e^{-t/\tau}$,

$$\mathcal{L}(\tau) \overset{(1)}{=} \prod_{i=1}^{k}\frac{1}{\tau}e^{-t_i/\tau} = \tau^{-k}e^{-T/\tau}, \qquad \int_0^\infty \mathcal{L}(\tau)\,\mathrm{d}\tau \overset{(2)}{=} \frac{\Gamma(k-1)}{T^{k-1}} = 4.920\times10^{-4},$$

$$\mathcal{L}(\lambda) \overset{(3)}{=} \prod_{i=1}^{k}\lambda e^{-\lambda t_i} = \lambda^k e^{-\lambda T}, \qquad \int_0^\infty \mathcal{L}(\lambda)\,\mathrm{d}\lambda \overset{(4)}{=} \frac{\Gamma(k+1)}{T^{k+1}} = 8.910\times10^{-5}.$$

(1) (3.80) with the exponential density.

(2) Substitute $u = T/\tau$, $\mathrm{d}\tau = -T\,\mathrm{d}u/u^2$: $\int_0^\infty \tau^{-k}e^{-T/\tau}\mathrm{d}\tau = T^{1-k}\int_0^\infty u^{k-2}e^{-u}\mathrm{d}u = T^{1-k}\Gamma(k-1)$.

(3) The same density written with λ: $f(t;\lambda) = \lambda e^{-\lambda t}$.

(4) The Gamma integral $\int_0^\infty \lambda^k e^{-\lambda T}\mathrm{d}\lambda = \Gamma(k+1)/T^{k+1}$.

The two areas differ by a factor $T^2/[k(k-1)] = 5.522$. Yet at corresponding points the two functions are *equal*: putting $\lambda = 1/\tau$ into $\lambda^k e^{-\lambda T}$ gives $\tau^{-k}e^{-T/\tau}$, so $\mathcal{L}(\lambda = 1/\tau) = \mathcal{L}(\tau)$. The likelihood behaves like a scalar field. It assigns a number to each physical hypothesis ("the lifetime is 1.3 ns"), whatever coordinate we use to name that hypothesis.

A genuine probability density behaves differently. If $p_\tau(\tau)$ were a density for τ, the probability of a small interval $\mathrm{d}\tau$ would be $p_\tau\,\mathrm{d}\tau$. The same interval written in λ has width $\mathrm{d}\lambda = \mathrm{d}\tau/\tau^2$, and the probability must be the same, so the density for λ would be

$p_\lambda(\lambda) = p_\tau(1/\lambda)\,|\mathrm{d}\tau/\mathrm{d}\lambda| = p_\tau(1/\lambda)/\lambda^2$. The factor $1/\lambda^2$ is the Jacobian. The likelihood never picks one up, so the areas under it in different coordinates disagree, and neither area means anything. The right panel of Figure 3.30 shows the two curves, each scaled to peak height one: the same heights at corresponding points, but different shapes along the axis.

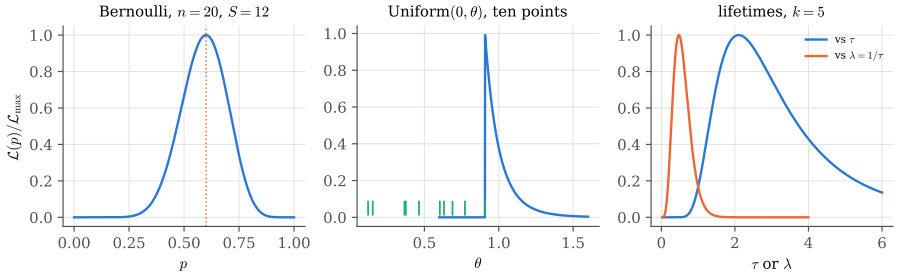

Figure 3.30: Three likelihoods, each scaled to a maximum of one. Left: a yes/no detector that fired 12 times in 20 trials, a smooth bump peaked at $p = 0.6$. Middle: ten points from a uniform box of unknown length (ticks at the bottom). The likelihood is zero until θ reaches the largest point, then decays as θ^{-10}. Right: five decay times, with the likelihood drawn once against the mean life τ and once against the rate $\lambda = 1/\tau$. The two curves take the same value at $\lambda = 1/\tau$, but they enclose different areas.

Key idea: The likelihood is a function of θ, not a distribution over θ

$\mathcal{L}(\theta) = p(\boldsymbol{d}_{\text{obs}} \mid \theta)$ is normalised over the *data*, $\int p(\boldsymbol{d} \mid \theta)\,\mathrm{d}\boldsymbol{d} = 1$ for every θ. Over θ it has no normalisation, it changes no Jacobian under a change of parameter, and only ratios $\mathcal{L}(\theta_1)/\mathcal{L}(\theta_2)$ are meaningful [Wasserman p. 122]. To get a probability distribution over θ one needs a prior, and Bayes' theorem (Chapter 5).

3.8.4 Prediction and inference: where the likelihood sits

The two readings of $p(\boldsymbol{d} \mid \theta)$ are the two directions of probability that run through the whole book (Chapter 1). Read forward, it starts from a fixed θ and says which data sets that θ can produce, and how often. Read backward, the data set is already in hand, and we ask which values of θ could have produced it and how much each one deserves to be believed now that we have it.

Prediction is the first reading, *inference* the second. Figure 3.31 draws both as trees. In the prediction tree one parameter value fans out into many possible data sets, and their probabilities add to one. In the inference tree many parameter values point at the one data set we have, and the numbers attached to the branches are the likelihoods. They need not add to anything.

So, facing data, we ask two questions in words before writing anything. First: which values of θ could have produced these data? Second: how probable would these data have been under each of them? The answers to the second question, read across all θ, are the likelihood. The first question fixes what the posterior will be a distribution over. Turning the likelihood into that distribution needs one more ingredient, a prior (Chapter 5).

Bayes' theorem is the bridge from one tree to the other. Written for parameters it reads [HobsonBMC p. 11, (1.25)]

$$\underbrace{p(\theta)}_{\text{prior}}\ \underbrace{p(\boldsymbol{d} \mid \theta)}_{\text{likelihood}} = p(\theta, \boldsymbol{d}) = \underbrace{p(\boldsymbol{d})}_{\text{evidence } Z}\ \underbrace{p(\theta \mid \boldsymbol{d})}_{\text{posterior}}. \tag{3.81}$$

Both sides are the joint probability of parameter and data, $p(\theta, \boldsymbol{d})$, split into two factors in the two possible orders. The likelihood is the part the experiment supplies. It is also the least

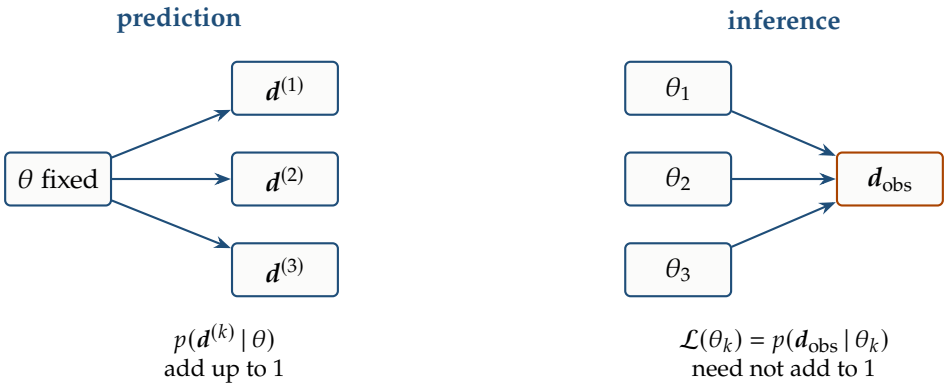

Figure 3.31: The same conditional probability read two ways. Left: one hypothesis produces many possible data sets, and the probabilities of all of them sum to one. Right: many hypotheses could have produced the single data set we observed (orange). The likelihood attaches to each hypothesis the probability that it would have produced exactly these data. These numbers compare hypotheses with each other but are not a distribution over them.

controversial part. We can calibrate the instrument with known inputs and count how often it produces each output, which pins $p(\boldsymbol{d} \mid \theta)$ down to any desired precision [HobsonBMC p. 11]. The prior, the evidence and the posterior belong to Chapter 5. Two facts about them are needed now. First, with a flat prior $p(\theta) = \text{const}$ the posterior is proportional to the likelihood, so the peak of the posterior is the peak of the likelihood [Sivia p. 64, (3.61)]. Second, "flat" depends on the parametrisation. A prior flat in τ is not flat in $\lambda = 1/\tau$, because of the Jacobian $1/\lambda^2$ found above. From here on we stay on the frequentist side and use the likelihood by itself, without any prior.

What the likelihood keeps: sufficiency. In each of the three examples the likelihood depended on the data through one number only: the count S of detector firings, the total decay time T, and the largest value $x_{(n)}$ of the uniform box. Two detector data sets with the same S give the same likelihood function, so nothing computed from the likelihood can tell them apart. A statistic with this property is called **sufficient** [knowing its value lets us write down the whole likelihood function, up to a constant factor] [Wasserman p. 137, Def. 9.32]. The factorisation theorem [Wasserman p. 140, Thm. 9.40] gives a quick test: $T(\boldsymbol{d})$ is sufficient exactly when $p(\boldsymbol{d} \mid \theta) = g\big(T(\boldsymbol{d}), \theta\big)\, h(\boldsymbol{d})$. For Gaussian data with unknown μ and σ the pair $(\bar{x}, S^2)$ is sufficient [Wasserman p. 138, Ex. 9.34]: the likelihood $\propto \sigma^{-n} \exp\{-[(n-1)S^2 + n(\bar{x}-\mu)^2]/2\sigma^2\}$ uses nothing else. Cosmologists use the same compression every day: when a map is Gaussian and statistically isotropic, its power spectrum carries all the information about the parameters. Sufficiency also improves estimators. The Rao–Blackwell theorem says that averaging any estimator over all data sets that share the observed value of a sufficient statistic gives a new estimator whose mean squared error is never larger [Wasserman p. 140, Thm. 9.42]: an estimator that uses anything beyond the sufficient statistic is only adding noise.

The likelihood principle. The **likelihood principle** goes one step further [CasellaBerger §6.3.1]. It says that if two data sets $\boldsymbol{d}$ and $\boldsymbol{d}'$ give proportional likelihoods, $\mathcal{L}(\theta \mid \boldsymbol{d}) = c\, \mathcal{L}(\theta \mid \boldsymbol{d}')$ for all θ, then they carry the same evidence about θ and should lead to the same conclusion. Two coin experiments show what this means. Experimenter A decides to toss a coin $n = 20$ times and sees $S = 12$ heads. The count is binomial, and $\mathcal{L} \propto p^{12}(1-p)^8$. Experimenter B decides to toss until the eighth tail, and the eighth tail comes on toss 20, so B also saw 12 heads and 8 tails. That count is negative binomial, and again $\mathcal{L} \propto p^{12}(1-p)^8$, only with a different constant in front. The likelihoods are proportional, so by the principle A and B have learned the same

thing about p. Estimates and intervals built from the likelihood alone respect the principle. Procedures that average over data sets that could have been observed but were not, such as p-values (Chapter 4), depend on the stopping rule, so they violate it. Bayesian inference satisfies it automatically, because the posterior uses the data only through $\mathcal{L}(\theta)$ [CasellaBerger §6.3.2].

3.9 Maximum likelihood: pick the value that needs the least unusual noise

The likelihood $\mathcal{L}(\theta)$ of Section 3.8 gives every candidate value of θ a number: how readily that value would have produced the data we hold. If we must report a single value, the natural choice is the one with the highest number. Its prediction needs the most ordinary noise to become the data. This is the **maximum likelihood estimator**, and it is the workhorse of experimental physics. Almost every fitted mass, lifetime, cross-section and cosmological parameter you have seen was obtained this way, or by its Gaussian special case, least squares.

Turning the idea into recipes raises three questions.

1. How do we find the maximum when we can do the calculus by hand, and what do the answers look like for the standard models?
2. How does it compare with the older recipe of matching moments?
3. How do we find the maximum when we cannot do the calculus, and how does that look in Python?

The recipe is worth using because, for large samples, it homes in on the truth, is nearly unbiased, and is as precise as any estimator can be. These properties are proved in Section 3.13. Its error bar comes from the width of the likelihood (Section 3.12).

Working definition 3.11 (maximum likelihood estimator)

The **maximum likelihood estimator** (MLE) $\hat{\theta}$ is the value of θ that maximises $\mathcal{L}(\theta)$, or equivalently $\ell(\theta) = \ln \mathcal{L}(\theta)$ [Wasserman p. 122, Def. 9.8]. When the maximum is inside the allowed range and ℓ is smooth, it solves the **score equation**

$$S(\theta) \equiv \frac{\partial \ell}{\partial \theta} = 0, \qquad \frac{\partial^2 \ell}{\partial \theta^2} < 0,$$

where the **score** $S(\theta)$ [the slope of the log-likelihood, a random quantity because it depends on the data] measures how much the data pull θ up or down. For several parameters every component of the gradient vanishes and the matrix of second derivatives is negative definite.

Before differentiating we may throw away every factor of $\mathcal{L}$ that does not contain θ. Two facts allow it. First, ln is increasing, so $\mathcal{L}$ and ℓ peak at the same θ. Second, a constant factor in $\mathcal{L}$ becomes an added constant in ℓ, and the derivative of a constant is zero.

3.9.1 Solving the score equation by hand

Example: the mean lifetime of an unstable particle. We record n decay times $t_1, \dots, t_n$ from $f(t;\tau) = \tau^{-1} e^{-t/\tau}$ [Cowan §6.2]. Then

$$\ell(\tau) \overset{(1)}{=} \sum_{i=1}^{n} \left(-\ln \tau - \frac{t_i}{\tau} \right) = -n \ln \tau - \frac{T}{\tau}, \qquad T \equiv \sum_i t_i,$$

$$S(\tau) \overset{(2)}{=} -\frac{n}{\tau} + \frac{T}{\tau^2} \overset{(3)}{=} 0 \quad\Longrightarrow\quad \hat\tau = \frac{T}{n} = \bar t, \tag{3.82}$$
$$\ell''(\hat\tau) \overset{(4)}{=} \frac{n}{\hat\tau^2} - \frac{2T}{\hat\tau^3} \overset{(5)}{=} -\frac{n}{\hat\tau^2} < 0.$$

(1) Logarithm of the product (3.80): $\ln(\tau^{-1}e^{-t/\tau}) = -\ln\tau - t/\tau$.
(2) Differentiate term by term: $\mathrm{d}(-n\ln\tau)/\mathrm{d}\tau = -n/\tau$ and $\mathrm{d}(-T/\tau)/\mathrm{d}\tau = T/\tau^2$.
(3) The score equation. Multiply by τ^2 to get $-n\tau + T = 0$.
(4) Differentiate once more: $\mathrm{d}(-n/\tau)/\mathrm{d}\tau = n/\tau^2$, $\mathrm{d}(T/\tau^2)/\mathrm{d}\tau = -2T/\tau^3$.
(5) At $\hat\tau$ we have $T = n\hat\tau$, so $2T/\hat\tau^3 = 2n/\hat\tau^2$.

The maximum likelihood lifetime is the average decay time. It is unbiased, $\mathbb{E}\,\bar t = \tau$, and its variance is τ^2/n, because the exponential has variance τ^2 and averaging n independent times divides the variance by n. This is the same estimator whose sampling distribution we simulated for the muon lifetime in Section 3.1.3. The number $-\ell''(\hat\tau) = n/\hat\tau^2$ is one over the square of the error bar, as Section 3.12 shows.

Example: the centre and width of a Gaussian. Let $x_i \sim \mathcal{N}(\mu, \sigma^2)$ with both parameters unknown [Wasserman p. 123, Ex. 9.11], [Cowan §6.3], [CasellaBerger Ex. 7.2.11]. Dropping the constant $-\frac{n}{2}\ln 2\pi$,

$$\ell(\mu,\sigma) \overset{(1)}{=} -n\ln\sigma - \frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\mu)^2,$$
$$\frac{\partial\ell}{\partial\mu} \overset{(2)}{=} \frac{1}{\sigma^2}\sum_i (x_i-\mu) = 0 \implies \hat\mu = \bar x,$$
$$\frac{\partial\ell}{\partial\sigma} \overset{(3)}{=} -\frac{n}{\sigma} + \frac{1}{\sigma^3}\sum_i (x_i-\mu)^2 = 0 \implies \hat\sigma^2 = \frac{1}{n}\sum_i (x_i-\bar x)^2.$$

(1) ln of $\prod_i (2\pi\sigma^2)^{-1/2} e^{-(x_i-\mu)^2/2\sigma^2}$, with $\ln(\sigma^2)^{-n/2} = -n\ln\sigma$.
(2) The chain rule on $(x_i-\mu)^2$ gives $-2(x_i-\mu)$. The sum vanishes when $n\mu = \sum_i x_i$.
(3) Differentiate $-n\ln\sigma$ and σ^{-2}; multiply the equation by σ^3/n; and insert the solution $\mu = \bar x$ of the first equation, because both equations must hold at once.

The centre is the sample mean, as one would guess. The width divides by n, not $n-1$, and so it is *biased*. In Section 3.4.1 we showed that $\mathbb{E}\sum_i (x_i-\bar x)^2 = (n-1)\sigma^2$. Dividing by n gives $\mathbb{E}\,\hat\sigma^2 = \frac{n-1}{n}\sigma^2$: the MLE is low by a factor $(n-1)/n$. The bias is the price of estimating μ from the same data, and it vanishes as $n \to \infty$. Maximum likelihood promises good behaviour for large samples, not unbiasedness at every n.

Example: the firing probability of a detector. For the Bernoulli likelihood $p^S(1-p)^{n-S}$ of Section 3.8.2,

$$\ell(p) = S\ln p + (n-S)\ln(1-p), \qquad S(p) = \frac{S}{p} - \frac{n-S}{1-p} = 0 \implies \hat p = \frac{S}{n},$$

because multiplying the score equation by $p(1-p)$ gives $S(1-p) - (n-S)p = S - np = 0$. For $S = 12$ in $n = 20$ trials, $\hat p = 0.6$, the peak seen in Figure 3.30.

Example: when the maximum sits on an edge. For the uniform box the likelihood θ^{-n} decreases for all $\theta \geq x_{(n)}$ and is zero below, so the maximum is at the cliff, $\hat\theta = x_{(n)}$ [Wasserman p. 124]. The score equation $-n/\theta = 0$ has no solution at all; the maximum is found by

looking, not by differentiating. The estimator is biased low, because the largest of n points always falls short of the end of the box: $\mathbb{E}\, x_{(n)} = \frac{n}{n+1}\theta$. A related case arises whenever physics restricts the parameter. A signal strength μ cannot be negative. If we measure $x_i \sim \mathcal{N}(\mu, \sigma^2)$ and find $\bar{x} < 0$, the likelihood restricted to $\mu \geq 0$ is largest at the edge, so $\hat{\mu} = 0$ [CasellaBerger Ex. 7.2.8]. The derivative there is not zero, and several of the nice properties of Section 3.13 fail at such boundaries.

Watch out: The MLE is not "the most probable value of θ"

$\hat{\theta}$ is the value under which the *data* are most probable. It is the most probable value of θ only in a Bayesian analysis with a flat prior, and then only in the parametrisation in which the prior is flat [Sivia p. 64]. Because the likelihood carries no Jacobian, the MLE itself does not care about the parametrisation: $\hat{\lambda} = 1/\hat{\tau}$ (Section 3.13). The peak of a posterior *density* does move under a change of variables.

3.9.2 The method of moments, for comparison

Before maximum likelihood there was a simpler idea. A model with k parameters predicts the first k moments $\alpha_j(\theta) = \mathbb{E}_\theta\, X^j$ [the average of the j-th power of the data, as a function of the parameters]. The data give the sample moments $\hat{\alpha}_j = \frac{1}{n}\sum_i x_i^j$. The **method of moments** estimator sets the two equal and solves, $\alpha_j(\tilde{\theta}) = \hat{\alpha}_j$ for $j = 1, \ldots, k$ [Wasserman p. 121, Def. 9.3], [Cowan Ch. 8]. For the Bernoulli model, $\mathbb{E}\, X = p$ gives $\tilde{p} = \bar{x} = S/n$; for the Gaussian, $\mathbb{E}\, X = \mu$ and $\mathbb{E}\, X^2 = \sigma^2 + \mu^2$ give $\tilde{\mu} = \bar{x}$ and $\tilde{\sigma}^2 = \frac{1}{n}\sum x_i^2 - \bar{x}^2 = \frac{1}{n}\sum (x_i - \bar{x})^2$ [Wasserman p. 121, Exs. 9.4–9.5]. Both coincide with the MLE. Under mild conditions the moment estimator is consistent and asymptotically Gaussian [Wasserman p. 122, Thm. 9.6], but in general it throws information away, and the MLE is at least as precise for large samples (Section 3.13).

Example: an angular distribution. In $e^+e^- \to \mu^+\mu^-$ the distribution of $x = \cos\theta$ of the outgoing muon has the shape $1 + \alpha x + \beta x^2$, where β comes from the photon exchange and α, the forward–backward asymmetry, from its interference with the Z. The detector accepts only $x_{\min} \leq x \leq x_{\max}$, so the density is [Cowan §6.8, (8.9)]

$$f(x;\alpha,\beta) = \frac{1 + \alpha x + \beta x^2}{d_1 + \alpha d_2 + \beta d_3}, \qquad d_k \equiv \frac{x_{\max}^k - x_{\min}^k}{k}, \tag{3.83}$$

because $\int_{x_{\min}}^{x_{\max}} (1 + \alpha x + \beta x^2)\,\mathrm{d}x = d_1 + \alpha d_2 + \beta d_3$. The first two moments are ratios of the same kind,

$$\mathbb{E}\, x \overset{(1)}{=} \frac{d_2 + \alpha d_3 + \beta d_4}{d_1 + \alpha d_2 + \beta d_3}, \qquad \mathbb{E}\, x^2 \overset{(2)}{=} \frac{d_3 + \alpha d_4 + \beta d_5}{d_1 + \alpha d_2 + \beta d_3},$$

(1) $\int x(1 + \alpha x + \beta x^2)\,\mathrm{d}x = d_2 + \alpha d_3 + \beta d_4$.
(2) $\int x^2(1 + \alpha x + \beta x^2)\,\mathrm{d}x = d_3 + \alpha d_4 + \beta d_5$.

and setting them equal to $\hat{\alpha}_1 = \overline{x}$ and $\hat{\alpha}_2 = \overline{x^2}$ and multiplying out gives two *linear* equations for (α, β),

$$\alpha(\hat{\alpha}_1 d_2 - d_3) + \beta(\hat{\alpha}_1 d_3 - d_4) = d_2 - \hat{\alpha}_1 d_1, \qquad \alpha(\hat{\alpha}_2 d_2 - d_4) + \beta(\hat{\alpha}_2 d_3 - d_5) = d_3 - \hat{\alpha}_2 d_1.$$

For 2000 simulated events with $\alpha = \beta = 0.5$ on $-0.95 \leq x \leq 0.95$ (Cowan's set-up), these give $(\tilde{\alpha}, \tilde{\beta}) = (0.49, 0.4458)$. The maximum likelihood equations for the same model are not linear, so they need a numerical method.

3.9.3 When the calculus cannot be done: Newton–Raphson

For (3.83) the log-likelihood is $\ell(\alpha,\beta)=\sum_i \ln(1+\alpha x_i+\beta x_i^2)-n\ln(d_1+\alpha d_2+\beta d_3)$, and its score equations have no closed-form solution. The standard numerical maximiser replaces ℓ near a trial point by a parabola and jumps to the parabola's top. The same parabola gives the error bar in Section 3.12. Near a trial point θ_j,

$$\ell(\theta)\overset{(1)}{=}\ell(\theta_j)+\ell'(\theta_j)(\theta-\theta_j)+\tfrac12\ell''(\theta_j)(\theta-\theta_j)^2+\dots,$$
$$0\overset{(2)}{=}\ell'(\theta_j)+\ell''(\theta_j)(\theta_{j+1}-\theta_j)\quad\Longrightarrow\quad \theta_{j+1}=\theta_j-\frac{\ell'(\theta_j)}{\ell''(\theta_j)}. \tag{3.84}$$

(1) Taylor expansion to second order: we replace ℓ by the parabola that has the same value, slope and curvature at θ_j.
(2) Jump to the top of that parabola, where its derivative vanishes.

With several parameters, ℓ' becomes the gradient $\boldsymbol{g}$ and ℓ'' the matrix of second derivatives H (the **Hessian**), and the step is $\boldsymbol{\theta}_{j+1}=\boldsymbol{\theta}_j-H^{-1}\boldsymbol{g}$. Near the maximum the error shrinks quadratically, roughly squaring at every step, so a handful of iterations suffice. Figure 3.32 shows the first two steps on a lifetime likelihood.

Example: Newton by hand. Take $n=5$ decays with total time $T=6$, so that $\ell(\tau)=-5\ln\tau-6/\tau$, $\ell'=-5/\tau+6/\tau^2$, $\ell''=5/\tau^2-12/\tau^3$, and the exact answer is $\hat\tau=T/n=1.2$. Start at $\tau_0=0.8$:

$$\tau_1\overset{(1)}{=}0.8-\frac{-6.25+9.375}{7.8125-23.4375}=0.8+\frac{3.125}{15.625}=1.0,$$
$$\tau_2\overset{(2)}{=}1.0-\frac{-5+6}{5-12}=1+\frac17=1.1429,$$
$$\tau_3\overset{(3)}{=}1.1429+\frac{0.2188}{4.2109}=1.1948,\qquad \tau_4=1.19996,\qquad \tau_5=1.2000.$$

(1) (3.84) with $\ell'(0.8)=-5/0.8+6/0.64$ and $\ell''(0.8)=5/0.64-12/0.512$.
(2) The same at $\tau_1=1$.
(3) The same at τ_2, where $\ell'=0.2188$ and $\ell''=-4.2109$.

The distance to the answer goes $0.4,\ 0.2,\ 0.057,\ 0.0052,\ 0.00005$: the number of correct digits roughly doubles per step once we are close.

Newton's method trusts the parabola, and the parabola can lie. Here $\ell''=5/\tau^2-12/\tau^3$ is negative only when $5\tau<12$, that is for $\tau<2T/n=2.4$. Beyond that the curve bends upwards and the parabola has a minimum, not a maximum. Started at $\tau_0=3$, the step therefore points *away* from the maximum. Practical minimisers (the `MINUIT` of particle physics, `scipy.optimize`) therefore check that each step increases ℓ, shorten it if not, and start from a sensible guess. The method of moments is an excellent source of such guesses.

The angular fit in Python. The script `10_angular_ml.py` generates 2000 events from (3.83) by accept–reject (Chapter 6), computes the moment estimate, and hands it to Newton's method. The heart of it is the analytic gradient and Hessian,

$$\frac{\partial\ell}{\partial\alpha}=\sum_i\frac{x_i}{g_i}-\frac{n\,d_2}{D},\qquad \frac{\partial^2\ell}{\partial\alpha^2}=-\sum_i\frac{x_i^2}{g_i^2}+\frac{n\,d_2^2}{D^2},\qquad g_i=1+\alpha x_i+\beta x_i^2,\quad D=d_1+\alpha d_2+\beta d_3,$$

and the same with $x_i\to x_i^2$, $d_2\to d_3$ for β (the mixed derivative has x_i^3 and $d_2 d_3$). These follow from $\mathrm{d}\ln g/\mathrm{d}\alpha=x/g$ and $\mathrm{d}\ln D/\mathrm{d}\alpha=d_2/D$ and one more derivative of each.

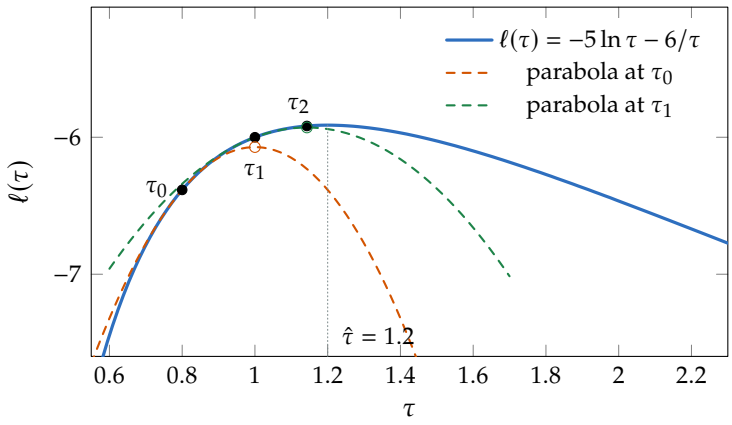

Figure 3.32: Newton–Raphson on a log-likelihood. At the starting point τ_0 the method replaces ℓ by the parabola (orange) with the same height, slope and curvature, and jumps to its top (open circle), which lies straight above τ_1. Repeating from τ_1 (green parabola) lands at τ_2, already close to the true maximum at $\hat\tau = 1.2$ (dotted line). Each parabola hugs the curve better than the last because the curve looks more and more like a parabola near its peak.

Listing 3.8: Newton–Raphson for the angular distribution, and the covariance from the Hessian (`code/ch03/10_angular_ml.py`)

```
def newton(x, th0, tol=1e-10, maxit=50):
    th, path = np.array(th0, float), [np.array(th0, float)]
    for it in range(maxit):
        g, H = grad_hess(th, x)
        step = -np.linalg.solve(H, g)                # theta_{j+1} = theta_j - H^{-1} grad
        th = th + step
        path.append(th.copy())
        if np.max(np.abs(step)) < tol:
            break
    return th, np.array(path)

# ---------- one experiment ----------
x = sample(n)
th_mom = mom(x)
th_ml, path = newton(x, th_mom)
_, H = grad_hess(th_ml, x)
V = np.linalg.inv(-H)                                # covariance = inverse of minus the
    Hessian
sa, sb = np.sqrt(np.diag(V))
rho = V[0, 1] / (sa * sb)
```

The loop is (3.84) in matrix form: `np.linalg.solve(H, g)` computes $H^{-1}g$ without forming the inverse. The last four lines compute the covariance of the estimates as the inverse of minus the Hessian at the maximum, a rule derived in Section 3.12. Starting from the moment estimate, Newton reaches $(\hat\alpha, \hat\beta) = (0.4885, 0.4396)$ in 4 iterations; after the first step the answer already agrees with the final one far better than its error bar. The left panel of Figure 3.33 shows the fitted density on the histogram of the events.

Repeating the whole experiment 500 times, the maximum likelihood estimates average $(0.502, 0.4986)$ (truth $(0.5, 0.5)$) and scatter by $\sigma_{\hat\alpha} = 0.05376$ and $\sigma_{\hat\beta} = 0.1081$. The moment estimates scatter by 0.05422 and 0.1109. Both methods were applied to the same 500 data sets, so the ratios of the spreads are measured well: 1.009 ± 0.007096 for α and 1.026 ± 0.009865 for β. For this mild distribution the two methods are close; the gap widens for sharply peaked densities, where low moments are poor summaries of the shape.

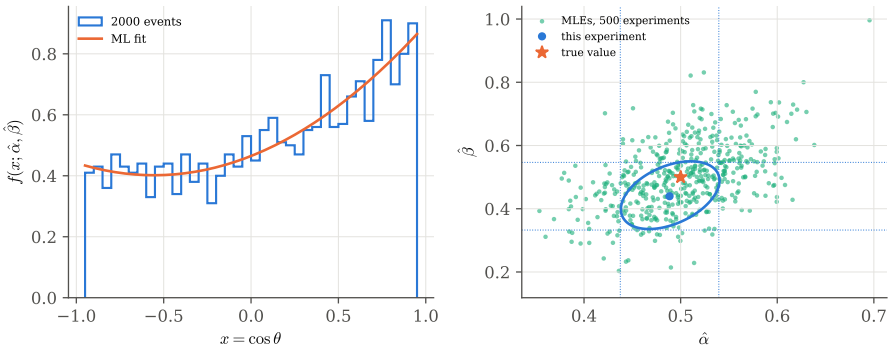

Figure 3.33: A two-parameter maximum likelihood fit. Left: 2000 simulated values of $\cos\theta$ and the fitted density $1+\hat\alpha x+\hat\beta x^2$ (normalised). Right: the fitted $(\hat\alpha,\hat\beta)$ of 500 independent repetitions of the experiment (green), the fit of the first experiment (blue dot), the truth (star), and the contour on which $\ln\mathcal{L}$ of the first experiment has dropped by $\frac{1}{2}$ from its maximum. The dotted lines tangent to the contour mark $\hat\alpha\pm\sigma_{\hat\alpha}$ and $\hat\beta\pm\sigma_{\hat\beta}$ from the inverse Hessian. The cloud of repetitions has the size, tilt and shape of the contour.

When the number of events is itself random. In a counting experiment the total number of events n is not fixed in advance: it is Poisson distributed with a mean ν that the theory may predict (a cross-section times a luminosity). Then the likelihood acquires one more factor [Cowan §6.9],

$$\mathcal{L}(\nu,\theta)=\frac{\nu^n e^{-\nu}}{n!}\prod_{i=1}^{n}f(x_i;\theta)=\frac{e^{-\nu}}{n!}\prod_{i=1}^{n}\nu f(x_i;\theta), \tag{3.85}$$

the **extended likelihood**. If ν is a free parameter unrelated to θ, the ν-dependent part of ℓ is $n\ln\nu-\nu$, whose derivative $n/\nu-1$ vanishes at $\hat\nu=n$. The θ-dependent part is the same as before, so $\hat\theta$ is unchanged. If $\nu=\nu(\theta)$, the total rate carries information about θ in addition to the shape, and the extended likelihood uses both. The product $\nu f(x;\theta)$ is the expected number of events per unit x, which is why the extended likelihood is the natural starting point for histograms of counts (Section 3.11).

Hidden variables. Some likelihoods are easy to maximise only if we knew something we were not told, for example which of two Gaussian populations each point came from (a mixture model). The **EM algorithm** alternates between guessing the hidden labels from the current parameters (the "E" step, an expectation) and maximising the likelihood as if the labels were known (the "M" step). No cycle can decrease $\mathcal{L}$ [Wasserman pp. 143–145]. It is the standard tool for fitting mixtures.

3.10 Gaussian noise: least squares and the χ^2

Every physics student has fitted a straight line through points with error bars by "minimising χ^2". The rule is usually taught without a reason. Why squares and not absolute values? Why divide by σ_i^2? What is the error on the slope, and how do we know whether the line is any good? All of this follows in a few lines from the likelihood of Section 3.8, once we assume that the noise is Gaussian. The same lines then cover noise that is correlated from point to point, which is the normal situation for binned power spectra and for gravitational-wave strain. Four questions need answers.

1. Why is least squares the maximum likelihood estimator for Gaussian noise, and when is it not?

2. For a model linear in its parameters, what are the estimates and their covariance, exactly?
3. What value of $\chi^2_{\min}$ should a correct model give, and how do we turn it into a test of the fit?
4. What changes when the noise is correlated, and what goes wrong if we ignore the correlation?

3.10.1 Least squares is Gaussian maximum likelihood

Take data $D_i = d_i(\boldsymbol{\theta}) + \epsilon_i$, $i = 1, \dots, N$: the model prediction $d_i(\boldsymbol{\theta})$ plus independent noise $\epsilon_i \sim \mathcal{N}(0, \sigma_i^2)$ with known σ_i. Its log-likelihood is (3.79) of Section 3.8.2. Written with the **normalised residuals** $R_i = (D_i - d_i(\boldsymbol{\theta}))/\sigma_i$ it reads [Sivia p. 65, (3.65)–(3.67)]

$$\ell(\boldsymbol{\theta}) \overset{(1)}{=} -\frac{1}{2}\sum_{i=1}^{N} R_i^2 - \sum_{i=1}^{N} \ln \sqrt{2\pi}\,\sigma_i \overset{(2)}{=} -\frac{1}{2}\chi^2(\boldsymbol{\theta}) + \text{const}, \qquad \chi^2(\boldsymbol{\theta}) \equiv \sum_{i=1}^{N} \frac{\big(D_i - d_i(\boldsymbol{\theta})\big)^2}{\sigma_i^2}. \tag{3.86}$$

(1) (3.79), with the residuals in units of their error bars.
(2) The error bars are known numbers, so the second sum does not depend on $\boldsymbol{\theta}$.

Maximising ℓ is minimising χ^2, because of the minus sign. So the **least-squares estimator** is the maximum likelihood estimator [Cowan §7.1], [HobsonBMC p. 50, (2.24)–(2.25)]. This answers the two "why" questions. The squares come from the exponent of the Gaussian. The $1/\sigma_i^2$ measures each residual against its own error bar: a residual of 0.3 is a one-sigma event for a point with $\sigma_i = 0.3$ and a ten-sigma event for a point with $\sigma_i = 0.03$. With equal error bars all points count equally. For a constant model, $\chi^2 = \sum_i (D_i - \mu)^2/\sigma_i^2$, and minimising it over μ gives the inverse-variance weighted mean of Section 3.7.

The derivation also says when least squares is *not* maximum likelihood. It used two assumptions, and each can fail. If the noise is not Gaussian (heavy tails, outliers, counts), the exponent is not a square. If the error bars depend on the parameters, for example $\sigma_i^2 = d_i(\boldsymbol{\theta})$ for counts, the term $\sum \ln \sigma_i$ depends on $\boldsymbol{\theta}$ and cannot be dropped. So least squares is what the likelihood reduces to under these two assumptions. When it misbehaves, the cure is to go back to the likelihood, not to patch the recipe [Sivia p. 66].

3.10.2 Linear models: the normal equations

Many models are linear in their parameters even when they are not linear in x: a straight line $a + bx$, a polynomial, a sum of templates with unknown amplitudes. Write such a model as $d_i(\boldsymbol{\theta}) = \sum_{k=1}^{m} A_{ik}\theta_k$, or $\boldsymbol{d} = A\boldsymbol{\theta}$, where the $N \times m$ **design matrix** A [column k is the model curve for $\theta_k = 1$ and all other parameters zero] is known. For a line, row i of A is $(1,\ x_i)$. Collect the error bars into the diagonal covariance $\mathbf{C} = \mathrm{diag}(\sigma_1^2, \dots, \sigma_N^2)$; everything below also holds for a general $\mathbf{C}$, which we use in Section 3.10.5. Then

$$\begin{aligned} \chi^2(\boldsymbol{\theta}) &\overset{(1)}{=} (\boldsymbol{D} - A\boldsymbol{\theta})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{D} - A\boldsymbol{\theta}), \\ \frac{\partial \chi^2}{\partial \boldsymbol{\theta}} &\overset{(2)}{=} -2A^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{D} - A\boldsymbol{\theta}) \overset{(3)}{=} \mathbf{0} \quad\Longrightarrow\quad (A^{\mathsf{T}}\mathbf{C}^{-1}A)\,\hat{\boldsymbol{\theta}} = A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}, \\ \hat{\boldsymbol{\theta}} &\overset{(4)}{=} (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D} \;\equiv\; B\boldsymbol{D}. \end{aligned} \tag{3.87}$$

(1) With a diagonal $\mathbf{C}$ this is $\sum_i (D_i - d_i)^2/\sigma_i^2$ written as a matrix product.
(2) Differentiate the quadratic form: for a symmetric matrix M, $\partial(\boldsymbol{v}^{\mathsf{T}}M\boldsymbol{v})/\partial\boldsymbol{\theta} = 2(\partial\boldsymbol{v}/\partial\boldsymbol{\theta})^{\mathsf{T}}M\boldsymbol{v}$, and here $\partial\boldsymbol{v}/\partial\boldsymbol{\theta} = -A$.

(3) The score equation. These m linear equations are the **normal equations**.
(4) The matrix $A^{\mathsf{T}}\mathbf{C}^{-1}A$ is $m \times m$ and invertible as long as the columns of A are linearly independent (no two parameters do the same thing to the model).

The estimator is a fixed matrix B times the data. So its mean and covariance follow from linear error propagation, which is exact for linear maps (Section 3.6.2):

$$\begin{aligned} \mathbb{E}\,\hat{\boldsymbol{\theta}} &\overset{(1)}{=} B\,\mathbb{E}\,\boldsymbol{D} \overset{(2)}{=} (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}A\boldsymbol{\theta} = \boldsymbol{\theta}, \\ \operatorname{Cov}\hat{\boldsymbol{\theta}} &\overset{(3)}{=} B\,\mathbf{C}\,B^{\mathsf{T}} \overset{(4)}{=} (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}\,\mathbf{C}\,\mathbf{C}^{-1}A(A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1} \overset{(5)}{=} (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1} \equiv U. \end{aligned} \tag{3.88}$$

(1) Expectation is linear.
(2) The noise has mean zero, so $\mathbb{E}\,\boldsymbol{D} = A\boldsymbol{\theta}$.
(3) Covariance of a linear map, $\operatorname{Cov}(B\boldsymbol{D}) = B\operatorname{Cov}(\boldsymbol{D})B^{\mathsf{T}}$.
(4) Insert B and B^{T}; $\mathbf{C}$ and $A^{\mathsf{T}}\mathbf{C}^{-1}A$ are symmetric.
(5) $\mathbf{C}^{-1}\mathbf{C} = \mathbb{1}$, and then $(A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}(A^{\mathsf{T}}\mathbf{C}^{-1}A) = \mathbb{1}$.

So for a linear model with Gaussian noise the least-squares estimates are unbiased and have covariance $U = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}$, with no approximation. Now look at the curvature of χ^2. Differentiating (3.87) once more gives $\partial^2\chi^2/\partial\boldsymbol{\theta}\,\partial\boldsymbol{\theta}^{\mathsf{T}} = 2A^{\mathsf{T}}\mathbf{C}^{-1}A = 2U^{-1}$. Because χ^2 is exactly quadratic in $\boldsymbol{\theta}$, its Taylor series stops there:

$$\chi^2(\boldsymbol{\theta}) = \chi^2_{\min} + (\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}}U^{-1}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}), \qquad \ell(\boldsymbol{\theta}) = \ell_{\max} - \tfrac{1}{2}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}}U^{-1}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}). \tag{3.89}$$

The likelihood is an exact Gaussian in $\boldsymbol{\theta}$, centred on $\hat{\boldsymbol{\theta}}$, whose width matrix is the covariance of the estimator. In one dimension $\chi^2(\theta) = \chi^2_{\min} + (\theta-\hat{\theta})^2/\sigma^2_{\hat{\theta}}$, so the parameter values at which χ^2 has risen by one from its minimum are exactly $\hat{\theta} \pm \sigma_{\hat{\theta}}$ [Cowan §7.2]. This is the model case for the rule "the curvature of the log-likelihood is the error", which Section 3.12 extends to every smooth likelihood.

Key idea: Linear least squares

For data $\boldsymbol{D} = A\boldsymbol{\theta} + \boldsymbol{\epsilon}$ with Gaussian noise of covariance $\mathbf{C}$,

$$\hat{\boldsymbol{\theta}} = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}, \qquad \operatorname{Cov}\hat{\boldsymbol{\theta}} = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1},$$

the estimator is unbiased and Gaussian, and χ^2 rises by exactly one at $\hat{\theta}_k \pm \sigma_{\hat{\theta}_k}$ when the other parameters are re-minimised. Nothing here is asymptotic.

Example: a straight line through three points. Fit $y = a + bx$ to $(x_i, y_i) = (0, 1.1), (1, 1.9), (2, 3.2)$, all with $\sigma = 0.1$. For a line the normal equations are 2×2, and it pays to name the sums $S = \sum 1/\sigma_i^2$, $S_x = \sum x_i/\sigma_i^2$, $S_{xx} = \sum x_i^2/\sigma_i^2$, $S_y = \sum y_i/\sigma_i^2$, $S_{xy} = \sum x_i y_i/\sigma_i^2$ and $\Delta = SS_{xx} - S_x^2$. In units of $1/\sigma^2 = 100$ they are $S = 3$, $S_x = 3$, $S_{xx} = 5$, $S_y = 6.2$, $S_{xy} = 8.3$. Then

$$\begin{aligned} \begin{pmatrix}\hat{a}\\ \hat{b}\end{pmatrix} &\overset{(1)}{=} \begin{pmatrix} S & S_x \\ S_x & S_{xx}\end{pmatrix}^{-1}\begin{pmatrix} S_y \\ S_{xy}\end{pmatrix} \overset{(2)}{=} \frac{1}{\Delta}\begin{pmatrix} S_{xx}S_y - S_xS_{xy} \\ SS_{xy} - S_xS_y\end{pmatrix} = \frac{1}{6}\begin{pmatrix} 31 - 24.9 \\ 24.9 - 18.6\end{pmatrix} = \begin{pmatrix} 1.017 \\ 1.050\end{pmatrix}, \\ U &\overset{(3)}{=} \frac{1}{\Delta}\begin{pmatrix} S_{xx} & -S_x \\ -S_x & S\end{pmatrix} = \sigma^2\begin{pmatrix} 5/6 & -1/2 \\ -1/2 & 1/2\end{pmatrix}, \qquad \sigma_{\hat{a}} = 0.091, \quad \sigma_{\hat{b}} = 0.071, \quad \rho = -0.775. \end{aligned}$$

(1) The normal equations (3.87): with rows $(1, x_i)$, $A^{\mathsf{T}}\mathbf{C}^{-1}A$ has entries S, S_x, S_x, S_{xx} and $A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{y} = (S_y, S_{xy})^{\mathsf{T}}$.
(2) Inverse of a 2×2 matrix: swap the diagonal, negate the off-diagonal, divide by the determinant Δ. Here $\Delta = 3 \cdot 5 - 3^2 = 6$ in units of σ^{-4}; the powers of σ cancel in $\hat{a}, \hat{b}$.

(3) $U = (A^\mathsf{T}\mathbf{C}^{-1}A)^{-1}$ from (3.88); restoring the units, $1/\Delta = \sigma^4/6$ and the matrix entries carry $1/\sigma^2$.

The intercept and slope are strongly anticorrelated, $\rho = -(1/2)/\sqrt{(5/6)(1/2)}$: if the fitted slope is a little too steep, the line must start a little lower to pass through the middle of the data. Choosing the origin of x at the weighted mean, $\bar{x} = S_x/S = 1$, would make $S_x = 0$ and the two estimates uncorrelated. The residuals are $y_i - \hat{a} - \hat{b}x_i = (0.083, -0.167, 0.083)$, so $\chi^2_{\min} = (0.0069 + 0.0278 + 0.0069)/0.01 = 4.17$. Is that good or bad?

3.10.3 How good is the fit? The distribution of $\chi^2_{\min}$

If the model is right, every normalised residual is a standard Gaussian before fitting, and $\chi^2(\boldsymbol{\theta}_{\text{true}})$ is a sum of N squared standard Gaussians, so it follows the χ^2_N distribution (Chapter 2). Fitting lowers it: the fitted curve bends towards the data and eats part of the noise. By how much? The cleanest way to see it is geometric.

Whiten the data first. Factor the covariance as $\mathbf{C} = LL^\mathsf{T}$ (for a diagonal $\mathbf{C}$, simply $L = \operatorname{diag}(\sigma_i)$; in general the Cholesky factor). Then $\boldsymbol{z} = L^{-1}\boldsymbol{D}$, $\tilde{A} = L^{-1}A$ and $\boldsymbol{\eta} = L^{-1}\boldsymbol{\epsilon}$ satisfy $\boldsymbol{z} = \tilde{A}\boldsymbol{\theta} + \boldsymbol{\eta}$ with $\boldsymbol{\eta} \sim \mathcal{N}(\mathbf{0}, \mathbb{1}_N)$, and $\chi^2 = |\boldsymbol{z} - \tilde{A}\boldsymbol{\theta}|^2$ is an ordinary squared distance in $\mathbb{R}^N$. The model predictions $\tilde{A}\boldsymbol{\theta}$, as $\boldsymbol{\theta}$ ranges over $\mathbb{R}^m$, fill an m-dimensional flat subspace (the column space of $\tilde{A}$). Minimising the distance means dropping a perpendicular: the fit is the orthogonal projection of $\boldsymbol{z}$ onto that subspace (Figure 3.34). With the projector $P = \tilde{A}(\tilde{A}^\mathsf{T}\tilde{A})^{-1}\tilde{A}^\mathsf{T}$ [the matrix that maps any vector to its closest point in the model subspace. It satisfies $P^2 = P$ and $P^\mathsf{T} = P$],

$$\begin{aligned} \chi^2_{\min} &\overset{(1)}{=} \big|(1-P)\boldsymbol{z}\big|^2 \overset{(2)}{=} \big|(1-P)\boldsymbol{\eta}\big|^2 \overset{(3)}{=} \boldsymbol{\eta}^\mathsf{T}(\mathbb{1}-P)\boldsymbol{\eta}, \\ \mathbb{E}\,\chi^2_{\min} &\overset{(4)}{=} \operatorname{tr}\big[(\mathbb{1}-P)\;\mathbb{E}(\boldsymbol{\eta}\boldsymbol{\eta}^\mathsf{T})\big] \overset{(5)}{=} \operatorname{tr}(\mathbb{1}_N) - \operatorname{tr} P \overset{(6)}{=} N - m \equiv \nu. \end{aligned} \tag{3.90}$$

(1) The fitted point is $P\boldsymbol{z}$, so the residual vector is $\boldsymbol{z} - P\boldsymbol{z}$.
(2) $\boldsymbol{z} = \tilde{A}\boldsymbol{\theta} + \boldsymbol{\eta}$, and $(\mathbb{1} - P)\tilde{A} = 0$ because P leaves every vector of the model subspace unchanged. The true model drops out: only the noise is left.
(3) $|\boldsymbol{v}|^2 = \boldsymbol{v}^\mathsf{T}\boldsymbol{v}$ with $(\mathbb{1} - P)^\mathsf{T}(\mathbb{1} - P) = \mathbb{1} - P$, using $P^\mathsf{T} = P$ and $P^2 = P$.
(4) A number equals its own trace, $\boldsymbol{\eta}^\mathsf{T}M\boldsymbol{\eta} = \operatorname{tr}(M\boldsymbol{\eta}\boldsymbol{\eta}^\mathsf{T})$, and the trace is linear, so it commutes with $\mathbb{E}$.
(5) Whitened noise has $\mathbb{E}(\boldsymbol{\eta}\boldsymbol{\eta}^\mathsf{T}) = \mathbb{1}_N$.
(6) $\operatorname{tr} P = \operatorname{tr}[(\tilde{A}^\mathsf{T}\tilde{A})^{-1}\tilde{A}^\mathsf{T}\tilde{A}] = \operatorname{tr}\mathbb{1}_m = m$, by the cyclic property of the trace.

The fit removes on average exactly one unit of χ^2 per fitted parameter. The whole distribution follows too. P is a projector of rank m, so it has m eigenvalues 1 and $N - m$ eigenvalues 0, and $\mathbb{1} - P$ has the reverse. Rotate to the eigenbasis of P. A rotation of independent standard Gaussians gives independent standard Gaussians again, because $\mathcal{N}(\mathbf{0}, \mathbb{1})$ looks the same in every direction. In the new basis $\chi^2_{\min} = \boldsymbol{\eta}^\mathsf{T}(\mathbb{1} - P)\boldsymbol{\eta}$ keeps only the $N - m$ components with eigenvalue 1, so it is a sum of $N - m$ squared independent standard Gaussians:

$$\chi^2_{\min} \sim \chi^2_\nu, \qquad \nu = N - m, \qquad \mathbb{E}\,\chi^2_{\min} = \nu, \qquad \operatorname{Var}\chi^2_{\min} = 2\nu. \tag{3.91}$$

This is the argument that gave the divisor $N - 1$ in the sample variance (Section 3.4.1), where one parameter, the mean, was fitted. Now there are m. The number ν is the number of **degrees of freedom** of the fit.

Turning $\chi^2_{\min}$ into a test. Given (3.91), a correct model with correct error bars gives $\chi^2_{\min} \approx \nu \pm \sqrt{2\nu}$. The standard summary is the **goodness-of-fit p-value**, the probability that a correct

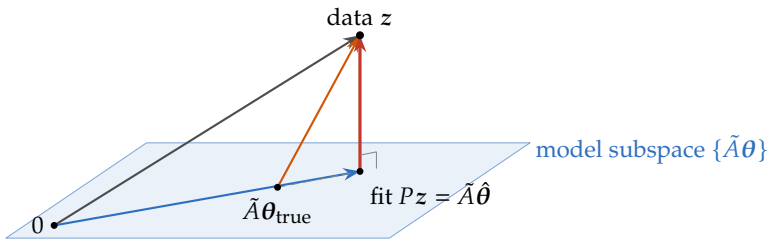

Figure 3.34: Least squares as a projection, after whitening so that the noise is the same in every direction. The data vector lies off the model subspace by the noise vector (orange). The fit drops a perpendicular onto the subspace. The residual (red) is the part of the noise perpendicular to the subspace; the part lying inside it has been absorbed into the fitted parameters, which is why the fit sits away from the truth along the plane. With m parameters, m of the N noise components are absorbed and $N - m$ are left in χ^2_{min}.

model would give a χ^2_{min} at least as large as the one observed, $p = \text{P}(\chi^2_\nu \geq \chi^2_{\text{min}})$ [Padilla §3.5], [Cowan §7.5]. A tiny p says that the data are hard to reconcile with the model and the error bars together: the model is wrong, or the errors are underestimated, or the noise is not Gaussian. A p very close to one ($\chi^2_{\text{min}} \ll \nu$) is also a warning: the errors are overestimated, or there are correlations that were ignored (Section 3.10.5), or the data were "cleaned" by hand. The ratio χ^2_{min}/ν, the **reduced** χ^2, should be near one, with a spread of $\sqrt{2/\nu}$. The full logic of tests, and what a p-value does and does not mean, is Chapter 4.

Example: the three-point line again. Two parameters from three points leave $\nu = 1$. The observed $\chi^2_{\text{min}} = 4.17$ has $p = \text{P}(\chi^2_1 \geq 4.17) = \text{P}(|Z| \geq 2.04) = 0.041$, where $Z \sim \mathcal{N}(0,1)$ and we used that a χ^2_1 variable is the square of one standard Gaussian. Such a large χ^2 happens in about four per cent of experiments if the line and the error bars are both right. With one degree of freedom this is weak evidence, but it would be worth checking whether $\sigma = 0.1$ is honest.

Confidence regions from $\Delta\chi^2$. The quadratic form (3.89), evaluated at the true parameters, is $\chi^2(\boldsymbol{\theta}_{\text{true}}) - \chi^2_{\text{min}} = (\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_{\text{true}})^{\text{T}} U^{-1} (\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_{\text{true}})$, and since $\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_{\text{true}} \sim \mathcal{N}(\mathbf{0}, U)$, it is a sum of m squared standard Gaussians (whiten with U as we whitened with $\mathbf{C}$): $\Delta\chi^2 \sim \chi^2_m$. The region $\{\boldsymbol{\theta} : \chi^2(\boldsymbol{\theta}) \leq \chi^2_{\text{min}} + \Delta\chi^2_\alpha\}$ therefore covers the truth in a fraction $1 - \alpha$ of repeated experiments if $\Delta\chi^2_\alpha$ is the corresponding quantile of χ^2_m [Padilla §3.6, Table III]:

coverage	$m = 1$	$m = 2$	$m = 3$
68.3%	1.00	2.30	3.53
95.4%	4.00	6.17	8.02
99.73%	9.00	11.8	14.2

The threshold depends on the number m of parameters in the joint region, not on the number N of data points.[2] For one parameter at a time, with the others re-minimised, $\Delta\chi^2 = 1$ gives the $\hat{\theta} \pm \sigma_{\hat{\theta}}$ interval found from (3.89). A joint two-parameter 68% region needs $\Delta\chi^2 = 2.30$, a larger ellipse. Since $\ell = -\tfrac{1}{2}\chi^2 + \text{const}$, the same ellipse is the contour on which $\ln \mathcal{L}$ has dropped by 2.30/2 from its maximum (Section 3.12).

[2] Padilla et al. write the recipe as $Q(n - M, \min \chi^2 + \Delta\chi^2) = p$ [Padilla (37)], which mixes the goodness-of-fit distribution (with $n - M$ degrees of freedom) with the distribution of $\Delta\chi^2$ (with M). Their Table III is correct and follows from $\text{P}(\chi^2_M \leq \Delta\chi^2) = p$.

3.10.4 Fitting a line in Python

The script `11_line_fit.py` fits $y = a + bx$ to $N = 10$ points at $x = 1, \dots, 10$ with error bars growing from 0.48 to 1.2, true values $a = 1$, $b = 0.5$. The whole of linear least squares is five lines.

Listing 3.9: Generalised least squares in five lines (`code/ch03/11_line_fit.py`)

```
def gls(y, C):
    """generalised least squares: theta = (A^T C^-1 A)^-1 A^T C^-1 y and its covariance"""
    Ci = np.linalg.inv(C)
    U = np.linalg.inv(A.T @ Ci @ A)
    th = U @ A.T @ Ci @ y.T
    r = y - (A @ th).T
    chi2 = np.einsum("...i,ij,...j->...", r, Ci, r)
    return th.T, U, chi2
```

Line by line: invert the covariance, form $U = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}$, apply (3.87), form the residuals and $\chi^2 = \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$. The function accepts a whole stack of data sets at once (one per row of `y`), which is how we fit 10^4 simulated experiments in one call.

For the first data set the fit gives $\hat{a} = 1.238 \pm 0.4113$, $\hat{b} = 0.4187 \pm 0.08767$ with correlation -0.8223, and $\chi^2_{\min} = 11.01$ for $\nu = 8$, a goodness-of-fit $p = 0.2012$: an unremarkable fit. Over 10^4 repetitions the estimates scatter by 0.4067 and 0.08717 with correlation -0.8182, exactly as U predicts, and $\chi^2_{\min}$ has mean 7.932 and variance 15.69, against $\nu = 8$ and $2\nu = 16$ from (3.91). Fitting the wrong model, a constant, to the same data gives an average $\chi^2_{\min}$ of 41.36 for 9 degrees of freedom: the test sees the missing slope at once (Figure 3.35).

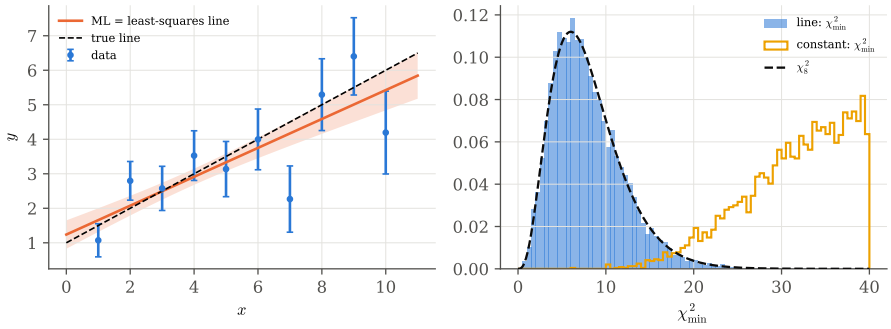

Figure 3.35: Least squares as Gaussian maximum likelihood. Left: ten points with error bars that grow to the right, the fitted line with its $\pm 1\sigma$ band from $U = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}$ (narrowest near the weighted centre of the data), and the true line (dashed). Right: $\chi^2_{\min}$ of 10^4 simulated experiments for the correct model (filled), which follows the χ^2_8 curve, and for a constant fitted to the same data (outline), which sits far to the right.

3.10.5 Correlated noise: $\chi^2 = \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$

Noise is often correlated from one data point to the next. Neighbouring bins of a power spectrum share modes. A slowly drifting baseline pushes consecutive readings up together. A common calibration error moves every point at once. The noise is then a Gaussian vector $\boldsymbol{\epsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{C})$ with a non-diagonal covariance, and the likelihood is the multivariate normal density (Chapter 2) evaluated at the required noise $\boldsymbol{r} = \boldsymbol{D} - \boldsymbol{d}(\boldsymbol{\theta})$:

$$\mathcal{L}(\boldsymbol{\theta}) \overset{(1)}{=} p_{\boldsymbol{\eta}}\big(L^{-1}\boldsymbol{r}\big)\,\big|\det L^{-1}\big| \overset{(2)}{=} \frac{1}{(2\pi)^{N/2}}\, e^{-\frac{1}{2}(L^{-1}\boldsymbol{r})^{\mathsf{T}}(L^{-1}\boldsymbol{r})}\, \frac{1}{|\det L|}$$

$$\overset{(3)}{=} \frac{1}{\sqrt{(2\pi)^N \det \mathbf{C}}} \exp\!\Big[-\tfrac{1}{2}\, \boldsymbol{r}^{\mathsf{T}} \mathbf{C}^{-1} \boldsymbol{r}\Big], \qquad -2\ell(\boldsymbol{\theta}) = \boldsymbol{r}^{\mathsf{T}} \mathbf{C}^{-1} \boldsymbol{r} + \ln\det \mathbf{C} + N \ln 2\pi. \tag{3.92}$$

(1) Write the noise as $\boldsymbol{\epsilon} = L\boldsymbol{\eta}$ with $\mathbf{C} = LL^{\mathsf{T}}$ and $\boldsymbol{\eta} \sim \mathcal{N}(\mathbf{0}, \mathbb{1})$. Changing variables from $\boldsymbol{\eta}$ to $\boldsymbol{\epsilon}$ multiplies the density by the Jacobian $|\det(\partial\boldsymbol{\eta}/\partial\boldsymbol{\epsilon})| = |\det L^{-1}|$.

(2) Independent standard Gaussians: the density is the product of N factors $(2\pi)^{-1/2} e^{-\eta_i^2/2}$.

(3) $(L^{-1}\boldsymbol{r})^{\mathsf{T}}(L^{-1}\boldsymbol{r}) = \boldsymbol{r}^{\mathsf{T}}(LL^{\mathsf{T}})^{-1}\boldsymbol{r} = \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$, and $(\det L)^2 = \det \mathbf{C}$.

So the correlated χ^2 is $\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$, and every result above, from the normal equations to $\chi^2_{\min} \sim \chi^2_{N-m}$, holds with this $\mathbf{C}$, because those derivations never used that $\mathbf{C}$ was diagonal. This is the likelihood written for cosmological data with correlated errors. One term needs care. The $\ln\det \mathbf{C}$ is a constant only if the covariance does not depend on the parameters. For the power spectrum of a Gaussian random field the covariance *is* the signal (cosmic variance scales with C_ℓ itself), and then $\ln\det \mathbf{C}(\boldsymbol{\theta})$ must be kept. Dropping it biases the fit (Chapter 7).

What goes wrong if we ignore the correlation? Suppose the noise has covariance $\mathbf{C}_{ij} = \sigma_i \sigma_j e^{-|x_i - x_j|/2}$ (neighbours correlated at $e^{-1/2} = 0.61$) but we fit with only the diagonal. The estimator is still $\hat{\boldsymbol{\theta}} = B_{\text{diag}}\boldsymbol{D}$, a linear function of the data with $B_{\text{diag}}A = \mathbb{1}$, so it is still *unbiased*. What is wrong is the error bar. The quoted covariance $(A^{\mathsf{T}}\mathbf{C}_{\text{diag}}^{-1}A)^{-1}$ assumes the noise we did not have; the true covariance is $B_{\text{diag}}\mathbf{C}B_{\text{diag}}^{\mathsf{T}}$ by the same propagation rule as (3.88). The second half of `11_line_fit.py` draws correlated noise as $L\boldsymbol{\eta}$ with the Cholesky factor and fits 10^4 data sets both ways. For the slope:

fit	mean $\hat{b}$	quoted $\sigma_{\hat{b}}$	true scatter of $\hat{b}$
diagonal χ^2	0.4986	0.08767	0.1282 (predicted 0.1284)
full $\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$	0.4994	0.121	0.1212

Both fits centre on the true slope 0.5. The diagonal fit claims an error of 0.08767 but actually scatters by 0.1282, so every quoted interval is too short by a third. The full fit quotes its error correctly, and that error is also smaller than the true error of the diagonal fit: using the correlations is not only honest but more precise. The goodness of fit misleads too. With the diagonal χ^2 the average $\chi^2_{\min}$ is 4.77 instead of 8, a fit that looks suspiciously good; with the full $\mathbf{C}$ it is 8.069 (Figure 3.36).

Watch out: Correlated noise makes a bad error bar look like a good fit

Positively correlated noise moves neighbouring points up and down together. A smooth model can follow such coherent wiggles, so the residuals come out smaller than independent noise of the same size would give, and $\chi^2_{\min} \ll \nu$. At the same moment the parameter errors computed from the diagonal are too small. A reduced χ^2 well below one is a hint to look for correlations, not a reason to celebrate.

The same idea for a gravitational-wave detector. Detector noise is correlated in time but, if stationary, it is uncorrelated between different frequencies: the Fourier transform diagonalises its covariance, and the diagonal entries are the noise power spectral density $S_n(f)$ [the noise variance per unit frequency. Frequencies where the detector is noisy have large S_n]. The sum $\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ then becomes an integral over frequency, with $\tilde{r}(f) = \int r(t) e^{-2\pi i f t}\,\mathrm{d}t$,

$$-2\ell(\boldsymbol{\theta}) = (D - h_{\boldsymbol{\theta}} \,|\, D - h_{\boldsymbol{\theta}}) + \text{const}, \qquad (a \,|\, b) \equiv 4\,\mathrm{Re}\int_0^\infty \frac{\tilde{a}(f)\,\tilde{b}^*(f)}{S_n(f)}\,\mathrm{d}f,$$

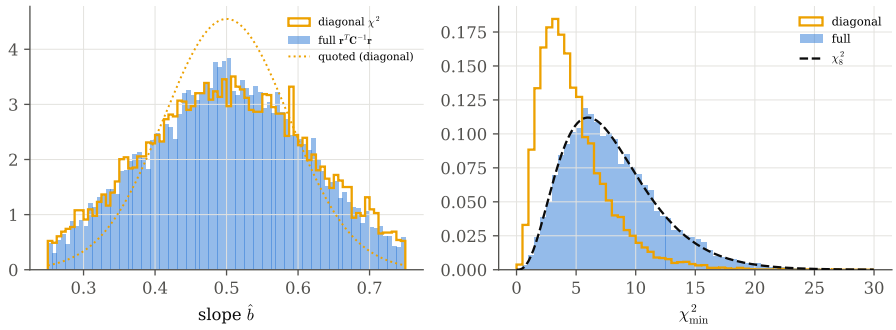

Figure 3.36: Fitting data with correlated noise, 10^4 simulated experiments. Left: the slope from the diagonal χ^2 (outline) and from the full $\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ (filled). Both are centred on the truth, but the diagonal fit is wider than the Gaussian it quotes (dotted). Right: the diagonal fit's $\chi^2_{\min}$ piles up well below the χ^2_8 curve, while the full fit's follows it.

where $h_{\boldsymbol{\theta}}$ is the waveform predicted for source parameters $\boldsymbol{\theta}$. The **noise-weighted inner product** $(a|b)$ is $\boldsymbol{a}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{b}$ in the basis where $\mathbf{C}$ is diagonal, with one-sided S_n and positive frequencies only, hence the factor 4. Every gravitational-wave parameter estimate, and the Fisher forecasts of Chapter 10, start from this one line.

3.11 Counting experiments: the Poisson likelihood of a histogram

A search at a collider histograms the invariant mass of candidate events into bins; an X-ray telescope histograms photon energies; a decay experiment histograms decay times. Far from the peak, or in a short run, many bins hold a handful of events, and some hold none. The habit of putting an error bar $\sqrt{n_i}$ on every bin and minimising χ^2 breaks down here. A bin with $n_i = 0$ gets an error bar of zero, and bins that fluctuated low get error bars that are too small. The reason is that the noise in a counting experiment is not Gaussian and is not added to the prediction. The count in a bin is a Poisson random number whose mean is the prediction. The likelihood has no trouble with this, because all it needs is the probability of what was observed. Four questions need answers.

1. What is the likelihood of a histogram of counts, and what does maximising it do to the total number of events?
2. Can the same likelihood also tell us whether the fit is good?
3. What exactly goes wrong with the two χ^2 recipes that use $\sqrt{n_i}$ or $\sqrt{\mu_i}$ as the error bar?
4. How does the idea carry over to other data: measurements with Gaussian errors, gravitational-wave strain, CMB maps?

3.11.1 The likelihood of a histogram

Divide the range of x into N bins. If events arrive independently at a constant rate, the count n_i in bin i is Poisson distributed (Chapter 2) with mean

$$\mu_i(\nu, \boldsymbol{\theta}) = \nu \int_{\text{bin } i} f(x;\boldsymbol{\theta})\,\mathrm{d}x \equiv \nu\, p_i(\boldsymbol{\theta}), \qquad \sum_{i=1}^{N} p_i(\boldsymbol{\theta}) = 1,$$

where ν is the expected total and p_i the probability that an event falls in bin i [Cowan §6.10]. Different bins are independent, so

$$\mathcal{L}(\nu, \boldsymbol{\theta}) \overset{(1)}{=} \prod_{i=1}^{N} \frac{\mu_i^{n_i} e^{-\mu_i}}{n_i!},$$
$$\ell(\nu, \boldsymbol{\theta}) \overset{(2)}{=} \sum_{i=1}^{N} \big(n_i \ln \mu_i - \mu_i\big) - \sum_{i=1}^{N} \ln n_i! \overset{(3)}{=} -\tfrac{1}{2}\, C(\nu, \boldsymbol{\theta}) + \text{const}, \qquad C \equiv 2 \sum_{i=1}^{N} \big(\mu_i - n_i \ln \mu_i\big). \tag{3.93}$$

(1) Poisson probability of n_i counts for mean μ_i, multiplied over independent bins [Cowan (6.44)].
(2) $\ln(\mu^n e^{-\mu}/n!) = n \ln \mu - \mu - \ln n!$.
(3) The counts are data, so $\sum \ln n_i!$ does not depend on the parameters.

The quantity $C = -2\ell + \text{const}$ is the **Cash statistic**, introduced for X-ray astronomy [20]; minimising it is maximising the Poisson likelihood. In the language of Section 3.8, each bin asks how probable it is that a Poisson source with mean $\mu_i(\boldsymbol{\theta})$ produced the count we saw, and an empty bin contributes simply $e^{-\mu_i}$, the probability of seeing nothing.

The total number of events is conserved. Split the Poisson product into a statement about the total and a statement about the shape. With $n = \sum_i n_i$ and $\mu_i = \nu p_i$,

$$\prod_{i=1}^{N} \frac{\mu_i^{n_i} e^{-\mu_i}}{n_i!} \overset{(1)}{=} \frac{\nu^n e^{-\nu}}{n!} \, \frac{n!}{\prod_i n_i!} \prod_{i=1}^{N} p_i^{n_i}, \tag{3.94}$$
$$\frac{\partial \ell}{\partial \nu} \overset{(2)}{=} \frac{n}{\nu} - 1 \overset{(3)}{=} 0 \quad \Longrightarrow \quad \hat{\nu} = n.$$

(1) $\prod_i \mu_i^{n_i} = \nu^{\sum n_i} \prod_i p_i^{n_i}$ and $\prod_i e^{-\mu_i} = e^{-\nu \sum p_i} = e^{-\nu}$; then multiply and divide by $n!$. The first factor is the Poisson probability of the total, the second the multinomial probability of the split into bins [Cowan (6.41), (6.43)].
(2) Only the first factor depends on ν, and $\partial_\nu(n \ln \nu - \nu) = n/\nu - 1$.
(3) The score equation for ν; the multinomial factor is untouched, so $\hat{\boldsymbol{\theta}}$ is the same as in a fit with the total fixed.

The fitted normalisation equals the observed number of events, exactly, in every experiment, whatever the shape parameters do. This is the binned form of the extended likelihood (3.85). It is also the property the two χ^2 recipes below lack.

Working definition 3.12 (Poisson likelihood of a histogram)

For counts n_i with predicted means $\mu_i(\boldsymbol{\theta})$,

$$-2\ell(\boldsymbol{\theta}) = 2 \sum_i \big(\mu_i - n_i \ln \mu_i\big) + \text{const}.$$

Operationally: compute the expected count in every bin from the model (integrate the density over the bin and multiply by the expected total), evaluate this sum, minimise. Empty bins stay in the sum and contribute $2\mu_i$. No bins need to be merged, and no error bars are assigned.

Example: one bin. For a single bin with $n = 9$ counts, $\ell(\mu) = 9 \ln \mu - \mu$ gives $\hat{\mu} = 9$ and $-\ell''(\hat{\mu}) = n/\hat{\mu}^2 = 1/9$, a curvature error of $3 = \sqrt{n}$, the familiar rule. The likelihood itself is

skewed: solving $\ell(\mu) = \ell_{\max} - \frac{1}{2}$ gives $\mu \in [6.32, 12.34]$, that is $9^{+3.34}_{-2.68}$. The interval reaches further up than down. Why? A Poisson count with mean μ has spread $\sqrt{\mu}$. A large mean such as 12.34 has a large spread, 3.5, so a count of 9 is less than one spread below it. A small mean such as 6.32 has a small spread, 2.5, so the same count is slightly more than one spread above it. Large means can therefore stray further from the data and still explain them about as well (Section 3.12).

3.11.2 Fitting and testing with one number: the Baker–Cousins χ^2_λ

The value of C at its minimum does not by itself say whether the fit is good. Its constant is arbitrary, and it grows with the total number of events even for a perfect model. To make it a measure of fit, compare the model with the best any model could do [21]. That best is the **saturated model** [a "model" with one free mean per bin, which therefore sets $\mu_i = n_i$ and fits the data perfectly]. The likelihood ratio is

$$\chi^2_\lambda(\boldsymbol{\theta}) \overset{(1)}{=} -2\ln\frac{\mathcal{L}(\boldsymbol{\mu}(\boldsymbol{\theta}))}{\mathcal{L}(\boldsymbol{\mu}=\boldsymbol{n})} \overset{(2)}{=} -2\sum_i\Big[(n_i\ln\mu_i-\mu_i)-(n_i\ln n_i-n_i)\Big]$$
$$\overset{(3)}{=} 2\sum_{i=1}^{N}\Big[\mu_i-n_i+n_i\ln\frac{n_i}{\mu_i}\Big] \tag{3.95}$$

[Cowan (6.52)].

(1) Definition of the likelihood-ratio statistic against the saturated model.
(2) (3.93) at μ_i and at $\mu_i = n_i$; the $\ln n_i!$ cancel in the ratio.
(3) Collect terms; $n_i\ln n_i - n_i\ln\mu_i = n_i\ln(n_i/\mu_i)$. An empty bin contributes $2\mu_i$ (since $n\ln n \to 0$ as $n \to 0$).

Since $\chi^2_\lambda = C +$(terms in n_i only), minimising it is the same as maximising the Poisson likelihood. Every term is non-negative. To see it, write the bracket as $n_i(u - 1 - \ln u)$ with $u = \mu_i/n_i$, and note that $u - 1 - \ln u \geq 0$, with equality only at $u = 1$ (the line $u - 1$ lies above the curve $\ln u$ and touches it at $u = 1$). So χ^2_λ vanishes only for a perfect fit, $\mu_i = n_i$ in every bin.

Why call it a χ^2? Expand one term for a count close to its mean, $n = \mu + \delta$ with $|\delta| \ll \mu$:

$$\mu - n + n\ln\frac{n}{\mu} \overset{(1)}{=} -\delta + (\mu+\delta)\ln\Big(1+\frac{\delta}{\mu}\Big) \overset{(2)}{=} -\delta + (\mu+\delta)\Big(\frac{\delta}{\mu} - \frac{\delta^2}{2\mu^2} + O\big(\tfrac{\delta^3}{\mu^3}\big)\Big)$$
$$\overset{(3)}{=} -\delta + \delta + \frac{\delta^2}{\mu} - \frac{\delta^2}{2\mu} + O\Big(\frac{\delta^3}{\mu^2}\Big) = \frac{\delta^2}{2\mu} + O\Big(\frac{\delta^3}{\mu^2}\Big).$$

(1) Substitute $n = \mu + \delta$, and $n/\mu = 1 + \delta/\mu$.
(2) Taylor series $\ln(1 + u) = u - u^2/2 + O(u^3)$.
(3) Multiply out and keep terms up to δ^2/μ.

So $\chi^2_\lambda \approx \sum_i (n_i - \mu_i)^2/\mu_i$ when every bin has many counts: a Pearson χ^2, a sum of squared standardised Poisson fluctuations. In that limit $\chi^2_{\lambda,\min} \sim \chi^2_{N-m}$ for m fitted parameters, the Poisson analogue of (3.91). The general statement is **Wilks' theorem** [22]: for nested models, $-2\ln$ of the ratio of maximised likelihoods is asymptotically χ^2 with as many degrees of freedom as the difference in the number of free parameters, here $N - m$ (the saturated model has N). Chapter 4 treats it properly. Baker and Cousins' point is that χ^2_λ reaches this limit faster than the χ^2 recipes, and one statistic serves both to fit and to test.

Key idea: Binned counts: use the Poisson likelihood

Minimise $\chi^2_\lambda = 2\sum_i[\mu_i - n_i + n_i \ln(n_i/\mu_i)]$. It is $-2\ln\mathcal{L}$ up to a constant, so it gives the maximum likelihood fit; the fitted total equals the observed total exactly; empty bins are harmless; and its minimum is approximately χ^2_{N-m}, so it is also the goodness-of-fit statistic.

3.11.3 What goes wrong with $\sqrt{n}$ error bars

Two least-squares recipes are common for histograms [Cowan §7.4]. The **Neyman** χ^2 takes the variance of each bin from the data, $\chi^2_N = \sum_i (n_i - \mu_i)^2/n_i$. The **Pearson** χ^2 takes it from the model, $\chi^2_P = \sum_i (n_i - \mu_i)^2/\mu_i$. Both treat the counts as Gaussian, and both get the normalisation wrong, in opposite directions. Let the model be $\mu_i = \nu p_i$ with $\sum_i p_i = 1$ and minimise over ν.

Neyman. Setting the derivative to zero,

$$\frac{\partial \chi^2_N}{\partial \nu} \overset{(1)}{=} -2\sum_i \frac{p_i(n_i - \nu p_i)}{n_i} = 0 \quad\Longrightarrow\quad 1 = \nu \sum_i \frac{p_i^2}{n_i},$$

$$\chi^2_{N,\min} \overset{(2)}{=} \sum_i n_i - 2\nu \sum_i p_i + \nu^2 \sum_i \frac{p_i^2}{n_i} \overset{(3)}{=} n - 2\nu + \nu \quad\Longrightarrow\quad \hat{\nu}_N = n - \chi^2_{N,\min}.$$

(1) Chain rule on $(n_i - \nu p_i)^2$, then $\sum_i p_i n_i/n_i = \sum_i p_i = 1$.
(2) Expand the square: $(n_i - \nu p_i)^2/n_i = n_i - 2\nu p_i + \nu^2 p_i^2/n_i$.
(3) $\sum_i n_i = n$, $\sum_i p_i = 1$, and the first line gives $\nu^2 \sum p_i^2/n_i = \nu$.

Pearson. In the same way,

$$\frac{\partial \chi^2_P}{\partial \nu} \overset{(1)}{=} -\sum_i \frac{n_i^2}{\nu^2 p_i} + 1 = 0 \quad\Longrightarrow\quad \nu^2 = \sum_i \frac{n_i^2}{p_i},$$

$$\chi^2_{P,\min} \overset{(2)}{=} \sum_i \frac{n_i^2}{\nu p_i} - 2n + \nu \overset{(3)}{=} \nu - 2n + \nu \quad\Longrightarrow\quad \hat{\nu}_P = n + \tfrac{1}{2}\chi^2_{P,\min}.$$

(1) Expand first: $(n_i - \nu p_i)^2/(\nu p_i) = n_i^2/(\nu p_i) - 2n_i + \nu p_i$, then differentiate in ν.
(2) Sum the expanded terms.
(3) The first line gives $\sum n_i^2/(\nu p_i) = \nu$.

These are Cowan's (7.22) and (7.21). They say that the Neyman fit undershoots the observed total by $\chi^2_{N,\min}$ and the Pearson fit overshoots it by $\frac{1}{2}\chi^2_{P,\min}$. Both relations hold exactly at the minimum, also when shape parameters are fitted at the same time, because the derivative with respect to ν must vanish there too. A correct model gives $\chi^2_{\min} \approx N - m$, so the Neyman fit is low by about the number of bins and the Pearson fit high by about half of it. The definitions show why. Neyman gives a bin that fluctuated down a small variance, hence a large weight, and the fit is dragged down. Pearson can lower its χ^2 by raising μ_i, which inflates the variances it divides by, and the fit drifts up. With $N = 20$ bins and $n \approx 120$ events the Neyman bias is about ten per cent, comparable to the statistical error $\sqrt{n} \approx 11$ on the total itself: a systematic error as large as the statistical one, introduced by the fitting recipe alone.

Example: two bins by hand. Suppose the model says the two halves of a range are equally likely, $p_1 = p_2 = \tfrac{1}{2}$, and we observe $n_1 = 4$, $n_2 = 16$, so $n = 20$. Then

$$\hat\nu_{\mathrm{ML}} = 20,$$
$$\hat\nu_N \overset{(1)}{=} \left(\frac{1/4}{4} + \frac{1/4}{16}\right)^{-1} = 12.8, \qquad \chi^2_{N,\min} \overset{(2)}{=} 20 - 12.8 = 7.2,$$
$$\hat\nu_P \overset{(3)}{=} \sqrt{\frac{16}{1/2} + \frac{256}{1/2}} = \sqrt{544} = 23.3, \qquad \chi^2_{P,\min} \overset{(4)}{=} 2(23.3 - 20) = 6.65.$$

(1) The Neyman condition $1 = \nu \sum p_i^2/n_i$.
(2) $\hat\nu_N = n - \chi^2_{N,\min}$.
(3) The Pearson condition $\nu^2 = \sum n_i^2/p_i$.
(4) $\hat\nu_P = n + \tfrac{1}{2}\chi^2_{P,\min}$.

Twenty events were seen. Only the likelihood says twenty.

3.11.4 A histogram fit in Python

The script `12_poisson_bins.py` histograms decay times into $N = 20$ bins on $0 \le t \le 5$ (in units of the true lifetime), with an expected total of $\nu = 120$, and fits (ν, τ) with the three statistics.

Listing 3.10: The three statistics for a histogram (`code/ch03/12_poisson_bins.py`)

```
def cash(par, n):          # -2 ln L up to a constant: 2 sum (mu - n ln mu)
    m = mu(par)
    return 2 * np.sum(m - n * np.log(m))

def baker_cousins(par, n):  # 2 sum (mu - n + n ln(n/mu)), with n ln n -> 0 for n = 0
    m = mu(par)
    return 2 * np.sum(m - n + special.xlogy(n, n) - special.xlogy(n, m))

def neyman(par, n):
    m = mu(par)
    return np.sum((n - m) ** 2 / np.maximum(n, 1))

def pearson(par, n):
    m = mu(par)
    return np.sum((n - m) ** 2 / m)
```

The Cash and Baker–Cousins functions differ only by terms in n_i, so they have the same minimum; `special.xlogy(n, n)` evaluates $n \ln n$ with the convention $0 \ln 0 = 0$. The Neyman function needs a patch for empty bins, `np.maximum(n, 1)`, which is itself a sign of trouble.

For the example histogram, with $n = 122$ events and 4 empty bins, the fitted totals are $\hat\nu = 122$ (Poisson), 110.7 (Neyman) and 129 (Pearson), with lifetimes 1.076, 0.9253 and 1.18 (Figure 3.37). The Baker–Cousins statistic at the minimum is 18.47 for 18 degrees of freedom, a normal-looking fit.

Over 3000 simulated histograms the Poisson fit returns $|\hat\nu - n| \le 3.996 \times 10^{-9}$ in every one of them, the exact conservation law of (3.94) up to the tolerance of the minimiser. The Pearson fit is high by 7.883 events on average, exactly $\tfrac{1}{2}\chi^2_{P,\min} = 7.883$. The Neyman fit is low by -11.65; the relation $\hat\nu_N = n - \chi^2_{N,\min}$ predicts -13.73, and the difference is entirely due to the patch for empty bins, which breaks the identity $\sum_i p_i n_i/n_i = 1$ used in its derivation. The bias leaks into the shape: the mean fitted lifetimes are 1.002, 0.8992 and 1.114 for a true value of 1. Finally, the

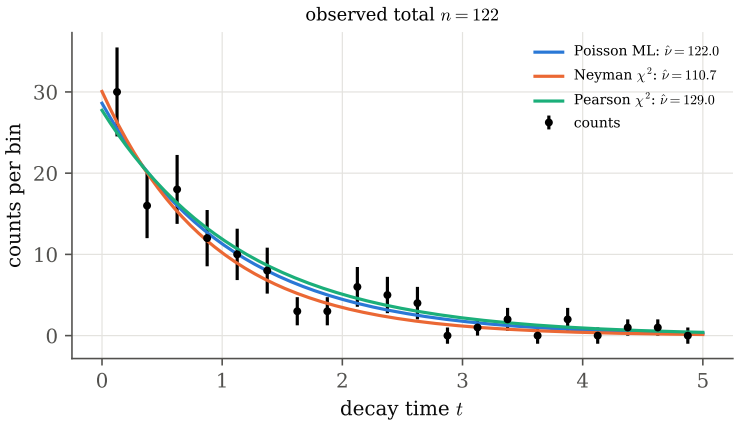

Figure 3.37: One histogram of decay times with few counts per bin (points, with $\sqrt{\max(n_i, 1)}$ bars for orientation only) and three fits of the same exponential shape. The Poisson likelihood fit reproduces the observed total. The Neyman χ^2 fit sits low, pulled down by the bins that fluctuated low; the Pearson χ^2 fit sits high.

Baker–Cousins $\chi^2_{\lambda,\min}$ averages 18.73 against 18 degrees of freedom and follows the χ^2_{18} curve even with this sparse histogram (Figure 3.38).

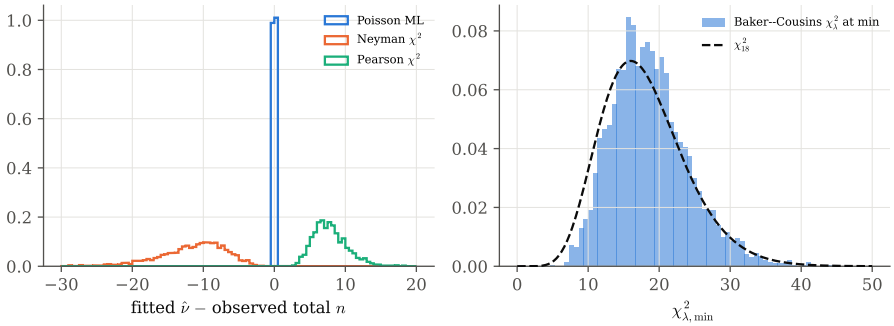

Figure 3.38: Three thousand simulated histograms. Left: fitted total minus observed total. The Poisson fit is a spike at zero; the Neyman fit is biased low by about ten events and the Pearson fit high by about eight. Right: the Baker–Cousins statistic at its minimum follows the χ^2 distribution for $20 - 2 = 18$ degrees of freedom, so it can be used as a goodness-of-fit test.

3.11.5 One idea, three implementations

The recipe is always the same: write the prediction, write the probability of the fluctuation needed to turn it into the data, and multiply over independent pieces. Only the noise model changes from one field to another. Three noise models cover most data in physics and cosmology: Poisson counts; Gaussian noise with a covariance that does not depend on the parameters (gravitational-wave strain is this case written in frequency); and a Gaussian field whose covariance is itself the signal, as for the CMB.

The last line needs a derivation, because it is the first case where the parameters sit in the covariance rather than in the mean. In a statistically isotropic Gaussian sky the spherical-harmonic coefficients $a_{\ell m}$ have mean zero and variance C_ℓ, the theory's power spectrum. The measured spectrum is $\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2$. Because the sky is real, $a_{\ell,-m}$ is fixed by $a_{\ell m}$, so at each ℓ there are $2\ell + 1$ independent real numbers: $a_{\ell 0}$, and $\sqrt{2}\,\mathrm{Re}\,a_{\ell m}$ and $\sqrt{2}\,\mathrm{Im}\,a_{\ell m}$ for $m = 1, \ldots, \ell$. Call them $y_{\ell k}$, $k = 1, \ldots, 2\ell + 1$. Each is Gaussian with variance C_ℓ, and

Taxonomy: Which likelihood when

data	noise model	$-2\ln\mathcal{L}$ (up to constants)
counts in bins (colliders, X-ray, decay histograms)	$n_i \sim \text{Poisson}(\mu_i(\boldsymbol{\theta}))$, independent bins	$2\sum_i[\mu_i - n_i \ln \mu_i]$ (3.93)
measurements with error bars; binned spectra	Gaussian, covariance $\mathbf{C}$ independent of $\boldsymbol{\theta}$	$\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ (3.92)
GW strain	stationary Gaussian noise with PSD $S_n(f)$	$(D - h_{\boldsymbol{\theta}}\|D - h_{\boldsymbol{\theta}})$ (Section 3.10.5)
CMB map, full sky, no noise	$a_{\ell m}$ Gaussian with variance $C_\ell(\boldsymbol{\theta})$	$\sum_\ell (2\ell+1)\big[\widehat{C}_\ell/C_\ell + \ln C_\ell\big]$

$\sum_k y_{\ell k}^2 = \sum_m |a_{\ell m}|^2 = (2\ell+1)\widehat{C}_\ell$. Then

$$-2\ell(\boldsymbol{\theta}) \overset{(1)}{=} \sum_\ell \sum_{k=1}^{2\ell+1}\Big[\frac{y_{\ell k}^2}{C_\ell(\boldsymbol{\theta})} + \ln C_\ell(\boldsymbol{\theta}) + \ln 2\pi\Big] \overset{(2)}{=} \sum_\ell (2\ell+1)\Big[\frac{\widehat{C}_\ell}{C_\ell(\boldsymbol{\theta})} + \ln C_\ell(\boldsymbol{\theta})\Big] + \text{const.}$$

(1) (3.92) with a diagonal covariance whose entries are C_ℓ: $-2\ln$ of each Gaussian factor is $y^2/C_\ell + \ln C_\ell + \ln 2\pi$.

(2) Sum over k using $\sum_k y_{\ell k}^2 = (2\ell+1)\widehat{C}_\ell$; the $2\ell+1$ copies of $\ln C_\ell$ give the second term.

The $\ln C_\ell$ term is the $\ln\det\mathbf{C}$ of (3.92), and it cannot be dropped: without it the fit would push every C_ℓ to infinity. If the model sets each C_ℓ free, the score equation $-\widehat{C}_\ell/C_\ell^2 + 1/C_\ell = 0$ gives $\hat{C}_\ell = \widehat{C}_\ell$, so the familiar estimator is the maximum likelihood estimator. As a function of C_ℓ this likelihood is skewed, like the Poisson one above, and for the same reason: the spread of $\widehat{C}_\ell$ grows with its mean. A mask, instrument noise and a beam change this likelihood, as Chapters 7 and 8 show.

3.12 The width of the likelihood is the error bar

The width of the likelihood is the error bar of the estimate. To see why one would expect this, look at a likelihood with a sharp peak. Only a narrow range of parameter values can turn the prediction into the data with an ordinary fluctuation. Move a little away and the noise required becomes implausible. A broad likelihood says the opposite: many values would have done about equally well. For linear models with Gaussian noise we proved the claim exactly in Section 3.10.2: the log-likelihood is a parabola whose width is the standard deviation of $\hat{\theta}$. For any smooth likelihood with enough data it holds approximately, and a check on 10^4 simulated experiments shows how well. Three questions follow.

1. How do we read an error bar off the log-likelihood, from its curvature or from where it has dropped by $\frac{1}{2}$?
2. Why should the width of a function of θ, computed from one data set, equal the scatter of $\hat{\theta}$ over many data sets? The answer introduces the Fisher information.
3. How well does it work at a realistic sample size?

3.12.1 Curvature at the peak

Expand the log-likelihood about its maximum, where the first derivative vanishes [Padilla (29)–(31)]:

$$\ell(\theta) \overset{(1)}{=} \ell(\hat\theta) + \underbrace{\ell'(\hat\theta)}_{=0}(\theta-\hat\theta) + \tfrac{1}{2}\ell''(\hat\theta)(\theta-\hat\theta)^2 + \ldots \overset{(2)}{=} \ell_{\max} - \frac{(\theta-\hat\theta)^2}{2\hat\sigma^2} + \ldots, \qquad \hat\sigma^2 \equiv \frac{1}{-\ell''(\hat\theta)}. \tag{3.96}$$

(1) Taylor's theorem at the maximum; the score vanishes there.
(2) $\ell''(\hat\theta) < 0$ at a maximum, so $-1/\ell''$ is positive and we may call it $\hat\sigma^2$.

Near its peak the likelihood is therefore $\mathcal{L}(\theta) \approx \mathcal{L}_{\max}\exp[-(\theta-\hat\theta)^2/2\hat\sigma^2]$, a Gaussian bump of width $\hat\sigma$. The rule is: *the error bar is one over the square root of minus the second derivative of* $\ln\mathcal{L}$ *at its maximum* [Cowan §6.4]. For several parameters, minus the matrix of second derivatives (the Hessian with a minus sign) plays the role of $1/\hat\sigma^2$, and its inverse is the estimated covariance matrix. That is the line `V = np.linalg.inv(-H)` in the Newton–Raphson fit of the muon angular distribution (Section 3.9.3).

Example: the lifetime. For n decay times the maximum likelihood lifetime is $\hat\tau = \bar t$, and (3.82) gave $-\ell''(\hat\tau) = n/\hat\tau^2$. So $\hat\sigma_{\hat\tau} = \hat\tau/\sqrt{n}$. Fifty decays measure a lifetime to $1/\sqrt{50} \approx 14\%$. The true standard deviation of $\bar t$ is $\tau/\sqrt{n}$ (Section 3.9.1), and the curvature gives the same formula with the unknown τ replaced by its estimate.

Example: the detector efficiency. For the detector that fires S times in n trials, the log-likelihood is $\ell(p) = S\ln p + (n-S)\ln(1-p)$ and $\hat p = S/n$ (Section 3.9.1). Then

$$-\ell''(p) \overset{(1)}{=} \frac{S}{p^2} + \frac{n-S}{(1-p)^2}, \qquad -\ell''(\hat p) \overset{(2)}{=} \frac{n}{\hat p} + \frac{n}{1-\hat p} \overset{(3)}{=} \frac{n}{\hat p(1-\hat p)}, \qquad \hat\sigma_{\hat p} = \sqrt{\frac{\hat p(1-\hat p)}{n}}.$$

(1) Differentiate $S/p - (n-S)/(1-p)$ once more.
(2) At $\hat p = S/n$: $S/\hat p^2 = n/\hat p$ and $(n-S)/(1-\hat p)^2 = n/(1-\hat p)$.
(3) Common denominator: $1/\hat p + 1/(1-\hat p) = 1/[\hat p(1-\hat p)]$.

For $S = 12$ out of $n = 20$ this is $\sqrt{0.6\cdot 0.4/20} = 0.11$, the binomial standard error.

3.12.2 The graphical method: where $\ln\mathcal{L}$ has dropped by one half

If ℓ were exactly the parabola (3.96), then at $\theta = \hat\theta \pm \hat\sigma$ it would be exactly $\ell_{\max} - \tfrac12$. That suggests a second recipe that does not need derivatives: draw $\ell(\theta)$ and read off where it crosses $\ell_{\max} - \tfrac12$ [Cowan §6.7]. For Gaussian data $-2\ell = \chi^2 + \text{const}$, so this is the $\Delta\chi^2 = 1$ rule of Section 3.10.3. When the log-likelihood is not a parabola, the two crossings are at different distances from $\hat\theta$, and one quotes an asymmetric error $\hat\theta^{+\sigma_+}_{-\sigma_-}$.

Example: the lifetime interval exactly. Measure τ in units of the estimate, $u = \tau/\hat\tau$. Using $T = n\hat\tau$,

$$\ell(\tau) - \ell(\hat\tau) \overset{(1)}{=} -n\ln\tau - \frac{n\hat\tau}{\tau} + n\ln\hat\tau + n \overset{(2)}{=} -n\left[\ln u + \frac{1}{u} - 1\right].$$

(1) $\ell(\tau) = -n\ln\tau - T/\tau$ at τ and at $\hat\tau$, with $T/\hat\tau = n$.

(2) $\ln\tau - \ln\hat{\tau} = \ln u$ and $\hat{\tau}/\tau = 1/u$.

The $\Delta\ln\mathcal{L} = \frac{1}{2}$ interval is the pair of roots of $\ln u + 1/u - 1 = 1/(2n)$, the same for every data set once expressed in units of $\hat{\tau}$. For small $u - 1$, $\ln u + 1/u - 1 \approx \frac{1}{2}(u-1)^2$, which returns $u = 1 \pm 1/\sqrt{n}$, the curvature error. For $n = 50$ the exact roots are $u = 0.871$ and $u = 1.156$: the interval reaches further up than down, because decay times drawn with a longer lifetime also scatter more.

Why the graphical interval is the better one. The curvature error depends on how we name the parameter; the $\Delta\ln\mathcal{L}$ interval does not. The likelihood assigns the same number to a hypothesis whatever we call it (Section 3.8.3). So if we switch from τ to the rate $\lambda = 1/\tau$, the set of hypotheses with $\ell \geq \ell_{\max} - \frac{1}{2}$ is the same set, merely relabelled. If τ_- and τ_+ are the lower and upper ends of the τ interval, the λ interval is $[1/\tau_+, 1/\tau_-]$. The curvature, by contrast, changes: $-\partial^2\ell/\partial\lambda^2$ at $\hat{\lambda}$ is $n/\hat{\lambda}^2$, so the curvature interval in λ is $\hat{\lambda}(1 \pm 1/\sqrt{n})$, which is *not* the image of $\hat{\tau}(1 \pm 1/\sqrt{n})$. The two symmetric recipes disagree with each other, and each is right only to leading order. The graphical interval behaves as if we had found and used the parametrisation in which ℓ is most nearly a parabola, without our having to find it.

Watch out: A curvature error assumes a parabola

$\hat{\sigma} = (-\ell'')^{-1/2}$ describes the peak only. If ℓ is skewed, has a second maximum, or is cut off by a physical boundary (a mass that cannot be negative, a cliff like the uniform box), the curvature says nothing about the tails. Always plot $\ln\mathcal{L}$, or at least find the two $\Delta\ln\mathcal{L} = \frac{1}{2}$ crossings, before quoting $\pm\hat{\sigma}$.

Several parameters. With two parameters the level set $\ell = \ell_{\max} - \frac{1}{2}$ is a closed curve, an ellipse when ℓ is quadratic. In the right panel of Figure 3.33 it is drawn for the fit of the angular distribution $1 + \alpha x + \beta x^2$ (Section 3.9.3). The dotted lines tangent to it are at $\hat{\alpha} \pm \sigma_{\hat{\alpha}}$ and $\hat{\beta} \pm \sigma_{\hat{\beta}}$, with the errors from the inverse Hessian [Cowan §6.8]. Why tangent lines? Fix α and move β to make ℓ as large as possible. As α moves away from $\hat{\alpha}$ this best value falls, and it reaches $\ell_{\max} - \frac{1}{2}$ exactly where the vertical line at that α touches the contour. That best value as a function of α is the profile likelihood of Section 3.14. The tilt of the ellipse shows the correlation between the two estimates. For that fit the inverse Hessian gives $\sigma_{\hat{\alpha}} = 0.05099$, $\sigma_{\hat{\beta}} = 0.107$ and $\rho = 0.4237$; the 500 repetitions scatter with 0.05376, 0.1081 and $\rho = 0.4919$. The standard deviations agree to a few per cent. The correlation from 500 pairs is itself uncertain by $(1-\rho^2)/\sqrt{500} = 0.0339$, so the two values of ρ should be compared within that error. The Hessian's own ρ also changes from one experiment to the next: over the 500 repetitions it averages 0.4263 and scatters by 0.03868. Its average and the repetitions' ρ are consistent within about two of the repetitions' errors: 500 repetitions are not enough to tell them apart. The $\frac{1}{2}$-contour projects onto each axis as a 68% interval for that parameter alone. A region that should contain *both* true values with 68% probability is the larger contour $\Delta\ln\mathcal{L} = 2.30/2 = 1.15$, as in the $\Delta\chi^2$ table of Section 3.10.3.

3.12.3 Why the curvature is the error: score and Fisher information

We now have a recipe that uses one data set, a second derivative of a function of θ. The error bar we want is a statement about many data sets: the standard deviation of $\hat{\theta}$ over imagined repetitions. Why should they agree? The bridge is the score, $S(\theta) = \ell'(\theta)$, viewed as a random variable. For a fixed θ, each data set gives a different score. Two identities about its distribution do all the work. They hold whenever we may differentiate under the integral sign, which requires, in particular, that the range of the data does not depend on θ (it fails for the uniform

box).

The score has mean zero. For a single observation with density $f(x;\theta)$,

$$\mathbb{E}_\theta\Big[\frac{\partial \ln f(X;\theta)}{\partial\theta}\Big] \overset{(1)}{=} \int \frac{\partial_\theta f(x;\theta)}{f(x;\theta)}\, f(x;\theta)\,\mathrm{d}x \overset{(2)}{=} \frac{\partial}{\partial\theta}\int f(x;\theta)\,\mathrm{d}x \overset{(3)}{=} \frac{\partial}{\partial\theta}1 = 0. \tag{3.97}$$

(1) Expectation over the density of the data at the *same* θ; $\partial_\theta \ln f = \partial_\theta f / f$.
(2) The f cancels. Exchange the derivative and the integral (the regularity condition).
(3) Every density integrates to one, for every θ.

At the true parameter, the data pull neither up nor down on average.

The variance of the score is minus the mean curvature. Now differentiate the identity

$$\int (\partial_\theta \ln f)\, f\,\mathrm{d}x = 0$$

once more with respect to θ:

$$0 \overset{(1)}{=} \int \Big[(\partial_\theta^2 \ln f)\, f + (\partial_\theta \ln f)\,\partial_\theta f\Big]\mathrm{d}x \overset{(2)}{=} \int \Big[\partial_\theta^2 \ln f + (\partial_\theta \ln f)^2\Big] f\,\mathrm{d}x,$$
$$I(\theta) \equiv \mathbb{E}_\theta\big[(\partial_\theta \ln f)^2\big] \overset{(3)}{=} -\,\mathbb{E}_\theta\big[\partial_\theta^2 \ln f\big]. \tag{3.98}$$

(1) Product rule under the integral.
(2) $\partial_\theta f = (\partial_\theta \ln f)\, f$.
(3) Split the integral. Since the score has mean zero, the first form is its variance.

For n independent observations, $\ell = \sum_i \ln f(x_i;\theta)$ is a sum of independent terms, so the variance of the total score and the expected curvature both add: $I_n(\theta) = nI(\theta)$ [Wasserman p. 128, Thm. 9.17].

Working definition 3.13 (Fisher information)

The **Fisher information** in n observations is

$$I_n(\theta) = \mathrm{Var}_\theta\big[S(\theta)\big] = -\,\mathbb{E}_\theta\big[\ell''(\theta)\big] = nI(\theta),$$

the average curvature of the log-likelihood at the true parameter [Wasserman p. 128, Def. 9.16]. The **observed information** $-\ell''(\hat\theta)$ is the curvature of the one log-likelihood we have, at its peak. *Operationally:* differentiate $\ln f$ twice, take minus its average over the model, multiply by n. For several parameters, $I_{jk} = -\mathbb{E}[\partial_j \partial_k \ell]$ is the **Fisher matrix** (Chapter 10).

From the score to the scatter of $\hat\theta$. Now expand the score equation of one data set about the true value θ [Wasserman p. 136]:

$$0 \overset{(1)}{=} \ell'(\hat\theta) \overset{(2)}{=} \ell'(\theta) + (\hat\theta - \theta)\,\ell''(\theta) + \ldots \quad\Longrightarrow\quad \hat\theta - \theta \approx \frac{\ell'(\theta)}{-\ell''(\theta)} \overset{(3)}{=} \frac{\frac{1}{\sqrt n}\,\ell'(\theta)}{\frac{1}{\sqrt n}\,[-\ell''(\theta)]}$$
$$\sqrt{n}\,(\hat\theta - \theta) \approx \frac{\frac{1}{\sqrt n}\sum_i S_i}{\frac{1}{n}\sum_i [-\partial_\theta^2 \ln f(x_i;\theta)]} \overset{(4)}{\rightsquigarrow} \frac{\mathcal{N}\big(0, I(\theta)\big)}{I(\theta)} \overset{(5)}{=} \mathcal{N}\Big(0, \frac{1}{I(\theta)}\Big). \tag{3.99}$$

(1) $\hat\theta$ solves the score equation.

(2) Taylor expansion of ℓ' about the true value; for large n, $\hat{\theta}$ is close to θ (consistency, Section 3.13) and the dropped terms are smaller.
(3) Multiply numerator and denominator by $1/\sqrt{n}$ and move one $\sqrt{n}$ to the left.
(4) The numerator is $\sqrt{n}$ times the average of the n independent scores $S_i = \partial_\theta \ln f(x_i;\theta)$, each of mean 0 (3.97) and variance $I(\theta)$ (3.98), so by the central limit theorem it tends to $\mathcal{N}(0, I)$. The denominator is an average of n independent curvatures with mean $I(\theta)$, so by the law of large numbers it tends to the constant $I(\theta)$.
(5) Dividing a $\mathcal{N}(0, I)$ variable by the number I gives variance $I/I^2 = 1/I$.

So the scatter of $\hat{\theta}$ over repetitions is set by the Fisher information, the *average* curvature of the log-likelihood. The curvature $-\ell''(\hat{\theta})$ of the one data set we have is an average of n independent curvatures, so by the same law of large numbers it is close to I_n. That is why the width read off our one likelihood gives the error bar.

Key idea: The curvature of $\ln \mathcal{L}$ is the error bar

For a regular model and large n the MLE is approximately Gaussian,

$$\hat{\theta} \approx \mathcal{N}\Big(\theta,\ \frac{1}{I_n(\theta)}\Big), \qquad \widehat{\mathrm{se}} = \frac{1}{\sqrt{I_n(\hat{\theta})}} \approx \frac{1}{\sqrt{-\ell''(\hat{\theta})}},$$

and $\hat{\theta} \pm 1.96\,\widehat{\mathrm{se}}$ is an approximate 95% confidence interval [Wasserman pp. 129–130, Thms. 9.18–9.19]. With several parameters, $\mathrm{Cov}\,\hat{\boldsymbol{\theta}} \approx I_n^{-1}$.

Examples of Fisher information. The standard cases follow from (3.98) in one line each [Wasserman p. 130, Exs. 9.20–9.22].

- Gaussian mean, known σ: $\ln f = -(x-\mu)^2/2\sigma^2 + \ldots$, $\partial_\mu^2 \ln f = -1/\sigma^2$, so $I = 1/\sigma^2$ and $\mathrm{se} = \sigma/\sqrt{n}$. The curvature is the same for every data set, so observed and expected information coincide exactly.
- Poisson counts, mean λ: $\ln f = x \ln\lambda - \lambda - \ln x!$, $\partial_\lambda^2 \ln f = -x/\lambda^2$, and $\mathbb{E}\,X = \lambda$ gives $I = 1/\lambda$, $\mathrm{se} = \sqrt{\lambda/n}$.
- Bernoulli: $\partial_p^2 \ln f = -x/p^2 - (1-x)/(1-p)^2$, with $\mathbb{E}\,X = p$, so $I = 1/p + 1/(1-p) = 1/[p(1-p)]$.
- Exponential lifetime: $\partial_\tau^2(-\ln\tau - t/\tau) = 1/\tau^2 - 2t/\tau^3$, with $\mathbb{E}\,t = \tau$, so $I = 1/\tau^2$ and $\mathrm{se} = \tau/\sqrt{n}$.

The information per observation is large where the density changes quickly as θ changes, because then each observation discriminates sharply between nearby values: a Gaussian of small σ, a Poisson mean near zero, a coin whose p is near 0 or 1.

3.12.4 Testing the recipe on 10^4 experiments

The script `09_mle_decay.py` tests the whole argument on the lifetime, for $n = 50$ decays with true lifetime $\tau = 1$. It first analyses one experiment, the way an experimenter would.

Listing 3.11: One experiment: the MLE, the curvature error and the $\Delta \ln \mathcal{L} = \frac{1}{2}$ interval (`code/ch03/09_mle_decay.py`)

```
# ---------- one experiment ----------
```

```
t = rng.exponential(tau_true, n)
tau_hat = t.mean()                                          # analytic MLE
tau_num = optimize.minimize_scalar(lambda s: -lnL(s, t), bounds=(0.1, 5),
    method="bounded").x
sig_curv = tau_hat / np.sqrt(n)                             # 1/sqrt(-d2 lnL/dtau2) at tau_hat
lmax = lnL(tau_hat, t)
f = lambda s: lnL(s, t) - lmax + 0.5                        # zero where ln L has dropped by 1/2
lo = optimize.brentq(f, 0.3 * tau_hat, tau_hat)
hi = optimize.brentq(f, tau_hat, 3 * tau_hat)
```

The analytic MLE is the mean; `minimize_scalar` confirms it numerically (0.8831). The curvature error is $\hat{\tau}/\sqrt{n}$. The function `f` is zero where $\ln \mathcal{L}$ has dropped by $\frac{1}{2}$, and `brentq` finds its two roots on either side of the peak. The result is

$$\hat{\tau} = 0.8831 \pm 0.1249 \text{ (curvature)}, \qquad \hat{\tau} = 0.8831^{+0.1376}_{-0.114} \ (\Delta \ln \mathcal{L} = \tfrac{1}{2}).$$

Figure 3.39 shows the log-likelihood and its parabola: close near the peak, with the curve falling more steeply on the low side.

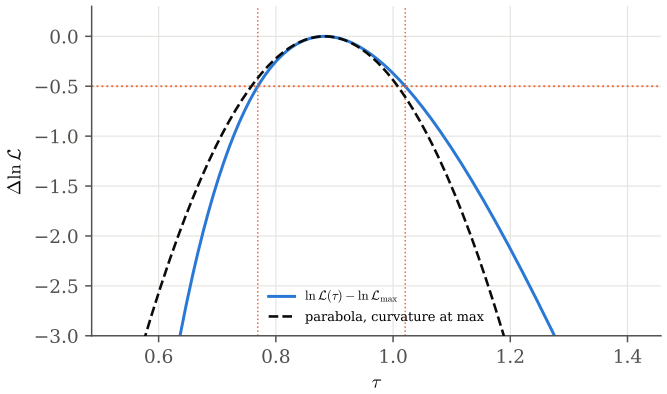

Figure 3.39: The log-likelihood of one experiment with fifty decays (solid) and the parabola with the same curvature at the peak (dashed). The dotted horizontal line is $\ln \mathcal{L}_{\max} - \frac{1}{2}$; its crossings with the curve (dotted verticals) give the asymmetric interval. The curve drops faster than the parabola on the left and slower on the right.

Then the script does what no experimenter can: it repeats the experiment 10^4 times and looks at the scatter.

Listing 3.12: Ten thousand experiments: scatter and coverage (`code/ch03/09_mle_decay.py`)

```
# ---------- 10^4 experiments ----------
T = rng.exponential(tau_true, (M, n))
th = T.mean(1)                                              # MLE of each experiment
sc = th / np.sqrt(n)                                        # its curvature error
sd_mc = th.std(ddof=1)
cover_curv = np.mean(np.abs(th - tau_true) <= sc)
# Delta lnL = 1/2 interval: solve n[ln(tau/th) + th/tau - 1] = 1/2 on both sides, per
    experiment
# in units u = tau/th the equation is u-independent: ln u + 1/u - 1 = 1/(2n)
g = lambda u: np.log(u) + 1 / u - 1 - 0.5 / n
ulo = optimize.brentq(g, 0.3, 1.0); uhi = optimize.brentq(g, 1.0, 3.0)
cover_dl = np.mean((ulo * th <= tau_true) & (tau_true <= uhi * th))
```

The numbers are

quantity	value
mean of $\hat{\tau}$ over 10^4 experiments	1.003
true scatter of $\hat{\tau}$ (Monte Carlo)	0.1406
$1/\sqrt{I_n(\tau)} = \tau/\sqrt{n}$	0.1414
average curvature error $\hat{\tau}/\sqrt{n}$	0.1419
coverage of $\hat{\tau} \pm \hat{\tau}/\sqrt{n}$	0.6913
coverage of the $\Delta \ln \mathcal{L} = \frac{1}{2}$ interval	0.6866

The scatter of the MLE over repetitions is the inverse square root of the Fisher information, to within the Monte Carlo error (about 0.7% for 10^4 experiments). The curvature error of an individual experiment fluctuates with $\hat{\tau}$, as the right panel of Figure 3.40 shows, but it is correct on average. Both intervals cover the true value in about 68% of the experiments, the fraction a $\pm 1\sigma$ Gaussian interval should cover (0.683). At $n = 50$ the asymptotic theory is already good. The left panel shows that the exact sampling distribution of $\hat{\tau}$, a Gamma distribution with shape n (the sum of n exponentials, Chapter 2), is slightly skewed compared with the Gaussian of (3.99); the skewness shrinks like $1/\sqrt{n}$.

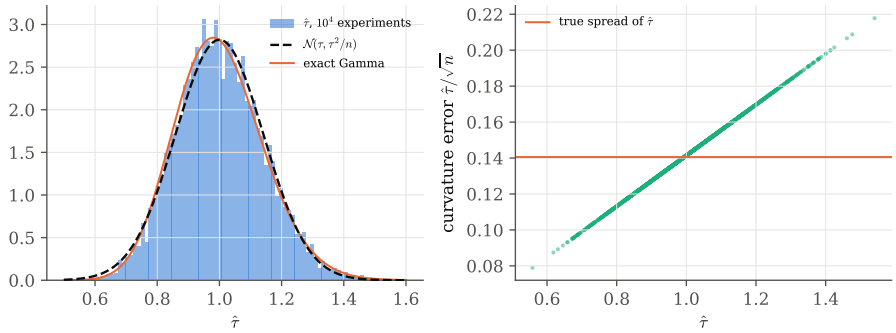

Figure 3.40: Ten thousand repetitions of the fifty-decay experiment. Left: the histogram of the maximum likelihood lifetimes, the Gaussian predicted by the Fisher information (dashed) and the exact Gamma distribution (solid). Right: each experiment's curvature error plotted against its estimate. The error grows with $\hat{\tau}$, because it is $\hat{\tau}/\sqrt{n}$, and it scatters around the true spread of the estimates (horizontal line).

3.13 What makes maximum likelihood good

We now have many ways to turn data into a number: the mean, the median, the method of moments, least squares, maximum likelihood. Why is maximum likelihood the default of experimental physics? Not because it is always unbiased. The Gaussian width $\hat{\sigma}^2$ is not (Section 3.9.1), and the decay rate $1/\hat{\tau}$ is not either (Section 3.13.2). The reason is a set of large-sample properties [Wasserman p. 125]. For a regular model (smooth in θ, with a support that does not move with θ, and a true value inside the parameter space) the MLE is

1. *consistent*: it converges to the true value;
2. *equivariant*: the MLE of $g(\theta)$ is $g(\hat{\theta})$;
3. *asymptotically Gaussian*, with variance $1/I_n(\theta)$ (Section 3.12.3);
4. *asymptotically efficient*: no unbiased estimator has a smaller variance than $1/I_n$, so for large n nothing beats it;
5. *approximately Bayesian*: for large n the posterior with any smooth prior peaks near $\hat{\theta}$ with width $1/\sqrt{I_n}$ (Chapter 5).

The third is (3.99). Each of the first, second and fourth has a short reason, each can be seen working on simulated data, and each fails when one of the regularity conditions fails.

3.13.1 Consistency: the log-likelihood peaks at the truth

Why should the peak of the likelihood of one finite data set sit near the true value $\theta_\star$? The answer is that, as n grows, the log-likelihood per observation settles down to a fixed curve, and that curve peaks at $\theta_\star$. To see it, compare each θ with the truth through the average log-likelihood ratio

$$M_n(\theta) = \frac{1}{n}\sum_{i=1}^{n} \ln \frac{f(x_i;\theta)}{f(x_i;\theta_\star)}.$$

It differs from $\ell(\theta)/n$ only by a term that does not depend on θ, so it peaks at $\hat\theta$. It is an average of n independent terms, so by the law of large numbers it approaches its expectation,

$$M_n(\theta) \;\to\; \mathbb{E}_{\theta_\star}\!\left[\ln \frac{f(X;\theta)}{f(X;\theta_\star)}\right] \overset{(1)}{=} -\int f(x;\theta_\star)\ln\frac{f(x;\theta_\star)}{f(x;\theta)}\,\mathrm{d}x \equiv -D(\theta_\star,\theta), \tag{3.100}$$

(1) Write the expectation as an integral over the true density and flip the ratio inside the logarithm, which flips the sign.

where $D(f,g) = \int f \ln(f/g)$ is the **Kullback–Leibler divergence** [how badly the density g describes data that really come from f, in units of log-probability per observation] [Wasserman p. 126]. It is never negative, and it vanishes only when the two densities are equal:

$$-D(f,g) \overset{(1)}{=} \mathbb{E}_f\left[\ln\frac{g(X)}{f(X)}\right] \overset{(2)}{\le} \ln \mathbb{E}_f\left[\frac{g(X)}{f(X)}\right] \overset{(3)}{=} \ln\int f(x)\frac{g(x)}{f(x)}\,\mathrm{d}x \overset{(4)}{=} \ln 1 = 0.$$

(1) Definition of D with the ratio inverted.
(2) Jensen's inequality: ln is concave, so the average of the logarithm is at most the logarithm of the average, with equality only if g/f is constant.
(3) Expectation over f.
(4) g is a density and integrates to one. A constant ratio g/f must therefore equal one.

Physicists know this as the Gibbs inequality of statistical mechanics: relative entropy is non-negative. So the limit of M_n is a function with a unique maximum, equal to zero, at $\theta = \theta_\star$, provided different parameter values give different densities (the model is **identifiable**). The M_n curves converge to that function, and their peaks, which are the MLEs, converge to its peak. That is Wasserman's consistency theorem [Wasserman p. 127, Thm. 9.13]; the proof needs the convergence to hold uniformly in θ, which is where regularity conditions enter.

Example: the lifetime. For exponential decays,

$$D(\tau_\star,\tau) \overset{(1)}{=} \mathbb{E}_{\tau_\star}\left[\ln\frac{\tau_\star^{-1}e^{-t/\tau_\star}}{\tau^{-1}e^{-t/\tau}}\right] \overset{(2)}{=} \ln\frac{\tau}{\tau_\star} + \mathbb{E}_{\tau_\star}[t]\left(\frac{1}{\tau}-\frac{1}{\tau_\star}\right) \overset{(3)}{=} \ln\frac{\tau}{\tau_\star} + \frac{\tau_\star}{\tau} - 1.$$

(1) Definition (3.100) with the exponential density.
(2) ln of the ratio is $\ln(\tau/\tau_\star) - t/\tau_\star + t/\tau$; take the expectation term by term.
(3) $\mathbb{E}_{\tau_\star} t = \tau_\star$.

This is the same function $\ln u + 1/u - 1$ that appeared in the exact $\Delta\ln\mathcal{L}$ interval, now with $u = \tau/\tau_\star$: the expected shape of the log-likelihood, per event, is minus the Kullback–Leibler divergence. The script `13_efficiency.py` draws $M_n(\tau)$ for one data set each of $n = 10$, 100 and

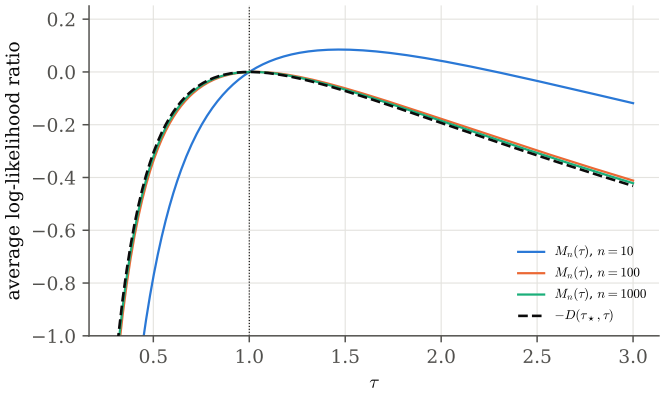

Figure 3.41: Why the MLE is consistent. The average log-likelihood ratio $M_n(\tau)$ of one simulated data set, for 10, 100 and 1000 decays, approaches minus the Kullback–Leibler divergence (dashed), which has its maximum, zero, exactly at the true lifetime (dotted). The peak of each M_n is that data set's MLE, and it is dragged towards the truth as the curves converge.

1000 decays (Figure 3.41). Their peaks, the MLEs, are at 1.47, 1.031 and 1.016, and the curves close in on $-D(\tau_\star, \tau)$ as n grows.

The same argument says what happens when the model is wrong. If the data come from a density g that is not in the family $f(x;\theta)$, M_n still converges, now to $-D(g, f(\cdot;\theta))$ plus a constant, and the MLE converges to the parameter whose density is closest to the truth in the Kullback–Leibler sense. The fit converges, but to the best wrong answer.

3.13.2 Invariance: the MLE does not care what we call the parameter

If $\eta = g(\theta)$ is a one-to-one reparametrisation, the likelihood in terms of η is $\mathcal{L}^*(\eta) = \mathcal{L}(g^{-1}(\eta))$: the same numbers attached to the same hypotheses (Section 3.8.3). Its maximum is therefore at the η that corresponds to $\hat\theta$,

$$\hat\eta = g(\hat\theta)$$

[Wasserman p. 127, Thm. 9.14], [CasellaBerger Thm. 7.2.10]. For a g that is not one-to-one (say $\eta = \theta^2$), Casella and Berger define the likelihood of η as the largest $\mathcal{L}(\theta)$ over all θ with $g(\theta) = \eta$, and the statement still holds. The MLE of the decay rate is $1/\hat\tau$, the MLE of σ is $\sqrt{\hat\sigma^2}$, and the MLE of the Hubble time is $1/\hat H_0$.

Unbiasedness does not survive such a change. Take $\hat\lambda = 1/\hat\tau = n/T$ with $T = \sum_i t_i$, a sum of n exponentials, which has the Gamma density $T^{n-1}e^{-T/\tau}/[\Gamma(n)\tau^n]$ (Chapter 2). Then

$$\mathbb{E}\Big[\frac{1}{T}\Big] \overset{(1)}{=} \int_0^\infty \frac{1}{T}\,\frac{T^{n-1}e^{-T/\tau}}{\Gamma(n)\tau^n}\,\mathrm{d}T \overset{(2)}{=} \frac{\Gamma(n-1)\,\tau^{n-1}}{\Gamma(n)\,\tau^n} \overset{(3)}{=} \frac{1}{(n-1)\tau}, \qquad \mathbb{E}\,\hat\lambda = \frac{n}{n-1}\,\lambda.$$

(1) Expectation of $1/T$ over the Gamma density.
(2) The remaining integrand is an unnormalised Gamma density of shape $n-1$, and $\int_0^\infty T^{n-2}e^{-T/\tau}\mathrm{d}T = \Gamma(n-1)\,\tau^{n-1}$.
(3) $\Gamma(n) = (n-1)\Gamma(n-1)$.

For $n = 50$ the bias factor is $50/49 = 1.02$; the 10^4 experiments of `09_mle_decay.py` give $\mathbb{E}\,\hat\lambda = 1.017$. Since $\hat\tau$ is exactly unbiased, $\hat\lambda$ cannot be. A nonlinear function of an unbiased estimator is biased, by Jensen's inequality, just as the sample standard deviation S is biased for σ even though S^2 is unbiased for σ^2 (Section 3.4.1). So an estimator can be unbiased in one parametrisation only. Maximum likelihood gives up unbiasedness and gains consistency in every parametrisation at once.

The error bar of $\hat\eta = g(\hat\theta)$ follows from the delta method (Section 3.6.3), now applied to the MLE [Wasserman p. 131, Thm. 9.24]: $\widehat{\mathrm{se}}(\hat\eta) \approx |g'(\hat\theta)|\,\widehat{\mathrm{se}}(\hat\theta)$. For $\lambda = 1/\tau$, $|g'| = 1/\tau^2$ and $\widehat{\mathrm{se}}(\hat\lambda) = \hat\tau^{-2}\cdot\hat\tau/\sqrt{n} = \hat\lambda/\sqrt{n}$, the same relative error, as it must be to first order. With several parameters the gradient replaces the derivative, $\widehat{\mathrm{se}}^2(\hat\eta) \approx \nabla g^{\mathsf T}\,\widehat{\mathrm{Cov}}(\hat{\boldsymbol\theta})\,\nabla g$, with the covariance from the inverse Fisher matrix [Wasserman p. 134, Thm. 9.28]. For example, take the coefficient of variation $\eta = \sigma/\mu$ of Gaussian data. One observation has $\ln f = -\ln\sigma - (x-\mu)^2/2\sigma^2 + \text{const}$. Its second derivatives are $\partial^2_\mu \ln f = -1/\sigma^2$, $\partial_\mu\partial_\sigma \ln f = -2(x-\mu)/\sigma^3$ and $\partial^2_\sigma \ln f = 1/\sigma^2 - 3(x-\mu)^2/\sigma^4$. Averaging with $\mathbb{E}(x-\mu) = 0$ and $\mathbb{E}(x-\mu)^2 = \sigma^2$ and multiplying by $-n$ gives a diagonal Fisher matrix with entries n/σ^2 and $2n/\sigma^2$, so $\mathrm{Var}\,\hat\mu \approx \sigma^2/n$ and $\mathrm{Var}\,\hat\sigma \approx \sigma^2/2n$. The gradient of η is $(\partial_\mu\eta, \partial_\sigma\eta) = (-\sigma/\mu^2,\ 1/\mu)$. Then $\widehat{\mathrm{se}}^2(\hat\eta) = \frac{\hat\sigma^2}{\hat\mu^4}\frac{\hat\sigma^2}{n} + \frac{1}{\hat\mu^2}\frac{\hat\sigma^2}{2n} = \hat\sigma^2/(n\hat\mu^2)\,[\hat\sigma^2/\hat\mu^2 + \tfrac12]$ [Wasserman p. 134, Ex. 9.29].

3.13.3 The Cramér–Rao bound: nobody can beat the information

The MLE has asymptotic variance $1/I_n(\theta)$. Could a cleverer estimator do better? The **Cramér–Rao inequality** (also called the Rao–Cramér–Fréchet bound) says no, for any unbiased estimator, at any sample size [CasellaBerger Thm. 7.3.9], [Cowan §6.6]. The proof is a single use of the Cauchy–Schwarz inequality for covariances, $\mathrm{Cov}(A,B)^2 \le \mathrm{Var}\,A\ \mathrm{Var}\,B$, applied to the estimator and the score.

Let $T(\boldsymbol d)$ be any estimator with mean $m(\theta) = \mathbb{E}_\theta\,T$, and $S(\theta) = \partial_\theta \ln p(\boldsymbol d\,|\,\theta)$ the score of the whole data set. Then

$$\mathrm{Cov}_\theta(T,S) \overset{(1)}{=} \mathbb{E}_\theta[T\,S] \overset{(2)}{=} \int T(\boldsymbol d)\,\frac{\partial_\theta p(\boldsymbol d\,|\,\theta)}{p(\boldsymbol d\,|\,\theta)}\,p(\boldsymbol d\,|\,\theta)\,\mathrm d\boldsymbol d \overset{(3)}{=} \frac{\partial}{\partial\theta}\int T(\boldsymbol d)\,p(\boldsymbol d\,|\,\theta)\,\mathrm d\boldsymbol d \overset{(4)}{=} m'(\theta),$$

$$m'(\theta)^2 \overset{(5)}{\le} \mathrm{Var}_\theta\,T\cdot\mathrm{Var}_\theta\,S \overset{(6)}{=} \mathrm{Var}_\theta\,T\cdot I_n(\theta) \quad\Longrightarrow\quad \mathrm{Var}_\theta\,T \ \ge\ \frac{m'(\theta)^2}{I_n(\theta)}. \tag{3.101}$$

(1) $\mathrm{Cov}(T,S) = \mathbb{E}[TS] - \mathbb{E}\,T\ \mathbb{E}\,S$, and $\mathbb{E}\,S = 0$ by (3.97).
(2) Write out the expectation; $S = \partial_\theta p/p$.
(3) Cancel p and move the derivative outside. T depends on the data only, not on θ. This exchange is the regularity condition.
(4) The integral is the definition of $m(\theta)$.
(5) Cauchy–Schwarz for covariances, with step (4) on the left.
(6) $\mathrm{Var}\,S = I_n$, (3.98).

For an unbiased estimator $m(\theta) = \theta$ and $m' = 1$, so that $\mathrm{Var}\,T \ge 1/I_n(\theta)$, which for independent, identically distributed data is $1/[nI(\theta)]$ [CasellaBerger Cor. 7.3.10]. If T has a bias $b(\theta)$, then $m = \theta + b$ and the bound is $(1+b')^2/I_n$, Cowan's form of the inequality.

Key idea: Cramér–Rao

For a regular model, every unbiased estimator satisfies

$$\mathrm{Var}_\theta\,\hat\theta \ \ge\ \frac{1}{I_n(\theta)} = \frac{1}{nI(\theta)}.$$

The Fisher information is the best precision the data can possibly give. The MLE reaches the bound as $n\to\infty$; it is **asymptotically efficient**. For several parameters, $\mathrm{Cov}\,\hat{\boldsymbol\theta} - \mathbf F^{-1}$ is positive semidefinite, where $\mathbf F$ is the Fisher matrix (Chapter 10).

When is the bound reached exactly? Cauchy–Schwarz is an equality only when the two variables are linearly related. The bound is attained by an unbiased T exactly when $S(\theta) =$

$a(\theta)\,[T(\boldsymbol{d}) - \theta]$ for some function a [CasellaBerger Cor. 7.3.15]. This happens for the exponential families of distributions [Wasserman p. 141]. The lifetime is an example: its score, $-n/\tau + T/\tau^2 = (n/\tau^2)(\bar{t} - \tau)$, has exactly this form, so $\bar{t}$ attains the bound τ^2/n at every n, not only asymptotically. So does $\bar{x}$ for a Gaussian mean. For the Gaussian variance with unknown mean the bound is $2\sigma^4/n$, while the best unbiased estimator, S^2, has variance $2\sigma^4/(n-1)$: close, but the bound is not attained [CasellaBerger Ex. 7.3.14].

When the bound does not apply: the uniform box again. For Uniform$(0, \theta)$, a blind application of the recipe gives $\partial_\theta \ln(1/\theta) = -1/\theta$, "information" $1/\theta^2$ per point, and a "bound" θ^2/n. But the unbiased estimator $\frac{n+1}{n} x_{(n)}$ does far better. Since $\mathrm{P}(x_{(n)} \le y) = (y/\theta)^n$, the scaled maximum $y = x_{(n)}/\theta$ has density $n y^{n-1}$ on $[0, 1]$, and

$$\mathbb{E}\, y \overset{(1)}{=} \frac{n}{n+1}, \qquad \mathbb{E}\, y^2 \overset{(2)}{=} \frac{n}{n+2},$$
$$\operatorname{Var}\Big[\frac{n+1}{n} x_{(n)}\Big] \overset{(3)}{=} \frac{(n+1)^2}{n^2}\,\theta^2\Big[\frac{n}{n+2} - \frac{n^2}{(n+1)^2}\Big] \overset{(4)}{=} \frac{\theta^2}{n(n+2)}.$$

(1) $\int_0^1 y \cdot n y^{n-1} \mathrm{d}y = n/(n+1)$.
(2) $\int_0^1 y^2 \cdot n y^{n-1} \mathrm{d}y = n/(n+2)$.
(3) $\operatorname{Var}(cX) = c^2 \operatorname{Var} X$ with $x_{(n)} = \theta y$, and $\operatorname{Var} y = \mathbb{E}\, y^2 - (\mathbb{E}\, y)^2$.
(4) Common denominator: $n(n+1)^2 - n^2(n+2) = n$, so the bracket is $n/[(n+1)^2(n+2)]$.

The variance falls like $1/n^2$, not $1/n$. The simulation in `13_efficiency.py` gives $n \operatorname{Var}/\theta^2 = 0.01877$ at $n = 51$, against the exact $1/(n+2) = 0.01887$ and the "bound" 1. There is no contradiction. Step (3) of (3.101) moved a derivative through an integral. Here the upper limit of that integral is θ itself, so differentiating it produces an extra boundary term and the exchange is not allowed. Indeed the "score" $-n/\theta$ does not have mean zero: it is not random at all [CasellaBerger Ex. 7.3.13]. The lesson is that a sharp edge in the data is worth more than any smooth feature, because a single point near the edge pins it down. Physicists use this all the time: the endpoint of a beta spectrum or of a kinematic distribution measures a mass far more sharply than the bulk of the distribution does.

3.13.4 Efficiency in practice: the mean against the median

The ratio of the variances of two consistent estimators, at large n, is their **asymptotic relative efficiency** [Wasserman p. 131, Thm. 9.23]. For Gaussian data the mean is the MLE of the centre and attains the bound σ^2/n. The sample median also estimates the centre, and it is popular because a single wild point cannot move it much. How much precision does it cost?

The asymptotic variance of the median follows from a counting argument. Let m be the true median and $f(m)$ the density there. The sample median lies below $m + \delta$ exactly when at least half the points do. The number of points below $m + \delta$ is binomial with n trials and success probability $F(m + \delta) \approx \frac{1}{2} + f(m)\delta$, so

$$\mathrm{P}(\hat{m} \le m + \delta) \overset{(1)}{=} \mathrm{P}\Big(\mathrm{Bin}\big(n, \tfrac{1}{2} + f\delta\big) \ge \tfrac{n}{2}\Big) \overset{(2)}{=} \mathrm{P}\Big(Z \ge \frac{n/2 - n/2 - nf\delta}{\sqrt{n}/2}\Big) \overset{(3)}{=} \Phi\big(2\sqrt{n}\, f(m)\, \delta\big),$$
$$\operatorname{Var} \hat{m} \overset{(4)}{=} \frac{1}{4n f(m)^2} \overset{(5)}{=} \frac{\pi\sigma^2}{2n} \quad \text{(Gaussian data)}.$$

(1) The median is below $m + \delta$ if at least $n/2$ points are. Near m, $F(m + \delta) \approx F(m) + f(m)\delta$ with $F(m) = \frac{1}{2}$.

(2) Gaussian approximation of the binomial (Chapter 2): mean $n(\frac{1}{2} + f\delta)$, variance $\approx n/4$ for small δ.
(3) $P(Z \geq -a) = \Phi(a)$ for a standard Gaussian Z.
(4) Step (3) says $\hat{m} - m$ is Gaussian with standard deviation $1/(2\sqrt{n}f)$.
(5) For $\mathcal{N}(\mu, \sigma^2)$, $f(m) = 1/(\sqrt{2\pi}\sigma)$ and $1/(4f^2) = 2\pi\sigma^2/4$.

The median's relative efficiency is $(\sigma^2/n)/(\pi\sigma^2/2n) = 2/\pi = 0.64$: using the median on Gaussian data is like throwing away 36% of the events [Wasserman p. 131]. The simulation, 60 000 data sets at each of several n, confirms it (Figure 3.42): at $n = 201$, n Var is 0.9981 σ^2 for the mean and 1.578 σ^2 for the median ($\pi/2 = 1.571$), an efficiency of 0.6327 against $2/\pi = 0.6366$.

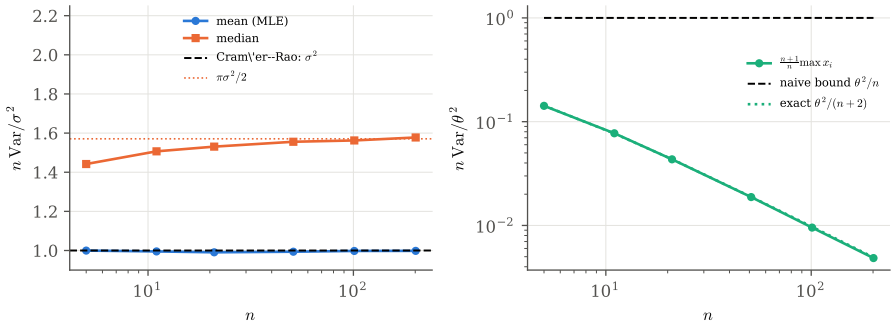

Figure 3.42: Efficiency, simulated. Left: n times the variance of the mean (the MLE) and of the median for Gaussian data. The mean sits on the Cramér–Rao bound at every n; the median approaches $\pi\sigma^2/2$ (dotted). Right: for the uniform box the estimator $\frac{n+1}{n}\max x_i$ falls far below the naive "bound" θ^2/n (dashed) and follows the exact $\theta^2/(n+2)$ (dotted), because the regularity conditions fail.

The lost precision buys robustness. For the Cauchy distribution, whose tails are so heavy that the sample mean does not converge at all, the median is consistent, with variance $\pi^2\gamma^2/(4n)$ for half-width γ (the same formula with $f(m) = 1/(\pi\gamma)$). The MLE is optimal only *within the model*. When the real data have heavier tails than the model allows, an estimator that is slightly inefficient under the model but robust to outliers can be far better in practice.

Watch out: The fine print of "the MLE is optimal"

Every property above is asymptotic and assumes a regular model with the true value inside the parameter space. At small n the MLE can be biased ($\hat{\sigma}^2$, $\hat{\lambda}$). At a boundary (a signal strength fitted to zero) the sampling distribution is not Gaussian. With a moving support (the uniform box) the Cramér–Rao bound does not apply. When the number of nuisance parameters grows with the data (one unknown mean per pair of measurements, say), the MLE of the common parameter need not even be consistent. Check with a simulation whenever any of these apply.

3.14 Nuisance parameters and the profile likelihood

Almost no real likelihood has only the parameters we care about. A search for a new particle wants the signal rate, but the background rate is also unknown. A cosmological fit wants Ω_m and σ_8, but the galaxy bias, the calibration of the telescope and the amplitude of a foreground come along. These are **nuisance parameters** [parameters that the likelihood depends on and the data constrain, but whose values we do not want to report] [Wasserman p. 120]. They cannot be ignored. Fixing them at a guessed value pretends we know them, and that makes the error on the interesting parameter too small. Three questions need answers.

1. How do we reduce a likelihood of several parameters to a function of the one we care about, without pretending the others are known?
2. Why does the honest answer have a wider interval, and by how much?
3. How does this compare with the Bayesian way of removing a nuisance parameter, by integrating it out?

3.14.1 A signal on top of a background

A standard counting experiment has two regions. In the *signal region* we count n_{on} events, expected to be $s + b$: signal plus background. In a *control region*, chosen so that it contains no signal, we count n_{off} events, expected to be kb, where the known factor k is the ratio of exposures (here $k = 1$). Both counts are Poisson, and they are independent:

$$\ell(s, b) = n_{\text{on}} \ln(s + b) - (s + b) + n_{\text{off}} \ln(kb) - kb.$$

The global maximum is easy. Setting the derivatives with respect to s and to b to zero gives the two score equations $n_{\text{on}}/(s + b) = 1$ and $n_{\text{on}}/(s + b) - 1 + n_{\text{off}}/b - k = 0$. By the first, the first two terms of the second cancel, which leaves $n_{\text{off}}/b = k$. So $\hat{b} = n_{\text{off}}/k$, and then the first gives $\hat{s} = n_{\text{on}} - n_{\text{off}}/k$. With $n_{\text{on}} = 20$ and $n_{\text{off}} = 8$, $\hat{s} = 12$ and $\hat{b} = 8$. The question is the error on $\hat{s}$.

Two ways to get a one-dimensional likelihood. To get the error on $\hat{s}$ we need a likelihood of s alone, and there are two ways to remove b. The lazy way is to fix b at its best value $\hat{b}$ and look at $\ell(s, \hat{b})$, the **conditional** likelihood. It pretends that the control region measured b perfectly. The honest way is to let b adjust: for each trial value of s, find the background that makes the data most probable, and use that.

Working definition 3.14 (profile likelihood)

For parameters $(\theta, \boldsymbol{\nu})$, with θ of interest and $\boldsymbol{\nu}$ nuisance, the **profile likelihood** is

$$\mathcal{L}_p(\theta) = \max_{\boldsymbol{\nu}} \mathcal{L}(\theta, \boldsymbol{\nu}) = \mathcal{L}\big(\theta, \hat{\hat{\boldsymbol{\nu}}}(\theta)\big),$$

where $\hat{\hat{\boldsymbol{\nu}}}(\theta)$ is the best value of the nuisance parameters at fixed θ [the ridge line of the likelihood, one point for every θ]. *Operationally:* on a grid of θ, maximise over everything else, record the maximum; then treat $\mathcal{L}_p$ like a one-parameter likelihood, with its maximum at the global $\hat{\theta}$.

For the on/off problem the inner maximisation can be done by hand. At fixed s,

$$\begin{aligned} 0 &\overset{(1)}{=} \frac{n_{\text{on}}}{s + b} - 1 + \frac{n_{\text{off}}}{b} - k \\ &\overset{(2)}{\Longrightarrow} n_{\text{on}}\, b - b(s + b) + n_{\text{off}}(s + b) - kb(s + b) = 0 \\ &\overset{(3)}{\Longrightarrow} (1 + k)\, b^2 + \big[(1 + k)s - n_{\text{on}} - n_{\text{off}}\big]\, b - n_{\text{off}}\, s = 0, \end{aligned}$$

(1) $\partial\ell/\partial b$ at fixed s.
(2) Multiply by $b(s + b) > 0$.
(3) Collect powers of b and multiply by -1.

and $\hat{\hat{b}}(s)$ is the positive root of this quadratic (the constant term is negative for $s > 0$, so there is exactly one). As s increases, the best background decreases: more of the n_{on} events are already explained by signal. That anticorrelation is what the conditional likelihood ignores.

3.14.2 Why profiling widens the interval

Near the maximum every smooth log-likelihood is quadratic, so it is enough to understand the Gaussian case. Take one parameter of interest θ and one nuisance parameter ν. Write $\boldsymbol{x} = (\theta - \hat\theta, \nu - \hat\nu)$ and $\ell = \ell_{\max} - \tfrac12 \boldsymbol{x}^{\mathsf T}\mathbf{F}\boldsymbol{x}$ with the information matrix $\mathbf{F} = \begin{pmatrix} F_{\theta\theta} & F_{\theta\nu} \\ F_{\theta\nu} & F_{\nu\nu} \end{pmatrix}$, whose inverse $V = \mathbf{F}^{-1}$ is the covariance matrix. Maximise over the nuisance direction:

$$
\begin{aligned}
\ell - \ell_{\max} &\overset{(1)}{=} -\tfrac12\left[F_{\theta\theta}x_\theta^2 + 2F_{\theta\nu}x_\theta x_\nu + F_{\nu\nu}x_\nu^2\right], \\
\frac{\partial \ell}{\partial x_\nu} = 0 &\overset{(2)}{\Longrightarrow}\; x_\nu = -\frac{F_{\theta\nu}}{F_{\nu\nu}}\, x_\theta, \\
\ell_p - \ell_{\max} &\overset{(3)}{=} -\tfrac12\left(F_{\theta\theta} - \frac{F_{\theta\nu}^2}{F_{\nu\nu}}\right)x_\theta^2 \overset{(4)}{=} -\frac{x_\theta^2}{2V_{\theta\theta}}.
\end{aligned}
\tag{3.102}
$$

(1) Write out the quadratic form.
(2) Derivative in x_ν: $-(F_{\theta\nu}x_\theta + F_{\nu\nu}x_\nu) = 0$. This is the profile path, a straight line through the maximum.
(3) Substitute: $2F_{\theta\nu}x_\theta x_\nu + F_{\nu\nu}x_\nu^2 = -F_{\theta\nu}^2 x_\theta^2/F_{\nu\nu}$.
(4) The (θ,θ) element of the inverse of a symmetric 2×2 matrix is $V_{\theta\theta} = F_{\nu\nu}/\det\mathbf{F}$, and $F_{\theta\theta} - F_{\theta\nu}^2/F_{\nu\nu} = \det\mathbf{F}/F_{\nu\nu} = 1/V_{\theta\theta}$.

The profile likelihood is a Gaussian of variance $V_{\theta\theta}$: the full marginal variance of $\hat\theta$, including the uncertainty it inherits from the nuisance parameter. The conditional likelihood at $\nu = \hat\nu$ has curvature $F_{\theta\theta}$, hence variance $1/F_{\theta\theta}$, and

$$
\frac{1}{F_{\theta\theta}} = V_{\theta\theta}\,(1-\rho^2) \;\le\; V_{\theta\theta},
$$

where ρ is the correlation coefficient of $\hat\theta$ and $\hat\nu$. The identity follows from the same 2×2 inverse, whose entries are $V_{\theta\theta} = F_{\nu\nu}/\det\mathbf{F}$, $V_{\nu\nu} = F_{\theta\theta}/\det\mathbf{F}$ and $V_{\theta\nu} = -F_{\theta\nu}/\det\mathbf{F}$:

$$
\rho^2 = \frac{V_{\theta\nu}^2}{V_{\theta\theta}V_{\nu\nu}} = \frac{F_{\theta\nu}^2}{F_{\theta\theta}F_{\nu\nu}}, \qquad V_{\theta\theta}(1-\rho^2) = \frac{F_{\nu\nu}}{\det\mathbf{F}}\cdot\frac{F_{\theta\theta}F_{\nu\nu} - F_{\theta\nu}^2}{F_{\theta\theta}F_{\nu\nu}} = \frac{1}{F_{\theta\theta}}.
$$

So the conditional interval is too short by the factor $\sqrt{1-\rho^2}$. The stronger the correlation, the more it understates the error. Figure 3.43 shows the geometry.

Example: the on/off errors in the Gaussian limit. For large counts, $\hat s = n_{\text{on}} - n_{\text{off}}/k$ is a difference of independent Poisson counts. A Poisson count has variance equal to its mean, estimated by the count itself, so the variances are about n_{on} and n_{off}. By linear error propagation (Section 3.6.1), $\sigma_{\hat s}^2 \approx n_{\text{on}} + n_{\text{off}}/k^2$. For $(20, 8)$ with $k = 1$ that is $\sqrt{28} = 5.292$. Fixing b leaves only the fluctuation of n_{on}, $\sqrt{20} = 4.472$. The profile likelihood reproduces the first number, the conditional likelihood the second.

3.14.3 The on/off problem in Python

Listing 3.13: Profile and conditional intervals for the on/off problem (`code/ch03/14_profile.py`)

```
def bhat_of_s(s, non, noff):
    """maximise over b at fixed s: (1+k) b^2 + ((1+k) s - non - noff) b - noff s = 0"""
    A = 1 + k; B = (1 + k) * s - non - noff; C = -noff * s
    return (-B + np.sqrt(B * B - 4 * A * C)) / (2 * A)
```

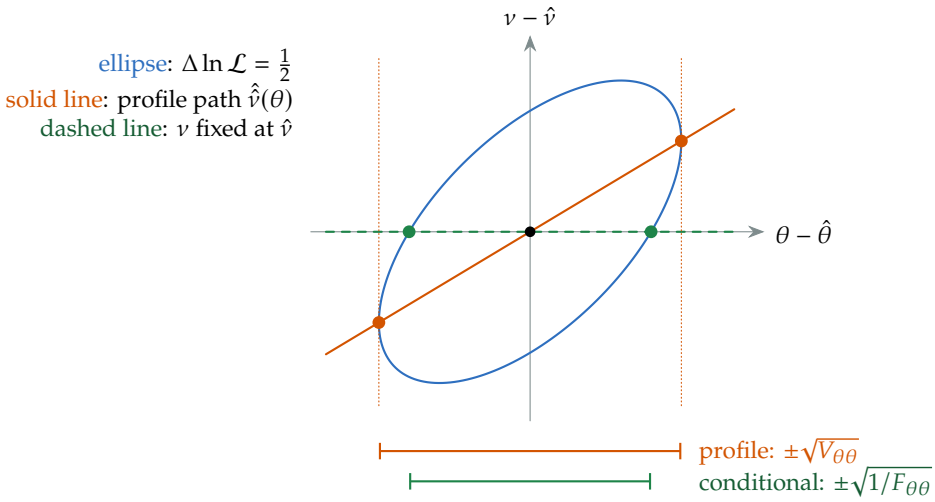

Figure 3.43: Profile versus conditional likelihood for a Gaussian likelihood with correlation $\rho = 0.6$ between the parameter of interest and the nuisance parameter. The profile path runs through the points where the ellipse has vertical tangents, so the profile likelihood drops by $\frac{1}{2}$ at the full width of the ellipse (orange bar). Holding the nuisance parameter fixed cuts the ellipse along the horizontal line and gives an interval shorter by the factor $\sqrt{1-\rho^2} = 0.8$ (green bar).

```
5
6
7  def intervals(non, noff):
8      b0 = noff / k; s0 = non - b0                        # the global MLE
9      Lmax = lnL(s0, b0, non, noff)
10     prof = lambda s: lnL(s, bhat_of_s(s, non, noff), non, noff) - Lmax + 0.5
11     cond = lambda s: lnL(s, b0, non, noff) - Lmax + 0.5
12     lo_s = -b0 + 1e-9                                    # s + b must stay positive
13     out = []
14     for f in (prof, cond):
15         lo = optimize.brentq(f, max(lo_s, s0 - 20 * np.sqrt(non + 1)), s0)
16         hi = optimize.brentq(f, s0, s0 + 20 * np.sqrt(non + 1))
17         out.append((lo, hi))
18     return s0, b0, out
```

The function `bhat_of_s` is the positive root of the quadratic for $\hat{\hat{b}}(s)$ in Section 3.14.1. The functions `prof` and `cond` are the two one-dimensional log-likelihoods shifted so that their zeros are the $\Delta \ln \mathcal{L} = \frac{1}{2}$ crossings, which `brentq` finds on either side of $\hat{s}$. For the observed counts the result is

$$\text{profile: } \hat{s} = 12^{+5.47}_{-5.192}, \qquad \text{conditional: } \hat{s} = 12^{+4.811}_{-4.145}.$$

The profile interval is about 20% wider, as the Gaussian estimates 5.292 and 4.472 said, and both are asymmetric because the counts are small. Figure 3.44 shows the two-dimensional contours, the profile path and the two curves.

Which interval is right? The script simulates 10^4 experiments with $s = 12$ and $b = 8$ and counts how often each interval contains the true signal. (In 9995 of them both intervals exist; the rest have $n_{\text{off}} = 0$ or a similar degenerate outcome.) The profile interval covers the truth in 0.6849 of the experiments, the 68% a $\pm 1\sigma$ interval promises. The conditional interval covers it in only 0.6088. The reason the profile works is **Wilks' theorem** again [22]: $-2\ln[\mathcal{L}_p(\theta)/\mathcal{L}_{\max}]$ at the true θ is asymptotically χ^2_1, whatever the number of nuisance parameters that were maximised over, so the $\Delta \ln \mathcal{L}_p = \frac{1}{2}$ interval has 68% coverage for large samples. This is what the `MINOS` errors of `MINUIT` compute, and it is the basis of the profile-likelihood test statistics used in every LHC search (Chapter 4).

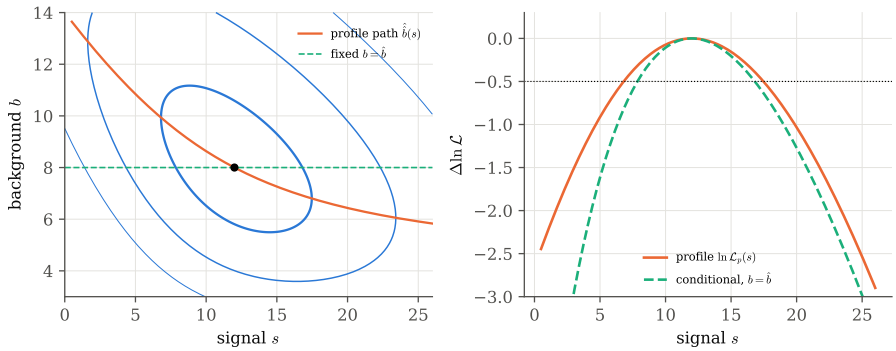

Figure 3.44: A signal on top of a background, from 20 counts in the signal region and 8 in the control region. Left: contours of $\ln \mathcal{L}(s, b)$ at $\Delta \ln \mathcal{L} = \frac{1}{2}$, 2 and 4.5, the profile path (the best background for each signal value, falling as s rises) and the line of fixed background. Right: the profile log-likelihood is wider than the conditional one; the dotted line at $-\frac{1}{2}$ marks the interval endpoints.

Key idea: Profile out nuisance parameters

Maximise over the nuisance parameters at each value of the parameter of interest, and read the interval from $\Delta \ln \mathcal{L}_p = \frac{1}{2}$. For a Gaussian likelihood this gives exactly the marginal error $\sqrt{V_{\theta\theta}}$; fixing the nuisance parameters instead gives $\sqrt{1/F_{\theta\theta}}$, too small by $\sqrt{1-\rho^2}$.

3.14.4 Profiling and marginalising

The Bayesian removes a nuisance parameter differently: by integrating it out of the posterior, $p(\theta \mid \boldsymbol{d}) = \int p(\theta, \nu \mid \boldsymbol{d})\, \mathrm{d}\nu$ [Padilla (38)], [HobsonBMC p. 49]. This is the marginalisation of a joint distribution that we have used since Chapter 1: average over the variable we do not want. For a Gaussian likelihood and a flat prior the two operations give the same answer, because the integral of a two-dimensional Gaussian over one variable is a Gaussian in the other with variance $V_{\theta\theta}$, the same as (3.102). They differ when the likelihood is not Gaussian, and the difference is itself a warning that the asymptotic theory is being stretched.

Example: an unknown noise level. Hobson et al. consider a fit where every datum has Gaussian noise of the same, unknown size σ [HobsonBMC p. 50, (2.25)–(2.26)]. With $Q(\theta) = \sum_i (D_i - d_i(\theta))^2$ the likelihood is $\mathcal{L}(\theta, \sigma) = (2\pi\sigma^2)^{-N/2} \exp[-Q(\theta)/2\sigma^2]$. Profile over σ:

$$\frac{\partial \ell}{\partial \sigma} \overset{(1)}{=} -\frac{N}{\sigma} + \frac{Q}{\sigma^3} = 0 \;\Rightarrow\; \hat{\sigma}^2(\theta) = \frac{Q(\theta)}{N}, \qquad \mathcal{L}_p(\theta) \overset{(2)}{=} \left(\frac{2\pi Q(\theta)}{N}\right)^{-N/2} e^{-N/2} \;\propto\; Q(\theta)^{-N/2}.$$

(1) Differentiate $-N \ln \sigma - Q/2\sigma^2$.
(2) Substitute: the exponent becomes $-Q/(2Q/N) = -N/2$.

Now marginalise instead, with the prior $p(\sigma) \propto 1/\sigma$ (flat in $\ln \sigma$, the prior Hobson et al. use):

$$\int_0^\infty \sigma^{-N} e^{-Q/2\sigma^2} \frac{\mathrm{d}\sigma}{\sigma} \overset{(1)}{=} \int_0^\infty \left(\frac{2u}{Q}\right)^{N/2} e^{-u} \frac{\mathrm{d}u}{2u} \overset{(2)}{=} \frac{1}{2}\left(\frac{2}{Q}\right)^{N/2} \Gamma\!\left(\frac{N}{2}\right) \;\propto\; Q(\theta)^{-N/2}.$$

(1) Substitute $u = Q/2\sigma^2$, so $\sigma^{-2} = 2u/Q$ and $\mathrm{d}\sigma/\sigma = -\mathrm{d}u/(2u)$ (the sign is absorbed by swapping the limits).
(2) $\int_0^\infty u^{N/2-1} e^{-u} \mathrm{d}u = \Gamma(N/2)$.

The two routes give the same function of θ, which is Hobson's (2.26) up to a constant. The unknown noise level turns the Gaussian $e^{-\chi^2/2}$ into the heavier-tailed $Q^{-N/2}$, a Student-t shape in θ (Chapter 2): not knowing the size of the error bars costs precision, and the likelihood knows it. The same device, an unknown scale factor on all quoted error bars, is Hobson's "safety valve" for data with underestimated errors [HobsonBMC p. 52].

3.15 The bootstrap: the sampling distribution from one data set

Every error bar so far came from a formula: $\sigma/\sqrt{n}$ for the mean, the curvature of $\ln \mathcal{L}$ for the MLE, the delta method for a function of estimates. To check those formulas we also used a luxury no experimenter has: we simulated 10^4 fresh experiments from the true distribution and looked at the scatter. Now suppose there is no formula (the median of lifetimes, a ratio of two fitted amplitudes, the peak position of a smoothed histogram) and no known truth to simulate from. All we have is one data set. The **bootstrap** lets that one data set stand in for the unknown distribution, and then simulates from it [23]. Three questions need answers.

1. What does it mean to "simulate from the data", and why does it estimate the sampling distribution?
2. How do we turn the simulated replicas into a standard error and a confidence interval?
3. When does it fail?

3.15.1 Two worlds

Let the data $x_1, \dots, x_n$ come independently from an unknown distribution F, and let $T_n = g(x_1, \dots, x_n)$ be any statistic. Its standard error is $\sqrt{\mathrm{Var}_F(T_n)}$, which we could compute by simulation if we knew F: draw many samples of size n from F, compute T_n on each, take the standard deviation. We do not know F. But we have an estimate of it, the **empirical distribution** $\hat{F}_n$ [the distribution that puts probability $1/n$ on each observed data point, and nothing elsewhere]. The bootstrap replaces F by $\hat{F}_n$ and then does the simulation [Wasserman pp. 108–109]:

$$\mathrm{Var}_F(T_n) \overset{\text{(i)}}{\approx} \mathrm{Var}_{\hat{F}_n}(T_n) \overset{\text{(ii)}}{\approx} v_{\text{boot}} = \frac{1}{B-1}\sum_{b=1}^{B}\left(T^*_{n,b} - \overline{T^*}\right)^2 .$$

Approximation (i) is the statistical one: it is good when $\hat{F}_n$ is close to F, which requires n to be reasonably large, and it cannot be improved without more data. Approximation (ii) is pure Monte Carlo: its error falls as $1/\sqrt{B}$, and we make it small by running the computer longer.

Drawing a sample of size n from $\hat{F}_n$ means picking n of the observed points at random, *with replacement*: some points appear twice or three times, others not at all. Each such **bootstrap sample** $x^*_1, \dots, x^*_n$ gives a **replica** T^*_n of the statistic. Figure 3.45 lays out the analogy.

Working definition 3.15 (nonparametric bootstrap)

To estimate the standard error of a statistic T_n from one data set of size n: for $b = 1, \dots, B$, draw n indices uniformly from $\{1, \dots, n\}$ with replacement, form the bootstrap sample, and compute the replica $T^*_{n,b}$. The bootstrap standard error is the sample standard deviation of the B replicas [Wasserman p. 109, (8.1)]. B of a few hundred suffices for a standard error; intervals need a few thousand.

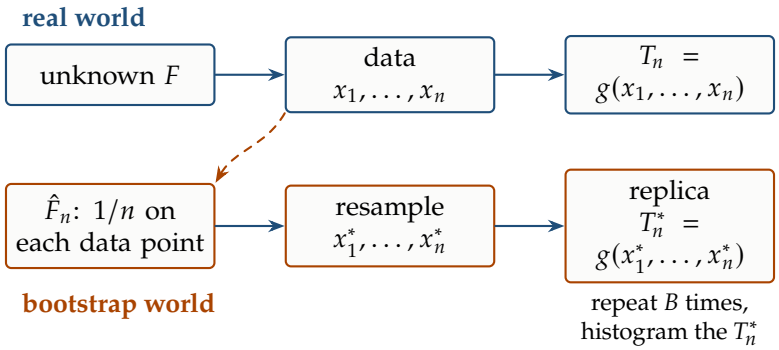

Figure 3.45: The two worlds of the bootstrap. In the real world an unknown distribution produced one data set and one value of the statistic, and we cannot repeat it. In the bootstrap world the empirical distribution (built from the data, dashed arrow) plays the role of the truth. We can draw from it as often as we like, and the scatter of the replicas stands in for the scatter of the statistic in the real world.

Example: the bootstrap of the mean, exactly. For the mean we can do the bootstrap world by hand. A single resampled point x^* equals each x_i with probability $1/n$, so

$$\mathbb{E}_{\hat{F}}\, x^* \overset{(1)}{=} \frac{1}{n}\sum_i x_i = \bar{x}, \qquad \mathrm{Var}_{\hat{F}}\, x^* \overset{(2)}{=} \frac{1}{n}\sum_i (x_i - \bar{x})^2 \equiv \hat{\sigma}^2,$$

$$\mathrm{Var}_{\hat{F}}\, \bar{x}^* \overset{(3)}{=} \frac{\hat{\sigma}^2}{n} \overset{(4)}{=} \frac{n-1}{n}\,\frac{S^2}{n}.$$

(1) The expectation over the empirical distribution is the plain average of the data.
(2) Its variance is the average squared deviation from that average, with divisor n.
(3) The n resampled points are independent draws from $\hat{F}$, so the variance of their mean is the single-point variance over n.
(4) $S^2 = \sum_i (x_i - \bar{x})^2/(n-1)$ is the unbiased sample variance.

The bootstrap reproduces the textbook standard error $S/\sqrt{n}$, up to the factor $\sqrt{(n-1)/n}$ that is negligible for n of a few tens. For the data $\{1, 2, 6\}$, $\bar{x} = 3$ and $\hat{\sigma}^2 = (4 + 1 + 9)/3 = 14/3$, so the bootstrap variance of the mean is $14/9 = 1.56$, against $S^2/n = 7/3 = 2.33$ from the unbiased formula: with three points the factor $(n-1)/n = 2/3$ matters. There are only $\binom{2n-1}{n} = 10$ distinct bootstrap samples here, so for tiny n the bootstrap distribution is coarse; for $n = 50$ there are about 5×10^{28}.

The parametric bootstrap. If we trust a parametric model $f(x;\theta)$, there is a better stand-in for F than $\hat{F}_n$: the fitted model $f(x;\hat{\theta})$. The **parametric bootstrap** simulates B data sets of size n from $f(x;\hat{\theta})$ and refits each one [Wasserman p. 134]. This is exactly what we did with the 10^4 simulated lifetime experiments of Section 3.12.4, except that the fitted value replaces the truth. It is also the standard way to calibrate a complicated analysis in physics: fit, simulate from the fit, analyse the simulations the same way, look at the scatter.

3.15.2 The bootstrap in Python

The script `15_bootstrap.py` takes one data set of $n = 50$ decay times and asks for the standard errors of two statistics: the mean $\hat{\tau}$, where we know the answer, and the median, where we have no simple formula (its asymptotic variance is $1/[4nf(m)^2]$ from Section 3.13.4, which needs the unknown density at the unknown median).

Listing 3.14: Nonparametric and parametric bootstrap of the mean and the median (code/ch03/15_bootstrap.py)

```
t = rng.exponential(tau_true, n)                        # the one data set we have
tau_hat, med_hat = t.mean(), np.median(t)

# the truth (available only because this is a simulation)
T = rng.exponential(tau_true, (B, n))
true_tau, true_med = T.mean(1), np.median(T, 1)

# nonparametric bootstrap: draw n points WITH replacement from the data
idx = rng.integers(0, n, (B, n))
Tb = t[idx]
np_tau, np_med = Tb.mean(1), np.median(Tb, 1)
# parametric bootstrap: simulate from the fitted model f(t; tau_hat)
Tp = rng.exponential(tau_hat, (B, n))
p_tau, p_med = Tp.mean(1), np.median(Tp, 1)

se = lambda a: a.std(ddof=1)
q = lambda a, p: np.quantile(a, p)
ci_norm = (med_hat - 1.96 * se(np_med), med_hat + 1.96 * se(np_med))
ci_piv = (2 * med_hat - q(np_med, 0.975), 2 * med_hat - q(np_med, 0.025))
ci_pct = (q(np_med, 0.025), q(np_med, 0.975))
```

Line 34 is the whole nonparametric bootstrap: a $B \times n$ array of random indices, used to pick data points with replacement, so that each row is one bootstrap sample. Line 38 is the parametric bootstrap, fresh exponential samples with the fitted lifetime. Lines 30–31 compute what no experimenter can, the true sampling distribution from 10^4 fresh experiments, as a referee.

standard error	true (fresh experiments)	nonparametric	parametric
mean $\hat{\tau}$	0.1425	0.1116	0.1162
median	0.1418	0.1352	0.1155

In this run the data set has $\hat{\tau} = 0.8176$ and median 0.5147, for true values 1 and $\ln 2 = 0.6931$. The bootstrap estimates the standard error of the distribution it simulates from, and that distribution is built from these fifty numbers, so it inherits their luck. The parametric bootstrap simulates from an exponential with mean $\hat{\tau}$, so its error for the mean follows $\hat{\tau}$, as does the curvature error $\hat{\tau}/\sqrt{n} = 0.1156$. The nonparametric bootstrap follows the spread of the data instead. A data set that comes out low or narrow gives error bars that are too small, one that comes out high or wide gives error bars that are too large, and no method that uses only these fifty numbers can tell which kind of draw it has. Dividing by the estimate removes the overall scale: the *relative* error here is $0.1116/0.8176 = 0.1365$ against the true $0.1425/1$. That too depends on the draw. Computed on each of the 10^4 fresh experiments, the same relative error averages 0.1375 but scatters by 0.01819 from one data set to the next, so a single data set can easily miss it by that much. For the median the bootstrap gives an error bar where we had no formula at all, with the same caveat: it comes from one data set and shares its luck. Figure 3.46 compares the shapes of the bootstrap distributions, each centred on its own estimate, with the true sampling distribution.

3.15.3 Bootstrap confidence intervals

A standard error gives the simplest interval, the **Normal interval** $T_n \pm z_{\alpha/2}\,\widehat{\mathrm{se}}_{\mathrm{boot}}$ [Wasserman p. 110, (8.2)], which assumes a Gaussian sampling distribution. The bootstrap distribution contains more than a width, and two other constructions use its shape.

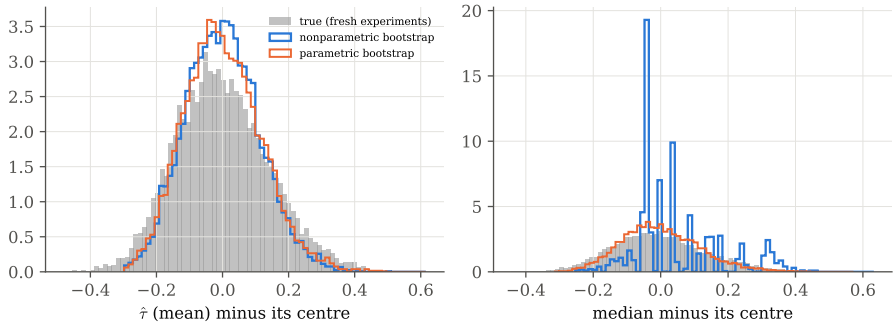

Figure 3.46: Bootstrap distributions from one data set of fifty decay times, each centred on its own centre so the shapes can be compared. Grey: the true sampling distribution from ten thousand fresh experiments. Blue: resampling the data with replacement. Orange: simulating from the fitted exponential. Left: the mean. Right: the median, whose nonparametric bootstrap distribution is lumpy because a resampled median can only take a few values near the middle of the data.

The pivotal interval. Let $R_n = \hat{\theta} - \theta$ be the error of the estimate, with unknown distribution function $H(r) = \mathrm{P}(R_n \le r)$. Choose $a = \hat{\theta} - H^{-1}(1-\alpha/2)$ and $b = \hat{\theta} - H^{-1}(\alpha/2)$. Then

$$\mathrm{P}(a \le \theta \le b) \overset{(1)}{=} \mathrm{P}\big(\hat{\theta} - b \le R_n \le \hat{\theta} - a\big) \overset{(2)}{=} H\big(\hat{\theta} - a\big) - H\big(\hat{\theta} - b\big)$$
$$\overset{(3)}{=} H\big(H^{-1}(1-\tfrac{\alpha}{2})\big) - H\big(H^{-1}(\tfrac{\alpha}{2})\big) = 1 - \alpha.$$

(1) $a \le \theta$ is the same as $\hat{\theta} - \theta \le \hat{\theta} - a$, and $\theta \le b$ is $\hat{\theta} - b \le \hat{\theta} - \theta$.
(2) Probability of an interval from the distribution function (for a continuous H).
(3) Insert the chosen a and b.

We do not know H, but the bootstrap gives its analogue: the distribution of $R^* = \theta^* - \hat{\theta}$, whose quantiles are $\theta^*_\beta - \hat{\theta}$ with θ^*_β the β-quantile of the replicas. Substituting gives the **pivotal interval** [Wasserman p. 111, (8.6)]

$$C_n = \big(2\hat{\theta} - \theta^*_{1-\alpha/2},\; 2\hat{\theta} - \theta^*_{\alpha/2}\big).$$

The interval is reflected. Suppose the replicas scatter further above $\hat{\theta}$ than below it. In the bootstrap world, then, the estimate overshoots its truth by larger amounts than it undershoots. Carried back to the real world, our $\hat{\theta}$ may sit well above the true θ, so the interval reaches further *down*.

The percentile interval. The simplest recipe of all takes the quantiles of the replicas directly, $(\theta^*_{\alpha/2}, \theta^*_{1-\alpha/2})$ [Wasserman p. 111]. It is exact when some monotone transformation makes the sampling distribution symmetric and Gaussian, and it respects the parametrisation in the way the $\Delta \ln \mathcal{L}$ interval does. All three intervals have coverage tending to $1-\alpha$ under weak conditions [Wasserman p. 111, Thm. 8.3].

Example: the median of the lifetimes. For the median of our fifty decay times, 95% intervals from 10^4 nonparametric replicas are

Normal: $(0.2496,\ 0.7798)$, pivotal: $(0.1678,\ 0.6632)$, percentile: $(0.3661,\ 0.8616)$,

for a true median of 0.6931. The replicas of a median are lumpy and lopsided, and the three recipes treat the lopsidedness differently: the percentile interval follows it, the pivotal interval reflects it about the estimate, and the Normal interval ignores it. So the three intervals differ,

and for one data set one of them can miss the true median while another contains it. Any 95% procedure misses in one experiment in twenty. Which of them misses less often for a given problem can be settled only by the same kind of simulation over many data sets, as in Chapter 4.

3.15.4 Where the bootstrap fails

The bootstrap works when the statistic depends smoothly on the whole distribution. It fails when the statistic is controlled by a few extreme points, because $\hat{F}_n$ has no probability beyond the largest observation. The cleanest example is the uniform box again, with $T_n = x_{(n)}$. The true sampling distribution of the maximum is continuous, with density $n x^{n-1}/\theta^n$ below θ. A bootstrap replica, however, is the maximum of n points drawn from the data, and it equals the observed maximum whenever that point is drawn at least once:

$$\mathrm{P}\big(x^*_{(n)} = x_{(n)}\big) \overset{(1)}{=} 1 - \mathrm{P}\big(x_{(n)} \text{ is never drawn}\big) \overset{(2)}{=} 1 - \left(1 - \frac{1}{n}\right)^n \xrightarrow{\;n\to\infty\;} 1 - e^{-1} = 0.632.$$

(1) The replica's maximum is $x_{(n)}$ as soon as $x_{(n)}$ is among the resampled points; otherwise it is smaller.

(2) Each of the n independent draws misses that point with probability $1 - 1/n$.

For $n = 50$ this is 0.6358, and the simulation gives 0.6386: almost two thirds of the replicas sit on a single value, a spike that the continuous true distribution does not have (Figure 3.47). No amount of resampling can put a replica above $x_{(n)}$, yet the true θ is always there. The same caution applies to any statistic that lives in the tails: extreme values, endpoint fits, the largest peak in a noisy map. For such statistics the parametric bootstrap, or a simulation from a physical model, is the right tool.

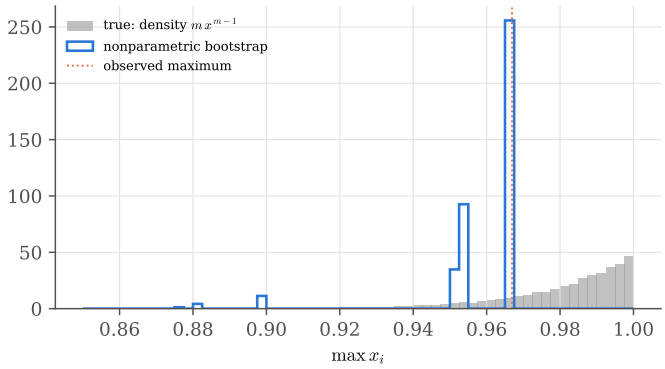

Figure 3.47: A statistic the bootstrap cannot handle: the maximum of fifty uniform points. Grey: its true sampling distribution, smooth and piled against the end of the box. Blue: the bootstrap replicas, about 63% of which equal the observed maximum (dotted line), with the rest spread over a few lower data values. None can exceed the observed maximum.

How this is used in real research: Verification versus research

Most of the simulations above *verified* results already derived: that $\chi^2_{\min}$ follows χ^2_{N-m}, that the curvature of $\ln \mathcal{L}$ equals the scatter of the MLE, that the Poisson fit conserves the total. Their job was to make the formulas believable and to show how large n must be before the asymptotic statements hold. In research the same machinery is the instrument itself, used exactly where no formula exists. A cosmological analysis estimates the covariance matrix of a masked, noisy power spectrum from hundreds of simulated skies, a parametric bootstrap from the fitted model (Chapters 7 and 8); an LHC search calibrates its profile-likelihood test statistic on pseudo-experiments when Wilks' theorem is doubtful; large-scale-structure

analyses resample patches of the sky (a jackknife or block bootstrap) to capture correlations no one can model analytically. The logic is always that of Figure 3.45: build the best stand-in for the truth, simulate from it, analyse each simulation exactly as the data, read the error off the scatter.

3.16 From a model to an estimator: how to find the right one

A theorist hands us a model: a prediction $d(\theta)$, a noise level, and a parameter θ to be measured. Nothing says which function of the data to quote as the answer. The sample mean, the median, the midrange, the value that minimises some χ^2: each is an estimator, each has a sampling distribution, and they differ in width. So the question is: which function of the data should we quote? The tools for answering it are already in hand. The likelihood gives the probability of the data. The score equation turns it into an estimate. The curvature gives an error bar. The Cramér–Rao bound says how narrow the error bar can ever be. Put in order, these tools become a procedure that starts from the model and ends with an estimator whose sampling distribution we know and cannot improve (Figure 3.48). The procedure has five steps, and every one has already appeared in a special case.

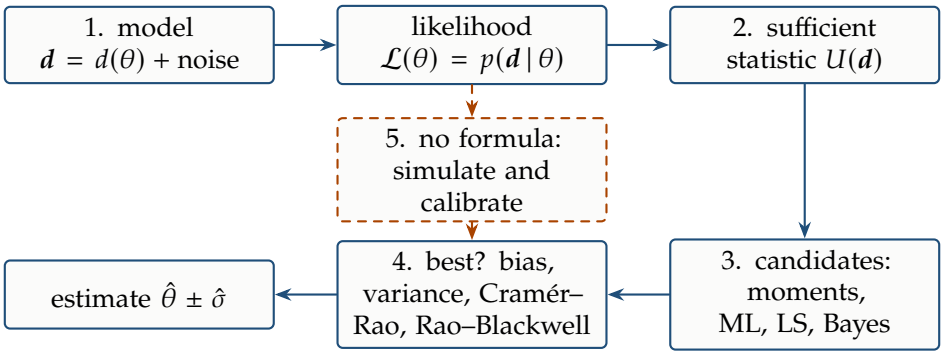

Figure 3.48: From a model to an estimator. The solid path is the procedure when the likelihood can be written down. If it cannot (dashed path), a simple statistic is computed and its bias and scatter are read off simulated data sets.

Four examples run through every step: independent Gaussian readings $x_i \sim \mathcal{N}(\mu, \sigma^2)$ with known σ; Poisson counts $X_i \sim \text{Poisson}(\lambda)$, the numbers of events in n equal time slots; exponential decay times t_i with mean lifetime τ; and the multipole coefficients $a_{\ell m}$ of a full-sky Gaussian CMB map. The CMB example is then followed through the whole chain in Section 3.16.6.

3.16.1 Step 1: write the likelihood

Everything starts from the statement that the data are the model plus noise (Section 3.8.1): the noise realisation that the data require has a known probability, and that probability, read as a function of the parameter, is $\mathcal{L}(\theta)$. For independent data the likelihood is the product (3.80). For the four examples, keeping only the factors that depend on the parameter,

$$\text{Gaussian mean:} \quad \mathcal{L}(\mu) \propto \exp\Big[-\frac{1}{2\sigma^2}\sum_i (x_i-\mu)^2\Big],$$

$$\text{Poisson rate:} \quad \mathcal{L}(\lambda) = \prod_i \frac{e^{-\lambda}\lambda^{X_i}}{X_i!} \propto e^{-n\lambda}\lambda^{K}, \qquad K \equiv \sum_i X_i,$$

$$\text{exponential lifetime:}\quad \mathcal{L}(\tau) = \tau^{-n} e^{-T/\tau}, \qquad T \equiv \sum_i t_i, \tag{3.103}$$

$$\text{full-sky CMB:}\quad \mathcal{L}(C_\ell) \propto C_\ell^{-(2\ell+1)/2} \exp\!\left[-\frac{(2\ell+1)\widehat{C}_\ell}{2C_\ell}\right].$$

The last line is the isotropic Gaussian sky of Section 3.11.5. Recall its ingredients. At multipole ℓ there are $2\ell+1$ independent real numbers $y_{\ell k}$: $a_{\ell 0}$, and $\sqrt{2}\,\mathrm{Re}\,a_{\ell m}$ and $\sqrt{2}\,\mathrm{Im}\,a_{\ell m}$ for $m = 1, \ldots, \ell$. (For $m > 0$ the real and imaginary parts of $a_{\ell m}$ each have variance $C_\ell/2$, and $a_{\ell,-m}$ is the complex conjugate of $a_{\ell m}$ up to a sign, so it adds nothing new; the factor $\sqrt{2}$ brings each variance up to C_ℓ.) Each $y_{\ell k}$ has density $(2\pi C_\ell)^{-1/2} e^{-y_{\ell k}^2/2C_\ell}$. Their product over the $2\ell+1$ values of k gives the last line, with $(2\ell+1)\widehat{C}_\ell = \sum_k y_{\ell k}^2 = \sum_m |a_{\ell m}|^2$.

3.16.2 Step 2: what can the data tell us? Sufficient statistics

Look at (3.103). The Gaussian likelihood contains the n readings, yet after expanding the square it depends on them only through $\bar{x}$ (and through a constant). The Poisson likelihood depends on the counts only through their total K, the exponential one only through T, the CMB one only through $\widehat{C}_\ell$. Every data set with the same K gives exactly the same likelihood curve, so no estimate, error bar or confidence interval computed from the likelihood can distinguish them. The remaining information in the n numbers, which ones were large, which came first, says nothing about θ.

Definition. A statistic $U(\boldsymbol{d})$ is **sufficient** for θ if the conditional distribution of the data given the value of U does not involve θ [Wasserman p. 137, Def. 9.32]. Given U, the data set is one of the points on the "surface" $\{\boldsymbol{d}' : U(\boldsymbol{d}') = U(\boldsymbol{d})\}$, and sufficiency says that θ has no influence on which point of the surface we land on: θ only decides how probable the surface is. Statistical mechanics has met this before. In the canonical ensemble $p(\text{microstate}\,|\,\beta) = e^{-\beta E}/Z(\beta)$, and given the energy E all microstates are equally likely, whatever β is. The energy is therefore a sufficient statistic for the inverse temperature β: a thermometer that reads only E loses nothing.

The coarsest statistic with this property is called **minimal sufficient**: two data sets have the same value of it exactly when the ratio of their likelihoods $p(\boldsymbol{d}\,|\,\theta)/p(\boldsymbol{d}'\,|\,\theta)$ does not depend on θ [Wasserman p. 138, Def. 9.35]. In all the examples below the statistic found is minimal, so no further compression is possible without losing information.

The factorisation theorem. Checking the definition directly needs the conditional distribution. The **Neyman–Fisher factorisation theorem** [Wasserman p. 140, Thm. 9.40], [CasellaBerger Thm. 6.2.6] replaces that with a test on the likelihood:

$$U \text{ is sufficient} \iff p(\boldsymbol{d}\,|\,\theta) = g\big(U(\boldsymbol{d}), \theta\big)\, h(\boldsymbol{d}) \quad \text{for some functions } g, h.$$

All the θ-dependence must pass through U, and whatever else depends on the data (the h) must not know about θ. The proof, for discrete data (sums become integrals for densities), has two halves. Write $\mathcal{A}_u$ for the set of all data sets with $U = u$.

Factorised form implies sufficiency. For a data set $\boldsymbol{d}$ with $U(\boldsymbol{d}) = u$,

$$\mathrm{P}(\boldsymbol{d}\,|\,U=u,\theta) \overset{(1)}{=} \frac{\mathrm{P}(\boldsymbol{d}\,|\,\theta)}{\mathrm{P}(U=u\,|\,\theta)} \overset{(2)}{=} \frac{g(u,\theta)\,h(\boldsymbol{d})}{\sum_{\boldsymbol{d}'\in\mathcal{A}_u} g(u,\theta)\,h(\boldsymbol{d}')} \overset{(3)}{=} \frac{h(\boldsymbol{d})}{\sum_{\boldsymbol{d}'\in\mathcal{A}_u} h(\boldsymbol{d}')}. \tag{3.104}$$

(1) The event $\{\boldsymbol{d}\}$ lies inside $\{U = u\}$, so $\mathrm{P}(\boldsymbol{d}, U = u\,|\,\theta) = \mathrm{P}(\boldsymbol{d}\,|\,\theta)$.

(2) Numerator by the factorisation. The denominator is the sum of the probabilities of all data sets in A_u, and $g(U(\boldsymbol{d}'), \theta) = g(u, \theta)$ for each of them.
(3) $g(u, \theta)$ is a common factor and cancels.

The result contains no θ, which is the definition.

Sufficiency implies the factorised form. If $\mathrm{P}(\boldsymbol{d} \mid U = u, \theta) = c(\boldsymbol{d})$ does not depend on θ, then

$$\mathrm{P}(\boldsymbol{d} \mid \theta) = \mathrm{P}(\boldsymbol{d} \mid U = U(\boldsymbol{d}), \theta)\ \mathrm{P}(U = U(\boldsymbol{d}) \mid \theta) = c(\boldsymbol{d})\ q\big(U(\boldsymbol{d}), \theta\big),$$

which is the factorised form with $h = c$ and $g = q$, the sampling distribution of U itself.

Examples. Expanding the square, $\sum_i (x_i - \mu)^2 = \sum_i (x_i - \bar{x})^2 + n(\bar{x} - \mu)^2$, so the Gaussian likelihood factorises with $g = \exp[-n(\bar{x} - \mu)^2/2\sigma^2]$ and $h = \exp[-\sum_i (x_i - \bar{x})^2/2\sigma^2]$: $\bar{x}$ is sufficient for μ. Reading (3.103), the Poisson total K is sufficient for λ with $g = e^{-n\lambda}\lambda^K$ and $h = \prod_i 1/X_i!$; the sum of decay times T is sufficient for τ with $h = 1$; and $\widehat{C}_\ell$, equivalently $\sum_m |a_{\ell m}|^2$, is sufficient for C_ℓ with $h = 1$. The last statement is the precise form of the everyday remark that for a Gaussian isotropic sky the power spectrum contains everything there is to know about the parameters: the phases of the $a_{\ell m}$ carry no information. It is a statement about the model. If the field is not Gaussian, h is no longer free of C_ℓ and the phases carry information that $\widehat{C}_\ell$ throws away, a point that returns when topological summaries of fields appear (Chapter 12).

The exponential family: sufficient statistics and moment matching. All four examples, and most of the distributions of Chapter 2, have the form

$$p(x \mid \theta) = h(x) \exp\big[\eta(\theta)\, \phi(x) - A(\theta)\big], \tag{3.105}$$

with $\phi(x)$ a single function of one observation (the Poisson has $\phi = x$, $\eta = \ln\lambda$, $A = \lambda$; the exponential lifetime has $\phi = t$, $\eta = -1/\theta$, $A = \ln\theta$ with θ the mean lifetime; the CMB coefficient has $\phi = y^2$, $\eta = -1/2C_\ell$, $A = \frac{1}{2}\ln 2\pi C_\ell$). For n independent observations, the product has $\exp[\eta \sum_i \phi(x_i) - nA] \prod_i h(x_i)$, so $\sum_i \phi(x_i)$ is sufficient by the factorisation theorem. More: the MLE is the solution of a moment-matching equation. Differentiating the normalisation $\int p\, \mathrm{d}x = 1$ with respect to θ gives

$$0 = \int (\eta' \phi - A')\, p\, \mathrm{d}x \quad \Longrightarrow \quad \mathbb{E}_\theta\, \phi = \frac{A'(\theta)}{\eta'(\theta)},$$

and then

$$\frac{\partial \ell}{\partial \theta} \overset{(1)}{=} \eta' \sum_i \phi(x_i) - nA' \overset{(2)}{=} \eta'(\theta)\Big[\sum_i \phi(x_i) - n\ \mathbb{E}_\theta\, \phi\Big]. \tag{3.106}$$

(1) Logarithm of the product, then differentiate; h does not contain θ.
(2) Insert $A' = \eta'\ \mathbb{E}_\theta\, \phi$.

With $\eta' \neq 0$ the score equation is

$$\mathbb{E}_{\hat{\theta}}\ \phi = \frac{1}{n} \sum_{i=1}^{n} \phi(x_i), \tag{3.107}$$

the model's mean of the sufficient statistic equals its observed mean. That is why the maximum-likelihood lifetime is the mean decay time, the Poisson rate estimate is the mean count $\hat{\lambda} = \bar{X}$, the CMB estimate is the mean of y^2, and in each case the method of moments (Section 3.9.2) gives the same answer as maximum likelihood. Outside the exponential family, for instance for the angular distribution (3.83), whose parameters also sit in the normalisation, the two methods give different estimates and the moment estimates are generally less precise.

3.16.3 Step 3: constructing candidate estimators

Having found what the data can tell us, we build estimators from it. The families met so far are the following.

- *Method of moments* (Section 3.9.2): set model moments equal to sample moments. No likelihood is needed, only moments of the model. Quick, consistent, often a good starting point for Newton–Raphson.
- *Maximum likelihood* (Section 3.9): maximise $\mathcal{L}(\theta)$. Always available when the likelihood is, invariant under reparametrisation, asymptotically efficient.
- *Least squares* (Section 3.10.1): the maximum likelihood estimator for independent Gaussian noise, $-2\ell = \chi^2$, and for correlated Gaussian noise with the weight matrix $\mathbf{C}^{-1}$. Not a separate principle.
- *Bayes estimators*, which use a prior and a cost of being wrong. They complete the list and are derived below; Chapter 5 develops them.

The EM algorithm: maximum likelihood with hidden variables. Sometimes the likelihood is a sum over quantities we did not observe, such as the unknown class of each event in a mixture of signal and background, $p(\boldsymbol{d} \mid \theta) = \sum_z p(\boldsymbol{d}, z \mid \theta)$, and the logarithm of a sum has no closed-form maximum. Given a current guess θ_t, let $q(z) = p(z \mid \boldsymbol{d}, \theta_t)$ be the posterior probability of each hidden assignment. Since the logarithm is concave, Jensen's inequality gives

$$\ln p(\boldsymbol{d} \mid \theta) \overset{(1)}{=} \ln \sum_z q(z) \frac{p(\boldsymbol{d}, z \mid \theta)}{q(z)} \overset{(2)}{\geq} \sum_z q(z) \ln p(\boldsymbol{d}, z \mid \theta) - \sum_z q(z) \ln q(z), \tag{3.108}$$

(1) Multiply and divide by $q(z)$, which sums to one.
(2) Jensen: the log of an average is at least the average of the log.

with equality at $\theta = \theta_t$. (There $p(\boldsymbol{d}, z \mid \theta_t)/q(z) = p(\boldsymbol{d} \mid \theta_t)$ is the same for every z, and Jensen's inequality is an equality for an average of equal numbers.) The right side differs from $Q(\theta \mid \theta_t) = \sum_z q(z) \ln p(\boldsymbol{d}, z \mid \theta)$ by a constant, and Q involves the logarithm of a single term, usually easy to maximise. The algorithm alternates the **E step** (compute $q(z)$, hence Q) with the **M step** ($\theta_{t+1} = \arg\max_\theta Q$). No cycle can decrease the likelihood, because the right side touches $\ln p(\boldsymbol{d} \mid \theta)$ at θ_t and lies below it elsewhere [Wasserman pp. 143–144]. Raising the right side therefore raises $\ln p$ at least as much. It converges to a stationary point, which can be a local maximum.

Bayes estimators: choose the answer that minimises the expected loss. Suppose we must announce one number a for θ, and being off by $\theta - a$ costs us $L(\theta, a)$. We do not know θ, but after the experiment we have the posterior $p(\theta \mid \boldsymbol{d}) \propto \mathcal{L}(\theta) p(\theta)$, the probability density of the value of θ given the data and a prior $p(\theta)$ (Eq. (3.81)). Announce the a that minimises the posterior expected loss

$$\rho(a) = \int L(\theta, a)\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta.$$

The expectation is over the plausible values of θ at fixed data, not over repeated data sets. Three choices of loss give three familiar summaries.

Squared loss, $L = (\theta - a)^2$. Let $m = \mathbb{E}[\theta \mid \boldsymbol{d}]$ be the posterior mean. Then

$$\rho(a) = \mathbb{E}\big[(\theta - a)^2 \mid \boldsymbol{d}\big] \tag{3.109}$$

$$\overset{(1)}{=} \mathbb{E}\big[(\theta - m)^2 \mid \boldsymbol{d}\big] + 2(m - a)\,\mathbb{E}\big[\theta - m \mid \boldsymbol{d}\big] + (m - a)^2 \tag{3.110}$$

$$\overset{(2)}{=} \operatorname{Var}[\theta \mid \boldsymbol{d}] + (m - a)^2. \tag{3.111}$$

(1) Write $\theta - a = (\theta - m) + (m - a)$ and expand the square. The number $m - a$ is a constant for the expectation.

(2) $\mathbb{E}[\theta - m \mid \boldsymbol{d}] = 0$ by definition of m, which kills the cross term.

The first term does not depend on a, so ρ is smallest at $a = m$: the *posterior mean* minimises the expected squared error.

Absolute loss, $L = |\theta - a|$. With $F(a) = \int_{-\infty}^{a} p\,\mathrm{d}\theta$,

$$\rho(a) = \int_{-\infty}^{a} (a - \theta)\,p\,\mathrm{d}\theta + \int_{a}^{\infty} (\theta - a)\,p\,\mathrm{d}\theta,$$

$$\frac{\mathrm{d}\rho}{\mathrm{d}a} \overset{(1)}{=} \int_{-\infty}^{a} p\,\mathrm{d}\theta - \int_{a}^{\infty} p\,\mathrm{d}\theta = 2F(a) - 1.$$

(1) Differentiate the integrals with respect to a in the integrand and at the limits; the limit terms contain $(a - \theta)p$ at $\theta = a$, which is zero.

The derivative vanishes at $F(a) = \frac{1}{2}$: the *posterior median*.

Zero–one loss, $L = 0$ if $|\theta - a| < h$ and 1 otherwise. Then $\rho(a) = 1 - \int_{a-h}^{a+h} p\,\mathrm{d}\theta \approx 1 - 2h\,p(a \mid \boldsymbol{d})$, smallest where the posterior is largest: the *posterior mode* (MAP, maximum *a posteriori*), obtained as $h \to 0$.

For a symmetric, single-peaked posterior the three coincide. For a skewed one they do not. The Poisson rate with a single observation $K = 2$ and a flat prior has posterior $p(\lambda \mid K) \propto \lambda^2 e^{-\lambda}$, a Gamma density with shape 3. Its mode is 2 (equal to the MLE, because the prior is flat, Section 3.8.4), its median is 2.67 and its mean is 3. Evaluating the expected losses on a grid of announced values (Figure 3.49, middle) reproduces the three minima at 2, 2.677 and 3.005. Which number is "the estimate" depends on what a mistake costs. A flat prior makes the maximum-likelihood estimate the Bayes estimator under zero–one loss, and only under it.

3.16.4 Step 4: choosing the best

Several candidates, several sampling distributions. Two tools rank them. The first is the Cramér–Rao bound (Section 3.13.3), a floor on the variance of an unbiased estimator. If a candidate sits on the floor it cannot be improved, and the search ends. The second tool says how to improve a candidate that is above it.

The Rao–Blackwell theorem. Let $W(\boldsymbol{d})$ be any unbiased estimator of $g(\theta)$ and U a sufficient statistic. Define

$$\tilde{W}(U) = \mathbb{E}[W \mid U],$$

the average of W over all data sets with the observed value of U. Three facts follow.

First, $\tilde{W}$ is a legitimate statistic. The average uses the conditional distribution of the data given U, which by sufficiency does not contain θ. Without sufficiency the average would need the unknown θ and could not be computed.

Second, $\tilde{W}$ is unbiased, by the law of total expectation, $\mathbb{E}\,\tilde{W} = \mathbb{E}[\mathbb{E}(W \mid U)] = \mathbb{E}\,W = g(\theta)$.

Third, its variance is never larger:

$$\operatorname{Var} W \overset{(1)}{=} \mathbb{E}\big[\operatorname{Var}(W \mid U)\big] + \operatorname{Var}\big[\mathbb{E}(W \mid U)\big] \overset{(2)}{=} \mathbb{E}\big[\operatorname{Var}(W \mid U)\big] + \operatorname{Var} \tilde{W} \overset{(3)}{\geq} \operatorname{Var} \tilde{W}. \tag{3.112}$$

(1) The law of total variance: split the scatter of W into the average scatter inside each slice $U = u$ and the scatter of the slice averages between slices.
(2) Definition of $\tilde{W}$.
(3) The first term is an average of variances, each ≥ 0. It vanishes only if W is already a function of U.

[Wasserman p. 140, Thm. 9.42], [CasellaBerger Thm. 7.3.17]. The reduction is exactly the average variance that W wasted on the part of the data that U does not contain. The theorem gives an algorithm: start with any crude unbiased estimator, however silly, and average it over the sufficient statistic.

Example: estimating $e^{-\lambda}$, the chance of an empty slot. In n time slots we count $X_i \sim \text{Poisson}(\lambda)$ events, and we want $g(\lambda) = e^{-\lambda} = \mathrm{P}(X = 0)$, the probability that a slot is empty. A crude unbiased estimator uses the first slot only: $W = \mathbf{1}\{X_1 = 0\}$, since $\mathbb{E}\, W = \mathrm{P}(X_1 = 0) = e^{-\lambda}$. It wastes $n - 1$ slots. Its variance is that of a 0/1 variable, $e^{-\lambda}(1 - e^{-\lambda})$. The total $K = \sum_i X_i$ is sufficient. The conditional mean is the probability that slot 1 is empty given the total $K = s$. Independent Poisson variables add to a Poisson variable, so

$$\mathrm{P}(X_1 = 0 \mid K = s) \overset{(1)}{=} \frac{\mathrm{P}(X_1 = 0)\ \mathrm{P}\big(\sum_{i \geq 2} X_i = s\big)}{\mathrm{P}(K = s)} \overset{(2)}{=} \frac{e^{-\lambda}\, e^{-(n-1)\lambda}\, [(n-1)\lambda]^s / s!}{e^{-n\lambda}\, (n\lambda)^s / s!} \overset{(3)}{=} \Big(\frac{n-1}{n}\Big)^s. \tag{3.113}$$

(1) Definition of conditional probability; $X_1 = 0$ and $K = s$ together mean $X_1 = 0$ and the other $n - 1$ slots add up to s, and the slots are independent.
(2) The sum of the other $n - 1$ slots is Poisson with mean $(n-1)\lambda$, the total is Poisson with mean $n\lambda$.
(3) The exponentials and factorials cancel, and so does λ^s, leaving $(n-1)^s / n^s$. This is the last place that λ could have entered.

So $\tilde{W} = (1 - 1/n)^K$. In words: given the total, each of the K events fell in slot 1 with probability $1/n$, independently, so slot 1 is empty with probability $(1 - 1/n)^K$. The variance is found from the generating function of the Poisson distribution, $\mathbb{E}\, z^K = \exp[n\lambda(z-1)]$: with $z = 1 - 1/n$ this gives $\mathbb{E}\, \tilde{W} = e^{-\lambda}$ (unbiased, as promised), and with $z^2 = 1 - 2/n + 1/n^2$ it gives $\mathbb{E}\, \tilde{W}^2 = e^{-2\lambda + \lambda/n}$, so

$$\operatorname{Var} \tilde{W} = e^{-2\lambda}\big(e^{\lambda/n} - 1\big).$$

For $n = 10$ and $\lambda = 1.5$ the crude estimator has variance 0.1733 and the Rao–Blackwellised one 0.008057, a reduction by a factor of more than twenty. The simulation of 20 000 experiments (Section 3.16.7) gives 0.1734 and 0.00799, both means at 0.2232 and 0.2231 against the truth 0.2231. The Cramér–Rao floor for estimating $g(\lambda)$ is $g'(\lambda)^2 / I_n = \lambda e^{-2\lambda}/n = 0.007468$ with $I_n = n/\lambda$. The improved estimator sits just above it. Expanding, $\operatorname{Var} \tilde{W} \approx (\lambda e^{-2\lambda}/n)(1 + \lambda/2n)$, so the excess over the floor is a factor $1 + \lambda/2n$, which tends to one as n grows.

Best unbiased estimators. Can averaging a second time, over a different crude starting estimator, improve it again? For the Poisson total, no. The total K is **complete** [the only function of K whose mean is zero for every λ is the zero function]. The Lehmann–Scheffé theorem [CasellaBerger Thm. 7.3.23] says that for a complete sufficient statistic U, any unbiased function of U is the unique minimum-variance unbiased estimator (UMVUE). Two unbiased functions of U

could be different only by a function of U with zero mean, and there is none. The exponential family (3.105) with a rich enough parameter has complete statistics, so $\tilde{W}$ above is the best unbiased estimator of $e^{-\lambda}$, even though it does not reach the Cramér–Rao floor. The bound is attained only when the score is a linear function of the estimator, which for $e^{-\lambda}$ it is not.

When a biased estimator beats an unbiased one. UMVUEs are the best among unbiased estimators. The mean squared error is bias squared plus variance (Section 3.2.1), and a small bias that buys a larger drop in variance can win. The maximum-likelihood estimate of $e^{-\lambda}$ is $e^{-\hat{\lambda}} = e^{-K/n}$. It is biased, but by $O(1/n)$, so its squared bias is $O(1/n^2)$ and the variance is $O(1/n)$: the MLE and $\tilde{W}$ have nearly the same variance, and which has the lower MSE depends on n and λ. The earlier example with the Gaussian variance went further: the divisor $N+1$ beats both $N-1$ and N (Section 3.4.2). The posterior mean with a prior centred away from the data is another example: it shrinks the estimate toward the prior, adds bias and removes variance (Chapter 5). Unbiasedness is a convenient property, not a goal. The MLE's claim to be good is asymptotic efficiency, and the Bayes and shrinkage estimates add to it when prior knowledge exists.

3.16.5 Step 5: when the likelihood cannot be written down

The procedure needs $p(\boldsymbol{d} \mid \theta)$. For a masked, noisy, beamed CMB map the field is still Gaussian, but the pixels are correlated, and the likelihood with a huge covariance matrix is too expensive to evaluate at every point of a Markov chain. For the large-scale-structure correlation function, the number of independent modes is far larger than the number of simulations available to estimate the covariance. For a topological summary of a field (Chapter 12) there is no likelihood at all. The procedure still works if we give up on optimality and compute a simple summary statistic, then replace the missing likelihood by simulation:

1. choose a statistic $\hat{S}(\boldsymbol{d})$ that is cheap and sensitive to θ (a pseudo-C_ℓ, a counts-in-cells histogram);
2. simulate many data sets from the model at several θ, through the same mask, noise and beam, and compute $\hat{S}$ for each (Chapter 6);
3. read off the mean $\langle \hat{S} \rangle_\theta$ (the bias and the transfer function of the estimator) and the covariance of $\hat{S}$ from the scatter over the simulations, with the Hartlap correction of Section 3.5.4;
4. use a Gaussian likelihood for $\hat{S}$ with that mean and covariance, or quote the parameter at which $\langle \hat{S} \rangle_\theta$ matches the observed $\hat{S}$, with an error bar from the simulated spread.

This works even if $\hat{S}$ is not sufficient: its bias is calibrated out and its error bar is honest, but the error bar is wider than the Cramér–Rao floor of the full data. A mask removing a fraction of the sky, for example, inflates the variance of the pseudo-spectrum roughly by one over the observed sky fraction and correlates neighbouring multipoles; the simulations measure both exactly. The same machinery, used for verification where a formula exists and as the research instrument where none does, is developed in Chapters 6 and 8.

3.16.6 The full chain on one example: the CMB power spectrum

Take a full-sky, noiseless, Gaussian isotropic temperature map, with the coefficients $a_{\ell m}$ of variance C_ℓ (the power spectrum of the theory), and ask for the best estimate of C_ℓ at one multipole. Write $\nu = 2\ell + 1$.

Step 1: likelihood. From (3.103),

$$\ln \mathcal{L}(C_\ell) = -\frac{\nu}{2}\left[\frac{\widehat{C}_\ell}{C_\ell} + \ln C_\ell\right] + \text{const}, \qquad \widehat{C}_\ell = \frac{1}{\nu}\sum_{m=-\ell}^{\ell} |a_{\ell m}|^2. \tag{3.114}$$

Step 2: sufficiency. $\widehat{C}_\ell$ enters alone, and the factorisation is complete with $h = 1$. Nothing about the phases or the sign of m is needed.

Step 3: the candidate. The score equation:

$$\frac{\partial \ln \mathcal{L}}{\partial C_\ell} \overset{(1)}{=} -\frac{\nu}{2C_\ell} + \frac{\nu\widehat{C}_\ell}{2C_\ell^2} \overset{(2)}{=} \frac{\nu}{2C_\ell^2}\left(\widehat{C}_\ell - C_\ell\right) = 0 \quad \Longrightarrow \quad \hat{C}_\ell^{\mathrm{ML}} = \widehat{C}_\ell. \tag{3.115}$$

(1) Differentiate (3.114): $\partial_C(\widehat{C}_\ell/C) = -\widehat{C}_\ell/C^2$ and $\partial_C \ln C = 1/C$.
(2) Common denominator $2C_\ell^2$.

The second derivative is $\nu/2C_\ell^2 - \nu\widehat{C}_\ell/C_\ell^3$. At the solution $C_\ell = \widehat{C}_\ell$ it equals $\nu/2\widehat{C}_\ell^2 - \nu/\widehat{C}_\ell^2 = -\nu/2\widehat{C}_\ell^2 < 0$, so this is a maximum. The familiar estimator, the average of $|a_{\ell m}|^2$ over the $2\ell+1$ values of m, is the maximum-likelihood estimator, the moment-matching solution (3.107) with $\phi = y^2$, and (with flat prior) the posterior mode.

Step 4: is it the best? Bias: $\mathbb{E}\, y^2 = C_\ell$ for each of the ν variables, so $\mathbb{E}\,\widehat{C}_\ell = C_\ell$, unbiased. Variance: $\nu\widehat{C}_\ell/C_\ell = \sum_k (y_k/\sqrt{C_\ell})^2$ is a sum of ν squares of unit Gaussians, which is χ^2_ν with mean ν and variance 2ν, so

$$\operatorname{Var}\widehat{C}_\ell = \frac{C_\ell^2}{\nu^2}\,2\nu = \frac{2C_\ell^2}{2\ell+1}. \tag{3.116}$$

Fisher information, the negative mean of the second derivative at the truth:

$$I(C_\ell) \overset{(1)}{=} -\mathbb{E}\left[\frac{\nu}{2C_\ell^2} - \frac{\nu\widehat{C}_\ell}{C_\ell^3}\right] \overset{(2)}{=} -\frac{\nu}{2C_\ell^2} + \frac{\nu}{C_\ell^2} = \frac{2\ell+1}{2C_\ell^2}. \tag{3.117}$$

(1) The identity $I = -\mathbb{E}\,\partial^2 \ln \mathcal{L}/\partial\theta^2$ (3.98).
(2) Only $\widehat{C}_\ell$ is random, and $\mathbb{E}\,\widehat{C}_\ell = C_\ell$.

The Cramér–Rao bound is $1/I = 2C_\ell^2/(2\ell+1)$, which is exactly (3.116). The estimator attains the bound: the score (3.115) is proportional to $\widehat{C}_\ell - C_\ell$, the exact condition for equality in Cauchy–Schwarz in the derivation of (3.101). No unbiased estimator of C_ℓ built from one sky can have a smaller variance. This number is **cosmic variance**: a fractional error of $\sqrt{2/(2\ell+1)}$, which is 63% at the quadrupole and 18% at $\ell = 30$, caused by nothing but the fact that we have one sky, with $2\ell+1$ independent numbers at each ℓ. No instrument improves it. In Section 3.4.3 the same number appeared as the variance of a variance. Here it is the Cramér–Rao bound of the model.

3.16.7 The recipe in Python

Listing 3.15: Rao–Blackwell for the empty-slot probability (`code/ch03/16_estimator_recipe.py`)

```
# ---------- (i) Rao-Blackwell: estimate g(lambda) = exp(-lambda) from n Poisson counts
    ----------
```

```
lam, n, M = 1.5, 10, 20000
X = rng.poisson(lam, size=(M, n))
T_crude = (X[:, 0] == 0).astype(float)            # unbiased: E 1{X_1 = 0} = exp(-lambda)
S = X.sum(axis=1)                                  # sufficient statistic
T_rb = ((n - 1) / n) ** S                          # E[T_crude | S] = ((n-1)/n)^S
g = np.exp(-lam)
out["RBTruth"] = g
out["RBCrudeMean"], out["RBCrudeVar"] = T_crude.mean(), T_crude.var()
out["RBRBMean"], out["RBRBVar"] = T_rb.mean(), T_rb.var()
out["RBRatio"] = T_rb.var() / T_crude.var()
out["RBCR"] = lam * np.exp(-2 * lam) / n           # Cramer-Rao bound for g: g'^2 / I_n
out["RBCrudeVarTh"] = g * (1 - g)                  # variance of a 0/1 variable
out["RBRBVarTh"] = np.exp(-2 * lam) * (np.exp(lam / n) - 1)
out["RBn"], out["RBlam"] = n, lam
```

The array `X` holds 20 000 experiments of $n = 10$ Poisson slots each. The crude estimator looks only at the first slot, and the sufficient statistic `S` is the row sum (the K of the text). The Rao–Blackwellised estimator is the function $((n-1)/n)^K$ of (3.113). The printed variances are the numbers quoted above: 0.1734 against 0.00799, a ratio of 0.04608, and both means agree with $e^{-\lambda} = 0.2231$.

Listing 3.16: Expected loss of three point estimates under a skewed posterior (code/ch03/16_estimator_recipe.py)

```
# ---------- (ii) Bayes estimators: minimise the expected loss under a skewed posterior ----------
post = rng.gamma(3.0, 1.0, size=400000)            # a posterior sample, Gamma(3,1)
grid = np.linspace(0.05, 8, 800)
sq = np.array([np.mean((post - a) ** 2) for a in grid])
ab = np.array([np.mean(np.abs(post - a)) for a in grid])
from scipy.stats import gamma as gamma_dist
h = 0.05                                           # 0-1 loss with a tolerance h: P(|theta-a| > h),
z1 = 1 - 2 * h * gamma_dist.pdf(grid, 3.0)         # evaluated with the exact posterior density
out["BayesSqArg"], out["BayesAbsArg"], out["BayesZOArg"] = grid[sq.argmin()], grid[ab.argmin()], grid[z1.argmin()]
out["BayesMean"], out["BayesMedian"], out["BayesMode"] = post.mean(), np.median(post), 2.0
```

A posterior sample of 400 000 points from the Gamma density is used to evaluate $\rho(a)$ on a grid, for squared and absolute loss. For the zero–one loss the exact density is used in $1 - 2h\,p(a)$. The grids have their minima at 3.005 (mean 3), 2.677 (median 2.672) and 2 (mode 2).

Listing 3.17: A full-sky Gaussian CMB: the maximum-likelihood C_ℓ and its variance (code/ch03/16_estimator_recipe.py)

```
# ---------- (iii) full-sky C_ell: a_lm Gaussian, variance C ----------
def sky(ell, C=1.0, M=20000):
    a = rng.normal(0, np.sqrt(C), size=(M, 2 * ell + 1))    # 2l+1 independent real degrees of freedom
    return (a ** 2).sum(axis=1)                             # sum_m |a_lm|^2
res = {}
for ell in (2, 30):
    Ssum = sky(ell)
    Chat = Ssum / (2 * ell + 1)
    w = {2: "Two", 30: "Thirty"}[ell]
    out[f"CMBMean{w}"], out[f"CMBVar{w}"] = Chat.mean(), Chat.var()
    out[f"CMBBound{w}"] = 2 / (2 * ell + 1)
    out[f"CMBRelErr{w}"] = Chat.std()
    res[ell] = Chat
# Fisher information from the score at the truth: S = -(2l+1)/(2C) + sum|a|^2/(2C^2), Var S = (2l+1)/(2C^2)
ell = 30; Ssum = sky(ell); score = -(2 * ell + 1) / 2 + Ssum / 2
```

```
out["CMBScoreVarThirty"], out["CMBFishThirty"] = score.var(), (2 * ell + 1) / 2
out["CMBScoreMeanThirty"] = score.mean()
```

For $\ell = 2$ and $\ell = 30$, 20 000 simulated skies supply $\sum_m |a_{\ell m}|^2$; dividing by $2\ell + 1$ gives $\widehat{C}_\ell$ for $C = 1$. The means are 0.9962 and 1.002 (unbiased), the variances 0.401 and 0.03236 against the bounds $2/(2\ell + 1) = 0.4$ and 0.03279, so the simulated estimator sits on the Cramér–Rao bound at both multipoles within sampling noise. The fractional errors are 0.6332 and 0.1799. The last lines evaluate the score (3.115) at the true C: its mean is 0.008949 (zero, (3.97)) and its variance is 30.16 against the Fisher information $\nu/2 = 30.5$ at $\ell = 30$, as (3.98) requires.

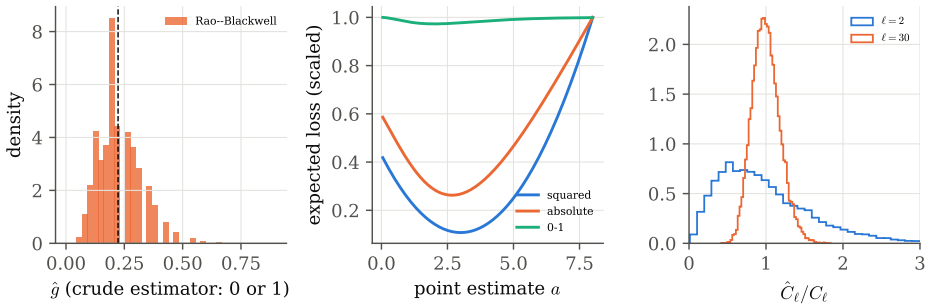

Figure 3.49: Three outcomes of the recipe. Left: the Rao–Blackwellised estimate of $e^{-\lambda}$ over 20 000 experiments; the crude estimator can only answer 0 or 1, while the averaged one is tightly peaked on the truth (dashed). Middle: expected loss for a skewed posterior as a function of the announced value, for squared, absolute and zero–one loss. Their minima are at the mean, the median and the mode, from right to left. Right: the maximum-likelihood $\widehat{C}_\ell / C_\ell$ from 20 000 skies at $\ell = 2$ and $\ell = 30$, centred on the truth with widths set by cosmic variance.

Taxonomy: Which estimator when

situation	estimator	why
exponential family (Poisson, exponential, Gaussian, χ^2_ν-type)	maximum likelihood = match the mean of the sufficient statistic	sufficient, efficient, on the Cramér–Rao floor for the mean parameter
Gaussian noise, known $\mathbf{C}$	least squares (weights $\mathbf{C}^{-1}$)	it is the ML estimator; exact for linear models
counts in bins	Poisson ML $(2\sum[\mu - n \ln \mu])$, not $\sqrt{n}$-weighted χ^2	no bias on the normalisation, valid for small counts
Gaussian isotropic sky	$\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m \lvert a_{\ell m}\rvert^2$	ML, unbiased, attains cosmic variance
a crude unbiased estimator exists	average it over a sufficient statistic	never increases the variance (Rao–Blackwell)
prior information, or a cost of error	Bayes: posterior mean, median or mode	minimises the expected squared, absolute, 0–1 loss
intractable likelihood, masks, non-Gaussian summaries	simple statistic, bias and covariance calibrated by simulation	honest error bar, not optimal

3.17 A worked problem: finding the estimator of the Hubble constant

A white dwarf in a binary system accretes matter from its companion until it approaches the Chandrasekhar mass, and then it explodes. The explosion, a type Ia supernova, is nearly the same every time: after a correction for how fast its light curve declines, its peak luminosity varies from one supernova to the next by only about 15%. That makes it a **standard candle** [an object whose true brightness is known, so its apparent brightness tells us its distance]. A spectrum of the host galaxy gives its redshift z to a few parts in 10^5. The peak apparent brightness, measured as a magnitude m, is known far less well: the intrinsic spread and the photometry together scatter it by about 0.15 magnitudes.

A survey collects N pairs (z_i, m_i). Nearby galaxies recede with velocities proportional to their distances, and the constant of proportionality is the Hubble constant H_0. So the pairs contain H_0. The obvious way to get it out is the one Hubble used: turn each magnitude into a distance, plot velocity against distance, and fit a straight line through the origin. That obvious estimator is wrong. For a survey of 100 supernovae its slope is too low by about half a km/s/Mpc, as large as its own error bar, and the offset does not shrink when the survey grows to 400 or 4000 supernovae. A different function of the same pairs has no offset and the smallest error bar any estimator can have. It comes out of the five-step procedure of Section 3.16: write the likelihood, find the sufficient statistic, build candidates, compare them with the Cramér–Rao bound, and simulate when formulas run out. The same constant returns several times later, each time reached by a different route: the distance ladder that supplies the supernova luminosity these mock surveys take as known (Section T2.12) and its disagreement with the CMB (Section T2.12.3), the baryon acoustic ruler read backwards as an inverse ladder (Section T2.15), a CMB chain reweighted by the ladder value (Section 9.23.1), the CMB forecast in which H_0 is a derived parameter (Section 10.6.3), cosmic chronometers that need no calibration at all (Sections 3.17.6 and 11.19), and the peculiar velocities of the local flow (Sections 11.16 and 11.17); Section 11.20 brings them together.

The question. Given redshifts z_i and apparent magnitudes m_i of N supernovae,

1. where does the noise live, and what is the likelihood?
2. which function of the data is an unbiased estimator of H_0 with the smallest scatter, and what is its error bar?
3. what can supernovae alone *not* tell us about H_0?
4. what changes when the supernovae are far enough away that the Hubble law is no longer a straight line?

3.17.1 Step 1: the model, and where the noise lives

Two standard results of cosmology are the physical inputs. The first is the **Hubble law**: at low redshift the recession velocity cz of a galaxy is proportional to its distance d,

$$cz = H_0\, d.$$

A galaxy also moves through space with a **peculiar velocity** [its velocity relative to the smooth expansion, caused by the pull of nearby structure]. Along the line of sight this adds a random velocity v_i to the recession velocity. Its spread is $\sigma_v \approx 300$ km/s, so that for galaxy i

$$cz_i = H_0\, d_i + v_i, \qquad v_i \sim \mathcal{N}(0, \sigma_v^2). \tag{3.118}$$

The second piece is the **distance modulus**: the apparent magnitude m and the absolute magnitude M (the magnitude the object would have at 10 pc) differ by

$$\mu \equiv m - M = 5\log_{10}\frac{D_L}{10\,\mathrm{pc}} = 5\log_{10}\frac{D_L}{\mathrm{Mpc}} + 25,$$

where D_L is the luminosity distance [the distance for which the observed flux is $L/4\pi D_L^2$]. At low redshift $D_L = d$. The +25 is $5\log_{10}(10^6\,\mathrm{pc}/10\,\mathrm{pc})$, the price of measuring distances in Mpc. Magnitudes are logarithmic and run backwards: 5 magnitudes fainter means 100 times less flux, and a larger m means a larger distance. From now on d is in Mpc, velocities are in km/s and H_0 is in km/s/Mpc.

The noise is Gaussian in the magnitude. The luminosity of a supernova scatters by a fixed *fraction* from one explosion to the next, and the photometry measures fluxes with a fixed fractional error. On a logarithmic scale a fixed fraction is a fixed additive amount, so the scatter is an additive Gaussian noise in the magnitude:

$$m_i = M + 5\log_{10} d_i + 25 + \epsilon_i, \qquad \epsilon_i \sim \mathcal{N}(0, \sigma_{\mathrm{int}}^2), \tag{3.119}$$

with $\sigma_{\mathrm{int}} = 0.15$ mag, the combined intrinsic and measurement scatter. The noise ϵ_i is independent of the peculiar velocity v_i. The distance "measured" from the magnitude is

$$\tilde{d}_i \equiv 10^{(m_i - M - 25)/5} = d_i\, 10^{\epsilon_i/5} = d_i\, e^{\kappa\epsilon_i}, \qquad \kappa \equiv \frac{\ln 10}{5} \approx 0.4605. \tag{3.120}$$

A Gaussian in the exponent makes $\tilde{d}_i$ **log-normal** [its logarithm, not itself, is Gaussian]. Its median is the true d_i, since ϵ_i is positive or negative with equal probability, but its mean is not. All the moments follow from one Gaussian integral, which we shall use repeatedly. For $\epsilon \sim \mathcal{N}(0, \sigma^2)$ and any real t,

$$\mathbb{E}\, e^{t\epsilon} = \int_{-\infty}^{\infty} \frac{\mathrm{d}\epsilon}{\sqrt{2\pi}\sigma}\, e^{t\epsilon - \epsilon^2/2\sigma^2} \overset{(1)}{=} \int_{-\infty}^{\infty} \frac{\mathrm{d}\epsilon}{\sqrt{2\pi}\sigma}\, e^{-(\epsilon - t\sigma^2)^2/2\sigma^2 + t^2\sigma^2/2} \overset{(2)}{=} e^{t^2\sigma^2/2}. \tag{3.121}$$

(1) Complete the square: $t\epsilon - \epsilon^2/2\sigma^2 = -(\epsilon - t\sigma^2)^2/2\sigma^2 + t^2\sigma^2/2$.

(2) The remaining integrand is a normalised Gaussian centred on $t\sigma^2$, which integrates to one.

With $t = \kappa$ and $t = 2\kappa$,

$$\mathbb{E}\,\tilde{d}_i = d_i\, e^{\kappa^2\sigma_{\mathrm{int}}^2/2}, \qquad \mathbb{E}\,\tilde{d}_i^{\,2} = d_i^2\, e^{2\kappa^2\sigma_{\mathrm{int}}^2}, \qquad \mathbb{E}\,\tilde{d}_i^{\,-1} = d_i^{-1}\, e^{\kappa^2\sigma_{\mathrm{int}}^2/2}. \tag{3.122}$$

For $\sigma_{\mathrm{int}} = 0.15$ mag, $\kappa^2\sigma_{\mathrm{int}}^2 = 0.004772$: the average distance built from magnitudes is too large by a quarter of a percent, and the average of its square by one percent. Both the distance and its inverse are biased *upwards*. These small factors are the whole story of the first two candidates below.

The likelihood, in the variable where the noise lives. The redshifts are measured almost exactly, so we condition on them and let the noise sit in m_i. Write $x_i \equiv v_i/cz_i$ for the fractional peculiar velocity. Solving (3.118) for d_i and putting it into (3.119),

$$\begin{aligned} m_i &\overset{(1)}{=} M + 25 + 5\log_{10}\frac{cz_i(1 - x_i)}{H_0} + \epsilon_i \\ &\overset{(2)}{=} M + 25 + 5\log_{10}(cz_i) - 5\log_{10} H_0 + \frac{5}{\ln 10}\ln(1 - x_i) + \epsilon_i \\ &\overset{(3)}{=} M + 25 + 5\log_{10}(cz_i) - a - \frac{5}{\ln 10}\, x_i + \epsilon_i + O(x_i^2), \qquad a \equiv 5\log_{10} H_0. \end{aligned} \tag{3.123}$$

(1) $d_i = (cz_i - v_i)/H_0 = cz_i(1 - x_i)/H_0$.
(2) The logarithm of a product is a sum of logarithms, and $\log_{10} y = \ln y / \ln 10$.
(3) $\ln(1-x) = -x + O(x^2)$. Even at $z = 0.01$, $cz = 3000$ km/s and $\sigma_v/cz = 0.1$, so the neglected term is small.

The parameter H_0 enters only through $a = 5\log_{10} H_0$, and it enters *additively*: in the variable where the noise is Gaussian, the model is a constant shift. The two noise terms are independent Gaussians, so their sum is Gaussian with the sum of the variances. This is linear error propagation (Section 3.6.1) of the velocity v_i through the factor $\partial m_i/\partial v_i = -(5/\ln 10)/cz_i$:

$$\sigma_i^2 = \sigma_{\text{int}}^2 + \left(\frac{5}{\ln 10}\,\frac{\sigma_v}{cz_i}\right)^2. \tag{3.124}$$

The peculiar-velocity term is 0.2173 mag at $z = 0.01$, larger than the intrinsic scatter, and 0.02173 mag at $z = 0.1$, where it is negligible. The very nearest supernovae are the least useful for H_0, because their own motions are a large fraction of their recession velocities. The data are the model plus noise, as in (3.75), and the likelihood is the probability of the noise realisation $m_i - \text{prediction}_i$ that the data require:

$$\ln \mathcal{L}(a, M) = -\frac{1}{2}\sum_{i=1}^{N} \frac{\left[m_i - M - 25 - 5\log_{10}(cz_i) + a\right]^2}{\sigma_i^2} + \text{const.} \tag{3.125}$$

Figure 3.50 shows one simulated survey of 100 supernovae with $0.01 < z < 0.1$, drawn from $H_0 = 70$ and $M = -19.25$ in a universe where (3.118) is exact. In the velocity–distance plane the points fan out as the distance grows, because a fixed magnitude error is a fixed *fractional* distance error. In the magnitude residuals the scatter is the same at all redshifts except the nearest, where the peculiar velocities widen the band (3.124).

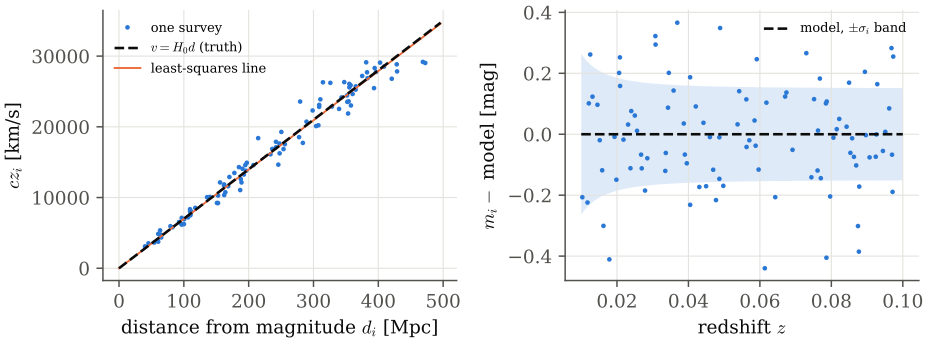

Figure 3.50: One mock survey of 100 supernovae. Left: recession velocity against the distance inferred from each magnitude, with the true Hubble line (dashed) and the least-squares line through the origin, which lies slightly below it. The scatter grows in proportion to the distance. Right: the magnitudes minus the model prediction at the true parameters. The noise is Gaussian in this variable, with a width (shaded, $\pm\sigma_i$) that is constant except at the lowest redshifts, where peculiar velocities add to it.

3.17.2 Steps 2 and 3: the sufficient statistic and three candidates

For the moment, pretend that the absolute magnitude M of a type Ia supernova is known exactly. (It is not, and Section 3.17.4 shows that this changes everything about the error bar.) Each supernova then gives its own estimate of $a = 5\log_{10} H_0$,

$$y_i \equiv M + 25 + 5\log_{10}(cz_i) - m_i, \qquad \mathbb{E}\, y_i = a, \quad \operatorname{Var} y_i = \sigma_i^2, \tag{3.126}$$

by reading (3.123) backwards. The likelihood (3.125) is $\ln \mathcal{L} = -\frac{1}{2}\sum_i w_i (y_i - a)^2$ with the weights $w_i \equiv 1/\sigma_i^2$.

Step 2: the sufficient statistic. Let $W \equiv \sum_i w_i$ and $\bar{y}_w \equiv \sum_i w_i y_i / W$, the inverse-variance weighted mean of the y_i. Then

$$\begin{aligned}\sum_i w_i (y_i - a)^2 &\overset{(1)}{=} \sum_i w_i \big[(y_i - \bar{y}_w) + (\bar{y}_w - a)\big]^2 \\ &\overset{(2)}{=} \sum_i w_i (y_i - \bar{y}_w)^2 + 2(\bar{y}_w - a)\sum_i w_i (y_i - \bar{y}_w) + W(\bar{y}_w - a)^2 \\ &\overset{(3)}{=} \sum_i w_i (y_i - \bar{y}_w)^2 + W(\bar{y}_w - a)^2. \end{aligned} \tag{3.127}$$

(1) Add and subtract $\bar{y}_w$.
(2) Expand the square; $\bar{y}_w - a$ does not depend on i.
(3) $\sum_i w_i (y_i - \bar{y}_w) = W\bar{y}_w - W\bar{y}_w = 0$.

So $\mathcal{L}(a) = \exp[-W(\bar{y}_w - a)^2/2] \times \exp[-\sum_i w_i (y_i - \bar{y}_w)^2/2]$. The first factor is the $g(U, a)$ of the factorisation theorem (Section 3.16.2) with $U = \bar{y}_w$, and the second is an $h(\boldsymbol{d})$ that knows nothing about a. The weighted mean $\bar{y}_w$ is sufficient for a, hence for $H_0 = 10^{a/5}$. Every estimator that is not a function of $\bar{y}_w$ uses part of the data that carries no information about H_0, and pays for it in variance or bias.

Candidate (a): fit the Hubble line to distances. Put $v_i \equiv cz_i$ on the vertical axis and the magnitude distances $\tilde{d}_i$ of (3.120) on the horizontal one, and minimise $\sum_i (v_i - H\tilde{d}_i)^2$. Setting the derivative $-2\sum_i \tilde{d}_i (v_i - H\tilde{d}_i)$ to zero,

$$\hat{H}_{\text{naive}} = \frac{\sum_i v_i \tilde{d}_i}{\sum_i \tilde{d}_i^2}. \tag{3.128}$$

This is least squares, but for a model in which the noise sits in v and the horizontal coordinate is exact. Here the horizontal coordinate carries the larger noise. For a large survey the numerator and the denominator, divided by N, each converge to their means by the law of large numbers, so $\hat{H}_{\text{naive}}$ converges to the ratio of the means. With $d_i = cz_i(1 - x_i)/H_0$ and ϵ_i independent of x_i,

$$\begin{aligned} \mathbb{E}\big[v_i \tilde{d}_i\big] &\overset{(1)}{=} cz_i \; \mathbb{E}[d_i] \; \mathbb{E}\big[e^{\kappa\epsilon_i}\big] \overset{(2)}{=} \frac{(cz_i)^2}{H_0}\, e^{\kappa^2\sigma_{\text{int}}^2/2}, \\ \mathbb{E}\big[\tilde{d}_i^2\big] &\overset{(3)}{=} \mathbb{E}[d_i^2] \; \mathbb{E}\big[e^{2\kappa\epsilon_i}\big] \overset{(4)}{=} \frac{(cz_i)^2 + \sigma_v^2}{H_0^2}\, e^{2\kappa^2\sigma_{\text{int}}^2}, \\ \hat{H}_{\text{naive}} &\xrightarrow{N\to\infty} \frac{\sum_i \mathbb{E}[v_i \tilde{d}_i]}{\sum_i \mathbb{E}[\tilde{d}_i^2]} \overset{(5)}{=} H_0\, e^{-3\kappa^2\sigma_{\text{int}}^2/2}\, \frac{\sum_i (cz_i)^2}{\sum_i \big[(cz_i)^2 + \sigma_v^2\big]}. \end{aligned} \tag{3.129}$$

(1) $v_i = cz_i$ is fixed; $\tilde{d}_i = d_i e^{\kappa\epsilon_i}$ and the two factors are independent.
(2) $\mathbb{E}\, d_i = cz_i/H_0$ since $\mathbb{E}\, x_i = 0$, and (3.121) with $t = \kappa$.
(3) As in (1), with $\tilde{d}_i^2 = d_i^2 e^{2\kappa\epsilon_i}$.
(4) $\mathbb{E}\, d_i^2 = (cz_i)^2\, \mathbb{E}(1 - x_i)^2/H_0^2 = [(cz_i)^2 + \sigma_v^2]/H_0^2$, and (3.121) with $t = 2\kappa$.
(5) Divide; $e^{\kappa^2\sigma^2/2}/e^{2\kappa^2\sigma^2} = e^{-3\kappa^2\sigma^2/2}$.

The limit is not H_0. The dominant factor, $e^{-3\kappa^2\sigma_{\text{int}}^2/2}$, gives a bias of -0.4992 km/s/Mpc for $\sigma_{\text{int}} = 0.15$; the peculiar velocities lower it a little further, to -0.5181 for the redshift range of the

survey. The mechanism is the textbook one for noise in the horizontal variable ("regression dilution"): the scatter of $\tilde{d}_i$ inflates $\sum \tilde{d}_i^2$ more than it inflates $\sum v_i \tilde{d}_i$, and the slope is pulled down. Because the limit (3.129) does not involve N, the estimator is *inconsistent*: more supernovae make it converge faster to the wrong number. Only the $O(1/N)$ corrections to the ratio of means depend on the survey size.

Candidate (b): average the individual ratios. Each supernova gives its own H_0 as $v_i/\tilde{d}_i$, and we average them: $\hat{H}_{\text{ratio}} = \frac{1}{N}\sum_i v_i/\tilde{d}_i$. Each term is

$$\frac{v_i}{\tilde{d}_i} = \frac{c z_i \, e^{-\kappa \epsilon_i}}{d_i} = H_0 \, \frac{e^{-\kappa \epsilon_i}}{1 - x_i},$$

and its mean follows from (3.121) with $t = -\kappa$ and $1/(1-x) = 1 + x + x^2 + \dots$, so that $\mathbb{E}(1-x_i)^{-1} \approx 1 + \sigma_v^2/(c z_i)^2$:

$$\mathbb{E}\,\hat{H}_{\text{ratio}} \approx H_0 \, e^{\kappa^2 \sigma_{\text{int}}^2/2} \, \frac{1}{N} \sum_i \Big[1 + \frac{\sigma_v^2}{(c z_i)^2} \Big]. \tag{3.130}$$

The bias now has the opposite sign, 0.1672 km/s/Mpc from the magnitude scatter and 0.2376 in total, because the nearest supernovae have large x_i. It is again independent of N. The mean of ratios is not the ratio of means, and averaging a nonlinear function of noisy numbers averages its bias too.

Candidate (c): maximum likelihood. The score of (3.125) is $\partial \ln \mathcal{L}/\partial a = \sum_i w_i (y_i - a) = W(\bar{y}_w - a)$, which vanishes at

$$\hat{a} = \bar{y}_w = \frac{\sum_i w_i \big[M + 25 + 5 \log_{10}(c z_i) - m_i \big]}{\sum_i w_i}, \qquad w_i = \frac{1}{\sigma_i^2}, \qquad \hat{H}_0 = 10^{\hat{a}/5}. \tag{3.131}$$

It is the weighted mean of Section 3.7, applied to the individual estimates y_i of a in the variable where their noise is Gaussian, and it is a function of the sufficient statistic only.

Bias. $\mathbb{E}\,\hat{a} = \sum_i w_i \, \mathbb{E}\, y_i / W = a$: unbiased, to the order of (3.123). The neglected term, $-(5/\ln 10)\ln(1 - x_i) = (5/\ln 10)(x_i + x_i^2/2 + \dots)$, has mean $(5/\ln 10)\,\sigma_v^2/2(c z_i)^2$, which after weighting is 7.927×10^{-4} mag, about a twentieth of the error bar.

Variance and efficiency. The y_i are independent, so

$$\operatorname{Var} \hat{a} \overset{(1)}{=} \frac{\sum_i w_i^2 \operatorname{Var} y_i}{W^2} \overset{(2)}{=} \frac{\sum_i w_i}{W^2} = \frac{1}{W}, \qquad I(a) \overset{(3)}{=} -\,\mathbb{E}\,\frac{\partial^2 \ln \mathcal{L}}{\partial a^2} = \sum_i w_i = W. \tag{3.132}$$

(1) The variance of a sum of independent terms is the sum of the variances, and a constant factor comes out squared.
(2) $w_i^2 \operatorname{Var} y_i = w_i^2 \sigma_i^2 = w_i$.
(3) Differentiate the score $\sum_i w_i (y_i - a)$ once more; the result $-W$ is not random, so the expectation does nothing.

The variance equals $1/I(a)$: the estimator sits on the Cramér–Rao bound (3.101). The score $W(\bar{y}_w - a)$ is a linear function of $\hat{a}$, the condition for equality. The error bar is $\sigma_a = W^{-1/2}$, and by linear propagation through $H_0 = e^{\kappa a}$, $\sigma_{H_0} = \kappa H_0 \sigma_a$.

From a to H_0. The invariance of maximum likelihood (Section 3.13.2) makes $\hat{H}_0 = 10^{\hat{a}/5}$ the maximum-likelihood estimator of H_0. It is not exactly unbiased, because the exponential is

convex. Expand $g(\hat{a}) = e^{\kappa\hat{a}}$ around the truth to second order (the delta method of Section 3.6.3, one order further):

$$\mathbb{E}\,\hat{H}_0 \overset{(1)}{=} \mathbb{E}\Big[g(a) + g'(a)(\hat{a}-a) + \tfrac{1}{2}g''(a)(\hat{a}-a)^2\Big] \overset{(2)}{=} H_0\Big(1 + \tfrac{1}{2}\kappa^2\sigma_a^2\Big) \overset{(3)}{\approx} H_0\, e^{\kappa^2\sigma_a^2/2}. \tag{3.133}$$

(1) Taylor expansion of g; higher orders are smaller by further powers of σ_a.
(2) $g' = \kappa H_0$, $g'' = \kappa^2 H_0$; $\mathbb{E}(\hat{a}-a) = 0$ and $\mathbb{E}(\hat{a}-a)^2 = \sigma_a^2$.
(3) Because $\hat{a}$ is exactly Gaussian, (3.121) with $t = \kappa$ gives the exponential exactly; the delta method gives its first two terms.

The bias-corrected estimator is $\hat{H}_0\, e^{-\kappa^2\sigma_a^2/2}$. Since $\sigma_a \to 0$ as N grows, the uncorrected $\hat{H}_0$ is consistent. For 100 supernovae $\sigma_a \approx 0.01611$ and the bias is 0.001926 km/s/Mpc, utterly negligible. It matters when σ_a is large: an H_0 from a single supernova ($\sigma_a = 0.15$) is biased by 0.24%, and averaging many such single-object values accumulates the bias coherently, which is exactly what went wrong with candidate (b). The cure is always the same: average in the variable where the noise is Gaussian and transform once at the end. The median of $\hat{H}_0$ is exactly H_0 (the exponential is monotonic), and the interval $[10^{(\hat{a}-\sigma_a)/5}, 10^{(\hat{a}+\sigma_a)/5}]$ has exactly the coverage of $\hat{a} \pm \sigma_a$.

Key idea: The maximum-likelihood estimator of H_0

Work in the variable where the noise is Gaussian. For low-redshift supernovae with calibrated M that is $a = 5\log_{10} H_0$, and the estimator is the inverse-variance weighted mean (3.131) of the single-object values $M + 25 + 5\log_{10}(cz_i) - m_i$, with σ_i^2 from (3.124). It is sufficient, unbiased for a, on the Cramér–Rao bound $\sigma_a = (\sum_i w_i)^{-1/2}$, and $10^{\hat{a}/5}$ is consistent for H_0. Converting magnitudes to distances first gives inconsistent estimators.

3.17.3 Step 4: comparing the candidates on simulated surveys

The three biases (3.129), (3.130), (3.133) are large-N approximations, and the claim that the maximum-likelihood error bar is right is a statement about repeated surveys. Both can be checked by simulating many surveys from a known truth, which is the verification use of Monte Carlo (Chapter 6).

Listing 3.18: Mock supernova surveys and the three estimators of H_0 (`code/ch03/17_hubble_estimator.py`)

```
def sigma_mag(z):
    """Total magnitude scatter: intrinsic plus the peculiar velocity propagated into magnitudes."""
    return np.sqrt(SIG_INT**2 + (5 / np.log(10) * SIG_V / (C * z))**2)

def mock_lowz(shape):
    """A universe where the Hubble law is exact: cz = H0 d + v_pec, m = M + 5 log10(d/10pc) + eps."""
    z = rng.uniform(0.01, 0.1, shape)
    d = (C * z - rng.normal(0, SIG_V, shape)) / H0                  # true distance, Mpc
    m = M_TRUE + 25 + 5 * np.log10(d) + rng.normal(0, SIG_INT, shape)
    return z, m

# ---------- the three candidate estimators ----------
def naive(z, m, M=M_TRUE):
    d = 10 ** ((m - M - 25) / 5)                                    # distance "measured" from each magnitude
    v = C * z
    return (v * d).sum(-1) / (d * d).sum(-1)                        # least squares of v = H0 d through the origin
```

```
17
18 def ratio(z, m, M=M_TRUE):
19     d = 10 ** ((m - M - 25) / 5)
20     return (C * z / d).mean(-1)
21
22 def ml(z, m, M=M_TRUE):
23     w = 1 / sigma_mag(z)**2
24     y = M + 25 + 5 * np.log10(C * z) - m                    # each SN's own estimate
       of a = 5 log10 H0
25     a = (w * y).sum(-1) / w.sum(-1)                         # inverse-variance
       weighted mean
26     sa = 1 / np.sqrt(w.sum(-1))                             # 1/sqrt(Fisher
       information)
27     return 10 ** (a / 5), a, sa
```

The function `sigma_mag` is (3.124). The function `mock_lowz` draws redshifts uniformly in $0.01 < z < 0.1$, a peculiar velocity for each galaxy, the true distance from (3.118) and a magnitude from (3.119); it generates the data from the physics, not from the linearised likelihood, so the approximation in (3.123) is tested too. The arrays have one row per survey, and every estimator sums over the last axis, so 20000 surveys of 100 supernovae are processed at once. `naive` is (3.128), `ratio` the mean of $v_i/\tilde{d}_i$, and `ml` returns $10^{\hat{a}/5}$, $\hat{a}$ and $\sigma_a = W^{-1/2}$ from (3.131) and (3.132).

estimator	mean bias [km/s/Mpc]	predicted bias [km/s/Mpc]	scatter [km/s/Mpc]	rms error [km/s/Mpc]
(a) least-squares line (3.128)	−0.5076	−0.5181	0.6265	0.8063
(b) mean of ratios	0.2388	0.2376	0.5362	0.587
(c) maximum likelihood (3.131)	0.02722	0.001926	0.5191	0.5198

The predicted biases are (3.129) and (3.130) averaged over the simulated redshifts, and for (c) the convexity term of (3.133). The first two agree with the simulation to within the $O(1/N)$ corrections: for surveys of 400 supernovae the measured biases are −0.5158 and 0.2403, no smaller, while the scatter of the maximum-likelihood estimator halves to 0.2588. The least-squares line is off by about one standard deviation for 100 supernovae and by two for 400. The small residual bias of (c) is not the convexity term but the second-order peculiar-velocity term: the simulated mean of $\hat{a}$ is too large by 7.845×10^{-4} mag, against the predicted 7.927×10^{-4}. The scatter of $\hat{a}$ is 0.0161 against the Cramér–Rao value 0.01611, and the interval $\hat{a}\pm\sigma_a$ covers the truth in a fraction 0.6853 of the surveys ($\pm1.96\sigma_a$: 0.948), as a 68% and a 95% interval should. Figure 3.51 shows the three sampling distributions.

3.17.4 What supernovae alone cannot tell us: the H_0–M degeneracy

Look again at the likelihood (3.125). The absolute magnitude M and $a = 5\log_{10}H_0$ appear only in the combination $M - a$. Increasing both by the same amount leaves every prediction, and so the likelihood, unchanged. The only thing the supernovae measure is the combination

$$\mathcal{M} \equiv M - 5\log_{10}H_0 + 25,$$

which is a statement about the product "luminosity times H_0^{-2}": brighter candles in a faster-expanding universe look exactly like fainter candles in a slower one. In the Fisher matrix of (3.125) for the two parameters (M, a),

$$\mathbf{F} \overset{(1)}{=} \sum_i w_i \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} = W \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}, \qquad \det\mathbf{F} \overset{(2)}{=} W^2 - W^2 = 0, \tag{3.134}$$

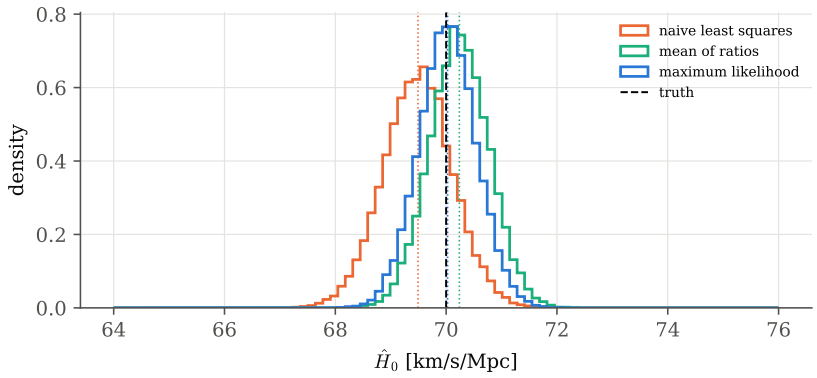

Figure 3.51: Sampling distributions of the three estimators of H_0 over 20 000 mock surveys of 100 supernovae with $H_0 = 70$ (dashed). The dotted lines mark the means. The least-squares line through the magnitude distances is shifted low and is also the widest; the mean of the individual ratios is shifted high; the maximum-likelihood estimator is centred on the truth and is the narrowest.

(1) $F_{jk} = -\mathbb{E}\,\partial^2 \ln \mathcal{L}/\partial\theta_j\partial\theta_k$; the residual is $m_i - M - 25 - 5\log_{10}(cz_i) + a$, whose derivatives are -1 for M and $+1$ for a, so each supernova contributes w_i times the product of the two derivatives.
(2) Determinant of the 2×2 matrix.

A singular Fisher matrix has a zero mode: the direction $(\delta M, \delta a) \propto (1, 1)$ costs no likelihood at all, and the variance along it is infinite. Figure 3.52 shows this for the survey of Figure 3.50. The $\Delta\chi^2$ contours in the (M, H_0) plane are an open band along $H_0 \propto 10^{M/5}$, and the χ^2 as a function of H_0 at three fixed values of M has three different minima of exactly the same depth. Evaluated numerically for that survey, $\det \mathbf{F} = 0$ to rounding.

The absolute magnitude must therefore come from somewhere else: from supernovae in galaxies whose distances are measured independently, with Cepheid variables or the tip of the red giant branch, which are in turn calibrated geometrically with parallaxes. This is the **distance ladder**. The distance-ladder value of H_0 is 73.04 ± 1.04 km/s/Mpc [24], while the CMB with ΛCDM gives 67.36 ± 0.54 [25], 4.8 standard deviations apart: the **Hubble tension**. Since supernovae only fix $M - 5\log_{10} H_0$, the same tension can be stated as a disagreement of $5\log_{10}(73.04/67.36) = 0.18$ mag in the absolute magnitude of type Ia supernovae. The ladder that supplies M is built as one linear model, with its error budget rung by rung, in Section T2.12, where the tension is also computed (Section T2.12.3).

A calibrated M as a nuisance parameter. Suppose the calibrators give $M = M_{\mathrm{cal}} \pm \sigma_M$ with Gaussian errors. That is one more measurement, independent of the Hubble-flow supernovae, and its log-likelihood $-(M - M_{\mathrm{cal}})^2/2\sigma_M^2$ adds to (3.125). The Fisher matrix gains $1/\sigma_M^2$ in its MM element. The variance of $\hat{a}$, with M treated as a nuisance parameter, is the aa element of the inverse:

$$\mathbf{F}' = \begin{pmatrix} W + \sigma_M^{-2} & -W \\ -W & W \end{pmatrix}, \qquad \det \mathbf{F}' \overset{(1)}{=} \frac{W}{\sigma_M^2},$$

$$\sigma_a^2 = (\mathbf{F}'^{-1})_{aa} \overset{(2)}{=} \frac{W + \sigma_M^{-2}}{W/\sigma_M^2} \overset{(3)}{=} \frac{1}{W} + \sigma_M^2. \tag{3.135}$$

(1) $(W + \sigma_M^{-2})W - W^2 = W/\sigma_M^2$.
(2) The $(2,2)$ element of the inverse of a 2×2 matrix is its $(1,1)$ element divided by the determinant.

(3) Divide term by term.

This is the profile-likelihood variance $V_{\theta\theta}$ of (3.102) with $\theta = a$ and $\nu = M$: maximising the likelihood over M at each a gives a parabola in a of exactly this width, and for a Gaussian likelihood marginalising over M gives the same (Section 3.14.4). The two errors add in quadrature: the statistical error of the Hubble-flow sample and the calibration error. The estimator itself is (3.131) with $M = M_{\rm cal}$, because the Hubble-flow supernovae cannot move M at all.

For the simulated surveys $W^{-1/2} = 0.01618$ mag, and with a calibration of $\sigma_M = 0.03$ mag, typical of current ladders, the total is $\sigma_a = 0.03409$ mag: the calibration dominates, and adding more Hubble-flow supernovae hardly helps. In the simulation each survey gets its own calibration $M_{\rm cal}$ drawn around the truth. The scatter of $\hat{H}_0$ is then 1.104 km/s/Mpc against the predicted $\kappa H_0 \sigma_a = 1.098$, and the interval with the full σ_a covers the truth in 0.6798 of the surveys. Quoting only the statistical error $W^{-1/2}$ would give intervals that cover the truth in 0.3605 of the surveys, instead of 68%.

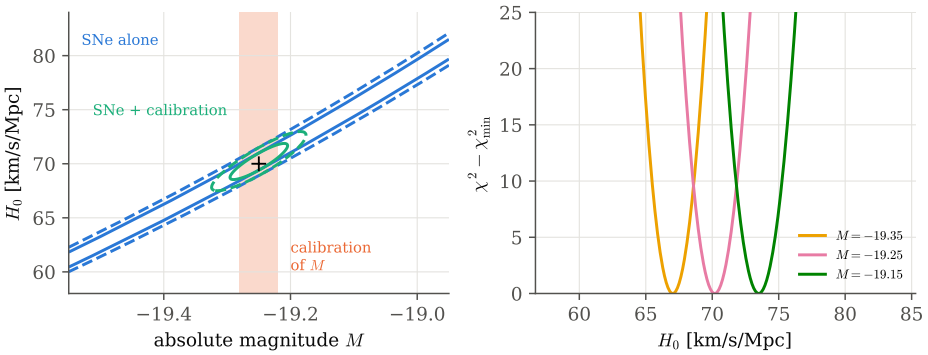

Figure 3.52: The degeneracy between H_0 and the absolute magnitude M for one survey of 100 supernovae. Left: $\Delta\chi^2 = 2.30$ (solid) and 6.18 (dashed) contours. The supernovae alone allow an open band; a calibration of M to ±0.03 mag (vertical strip) closes it into a small ellipse, whose height is set mostly by the width of the strip. Right: χ^2 against H_0 at three fixed values of M. Each has a perfectly good minimum of the same depth, at a different H_0.

Watch out: An error bar that forgets the calibration

Fixing M at a calibrated value and reporting the curvature error of the Hubble-flow fit, $\kappa H_0 W^{-1/2}$, conditions on the nuisance parameter instead of profiling it. The interval is too short by the factor $(1 + W\sigma_M^2)^{-1/2}$, here about one half, and its coverage falls from 68% to about a third. The calibration error must be carried into every number derived from the calibrated supernovae.

3.17.5 Beyond low redshift: the luminosity distance and a profile over Ω_{m0}

At larger redshift the Hubble law bends. In a flat universe with matter density parameter Ω_{m0} and a cosmological constant, neglecting radiation, the luminosity distance is a standard result of cosmology, taken here as an input:

$$D_L(z) = \frac{c}{H_0}\,(1+z)\int_0^z \frac{\mathrm{d}z'}{E(z')}, \qquad E(z) = \sqrt{\Omega_{m0}(1+z)^3 + 1 - \Omega_{m0}}, \tag{3.136}$$

the distance travelled by light through an expanding universe whose expansion rate is $H_0 E(z)$. The model for the magnitudes becomes $m_i = M + 25 + 5\log_{10}(D_L(z_i)/\mathrm{Mpc}) + \text{noise}$. Write

$\bar{D}_L \equiv H_0 D_L/c$ for the dimensionless integral, which depends on Ω_{m0} but not on H_0. Then

$$m_i = M + 25 + 5\log_{10}\left[c\,\bar{D}_L(z_i;\Omega_{m0})\right] - a + \text{noise}, \tag{3.137}$$

so a still enters additively, and M and a are still degenerate: the whole of Section 3.17.4 carries over unchanged. What is new is that the model depends on Ω_{m0} through an integral, nonlinearly. The maximum-likelihood estimator is the minimum of $\chi^2(a,\Omega_{m0}) = \sum_i w_i[y_i(\Omega_{m0}) - a]^2$, with $y_i(\Omega_{m0}) = M + 25 + 5\log_{10}[c\bar{D}_L(z_i;\Omega_{m0})] - m_i$. At fixed Ω_{m0} the minimum over a is the weighted mean $\hat{a}(\Omega_{m0}) = \sum_i w_i y_i(\Omega_{m0})/W$ as before, and substituting it leaves the profile $\chi^2_p(\Omega_{m0}) = \sum_i w_i[y_i - \hat{a}(\Omega_{m0})]^2$, a function of one variable that a one-dimensional minimiser handles.

Listing 3.19: The flat-ΛCDM luminosity distance (`code/ch03/17_hubble_estimator.py`)

```
def dl_bar(zv, Om):
    """H0 D_L / c for flat LambdaCDM (radiation neglected): (1+z) int_0^z dz'/E(z')."""
    E = np.sqrt(Om * (1 + ZG)**3 + 1 - Om)
    chi = cumulative_trapezoid(1 / E, ZG, initial=0)
    return (1 + zv) * np.interp(zv, ZG, chi)
```

`dl_bar` evaluates $\bar{D}_L$ by integrating $1/E$ with the trapezoidal rule on a fine grid and interpolating at the supernova redshifts. At the Planck 2018 best-fit parameters, it agrees with the luminosity distance computed by CAMB to a fractional 8.326×10^{-5} out to $z = 1$; CAMB includes radiation and massive neutrinos, which is the size of the difference.

Listing 3.20: Profiling $a = 5\log_{10} H_0$ analytically and minimising over Ω_{m0} (`code/ch03/17_hubble_estimator.py`)

```
def profile_chi2(Om, zv, mv, M=M_TRUE):
    """chi^2 minimised analytically over a = 5 log10 H0 at fixed Omega_m; returns (chi2_p, a_hat)."""
    w = 1 / sigma_mag(zv)**2
    y = M + 25 + 5 * np.log10(C * dl_bar(zv, Om)) - mv
    ah = (w * y).sum() / w.sum()
    return (w * (y - ah)**2).sum(), ah

Hfit, Omfit = np.empty(NMH), np.empty(NMH)
for k in range(NMH):
    r = optimize.minimize_scalar(lambda o: profile_chi2(o, zh[k], mh[k])[0], bounds=(0.02, 0.9),
                                 method="bounded", options={"xatol": 1e-5})
    Omfit[k] = r.x
    Hfit[k] = 10 ** (profile_chi2(r.x, zh[k], mh[k])[1] / 5)
```

The simulated surveys have 300 supernovae uniform in $0.01 < z < 1$, with $H_0 = 70$ and $\Omega_{m0} = 0.3$, and M known. `profile_chi2` returns χ^2_p and $\hat{a}$ at one Ω_{m0}, and `minimize_scalar` finds the minimum over Ω_{m0}. For the first survey a direct two-dimensional minimisation of $\chi^2(H_0,\Omega_{m0})$ with Nelder–Mead gives $H_0 = 70.79$, $\Omega_{m0} = 0.2878$, the same as the profile (70.79, 0.2878): analytic profiling over the linear parameter loses nothing.

Over 1000 surveys the estimates of H_0 average 69.99 with a scatter of 0.6258 km/s/Mpc, and those of Ω_{m0} average 0.3006 with a scatter of 0.02365: both are unbiased. The Fisher matrix in (a,Ω_{m0}), computed with a numerical derivative of $5\log_{10}\bar{D}_L$ with respect to Ω_{m0}, predicts 0.6333 and 0.02399. With Ω_{m0} held fixed the H_0 error would be only 0.2811: the two estimates are correlated with $\rho = -0.8957$, and profiling over Ω_{m0} widens the error by $1/\sqrt{1-\rho^2}$, exactly the mechanism of Section 3.14.2. A higher Ω_{m0} decelerates the expansion, makes distant supernovae nearer and brighter, and is compensated by a lower H_0.

When does the straight Hubble law fail? Expanding (3.136) in z gives the distance modulus $\mu = 25 + 5\log_{10}(cz/H_0) + 1.086\,(1 - q_0)\,z + O(z^2)$, where $1.086 = 5/(2\ln 10)$ and q_0 is the deceleration parameter, $q_0 = \frac{3}{2}\Omega_{m0} - 1 = -0.55$ for flat ΛCDM. The pure Hubble law drops the linear term. Applying the estimator (3.131) to noiseless ΛCDM magnitudes with redshifts up to $z_{\max}$ gives its bias directly, since the estimator is linear in the data (Figure 3.53, right). For $z_{\max} = 0.05$ the bias is -1.687 km/s/Mpc, for $z_{\max} = 0.1$ it is -2.965, about six times the statistical error 0.5192 of 100 supernovae. The Monte Carlo surveys confirm it: -2.988 at $z_{\max} = 0.1$ and -7.16 at 0.3 (predicted -7.171). The bias exceeds the statistical error of 100 supernovae already for $z_{\max} \approx 0.02$. Keeping the q_0 term moves this to $z_{\max} \approx 0.192$, with a bias of 0.1555 km/s/Mpc at $z_{\max} = 0.1$ but 2.873 at 0.5; beyond that only the full (3.136) is safe. In practice the "low-redshift" estimator means the Hubble law with the q_0 term (and often the next one) applied to $0.02 \lesssim z \lesssim 0.15$: the lower cut removes the supernovae whose peculiar velocities dominate, the upper cut keeps the expansion accurate. Like the bias of the least-squares line, this is a bias of a wrong model, and it does not average away.

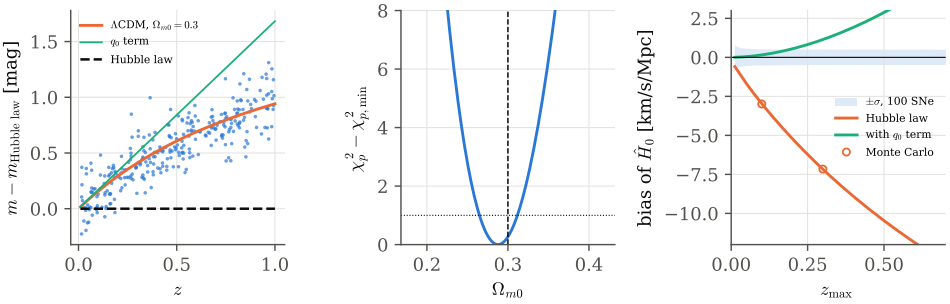

Figure 3.53: Supernovae beyond the linear Hubble law. Left: one survey of 300 supernovae to $z = 1$, as magnitudes minus the Hubble-law prediction; the ΛCDM curve follows the points, the first-order q_0 term follows them only at low redshift. Middle: the profile $\chi^2_p(\Omega_{m0})$ of that survey, with a minimised analytically at each Ω_{m0}; the dotted line is $\Delta\chi^2 = 1$, the dashed line the truth. Right: bias of $\hat{H}_0$ from fitting the pure Hubble law and the law with the q_0 term to supernovae up to $z_{\max}$, compared with the $\pm1\sigma$ statistical error of 100 supernovae (shaded); the circles are Monte Carlo checks.

How the measurement is done in research. Real analyses solve the same problem with the same structure, on a larger scale. The SH0ES measurement [24] writes the Cepheid magnitudes in the anchor galaxies (with geometric distances), the Cepheids and supernovae in the calibrator galaxies, and the Hubble-flow supernovae ($0.023 < z < 0.15$, with the q_0 and j_0 expansion terms) as one linear model $\boldsymbol{y} = A\boldsymbol{\theta}$ + noise with a full covariance matrix, and solves it by generalised least squares, $\hat{\boldsymbol{\theta}} = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{y}$ (3.87). The parameter vector contains M and $5\log_{10} H_0$ together with the Cepheid period–luminosity parameters and the host distances, so the degeneracy of Section 3.17.4 is broken inside one fit and σ_M is propagated automatically. The Pantheon+ analysis [26] fits 1550 supernovae with a covariance matrix that includes calibration and light-curve systematics, and fits M, H_0 and Ω_{m0} jointly with the SH0ES calibrators, profiling or marginalising over the light-curve standardisation parameters. Two things our mock surveys ignored enter there: a magnitude-limited survey preferentially finds the brighter supernovae at large distance, a selection bias that no choice of estimator removes and that is calibrated by simulating the survey (step 5, Section 3.16.5); and correlated systematics, which are what the off-diagonal covariance is for (Section 3.10.5). The same problem can be posed as Bayesian inference, with priors on (M, H_0, Ω_{m0}) and a Markov chain exploring the posterior; Chapter 9 builds those chains, and Section 9.23.1 uses one to add the SH0ES value to a CMB chain by reweighting. How the error on H_0 is assembled from the errors of the rungs, before any data

are taken, is the error budget of Section T2.12, and the Fisher matrix of Chapter 10 returns to H_0 as a parameter derived from the CMB in Section 10.6.3.

3.17.6 A second probe: cosmic chronometers, where H_0 enters linearly

Supernovae measure distances, and the expansion rate enters only through the integral that relates distance to $H(z)$. There is another method that measures $H(z)$ more directly. Consider galaxies that formed their stars early in cosmic history and then stopped forming new stars. Since no new stars are being added, their stellar populations simply grow older as the Universe evolves, and as the stars age, the spectrum of the galaxy changes in a predictable way. The observed spectrum can therefore be used to estimate the age of the stellar population at a given redshift. Comparing similar passively evolving galaxies at two nearby redshifts, the difference in their ages measures the difference in cosmic time between those redshifts, which gives $\mathrm{d}t/\mathrm{d}z$. Since $1+z=a^{-1}$,

$$H(z) = -\frac{1}{1+z}\frac{\mathrm{d}z}{\mathrm{d}t} = -\frac{1}{1+z}\left(\frac{\mathrm{d}t}{\mathrm{d}z}\right)^{-1}. \tag{3.138}$$

These galaxies are therefore used as **cosmic chronometers**: clocks whose age differences give $H(z)$ without any distance. A chronometer survey delivers N triples (z_i, H_i, σ_i): a redshift, a measured expansion rate in km/s/Mpc, and its error bar.

The event, and what could have produced it. What we observed is the number H_i at redshift z_i. What made it come out that way? Two things: the true expansion rate at z_i, and the measurement error. In flat ΛCDM the true rate is $H_{\rm th}(z;H_0,\Omega_{m0}) = H_0\,E(z;\Omega_{m0})$, with the same E as in (3.136). The errors of the age measurements are independent from point to point and Gaussian with standard deviation σ_i. So for each candidate pair (H_0,Ω_{m0}) the noise needed to turn the prediction into the data is $H_i - H_0E_i$, with $E_i \equiv E(z_i;\Omega_{m0})$, and how plausible that noise is gives the likelihood: $-2\ln\mathcal{L} = \chi^2 + \text{const}$ with

$$\chi^2(H_0,\Omega_{m0}) = \sum_{i=1}^{N}\frac{\left(H_i - H_0E_i\right)^2}{\sigma_i^2}.$$

Here is the feature that makes the problem easy. The matter density enters E_i through a square root, nonlinearly, but H_0 only multiplies it: *the model is linear in* H_0. At fixed Ω_{m0} the χ^2 is therefore a quadratic function of H_0, a parabola, and its minimum can be written down. With the three sums $S_{HH}\equiv\sum_i H_i^2/\sigma_i^2$, $S_{HE}\equiv\sum_i H_iE_i/\sigma_i^2$ and $S_{EE}\equiv\sum_i E_i^2/\sigma_i^2$,

$$\begin{aligned}
&\chi^2(H_0) \overset{(1)}{=} S_{HH} - 2H_0\,S_{HE} + H_0^2\,S_{EE},\\
&\frac{\mathrm{d}\chi^2}{\mathrm{d}H_0} \overset{(2)}{=} -2S_{HE} + 2H_0\,S_{EE} = 0 \quad\Longrightarrow\quad \hat{H}_0 = \frac{S_{HE}}{S_{EE}} = \frac{\sum_i H_iE_i/\sigma_i^2}{\sum_i E_i^2/\sigma_i^2},\\
&\chi^2(H_0) \overset{(3)}{=} S_{EE}\left(H_0-\hat{H}_0\right)^2 + \chi^2_{\rm min}, \qquad \chi^2_{\rm min} = S_{HH} - \frac{S_{HE}^2}{S_{EE}}.
\end{aligned} \tag{3.139}$$

(1) Expand $(H_i - H_0E_i)^2 = H_i^2 - 2H_0H_iE_i + H_0^2E_i^2$, divide by σ_i^2 and sum; H_0 does not depend on i.

(2) Differentiate the quadratic; $S_{EE} > 0$, so the stationary point is the minimum.

(3) Complete the square: $S_{EE}(H_0-\hat{H}_0)^2 = S_{EE}H_0^2 - 2H_0S_{HE} + S_{HE}^2/S_{EE}$.

No minimiser is needed. The estimator is a *weighted ratio*, and it is also a weighted mean: each point gives its own estimate H_i/E_i of H_0, with variance σ_i^2/E_i^2, and (3.139) is $\sum_i w_i(H_i/E_i)/\sum_i w_i$ with the inverse variances $w_i = E_i^2/\sigma_i^2$ as weights, exactly the weighted mean of Section 3.7.

Bias, variance and the bound. The H_i are independent with $\mathbb{E}\,H_i = H_0 E_i$ and $\operatorname{Var} H_i = \sigma_i^2$, and the E_i are fixed numbers at fixed Ω_{m0}. Then

$$\begin{aligned}
\mathbb{E}\,\hat{H}_0 &\overset{(1)}{=} \frac{\sum_i E_i\,\mathbb{E}\,H_i/\sigma_i^2}{S_{EE}} \overset{(2)}{=} \frac{H_0\sum_i E_i^2/\sigma_i^2}{S_{EE}} = H_0,\\
\operatorname{Var}\hat{H}_0 &\overset{(3)}{=} \frac{\sum_i E_i^2\,\operatorname{Var} H_i/\sigma_i^4}{S_{EE}^2} \overset{(4)}{=} \frac{S_{EE}}{S_{EE}^2} = \frac{1}{\sum_i E_i^2/\sigma_i^2},\\
I(H_0) &\overset{(5)}{=} \mathbb{E}\Big[\frac{\partial^2(-\ln\mathcal{L})}{\partial H_0^2}\Big] \overset{(6)}{=} \frac{1}{2}\,\frac{\mathrm{d}^2\chi^2}{\mathrm{d}H_0^2} = S_{EE}.
\end{aligned} \tag{3.140}$$

(1) The expectation is linear and the denominator is not random.
(2) $\mathbb{E}\,H_i = H_0 E_i$.
(3) Variances of independent terms add, each multiplied by the square of its coefficient $E_i/(\sigma_i^2 S_{EE})$.
(4) $\operatorname{Var} H_i = \sigma_i^2$, so each term is E_i^2/σ_i^2.
(5) The Fisher information of Section 3.13.3.
(6) $-\ln\mathcal{L} = \chi^2/2 + \text{const}$, and the second derivative of the parabola, $2S_{EE}$, is not random, so the expectation does nothing.

The estimator is unbiased and its variance is $1/I(H_0)$: it sits on the Cramér–Rao bound (3.101), as it must, since the score $\partial\ln\mathcal{L}/\partial H_0 = -\frac{1}{2}\mathrm{d}\chi^2/\mathrm{d}H_0 = S_{EE}(\hat{H}_0 - H_0)$ is a linear function of $\hat{H}_0$. The completed square in line 3 of (3.139) says the same thing graphically: χ^2 rises by one when H_0 moves by $S_{EE}^{-1/2}$ from its minimum.

Compare with the supernova estimator (3.131). There the parameter $a = 5\log_{10} H_0$ entered the magnitudes *additively*, as a shift, and the estimator was a weighted mean of the y_i; here H_0 enters the rates *multiplicatively*, as a scale, and the estimator is a weighted ratio. Both are instances of one rule: *a parameter that enters the model linearly, with Gaussian noise, has a closed-form maximum-likelihood estimator that is unbiased and on the Cramér–Rao bound.* Unlike candidate (b) of Section 3.17.2, the single-point ratios H_i/E_i carry no bias, because the noise sits in the numerator only and enters linearly.

The matter density. The closed form holds at fixed Ω_{m0}. The matter density is not known exactly, and it must be profiled or marginalised. Profiling is cheap here for the same reason as for the distant supernovae of Section 3.17.5: at each Ω_{m0} the best H_0 is $\hat{H}_0(\Omega_{m0})$ of (3.139), and substituting it leaves the profile $\chi^2_p(\Omega_{m0}) = S_{HH} - S_{HE}^2/S_{EE}$, the $\chi^2_{\min}$ of line 3, a function of one variable for a one-dimensional minimiser. As in Section 3.14.2, letting Ω_{m0} float widens the error on H_0, because a higher matter density raises $E(z)$ at high redshift and is compensated by a lower H_0.

A numerical illustration. Script `code/ch03/18_chronometers.py` draws 30 points uniform in $0.07 < z < 2$ from $H_0 = 70$, $\Omega_{m0} = 0.3$, with 8% errors. For one survey (Figure 3.54) the closed form gives $\hat{H}_0 = 69.74 \pm 1.02$ km/s/Mpc at $\Omega_{m0} = 0.3$. Over 4000 surveys the estimates average 70.02 ± 0.02, unbiased, and scatter by 1.019, against the bound $S_{EE}^{-1/2} = 1.022$. With Ω_{m0} profiled, the first survey gives $\hat{H}_0 = 71.02$ and $\hat{\Omega}_{m0} = 0.282$, and over the surveys the H_0 estimates average 69.95 with a scatter of 3.08, three times wider than at fixed Ω_{m0}, while Ω_{m0} scatters by 0.041. The full chronometer analysis, with real data, the systematic errors of stellar-population models and the comparison with supernovae, is in Section 11.19. Chronometers are the one route to H_0 in the book that needs neither a calibrated candle, as the supernovae of Section T2.12 do, nor a sound horizon, as the CMB of Section 10.6.3 and the BAO of Section T2.15 do.

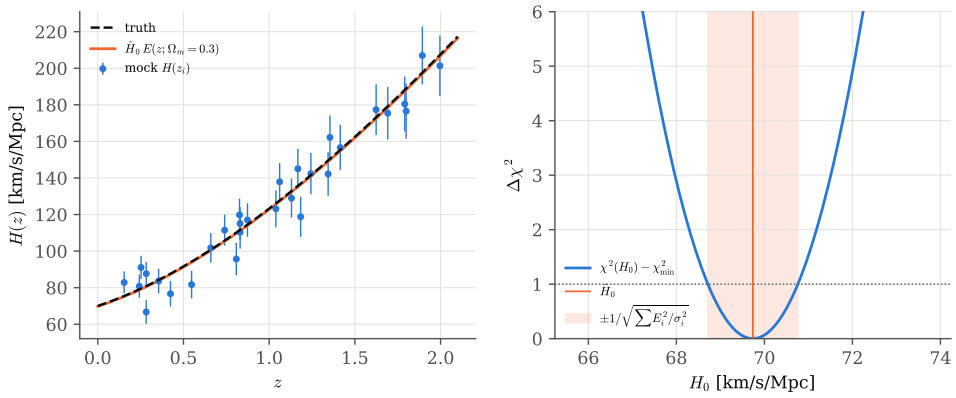

Figure 3.54: Cosmic chronometers. Left: one mock survey of $H(z_i)$ points with their error bars, the true expansion history (dashed) and the closed-form fit $\hat{H}_0 E(z)$ at $\Omega_{m0} = 0.3$ (orange). Right: the χ^2 of that survey as a function of H_0 is an exact parabola; its minimum is $\hat{H}_0$, and it rises by one (dotted) at $\hat{H}_0 \pm S_{EE}^{-1/2}$ (shaded).

Where this leaves us. The likelihood is the probability of the data, the object of Chapter 2 and of Section 3.1, read backwards. For every trial value of the parameters it asks how plausible the fluctuation is that would turn the prediction into the data we have. Everything else follows from its shape. Its peak is the estimate. Its width is the error bar. Its peak value, compared with that of a saturated model, tests the fit. Maximising it over the parameters we do not care about removes the nuisances. When no formula is available, the bootstrap and the parametric simulation give the sampling distribution directly. To find the best estimator, sufficiency says what the data can tell us; candidates come from moments, maximum likelihood or a loss function; and the Cramér–Rao bound and the Rao–Blackwell theorem say when to stop improving. The full-sky power spectrum went through every one of these steps. Chapter 4 turns likelihood ratios and χ^2 values into tests and p-values; Chapter 5 multiplies the likelihood by a prior and normalises it; Chapter 9 explores it with Markov chains when it has too many dimensions to plot; Chapter 10 replaces it by its curvature, the Fisher matrix, to forecast experiments before they are built.

Recap: Part 3b in one page

- Data = model + noise. The likelihood $\mathcal{L}(\boldsymbol{\theta}) = p(\boldsymbol{d}_{\text{obs}} \mid \boldsymbol{\theta})$ is the probability (density) of the noise realisation needed to turn the prediction $d(\boldsymbol{\theta})$ into the data. It is a function of $\boldsymbol{\theta}$, not a distribution over $\boldsymbol{\theta}$: no normalisation, no Jacobian, only ratios matter.
- Independent data multiply: $\ell = \sum_i \ln f(x_i;\boldsymbol{\theta})$. The MLE solves $\partial\ell/\partial\boldsymbol{\theta} = 0$; Newton–Raphson $\boldsymbol{\theta} \to \boldsymbol{\theta} - H^{-1}\boldsymbol{g}$ when it cannot be solved by hand.
- Gaussian noise: $-2\ell = \chi^2 = \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ (plus $\ln\det\mathbf{C}$ if $\mathbf{C}$ depends on $\boldsymbol{\theta}$). Linear models: $\hat{\boldsymbol{\theta}} = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}$ with covariance $(A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}$, exactly. $\chi^2_{\min} \sim \chi^2_{N-m}$, mean $\nu = N - m$. Ignoring correlations keeps the fit unbiased but makes its error bar wrong.
- Counts: $-2\ell = 2\sum[\mu_i - n_i \ln \mu_i]$; the fit conserves the total. Baker–Cousins χ^2_λ fits and tests; Neyman and Pearson χ^2 bias the normalisation by $-\chi^2$ and $+\chi^2/2$.
- Error bar: $\hat{\sigma} = (-\ell''(\hat{\theta}))^{-1/2}$ or the $\Delta\ln\mathcal{L} = \frac{1}{2}$ crossings (better when ℓ is skewed). Why: $\operatorname{Var} S = -\mathbb{E}\,\ell'' = I_n$, and $\hat{\theta} \approx \mathcal{N}(\theta, 1/I_n)$.

- The MLE is consistent (Kullback–Leibler), equivariant ($\widehat{g(\theta)} = g(\hat{\theta})$), asymptotically efficient: Cramér–Rao $\operatorname{Var}\hat{\theta} \geq 1/I_n$ for unbiased estimators of regular models. Median on Gaussian data: efficiency $2/\pi$.
- Nuisance parameters: profile, $\mathcal{L}_p(\theta) = \max_\nu \mathcal{L}(\theta, \nu)$; its width is the full marginal error. Fixing ν underestimates the error by $\sqrt{1-\rho^2}$.
- Finding the estimator: write $\mathcal{L}$; find the sufficient statistic from the factorisation $p = g(U, \theta)h(\boldsymbol{d})$; build candidates; compare with $1/I_n$. In an exponential family the MLE matches the model mean of U to its observed mean. Rao–Blackwell: $\mathbb{E}[W \mid U]$ never has larger variance than an unbiased W. Bayes estimators: posterior mean, median, mode for squared, absolute, zero–one loss. Full-sky $\widehat{C}_\ell = \sum_m |a_{\ell m}|^2/(2\ell+1)$ is sufficient, unbiased, and sits on the bound $2C_\ell^2/(2\ell+1)$.
- Bootstrap: resample the data with replacement (or simulate from the fit) and use the scatter of the replicas. It fails for statistics controlled by extremes, such as the maximum.

Chapter summary

A number computed from data is a random variable, with a sampling distribution over imagined repetitions of the experiment. The first idea is to ask how such an estimator scatters: its bias, its variance, the $1/\sqrt{N}$ law, the noise in variances and covariance matrices, the propagation of errors through formulas, and the combination of measurements. The second idea is to read the probability of the data backwards, as a function of the parameters. That gives the likelihood, which builds estimators and shows their error bars in its shape. On the pipeline of Chapter 0 these are the first tools for the last arrow, from a statistic's scatter to the physics: given the sampling distribution of a summary, they produce a number, an error bar and a check of the fit. The two tables list each concept, what it means operationally, and where it is used next.

Estimators and their errors (first half)

concept	operational meaning	used later in
statistical model	a family $f(x;\theta)$ of densities, one per parameter value; parametric if θ is finite-dimensional	every chapter
estimator, sampling distribution	a recipe $\hat{\theta} = g(x_1, \ldots, x_N)$; its histogram over simulated repetitions of the experiment; standard error = its width	Chapters 4, 6 and 8
bias, variance, MSE	centre offset and width of the sampling distribution; MSE = bias^2 + variance; compare estimators at several true values	Chapters 5 and 10
consistency	$\hat{\theta} \to \theta$ in probability; check that bias and variance both vanish as $N \to \infty$	Chapter 9
$1/\sqrt{N}$, LLN, CLT	Var $\bar{x} = \sigma^2/N$; means become Gaussian with width $\sigma/\sqrt{N}$; fails for the Cauchy	Chapters 6, 7 and 9
sample variance, $N-1$	divide by the number of residual degrees of freedom; Var $S^2 = 2\sigma^4/(N-1)$ for Gaussian data	Chapters 4 and 7
cosmic variance	the variance of a variance: Var $\widehat{C}_\ell = 2C_\ell^2/(2\ell+1)$	Chapters 7 and 8
sample covariance, Hartlap factor	$\hat{\mathbf{C}}$ from N_s simulations is noisy; multiply $\hat{\mathbf{C}}^{-1}$ by $(N_s - p - 2)/(N_s - 1)$	Chapters 8 and 12
error propagation	$U = AVA^\mathsf{T}$ with the Jacobian A; exact for linear maps; replace by Monte Carlo near poles and for noisy denominators	Chapters 6 and 10
weighted mean	weights $1/\sigma_i^2$; $1/\sigma_{\hat{\mu}}^2 = \sum 1/\sigma_i^2$; check $\chi^2_{\min} \sim \chi^2_{N-1}$; correlated case $V^{-1}\mathbf{1}/(\mathbf{1}^\mathsf{T}V^{-1}\mathbf{1})$	Chapters 4 and 10

The likelihood (second half)

concept	operational meaning	used later in
likelihood	write the noise model, evaluate the probability of the observed data, vary $\boldsymbol{\theta}$; compare values only through ratios	every later chapter
not a density in θ	area arbitrary, no Jacobian; a prior is needed to make it a distribution	Chapter 5
sufficiency, likelihood principle	the likelihood depends on the data only through a sufficient statistic; proportional likelihoods carry the same evidence	Chapters 4, 5 and 7
factorisation theorem, exponential family	$p = g(U,\theta)h(\boldsymbol{d})$ identifies U; in $h\,e^{\eta\phi - A}$ the MLE solves $\mathbb{E}_{\hat\theta}\,\phi = \overline{\phi}$	Chapters 5 and 7
Bayes estimator	minimise the posterior expected loss: mean for squared, median for absolute, mode for zero–one loss	Chapters 5 and 9
Rao–Blackwell, UMVUE	average a crude unbiased estimator over a sufficient statistic; with a complete statistic the result is the best unbiased estimator	Chapter 6
MC-calibrated statistic	when $\mathcal{L}$ is intractable, simulate, calibrate the mean and covariance of a simple statistic	Chapters 6 and 8
full-sky $\widehat{C}_\ell$	sufficient, unbiased, attains Cramér–Rao: cosmic variance $2C_\ell^2/(2\ell+1)$	Chapters 7, 8 and 10
noise lives in magnitudes	write the likelihood in the variable where the noise is Gaussian (m, not d); distances from magnitudes are log-normal, $\mathbb{E}\,\tilde{d} = d\,e^{\kappa^2\sigma^2/2}$	Chapter 9
naive vs ML estimator of H_0	a line fitted to magnitude distances or a mean of ratios is biased and inconsistent; the weighted mean of $5\log_{10} H_0$ is sufficient and on the Cramér–Rao bound	Chapters 9 and 10 and Section T2.12
H_0–M degeneracy	SNe fix only $M - 5\log_{10} H_0$ (singular Fisher matrix); a calibration adds σ_M^2 to $\sigma^2_{5\log_{10} H_0}$; the Hubble tension is 0.18 mag in M	Sections T2.12.3, 9.23.1 and 11.20
maximum likelihood	maximise ℓ; solve the score equation or iterate Newton–Raphson from a moment estimate	Chapters 4, 8 and 10
method of moments	match sample moments to model moments; a quick, consistent starting point	Chapter 6
extended likelihood	multiply by Poisson$(n;\nu)$ when the number of events is random	Chapter 4
least squares	minimise $\chi^2 = \boldsymbol{r}^\mathsf{T}\mathbf{C}^{-1}\boldsymbol{r}$; normal equations; covariance $(A^\mathsf{T}\mathbf{C}^{-1}A)^{-1}$	Chapters 7, 8 and 10
goodness of fit	$p = \mathrm{P}(\chi^2_{N-m} \geq \chi^2_{\min})$; reduced $\chi^2 \approx 1 \pm \sqrt{2/\nu}$	Chapter 4
$\Delta\chi^2$ regions	$\chi^2 \leq \chi^2_{\min} + \Delta\chi^2$ with $\Delta\chi^2$ from χ^2_m (1, 2.30, 3.53 for 68%)	Chapters 9 and 10
correlated and parameter-dependent noise	keep $\ln\det\mathbf{C}(\boldsymbol{\theta})$; GW: $(D-h\|D-h)$ with $S_n(f)$; CMB: $\sum(2\ell+1)[\widehat{C}_\ell/C_\ell + \ln C_\ell]$	Chapters 7, 8 and 10
Poisson binned likelihood	$2\sum[\mu_i - n_i\ln\mu_i]$ (Cash); Baker–Cousins χ^2_λ to test; never $\sqrt{n_i}$ errors for few counts	Chapters 4 and 6
curvature error, $\Delta\ln\mathcal{L} = \frac{1}{2}$	$\hat\sigma = (-\ell'')^{-1/2}$, or the two crossings of $\ell_{\max} - \frac{1}{2}$; covariance $(-H)^{-1}$	Chapters 9 and 10
score, Fisher information	$\mathbb{E}\,S = 0$, $\mathrm{Var}\,S = -\mathbb{E}\,\ell'' = I_n = nI$; $\hat\theta \approx \mathcal{N}(\theta, 1/I_n)$	Chapters 5 and 10
consistency, invariance	the MLE converges to the minimiser of the Kullback–Leibler divergence; $\widehat{g(\theta)} = g(\hat\theta)$, but bias is not invariant	Chapters 5 and 9
Cramér–Rao bound, efficiency	$\mathrm{Var}\,\hat\theta \geq 1/I_n$ for unbiased estimators of regular models; attained by exponential families; fails for moving supports	Chapter 10
profile likelihood	maximise over nuisance parameters at each θ; read $\Delta\ln\mathcal{L}_p = \frac{1}{2}$; Wilks gives the coverage	Chapters 4, 5 and 10
bootstrap	resample the data with replacement (nonparametric) or simulate from the fit (parametric); Normal, pivotal and percentile intervals; fails for extremes	Chapters 6, 8 and 12

Reading the literature

- **Main line.** [Wasserman Chs. 5–6] for convergence, the law of large numbers, the central limit theorem, estimators, bias, variance and consistency; [Wasserman Ch. 9] for the likelihood, maximum likelihood and its properties (consistency through the Kullback–Leibler divergence, equivariance, Fisher information, asymptotic normality, efficiency, the delta method, the parametric bootstrap), with sufficiency, the factorisation theorem, Rao–Blackwell and exponential families in its appendix; [Wasserman Ch. 8] for the bootstrap and its intervals.
- **The physicist's version.** [Cowan §§1.6–1.7, Ch. 5] for error propagation and estimators; [Cowan Ch. 6] for maximum likelihood with physics examples (lifetimes, the angular distribution, extended and binned likelihoods, goodness of fit); [Cowan Ch. 7] for least squares, binned χ^2 and the normalisation biases; [Cowan Ch. 8] for the method of moments.
- **Why least squares.** [Sivia §3.5]: maximum likelihood and least squares as what Bayes' theorem reduces to under a flat prior and Gaussian noise; [Sivia §2.3] for the weighted mean from a Gaussian posterior.
- **Careful derivations.** Casella and Berger give convergence and the delta method in [CasellaBerger §5.5], the likelihood principle and Birnbaum's argument in [CasellaBerger §6.3], maximum likelihood with restricted ranges and the invariance theorem in [CasellaBerger §7.2.2], in [CasellaBerger §6.2] sufficiency and the factorisation theorem, in [CasellaBerger §7.2.3] Bayes estimators, and in [CasellaBerger §7.3] mean squared error, the Cramér–Rao inequality with its attainment condition, and the Rao–Blackwell and Lehmann–Scheffé theorems.
- **Cosmology.** [HobsonBMC §1.3.1] for the four ingredients of Bayes' theorem and why the likelihood is the least controversial one; [HobsonBMC §2.4] for a χ^2 fit as a Gaussian likelihood and the marginalisation of an unknown noise level. [Padilla §§3.3–3.8] for the likelihood ratio, the Hessian, χ^2 goodness of fit, $\Delta\chi^2$ regions and a first look at the Fisher matrix.

Chapter 4

Hypothesis Testing: Asking the Null

Where this chapter is going

A physicist who sees a bump in a histogram asks one question before any other: *could this be luck?* Background alone fluctuates. Some bins come out high, some low, and if we look at enough histograms one of them will show something that looks like a new particle. Before we get excited, we want a number that says how surprising the bump would be if nothing new were there. We need to know how to compute that number, what it means, and what it does not mean.

The key move is to pick the one hypothesis we can simulate with no free choices: "only background, only chance". This is the **null hypothesis**. Its sampling distribution is the one we know, so we can work out how often chance alone would hand us a bump as large as ours or larger (Section 4.1.1). That frequency is a tail probability, the **p-value**. Everything else grows out of that question: how to choose the summary of the data whose tail we compute (the *test statistic*), what "this direction" means (one- and two-sided tests), how often a test fires by mistake and how often it catches a real effect (size and power), why the p-value is uniformly distributed when nothing is there, which statistic is the best one (the Neyman–Pearson lemma), and the workhorses built from it (likelihood ratios, Wilks' theorem, χ^2 and Kolmogorov–Smirnov goodness of fit). We end by translating p-values into the "$Z\sigma$" language of particle physics and asking why a discovery needs 5σ.

Recall the pipeline of Chapter 0: a theory produces data, the data are compressed into a statistic S, the scatter of S is its sampling distribution $P(S \mid \theta)$, and from that scatter we infer the physics. Testing is the last arrow. It uses the sampling distribution *under one special* θ, the null, and asks whether the observed summary is typical of it. Every test can also be turned into a confidence interval, and a search that looks in many places needs its p-value corrected for the look-elsewhere effect; both follow from the same tail probabilities. Chapter 5 then asks the question a p-value cannot answer: how probable is the hypothesis itself, given the data?

4.1 A bump in a histogram: new particle or luck?

We have recorded events in which two photons were produced, and for each event we computed the invariant mass $m_{\gamma\gamma}$ of the photon pair. Figure 4.2 shows the histogram: thirty bins of 2 GeV between 100 and 160 GeV. Known physics produces a smooth, falling spectrum, and from simulation we expect 60 background events in the whole range, distributed as the dashed line. Near 126 GeV two neighbouring bins stick out. A new particle decaying to two photons would show up exactly like this: a narrow excess at its mass. But background alone also fluctuates. Every bin is a Poisson count, some bins come out high and some low, and a pair of high bins can happen by luck.

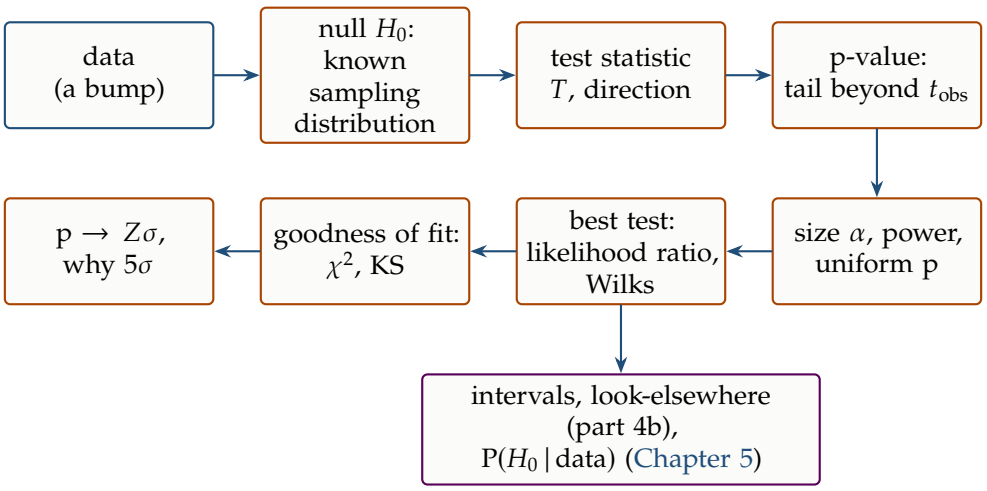

Figure 4.1: The route through this part. We start from data that look surprising and pick the hypothesis whose sampling distribution we know, the null. A summary of the data, the test statistic, and a direction of "more extreme" turn the question "could this be chance?" into a tail probability. The bottom row asks how good a test is, which test is best, how to test a whole model, and how to report the answer. The violet box points to what the p-value cannot tell us and to the next part.

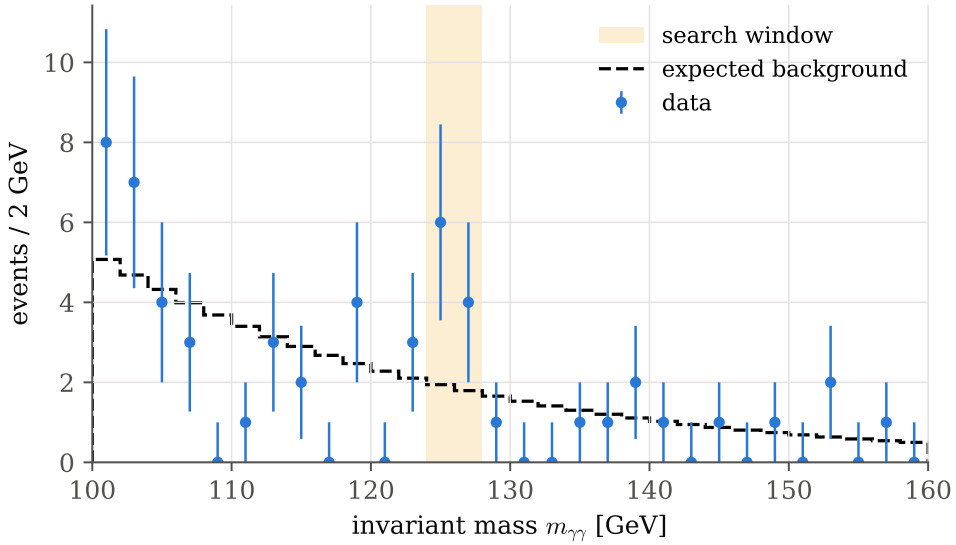

Figure 4.2: A simulated diphoton mass spectrum. The dots are the observed counts per 2 GeV bin, the dashed staircase is the background we expect with no new particle, and the shaded band is the two-bin window 124–128 GeV where the excess sits. The error bars are $\sqrt{n}$ and are drawn only to guide the eye; the pitfall at the end of Section 4.1 explains why they must not be used to judge the excess.

The first thing we can compute is not whether the particle exists. It is how surprising the bump would be *if nothing new were there*. That is weaker than what we want to know, but we can compute it exactly, and every discovery claim in physics starts with it.

The question in words. Before any formula, we can list the three things we need.

1. A hypothesis precise enough to *predict* the data, with no knob left to turn. "Only background" is such a hypothesis: the dashed line tells us the Poisson mean of every bin.

2. One number computed from the data that is large when there is a signal and small when

there is not. Here, the count in the window.

3. The answer to: if only background were present, how often would that number come out at least as large as the one we saw?

4.1.1 The null hypothesis is the one whose predictions we know

Every test starts by splitting the possible values of an unknown parameter into two sets, one for each hypothesis. This is the same for a particle search and for a medical trial. [Wasserman p. 149] opens with rats: expose one group to asbestos, leave another unexposed, and compare the disease rates. Either the two rates are the same, or they are not. In the bump, the unknown parameter is the expected number s of signal events in the window, and physics allows any $s \geq 0$. Writing θ for the parameter and Θ for the set of all its allowed values, the two hypotheses are two disjoint sets that together cover Θ:

$$H_0 : \theta \in \Theta_0 \qquad \text{versus} \qquad H_1 : \theta \in \Theta_1, \qquad \Theta_0 \cup \Theta_1 = \Theta, \quad \Theta_0 \cap \Theta_1 = \varnothing. \tag{4.1}$$

For the bump, $\theta = s$, $\Theta = [0, \infty)$, $\Theta_0 = \{0\}$ and $\Theta_1 = (0, \infty)$. For the rats, θ is the difference of the two disease rates, $\Theta_0 = \{0\}$, and Θ_1 is every nonzero difference.

The two hypotheses are not on an equal footing, and the asymmetry is the whole point. H_0 is the **null hypothesis**: the data came about by chance alone, from processes we already understand. We treat it this way *because we know its probability distribution*. With $s = 0$ the count in every bin is Poisson with a known mean, and we can compute, or simulate, the probability of any outcome. The alternative H_1 is a whole family: every $s > 0$, every possible mass and width of the new particle, each predicting something different. We cannot compute "the" probability of the data under H_1 without first choosing one of its members.

So we test "chance alone" not because we believe it, but because it is the one case whose probability density we actually know. A test therefore runs in the *prediction* direction of Chapter 1. We start from the one situation we can simulate, H_0, and ask what outcomes it produces and how often. Only then do we compare with what we saw.

The question a test asks. Suppose H_0 is true. Would a result like the one we got, or even more in this direction, then be a reasonable thing to expect?

If the answer is "hardly ever", the data give us evidence against H_0. If the answer is "quite often", they do not. Notice what we did *not* ask: how probable H_0 is. That question runs in the inference direction and needs Bayes' theorem, and we come back to it in Section 4.4.4 and Chapter 5.

4.1.2 Test statistic, rejection region, critical value

Data sets are long lists of numbers, and we cannot compare lists directly. We compress the data $\boldsymbol{x}$ into one number, the **test statistic** $T(\boldsymbol{x})$ [a function of the data alone, chosen to be large when H_1 is true]. For the bump, T is the count n in the window. Large n points to a signal, and n near the expected background points to nothing.

A test is then a rule for turning T into a decision. We choose a set of outcomes, the **rejection region** R, and agree in advance [Wasserman (10.2)], [Cowan §4.1]:

$$\boldsymbol{x} \in R \implies \text{reject } H_0, \qquad \boldsymbol{x} \notin R \implies \text{retain } H_0, \qquad R = \{\boldsymbol{x} : T(\boldsymbol{x}) > c\}. \tag{4.2}$$

The threshold c is the **critical value**. Cowan calls the rejection region the *critical region* and its complement the *acceptance region*. We say "retain" rather than "accept": not rejecting the

null only means the data did not contradict it, just as a jury that fails to convict has not proved innocence. The whole problem of testing is to choose a good T and a sensible c. Choosing c is the subject of Section 4.3; choosing T, of Section 4.6.

[Wasserman p. 150] adds a warning worth keeping in mind from the start: tests are for well-defined hypotheses. If the real question is "how big is the effect?", an estimate with a confidence interval answers it better than a test.

4.1.3 The p-value: the tail beyond what we saw

Instead of fixing c in advance and reporting only "reject" or "retain", we can report *where* the observed statistic t_{obs} falls in the null distribution. Figure 4.3 shows the picture that the whole chapter keeps returning to. The curve is $g(t \mid H_0)$, the sampling distribution of the test statistic when the null is true. The vertical line is the value we observed. The shaded area to the right is the probability, under H_0, of a result like ours or even more in the direction that signals H_1. That area is the p-value.

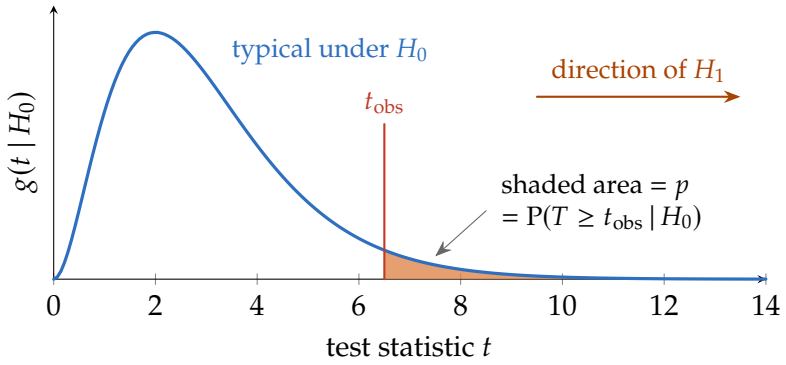

Figure 4.3: The p-value as a tail area. The blue curve is the distribution of the test statistic in a world where only chance operates. The observed value sits at the red line. The orange tail collects every outcome at least as extreme, in the direction the alternative predicts. A small tail means our result would be rare if the null were true.

Working definition 4.1 (p-value)

For a test that rejects H_0 when T is large, and a simple null $\Theta_0 = \{\theta_0\}$, the **p-value** of the observed data is

$$p = \mathrm{P}_{\theta_0}(T \geq t_{\text{obs}})$$

[the probability, computed as if H_0 were true, of a test statistic at least as large as the one observed]. It is computed from H_0 alone and is *not* the probability that H_0 is true. Operationally: simulate many data sets under H_0, compute T for each, and count the fraction with $T \geq t_{\text{obs}}$ [Wasserman Thm 10.12], [Cowan §4.5].

Three features of the definition matter.

- The p-value is a probability of *data*, not of hypotheses. The null value θ_0 sits in the subscript as a fixed assumption.
- It counts the observed value itself and everything beyond it. The words "or even more in this direction" are needed because, once the data are rich enough, the probability of getting exactly t_{obs} is tiny under any hypothesis, so it cannot measure surprise on its own.
- It needs a *direction*. We must say in advance which outcomes count as more extreme. Section 4.2 shows that this choice is part of the question.

4.1.4 The p-value of a Poisson excess

What we need. Under the null, the count N in the window adds up many rare, independent background events, so it is a Poisson variable (Chapter 2). Its mean b is the expected background in the window. So the first step is to find b, and the second is to add up the Poisson tail.

The expected background. Take the background to be exponential in mass, $f(m) \propto e^{-(m-m_0)/L}$ with $m_0 = 100\,\text{GeV}$, decay length $L = 25\,\text{GeV}$, and total expectation $B = 60$ over the range $[100, 160]\,\text{GeV}$. Its cumulative distribution on this range is $F(m) = \big(1 - e^{-(m-m_0)/L}\big)/\big(1 - e^{-60/L}\big)$, and the expected background in the window is

$$\begin{aligned} b &\overset{(1)}{=} B\,\big[F(128) - F(124)\big] \\ &\overset{(2)}{=} B\,\frac{e^{-24/25} - e^{-28/25}}{1 - e^{-60/25}} = 60 \times \frac{0.3829 - 0.3263}{1 - 0.0907} \approx 3.74. \end{aligned} \tag{4.3}$$

(1) The expected number of background events in a window is the total expectation times the fraction of the background probability that falls inside the window.
(2) Insert F. The denominators cancel between $F(128)$ and $F(124)$, and the ones cancel in the difference.

The tail. With b in hand, the p-value of observing n_{obs} events is the probability that a Poisson count with mean b comes out at n_{obs} or above [Cowan (4.38)]:

$$\begin{aligned} p = \mathrm{P}(N \geq n_{\text{obs}} \,|\, H_0) &\overset{(1)}{=} \sum_{n=n_{\text{obs}}}^{\infty} \mathrm{P}(N = n \,|\, s = 0) \\ &\overset{(2)}{=} \sum_{n=n_{\text{obs}}}^{\infty} \frac{b^n e^{-b}}{n!} \\ &\overset{(3)}{=} 1 - \sum_{n=0}^{n_{\text{obs}}-1} \frac{b^n e^{-b}}{n!}. \end{aligned} \tag{4.4}$$

(1) The events $\{N = n\}$ for different n are disjoint, so their probabilities add. The direction is "upwards", because a signal can only add events.
(2) Under H_0 the count is Poisson with mean b.
(3) The Poisson probabilities sum to one, because $\sum_{n\geq 0} b^n/n! = e^b$. So the infinite upper tail equals one minus a *finite* sum, which is what we actually evaluate.

Example: our bump. In the two-bin window there are $n_{\text{obs}} = 10$ events on an expected background of $b = 3.74$. The finite sum in (4.4) runs over $n = 0, \ldots, 9$, and

$$p = \mathrm{P}(N \geq 10 \,|\, b = 3.74) = 0.005172.$$

About one background-only experiment in 190 would give a window at least this full. Figure 4.4 shows the null distribution of the window count with this tail shaded, and the same distribution rebuilt from 10^6 simulated background-only experiments.

Example: Cowan's peak. [Cowan p. 60, Fig. 4.3] shows a histogram with a peak where two bins contain $n_{\text{obs}} = 11$ entries on an expected background of $b = 3.2$. The same formula gives

$$p = 1 - \sum_{n=0}^{10} \frac{3.2^n e^{-3.2}}{n!} = 4.972 \times 10^{-4},$$

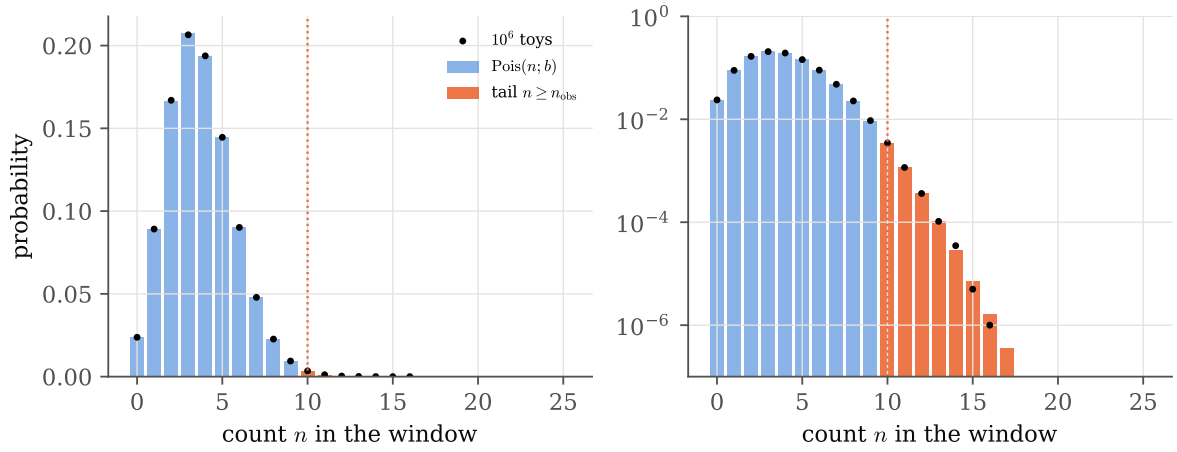

Figure 4.4: The null distribution of the window count, Pois$(n; b)$ with $b = 3.74$, on a linear scale (left) and a log scale (right). The orange bars are the outcomes at least as large as the observed $n_{\mathrm{obs}} = 10$, and their total height is the p-value. The black dots are the frequencies in a million simulated background-only experiments. They follow the bars even far out in the tail, where the log scale is needed to see them.

the value 5.0×10^{-4} quoted there. Fewer than one background-only histogram in two thousand would have such a full pair of bins *at that location*. The last three words matter: a peak could have appeared anywhere in the histogram, and [Cowan p. 61] points out that the fair question is how often a peak this improbable appears in *any* bin. That is the look-elsewhere effect, treated in the second part of the chapter.

Example: a few events on almost no background, and a background we do not quite know. The p-value is computed *entirely* from the null model, so an error in the expected background goes straight into it. Suppose we expect $b = 0.5$ background events and observe $n_{\mathrm{obs}} = 5$ [Cowan p. 59]. Then (4.4) gives $p = 1.721 \times 10^{-4}$. If the background estimate is off and the true value is $b = 0.8$, the same five events give $p = 0.001411$, almost ten times larger. A modest error in the background has turned a striking result into a much less striking one. This is why every real search spends most of its effort on the background estimate, and quotes p-values for a range of plausible b.

4.1.5 Python: exact tail and simulated tail

Listing 4.1 shows the lines of `code/ch04/01_bump_pvalue.py` that compute the p-value twice.

Listing 4.1: The window count, its exact Poisson p-value, and a Monte Carlo p-value (`code/ch04/01_bump_pvalue.py`)

```
win = (edges[:-1] >= 124.0) & (edges[1:] <= 128.0)   # two-bin window 124-128 GeV
b_win = b_bin[win].sum()
n_win = int(n_bin[win].sum())

# exact Poisson p-value:  P(N >= n_obs | b) = 1 - F(n_obs - 1)
p_exact = stats.poisson.sf(n_win - 1, b_win)
# Monte Carlo: background-only experiments in the window
M = 1_000_000
n_toys = rng.poisson(b_win, size=M)
p_mc = np.mean(n_toys >= n_win)
p_mc_err = np.sqrt(p_mc * (1 - p_mc) / M)
z_exact = stats.norm.isf(p_exact)
```

```
z_naive = (n_win - b_win) / np.sqrt(b_win)      # Gaussian approximation with sigma = sqrt(b)
z_wrong = (n_win - b_win) / np.sqrt(n_win)      # the "n +- sqrt(n)" error bar
```

The mask `win` picks the two bins between 124 and 128 GeV, and summing the expected background and the observed counts over it gives b and n_{obs}. The function `stats.poisson.sf(k, b)` is the *survival function* $\mathrm{P}(N > k)$, so asking for `sf(n_win - 1, b_win)` gives $\mathrm{P}(N \geq n_{\text{obs}})$, exactly the last line of (4.4). The off-by-one is the most common bug in this computation: $\mathrm{P}(N > n_{\text{obs}})$ leaves out the observed value itself.

The Monte Carlo version is the definition of the p-value turned into code, and it does not use the formula at all. It draws $M = 10^6$ background-only experiments, each a single Poisson count with mean b, and counts the fraction at least as large as the observation. It finds $p = 0.005133$, with a binomial standard error of $\sqrt{p(1-p)/M} = 7.146 \times 10^{-5}$, in agreement with the exact value 0.005172. Here the simulation is overkill, because the tail sum is exact. But when the test statistic is complicated and its null distribution has no formula, which is the usual situation in research, simulation is the only option.

The simulated data do contain a signal: 9 expected events from a narrow resonance at 126 GeV. The test does not know this. With these numbers it cannot tell a real signal of this size from a lucky fluctuation with much confidence. Section 4.3 asks how large a signal must be before a test catches it reliably.

Watch out: The $\sqrt{n}$ error bar answers the wrong question

It is tempting to write the observation as $n \pm \sqrt{n}$, subtract the background, and count standard deviations. For five events on $b = 0.5$ this gives 4.5 ± 2.2, "only two standard deviations" from zero, even though $p = 1.721 \times 10^{-4}$ says the excess is very unusual [Cowan p. 60]. The error bar $\sqrt{n}$ describes how a Poisson variable *with mean n* fluctuates down. The p-value asks how a Poisson variable *with mean b* fluctuates up, and only the second question is posed by the null. For our bump, $(n-b)/\sqrt{n} = 1.98$ and $(n-b)/\sqrt{b} = 3.24$, while the exact tail corresponds to 2.56 Gaussian standard deviations (the conversion is explained in Section 4.9). Neither shortcut is right for small counts. Compute the tail.

Two practical lessons from [Cowan p. 61] complete the recipe. The window must be fixed before we look at the data, with a width of a few times the mass resolution; widening or shifting it to make the excess look better destroys the meaning of the p-value, because the null distribution was computed for a fixed window. And the p-value of one window ignores the other bins, some of which are also a little high or low. A test of the whole histogram against the background shape is a goodness-of-fit test, the subject of Section 4.8.

4.2 Which way is "more extreme"? Sides, and the stopping rule

A coin is tossed $N = 20$ times and comes up heads $n_h = 17$ times [Cowan p. 58]. A fair coin gives 10 heads on average, so 17 looks suspicious. To turn the suspicion into a p-value we must say which other outcomes are "at least as extreme" as 17 heads. The answer is not a technicality. It depends on what we were worried about before we tossed, and, more surprisingly, on how we decided when to stop tossing. The coin is small enough that we can do every sum by hand and see both effects directly.

The question in words.

1. Which alternative are we guarding against: a coin biased towards heads, or a coin biased either way?
2. Given that choice, which outcomes count as "this, or even more in this direction"?
3. Did the experimenter fix the number of tosses in advance, or stop for some other reason? The imaginary repetitions that the p-value averages over must follow the same plan.

4.2.1 Simple and composite hypotheses, one and two sides

A hypothesis that fixes the distribution of the data completely is **simple**. "The coin is fair", $p = \frac{1}{2}$, is simple: it predicts $n_h \sim \text{Binomial}(20, \frac{1}{2})$ [the number of successes in 20 independent tries, each with success probability $\frac{1}{2}$]. A hypothesis that leaves at least one parameter free is **composite**, for example $p \le \frac{1}{2}$ or $p \neq \frac{1}{2}$ [Wasserman p. 151], [Cowan §4.1].

The alternative decides the shape of the rejection region.

- A **two-sided test**, $H_0 : \theta = \theta_0$ versus $H_1 : \theta \neq \theta_0$, guards against departures in both directions. For the coin, very many heads and very few heads are both evidence of bias, and a sensible statistic is the distance from the expected value, $T = |n_h - N/2|$.
- A **one-sided test**, $H_0 : \theta \le \theta_0$ versus $H_1 : \theta > \theta_0$ (or the mirror image), guards against a departure in one direction only. If the only suspicion is a coin loaded towards heads, then $T = n_h$ and only large values count.

In both cases the test statistic is built to be *large when H_1 is true*, so the rejection region is always "T large" and the p-value is always an upper tail of T. The direction lives in the choice of T. Figure 4.5 shows the two rejection regions for a statistic that is standard normal under the null, with the same total probability $\alpha = 0.05$ in each: all of it in one tail beyond $z = 1.645$, or half in each tail beyond ± 1.960.

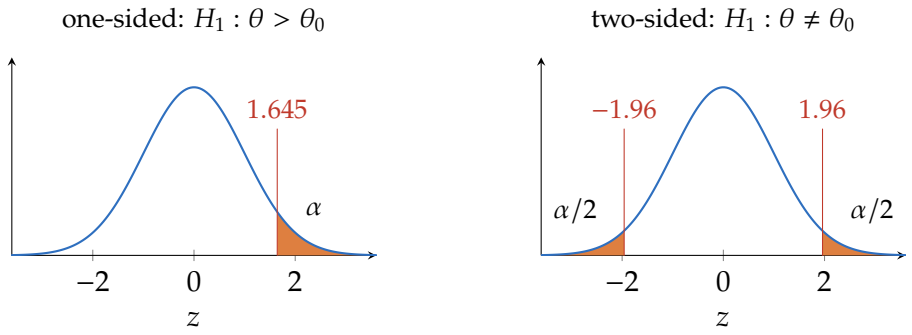

Figure 4.5: The same total probability $\alpha = 0.05$ placed in one tail (left) or split between two tails (right) of a standard normal null distribution. The one-sided test rejects sooner in the direction it cares about, at 1.645 instead of 1.96, and never rejects in the other direction.

Example: 17 heads in 20 tosses. The binomial probability of k heads for a fair coin is $\binom{20}{k}2^{-20}$, and $2^{20} = 1\,048\,576$. If we only feared a coin loaded towards heads, the p-value is

$$p_{\text{one}} = \text{P}(n_h \ge 17 \,|\, p = \tfrac{1}{2}) \overset{(1)}{=} \frac{1}{2^{20}}\left[\binom{20}{17} + \binom{20}{18} + \binom{20}{19} + \binom{20}{20}\right] \overset{(2)}{=} \frac{1140 + 190 + 20 + 1}{1\,048\,576} = \frac{1351}{1\,048\,576} \approx 0.00129. \tag{4.5}$$

(1) Add the probabilities of the disjoint outcomes 17, 18, 19, 20 heads.
(2) $\binom{20}{17} = \binom{20}{3} = \frac{20\cdot19\cdot18}{6} = 1140$, $\binom{20}{18} = \binom{20}{2} = 190$, $\binom{20}{19} = 20$, $\binom{20}{20} = 1$.

If any bias counts, the outcomes at least as far from 10 as 17 are $n_h \in \{0,1,2,3\} \cup \{17,\dots,20\}$, that is $|n_h - 10| \geq 7$. The binomial with $p = \frac{1}{2}$ is symmetric, $\binom{20}{k} = \binom{20}{20-k}$, so the lower tail equals the upper one and

$$p_{\text{two}} = \mathrm{P}\big(|n_h - 10| \geq 7 \,|\, p = \tfrac{1}{2}\big) = 2\,p_{\text{one}} = \frac{2702}{1\,048\,576} \approx 0.0026,$$

the value 0.0026 of [Cowan p. 58]. Figure 4.6 shows the eight outcomes that enter. The two answers differ by a factor of two, and both are correct answers to different questions.

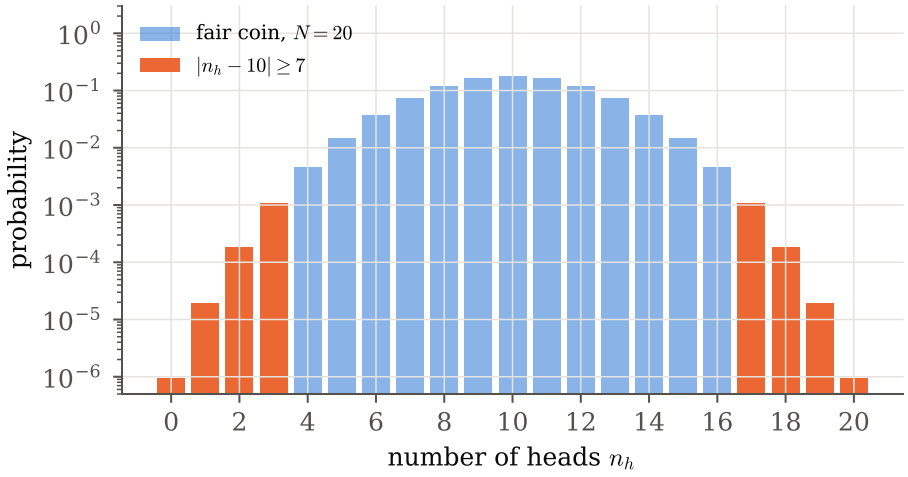

Figure 4.6: The binomial distribution of the number of heads in 20 tosses of a fair coin, on a logarithmic vertical scale so that the thin tails show. The orange bars are the outcomes at least as far from 10 as the observed 17, on either side. Their total is the two-sided p-value; the four bars on the right alone give the one-sided one.

A composite null. For a one-sided composite null, the p-value is the tail at the boundary of the null, so the composite test reduces to the simple test at θ_0. To see why, pose the one-sided coin question with the composite null $H_0 : p \leq \frac{1}{2}$, where p is now the probability of heads. The problem is that every p in Θ_0 gives a different tail probability $\mathrm{P}_p(n_h \geq 17)$. The rule [Wasserman Thm 10.12] is to report the largest of them, $\sup_{\theta\in\Theta_0} \mathrm{P}_\theta(T \geq t_{\text{obs}})$, so that the number is honest for every member of the null. The tail $\mathrm{P}_p(n_h \geq 17)$ grows with p, because a coin more inclined to heads gives more heads. So the largest tail is reached at the boundary $p = \frac{1}{2}$, and the answer is again 0.00129. The boundary value is the member of the null hardest to tell apart from the alternative.

When the null distribution is not symmetric. A skewed null needs a convention for its two-sided p-value. For the fair coin, "twice the one-sided tail" and "everything at least as far from the mean" agree. For a skewed null, such as a Poisson with small mean, they do not, and we must choose one of two rules: either double the smaller tail, or add the probabilities of all outcomes that are no more probable than the one observed. In searches for new physics the question is almost always one-sided anyway, because a signal can only add events.

Watch out: Choosing the side after seeing the data

The side is part of the question, so it must be chosen before looking at the data. Deciding on a one-sided test *because* the excess came out upwards halves the p-value without any new evidence. Under the null this procedure rejects whenever either tail holds α of the probability, so its true type I error rate is 2α, not α.

4.2.2 The same data, different p-values: the stopping rule

The same data can give different p-values, depending on how the experimenter decided when to stop. The reason is in what the p-value asks for: the probability of outcomes "like this or more extreme" in *repetitions of the experiment*. Those repetitions never happened. We imagine them, or, in the blunt words of [Lambert §2.8], to test a hypothesis we "invent fictitious samples". Lambert's example: if we hypothesise that heights are normal with mean 1.55 m and standard deviation 0.3 m and meet one person of 2.5 m, the p-value is the probability of meeting someone *at least* 2.5 m tall, although nobody taller was observed. To imagine the repetitions we must know the plan that produced the data, and the data alone do not tell us.

The data. [Kruschke §11.1] gives the example. A coin shows $z = 7$ heads in $N = 24$ tosses. Is it fair? We take two possible plans in turn.

Plan A: the number of tosses was fixed at $N = 24$. Then the random quantity is the number of heads z, it is Binomial$(24, \frac{1}{2})$ under the null, and few heads is the extreme direction:

$$p_A = \mathrm{P}(z \le 7 \,|\, N = 24) = \sum_{k=0}^{7} \binom{24}{k} 2^{-24} = 0.0320.$$

Plan B: the experimenter tossed until the seventh head. Now $z = 7$ is fixed by design and the random quantity is the number of tosses N it took. Needing *many* tosses to collect seven heads is the sign of a tail-heavy coin, so the extreme direction is $N \ge 24$. The event $\{N \ge 24\}$ is the same as "at most six heads in the first 23 tosses":

$$\begin{aligned} p_B = \mathrm{P}(N \ge 24 \,|\, z = 7) &\overset{(1)}{=} \mathrm{P}\big(\text{at most 6 heads in the first 23 tosses}\big) \\ &\overset{(2)}{=} \sum_{k=0}^{6} \binom{23}{k} 2^{-23} = 0.0173. \end{aligned} \tag{4.6}$$

(1) The seventh head arrives at toss 24 or later exactly when the first 23 tosses contain six heads or fewer.

(2) The first 23 tosses of a fair coin are Binomial$(23, \frac{1}{2})$, whatever happens afterwards.

The distribution of N itself is the negative binomial of Chapter 2: the n-th toss is the seventh head when it is a head and the previous $n - 1$ tosses hold exactly six heads, so $\mathrm{P}(N = n) = \binom{n-1}{6} 2^{-n}$. Figure 4.7 shows the two clouds of imaginary outcomes side by side.

What the two plans say. The very same sequence of tosses is "not significant" under one plan and "significant" under the other. With the conventional two-tailed threshold, which puts 2.5% in each tail, plan A gives $p_A = 0.0320$, above 0.025, and plan B gives $p_B = 0.0173$, below it. [Kruschke p. 309] adds two more plans. If the experimenter tossed for a fixed length of time, so that N itself is random (Poisson), the p-value is 0.024. If a second coin was tested in the same study and the question is whether *either* coin looks this extreme, the chance that at least one of two independent fixed-N experiments reaches the tail is $1 - (1 - p_A)^2 \approx 2p_A$, which is the 0.063 found there. The last case is our first taste of the look-elsewhere effect.

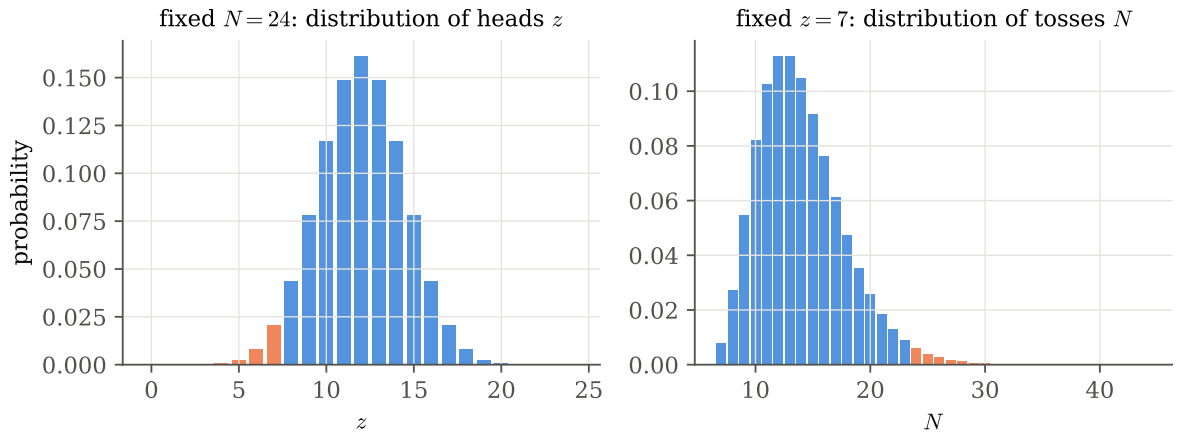

Figure 4.7: Two plans that can produce the same record of 7 heads in 24 tosses. Left: with $N = 24$ fixed, the random quantity is the number of heads, and its lower tail $z \le 7$ (orange) is the p-value. Right: when tossing stops at the seventh head, the random quantity is the number of tosses, and its upper tail $N \ge 24$ (orange) is the p-value. The observed data are identical; the imagined repetitions are not.

Example: Cowan's stopping rule. [Cowan p. 58] tells the same story with the 17 heads in 20 tosses. Suppose the plan was "toss until there are at least three heads and at least three tails", and the stopping happened at toss 20 (with 17 heads and 3 tails). Now the extreme outcomes are those that need 20 tosses or more:

$$\begin{aligned} \mathrm{P}(N_{\text{stop}} \ge 20) &\overset{(1)}{=} \mathrm{P}\big(\text{after 19 tosses, heads} \le 2 \text{ or tails} \le 2\big) \\ &\overset{(2)}{=} 2\,\mathrm{P}\big(\text{Binomial}(19, \tfrac{1}{2}) \le 2\big) \\ &\overset{(3)}{=} 2\,\frac{\binom{19}{0} + \binom{19}{1} + \binom{19}{2}}{2^{19}} = \frac{2\,(1 + 19 + 171)}{524\,288} \approx 7.286 \times 10^{-4}. \end{aligned} \tag{4.7}$$

(1) We are still tossing after toss 19 exactly when one of the two faces has appeared at most twice so far.
(2) The two events are disjoint (both at most 2 would mean at most 4 tosses, not 19), so their probabilities add, and by symmetry they are equal.
(3) Binomial sum with $\binom{19}{2} = 171$ and $2^{19} = 524\,288$.

That is 0.073% instead of the 0.26% of the fixed-N plan [Cowan p. 58]. Cowan's resolution is a convention: always interpret "similar experiments" as experiments with the same number of observations. It is arbitrary, but it makes a reported p-value unambiguous.

Python. The script `code/ch04/02_sides_and_stopping.py` evaluates every tail sum above with `scipy.stats.binom` and then checks each one by running the stated protocol many times.

Listing 4.2: Two stopping plans, and Cowan's rule, simulated (`code/ch04/02_sides_and_stopping.py`)

```
# ---------- (ii) 7 heads in 24 tosses, two stopping intentions ----------
N2, z2 = 24, 7
p_fixN = stats.binom.cdf(z2, N2, 0.5)                    # P(z <= 7 | N = 24)
# fixed z: stop at the 7th head.  "As extreme or more": needing N >= 24 tosses,
# i.e. at most 6 heads among the first 23 tosses.
p_fixz = stats.binom.cdf(z2 - 1, N2 - 1, 0.5)
# simulate the fixed-z protocol: number of tosses to get the 7th head = 7 + (tails before
    it)
```

```
Nstop = z2 + rng.negative_binomial(z2, 0.5, size=M)
p_fixz_mc = np.mean(Nstop >= N2)
p_fixN_mc = np.mean(rng.binomial(N2, 0.5, size=M) <= z2)

# ---------- (iii) Cowan: toss until >= 3 heads and >= 3 tails ----------
# needing >= 20 tosses <=> after 19 tosses, heads <= 2 or tails <= 2
p_cowan = 2 * stats.binom.cdf(2, 19, 0.5)
seqs = rng.integers(0, 2, size=(200_000, 60), dtype=np.int8)
h = np.cumsum(seqs, axis=1); t = np.arange(1, 61) - h
done = (h >= 3) & (t >= 3)
nstop = done.argmax(axis=1) + 1
p_cowan_mc = np.mean(nstop >= 20)
```

For plan B it uses the fact that the number of tails before the seventh head is a negative binomial variable, `rng.negative_binomial(7, 0.5)`, so the total number of tosses is seven plus that. For Cowan's rule it simply tosses: 200 000 sequences of 60 tosses, running totals of heads and tails with `np.cumsum`, and the first toss at which both totals reach three. The simulations give 0.0325, 0.0173 and 7.500×10^{-4} against the exact 0.0320, 0.0173 and 7.286×10^{-4}, and 0.0028 against 0.0026 for the two-sided coin test.

Key idea: A p-value depends on the outcomes that did not happen

A p-value is a sum over imaginary repetitions of the experiment. Which repetitions are imagined depends on the plan: the alternative we guard against (one or two sides), when the experimenter would have stopped, and how many other places or coins we would also have looked at. Change the plan and the p-value changes, even if the data do not.

A Bayesian analysis does not have this problem, because it uses only the probability of the data actually observed. In plan A that probability is $\binom{24}{7}p^7(1-p)^{17}$ and in plan B it is $\binom{23}{6}p^7(1-p)^{17}$. As functions of the coin's bias p, the two likelihoods differ only by a constant factor, which cancels in Bayes' theorem. Any inference built from the likelihood alone therefore reaches the same conclusion under both plans [Kruschke §11.1.7]. The p-value, which sums over outcomes that were not observed, does not. We take this up in Chapter 5. For now the practical rule is Cowan's: fix the plan in advance, state it, and compute the p-value for that plan.

4.3 Two ways to be wrong: size, power and how much data we need

A p-value tells us how surprising one data set is. Before the experiment runs, we face a different pair of questions. How often will our procedure cry "discovery" when there is nothing there? And if there *is* something there, of a given size, how often will we catch it? The first number protects the field from false claims. The second tells us whether the experiment is worth building. A detector that can only see a signal one time in ten is a bad investment, however careful the analysis.

[Wasserman p. 150] offers the legal trial as a model. The defendant is presumed innocent, the null, and is convicted only if the evidence is strong. Two mistakes are possible: convicting an innocent person, and acquitting a guilty one. A court that never convicts makes no mistakes of the first kind, and is useless. There is a trade-off, and it can be put into numbers.

The question in words.

1. If the null is true, what is the probability that the test rejects it?
2. If a particular alternative is true, what is the probability that the test rejects the null?

3. How do both depend on the critical value and on the amount of data, and how large must an experiment be to catch an effect of a given size?

4.3.1 Type I and type II errors

Every test ends in one of four situations [Wasserman Table 10.1]:

	retain H_0	reject H_0
H_0 true	correct	**type I error** (false alarm)
H_1 true	**type II error** (missed signal)	correct

Cowan calls them errors of the first and second kind [Cowan §4.1]. Picture the test statistic t with its two sampling distributions, $g(t \mid H_0)$ and $g(t \mid H_1)$, and a cut t_{cut} above which we reject (Figure 4.8). The probability of a type I error is the area of the null distribution above the cut, and the probability of a type II error is the area of the alternative below it [Cowan (4.1)–(4.2)]:

$$\alpha = \int_{t_{\text{cut}}}^{\infty} g(t \mid H_0)\, \mathrm{d}t, \qquad \beta_{\text{II}} = \int_{-\infty}^{t_{\text{cut}}} g(t \mid H_1)\, \mathrm{d}t. \tag{4.8}$$

Moving the cut to the right shrinks α and grows β_{II}; moving it left does the opposite. With a fixed statistic and a fixed amount of data we cannot shrink both. Only a better statistic (Section 4.6) or more data separates the two curves.

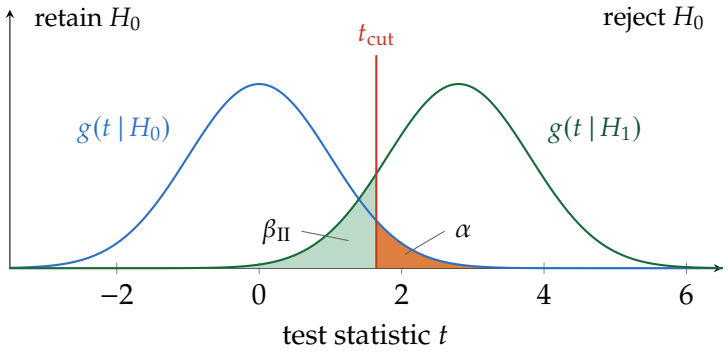

Figure 4.8: The trade-off behind every test. Blue: the distribution of the statistic when the null is true; green: when a particular alternative is true. Everything right of the red cut is rejected. The orange sliver is the probability of a false alarm, α; the pale green region is the probability of missing the signal, β_{II}. Sliding the cut trades one for the other.

4.3.2 The power function

The alternative is rarely a single value, so we want the rejection probability as a function of the true parameter.

Working definition 4.2 (power function, size, level)

The **power function** of a test with rejection region R is

$$\beta(\theta) = \mathrm{P}_\theta(\boldsymbol{X} \in R)$$

[the probability of rejecting H_0 when the true parameter is θ]. For $\theta \in \Theta_1$ it is the probability of a correct rejection; for $\theta \in \Theta_0$ it is a false-alarm rate. The **size** is the

worst false-alarm rate, $\alpha = \sup_{\theta\in\Theta_0}\beta(\theta)$, and a test has **level** α if its size is at most α [Wasserman Def. 10.1]. Operationally: simulate data at each θ and record the fraction of data sets that the test rejects.

A notational trap: Wasserman uses $\beta(\theta)$ for the power, while [Cowan (4.2)] uses β for the type II error probability, so that Cowan's power is $1-\beta$. Here we use Wasserman's convention and write the type II error probability at a point $\theta_1 \in \Theta_1$ as $\beta_{\text{II}} = 1-\beta(\theta_1)$.

Example: the one-sided test for a Gaussian mean. We take n readings $X_1,\dots,X_n \overset{\text{iid}}{\sim} \mathcal{N}(\mu,\sigma^2)$ with σ known and test $H_0 : \mu \le 0$ against $H_1 : \mu > 0$ by rejecting when the sample mean $\bar X$ exceeds a cut c [Wasserman Ex. 10.2]. Recall from Chapter 3 that $\bar X \sim \mathcal{N}(\mu,\sigma^2/n)$, so $Z = \sqrt{n}(\bar X-\mu)/\sigma$ is standard normal. The power function is

$$\begin{aligned}\beta(\mu) &\overset{(1)}{=} \mathrm{P}_\mu\big(\bar X > c\big)\\ &\overset{(2)}{=} \mathrm{P}_\mu\Big(\frac{\sqrt{n}(\bar X-\mu)}{\sigma} > \frac{\sqrt{n}(c-\mu)}{\sigma}\Big)\\ &\overset{(3)}{=} \mathrm{P}\Big(Z > \frac{\sqrt{n}(c-\mu)}{\sigma}\Big)\\ &\overset{(4)}{=} 1-\Phi\Big(\frac{\sqrt{n}(c-\mu)}{\sigma}\Big).\end{aligned} \tag{4.9}$$

(1) Definition of the power function with $R = \{\bar X > c\}$.
(2) Subtract μ and multiply by $\sqrt{n}/\sigma > 0$ on both sides; this does not change the event.
(3) The left-hand side is standard normal whatever μ is.
(4) Φ is the standard normal CDF, $\Phi(z) = \mathrm{P}(Z \le z)$.

As μ increases the argument of Φ decreases, so $\beta(\mu)$ increases. The largest false-alarm rate over the null region $\mu \le 0$ is therefore at the boundary:

$$\alpha = \sup_{\mu\le 0}\beta(\mu) = \beta(0) = 1-\Phi\Big(\frac{\sqrt{n}\,c}{\sigma}\Big) \quad\Longrightarrow\quad c = \frac{\sigma\, z_\alpha}{\sqrt{n}}, \qquad z_\alpha \equiv \Phi^{-1}(1-\alpha).$$

So the size-α test rejects when $\sqrt{n}\,\bar X/\sigma > z_\alpha$: the sample mean, measured in units of its own standard deviation, must exceed $z_{0.05} = 1.645$ for $\alpha = 0.05$.

Figure 4.9 (left) plots (4.9) for $n = 4$, 16 and 64 with $\sigma = 1$, together with simulated rejection rates. All three curves pass through $\alpha = 0.05$ at $\mu = 0$: the size does not depend on n, because the cut moves in as $1/\sqrt{n}$. What depends on n is the steepness. Quadrupling the data halves the width of $\bar X$'s distribution, so the curve rises over half the range of μ. In the simulation the rate of false alarms at $\mu = 0$ is 0.0508 for $n = 4$ and 0.0518 for $n = 64$, both equal to 0.05 within the simulation error $\sqrt{0.05\times 0.95/20\,000} \approx 0.0015$.

Example: how many readings do we need? Suppose we want power 0.8 at $\mu_1 = 0.5\sigma$, with $\alpha = 0.05$. Setting (4.9) equal to 0.8 at $\mu = \mu_1$, with $c = \sigma z_\alpha/\sqrt{n}$,

$$\begin{aligned}0.8 &\overset{(1)}{=} 1-\Phi\Big(z_\alpha - \frac{\sqrt{n}\,\mu_1}{\sigma}\Big) \overset{(2)}{=} \Phi\Big(\frac{\sqrt{n}\,\mu_1}{\sigma} - z_\alpha\Big)\\ &\Longrightarrow \frac{\sqrt{n}\,\mu_1}{\sigma} - z_\alpha \overset{(3)}{=} z_{0.2} \Longrightarrow n \overset{(4)}{=} \Big(\frac{(z_\alpha + z_{0.2})\,\sigma}{\mu_1}\Big)^2 = \Big(\frac{1.645+0.842}{0.5}\Big)^2 \approx 24.7.\end{aligned} \tag{4.10}$$

(1) Insert $c = \sigma z_\alpha/\sqrt{n}$ into $\sqrt{n}(c-\mu_1)/\sigma$.

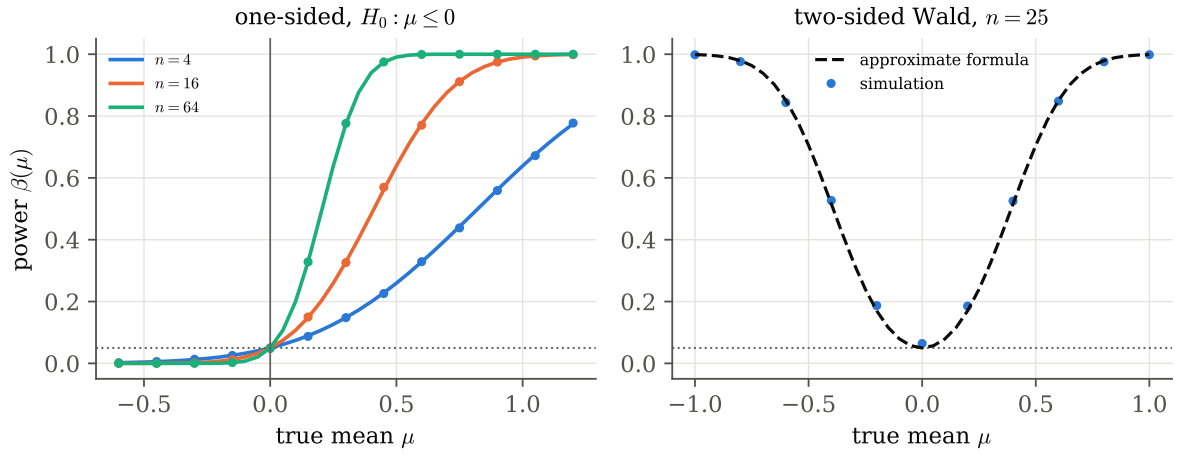

Figure 4.9: Power functions. Left: the one-sided test of $\mu \le 0$ for three sample sizes, with the formula as lines and simulated rejection rates as dots. Every curve crosses the dotted $\alpha = 0.05$ line at $\mu = 0$ and climbs faster the more data there are. Right: the two-sided Wald test with $n = 25$ and an estimated standard error; the dashed curve is the approximate formula and the dots are simulations. The curve is symmetric and bottoms out near α at $\mu = 0$.

(2) The normal CDF is symmetric: $1 - \Phi(x) = \Phi(-x)$.
(3) Apply Φ^{-1}; $\Phi^{-1}(0.8) = z_{0.2} = 0.842$ in the notation $z_a = \Phi^{-1}(1-a)$.
(4) Solve for n.

We need $n = 25$ readings, and the simulation with $n = 25$ rejects in a fraction 0.801 of experiments at $\mu = 0.5$. The formula says what experiment planning comes down to: the required number of readings grows as $1/\mu_1^2$, so detecting an effect half as large costs four times as much data. [Kruschke §11.5.1] makes the same point: planning an experiment is where sampling distributions are most useful.

Example: the power of the two-sided Wald test. Most tests are two-sided and use an estimate $\hat\theta$ with standard error $\widehat{\text{se}}$; the Wald test of Section 4.5 rejects $H_0 : \theta = \theta_0$ when $\left|\hat\theta - \theta_0\right| / \widehat{\text{se}} > z_{\alpha/2}$. Suppose the truth is $\theta_\star \neq \theta_0$ and $\hat\theta$ is approximately $\mathcal{N}(\theta_\star, \text{se}^2)$, so that $Z = (\hat\theta - \theta_\star)/\text{se}$ is approximately standard normal. Write $\delta = (\theta_0 - \theta_\star)/\text{se}$. Then

$$\begin{aligned}\beta(\theta_\star) &\overset{(1)}{=} \mathrm{P}_{\theta_\star}\Big(\frac{\hat\theta - \theta_0}{\text{se}} > z_{\alpha/2}\Big) + \mathrm{P}_{\theta_\star}\Big(\frac{\hat\theta - \theta_0}{\text{se}} < -z_{\alpha/2}\Big) \\ &\overset{(2)}{=} \mathrm{P}\big(Z > \delta + z_{\alpha/2}\big) + \mathrm{P}\big(Z < \delta - z_{\alpha/2}\big) \\ &\overset{(3)}{=} 1 - \Phi\Big(\frac{\theta_0 - \theta_\star}{\text{se}} + z_{\alpha/2}\Big) + \Phi\Big(\frac{\theta_0 - \theta_\star}{\text{se}} - z_{\alpha/2}\Big). \end{aligned} \tag{4.11}$$

(1) The two-sided rejection region is the union of two disjoint tails.
(2) $\hat\theta - \theta_0 = (\hat\theta - \theta_\star) + (\theta_\star - \theta_0)$, so dividing by se gives $Z - \delta$; move δ across.
(3) Write both tails with the normal CDF.

This is [Wasserman (10.6)]. Since se shrinks as $1/\sqrt{n}$, the argument δ grows, and one of the two terms tends to one: the power is large when $\theta_\star$ is far from θ_0 or when the sample is large [Wasserman p. 154]. In the right panel of Figure 4.9 the simulation follows the formula. At $\mu = 0$ it rejects in a fraction 0.0643 of experiments, a little above 0.05, because the standard error was estimated from only 25 readings. Section 4.5 explains that excess and removes it.

4.3.3 The power of a counting experiment

Return to a search like the bump: a window with known background $b = 3.2$ and an unknown signal $s \geq 0$, so that $N \sim \text{Pois}(s + b)$. Particle physics sets thresholds not as $\alpha = 0.05$ but as "3σ" and "5σ", meaning one-sided tail probabilities 0.00135 and 2.867×10^{-7} (Section 4.9 explains the translation). The test rejects when $N \geq n_{\text{crit}}$, where n_{crit} is the smallest count whose null tail is below the threshold:

$$n_{\text{crit}} = \min\{n : \mathrm{P}(N \geq n \mid s = 0) \leq p_{\text{thr}}\}, \qquad \beta(s) = \mathrm{P}(N \geq n_{\text{crit}} \mid s) = 1 - \sum_{k=0}^{n_{\text{crit}}-1} \frac{(s+b)^k e^{-(s+b)}}{k!}. \tag{4.12}$$

The first formula is the null tail (4.4) scanned in n. The second is the same tail sum evaluated with the signal switched on, because the power is the rejection probability under the alternative.

Example: 3σ and 5σ with $b = 3.2$. The script finds $n_{\text{crit}} = 11$ for 3σ and $n_{\text{crit}} = 17$ for 5σ. So Cowan's 11 events on 3.2 (Section 4.1.4) just reach 3σ. Figure 4.10 shows the power as a function of s. A signal of about 7.6 events is needed to cross 3σ half of the time, and about 13.6 to cross 5σ half of the time. With $s = 20$ the 5σ test fires with probability 0.924, and a direct simulation of 20 000 experiments gives 0.925.

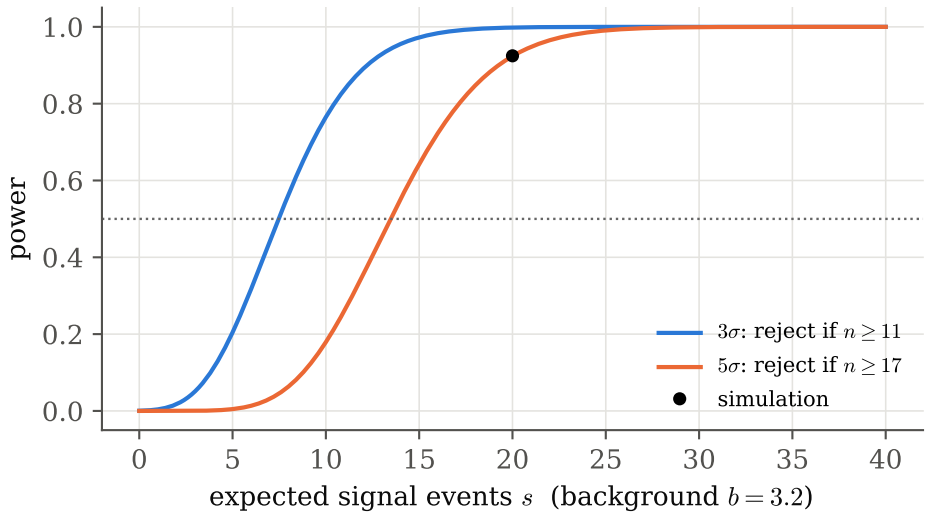

Figure 4.10: Power of a counting experiment with background $b = 3.2$, for the 3σ and the 5σ thresholds. Each curve rises from nearly zero to one as the expected signal grows. The dotted line marks power one half, and the black dot is a direct simulation at $s = 20$.

With discrete data a test usually has level α without having size exactly α: its false-alarm rate is below the target, and we call it *conservative*. The reason is that N takes only integer values, so the rejection probability under the null jumps as the cut moves from one integer to the next. For example, the size of the test "reject if $N \geq 11$" is $\mathrm{P}(N \geq 11 \mid b = 3.2) = 4.972 \times 10^{-4}$, smaller than the 3σ target 0.00135, and the next lower cut, $N \geq 10$, would overshoot it.

Listing 4.3: Critical count and power of a Poisson counting experiment (`code/ch04/03_power_curves.py`)

```
# ---------- (iii) counting experiment b = 3.2 ----------
b = 3.2
def n_crit(p_thr):
    """smallest n with P(N >= n | b) <= p_thr"""
    n = 0
```

```
    while stats.poisson.sf(n - 1, b) > p_thr:
        n += 1
    return n
p3, p5 = stats.norm.sf(3), stats.norm.sf(5)
n3, n5 = n_crit(p3), n_crit(p5)
s = np.linspace(0, 40, 201)
pow3 = stats.poisson.sf(n3 - 1, b + s)
pow5 = stats.poisson.sf(n5 - 1, b + s)
s50_3 = s[np.argmax(pow3 >= 0.5)]
s50_5 = s[np.argmax(pow5 >= 0.5)]
s_chk = 20.0
```

The helper `n_crit` steps n upward until the null tail `stats.poisson.sf(n - 1, b)` drops below the threshold, which is (4.12) read literally. The power curves are then the same survival function with mean `b + s`. Nothing here needs an approximation, which makes the counting experiment the best place to build intuition about power before we meet statistics whose distributions must be simulated.

Statistically significant is not the same as important. The power function of a consistent test climbs to one for *every* $\theta \in \Theta_1$ as $n \to \infty$, however close θ is to θ_0. With enough data, an effect too small to matter will be declared significant. [Wasserman p. 155] calls this the gap between statistical and scientific significance: a rejection says the effect is probably not zero, not that it is large. A confidence interval shows both at once, the distance from θ_0 and the precision, and is often the more informative report. Every test can be turned into a confidence interval, a construction taken up in the second part of the chapter.

4.4 The p-value is a random variable

A p-value changes from one repetition of an experiment to the next. Imagine a thousand groups, each running the same background-only experiment and each computing a p-value. They will not get the same number. The data fluctuate, so the test statistic fluctuates, so the p-value fluctuates [Cowan p. 58]. The p-value is therefore a random variable with its own distribution. That distribution is what gives "reject if $p < \alpha$" a known false-alarm rate. It also shows, more clearly than any argument in words, why a p-value is not the probability that the null is true.

The question in words.

1. How is the p-value related to the rejection regions of Section 4.3?
2. If the null is true, how are p-values distributed? If it is false?
3. In a collection of experiments where some nulls are true and some false, what fraction of the "significant" results are false alarms?

4.4.1 The smallest level at which we would reject

Suppose that for every $\alpha \in (0, 1)$ we have a size-α test, with rejection region $R_\alpha = \{T \geq c_\alpha\}$. A smaller α means a stricter test, a larger c_α and a smaller region, so the regions are nested. For our data, some of these tests reject and some do not, and there is a smallest level at which the test still rejects. [Wasserman Def. 10.11] takes that as the definition,

$$p = \inf\{\alpha : T(\boldsymbol{x}) \in R_\alpha\},$$

and [Wasserman Thm 10.12] shows that it is the same tail probability as before. For a simple null the argument is short. The observed value t_{obs} is on the boundary of the region exactly when $c_\alpha = t_{\text{obs}}$, and the size of that region is $\mathrm{P}_{\theta_0}(T \geq t_{\text{obs}})$. Any smaller α puts the cut above t_{obs} and retains; any larger one rejects. So

$$\text{reject at level } \alpha \quad \Longleftrightarrow \quad p \leq \alpha. \tag{4.13}$$

This is why a p-value is more useful than a bare "reject": every reader can apply their own α. For a composite null the tail probability depends on which $\theta \in \Theta_0$ is true, and the definition takes the worst case, $p = \sup_{\theta \in \Theta_0} \mathrm{P}_\theta(T \geq t_{\text{obs}})$, as we already did for the coin in Section 4.2.1.

A widely used vocabulary for p-values [Wasserman p. 157]:

p-value	evidence against H_0
< 0.01	very strong
0.01–0.05	strong
0.05–0.10	weak
> 0.10	little or none

Particle physicists would call $p = 0.01$ an unremarkable fluctuation, for reasons we come to in Section 4.9. The scale is a convention, and conventions differ between fields.

4.4.2 Under the null, p is uniform

Let T have a continuous distribution under H_0, with cumulative distribution function $F_0(t) = \mathrm{P}_{\theta_0}(T \leq t)$, increasing and continuous. For an observed value t, the p-value is the upper tail, $p = 1 - F_0(t)$. Now let the data be random, so that the p-value is the random variable $P = 1 - F_0(T)$. For any $u \in (0, 1)$,

$$\begin{aligned} \mathrm{P}_{\theta_0}(P \leq u) &\overset{(1)}{=} \mathrm{P}_{\theta_0}\big(1 - F_0(T) \leq u\big) \\ &\overset{(2)}{=} \mathrm{P}_{\theta_0}\big(F_0(T) \geq 1 - u\big) \\ &\overset{(3)}{=} \mathrm{P}_{\theta_0}\big(T \geq F_0^{-1}(1-u)\big) \\ &\overset{(4)}{=} 1 - F_0\big(F_0^{-1}(1-u)\big) \\ &\overset{(5)}{=} u. \end{aligned} \tag{4.14}$$

(1) Definition of P.
(2) Rearrange the inequality.
(3) F_0 is increasing, so applying F_0^{-1} to both sides keeps the direction of the inequality.
(4) $\mathrm{P}(T \geq a) = 1 - F_0(a)$ for a continuous variable, since $\mathrm{P}(T = a) = 0$.
(5) F_0 undoes F_0^{-1}.

A variable with $\mathrm{P}(P \leq u) = u$ for all u is uniform on $(0, 1)$ [Wasserman Thm 10.14]. The fact behind it is the **probability integral transform** [feeding a continuous random variable into its own CDF gives a uniform variable]. Run backwards, the same fact turns uniform random numbers into any distribution we like, by inversion (Chapter 6 uses it to simulate). Put together with (4.13), which says "reject at level α" is the same as "$p \leq \alpha$", it gives a test whose false-alarm probability is exactly α. So when nothing is there, a p-value is just a uniform random number. Values below 0.3 occur 30% of the time and values below 0.03 occur 3% of the time: both are things that happen, one ten times more often than the other.

When the alternative is true, the statistic tends to be larger, the tail beyond it smaller, and the p-values pile up near zero. How strongly they pile up is the power: by (4.13), $\mathrm{P}_\theta(P \leq \alpha) = \beta(\theta)$.

Example: p-values from Gaussian readings. Take $n = 10$ readings of $\mathcal{N}(\mu, 1)$ and the one-sided test of $\mu = 0$, with $p = 1 - \Phi(\sqrt{n}\,\bar{x})$. The script `code/ch04/04_pvalue_uniform.py` computes 200 000 such p-values for each of three true means. The left panel of Figure 4.11 shows the histograms. At $\mu = 0$ the histogram is flat, a fraction 0.0494 of the p-values fall below 0.05, and a Kolmogorov–Smirnov test of uniformity (Section 4.8.4) returns $p = 0.72$, no evidence against flatness. At $\mu = 0.3$ a fraction 0.242 fall below 0.05, and at $\mu = 0.8$ a fraction 0.813: these are the powers of the test at those means.

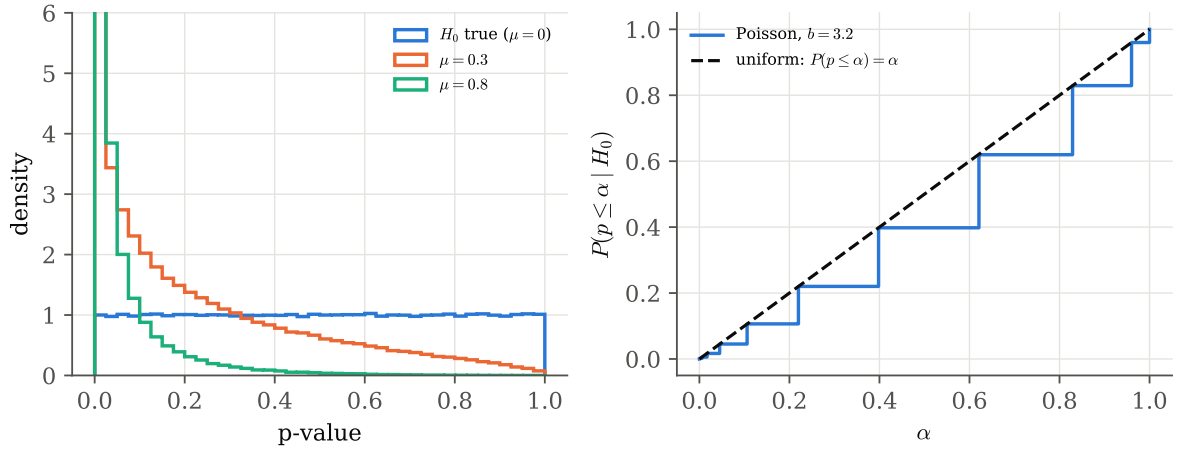

Figure 4.11: Left: histograms of p-values from many repetitions of the same experiment. With the null true (blue) the histogram is flat; with a real effect (orange, green) the p-values crowd towards zero, more so for the larger effect. Right: for Poisson counts with $b = 3.2$ the p-value takes only a few values, so its cumulative distribution is a staircase. The staircase touches the diagonal at its corners and otherwise stays below it, so "reject if $p \le \alpha$" never rejects more often than α.

4.4.3 Discrete data: valid, not uniform

For a count the argument breaks at step (4) of (4.14), because $\mathrm{P}(T = a)$ is no longer zero. The p-value can only take the values $\pi(n) = \mathrm{P}_0(N \ge n)$ for integer n, so it cannot be uniform. What survives is the inequality that matters for error control, the definition of a **valid p-value** [one that is at most α with probability at most α under the null, for every α] [CasellaBerger Def. 8.3.26]:

$$\mathrm{P}_\theta(P \le u) \le u \qquad \text{for every } \theta \in \Theta_0 \text{ and every } u \in [0, 1].$$

For a Poisson count the proof takes one line. The tail $\pi(n)$ decreases as n grows. Let n_u be the smallest integer with $\pi(n_u) \le u$. Then

$$\mathrm{P}_0(P \le u) \overset{(1)}{=} \mathrm{P}_0\big(\pi(N) \le u\big) \overset{(2)}{=} \mathrm{P}_0(N \ge n_u) \overset{(3)}{=} \pi(n_u) \overset{(4)}{\le} u. \tag{4.15}$$

(1) The p-value of an observed count N is $\pi(N)$.
(2) Because π is decreasing, $\pi(N) \le u$ holds exactly when $N \ge n_u$.
(3) Definition of π.
(4) Definition of n_u.

Equality holds only when u happens to be one of the attainable values $\pi(n)$, which are the corners of the staircase in the right panel of Figure 4.11. With $b = 3.2$ the simulated fraction of null experiments with $p \le 0.05$ is 0.0453, below 0.05. For a composite null, the supremum over Θ_0 in the definition of p keeps it valid for every member of the null [CasellaBerger Thm 8.3.27].

A large p-value is not evidence for the null. A large p can arise because H_0 is true, or because H_0 is false and the test has too little power to notice [Wasserman p. 157]. In the example above, at $\mu = 0.3$ three quarters of the p-values exceed 0.05 although the null is false. Failing to reject says "these data cannot tell". Testing is built to find evidence *against* a null, not to prove one [Wasserman p. 161].

4.4.4 What a p-value is not

The most common misreading of a p-value is "$p = 0.04$, so there is a 4% chance that the null is true". [Wasserman p. 157] and [Cowan p. 58] both warn against it. The two numbers answer questions in opposite directions:

$$p = \mathrm{P}\big(\text{data this extreme or more} \,|\, H_0\big) \qquad \text{versus} \qquad \mathrm{P}\big(H_0 \,|\, \text{data}\big).$$

The first is a prediction from the null; the second is an inference about it. Turning one into the other takes Bayes' theorem, and Bayes' theorem needs a number the p-value never uses: how often the null is true before we look. A simulation makes the difference concrete.

Example: a population of experiments. *The setting.* Picture a field in which 90% of the hypotheses people test are really null, $\pi_0 = 0.9$. The other 10% have an effect $\mu = 0.5$ in the same experiment as above: $n = 10$ Gaussian readings of unit variance, tested one-sided against $\mu = 0$. We simulate 10^6 experiments, each picking null or effect at random with these frequencies, and compute every p-value.

The question. Among the "significant" experiments, those with $p < 0.05$, what fraction had a true null?

The two routes to a significant result. A result can be significant because the null is true and chance gave a small p, which happens with probability 0.05 by uniformity. Or it can be significant because there is an effect and the test caught it, which happens with probability equal to the power at $\mu = 0.5$, 0.473.

Only then the numbers. Weighting each route by how often it is taken, Bayes' theorem gives

$$\begin{aligned} \mathrm{P}(H_0 \,|\, p < 0.05) &\overset{(1)}{=} \frac{\mathrm{P}(p < 0.05 \,|\, H_0)\,\pi_0}{\mathrm{P}(p < 0.05 \,|\, H_0)\,\pi_0 + \mathrm{P}(p < 0.05 \,|\, H_1)\,(1-\pi_0)} \\ &\overset{(2)}{=} \frac{0.05 \times 0.9}{0.05 \times 0.9 + 0.473 \times 0.1} \approx 0.487. \end{aligned} \tag{4.16}$$

(1) Bayes' theorem with the two hypotheses as the branches of a probability tree: first choose null or effect, then the p-value.

(2) Under the null P is uniform, so $\mathrm{P}(P < 0.05) = 0.05$; under the effect it is the power.

Almost half of the significant results are false alarms; the simulation counts a fraction 0.489. Now narrow the selection to results that only just made it, $0.04 < p < 0.05$. Under the null this band has probability 0.01 (uniformity again), and under the effect it has a probability we compute from (4.9). The same formula gives 0.682, and the simulation 0.681: two thirds of the barely significant results come from true nulls, while each of them reports "$p < 0.05$". Figure 4.12 shows why: the flat carpet of null p-values is ten times more populous than the effect experiments, and near $p = 0.05$ the carpet dominates.

Listing 4.4: A population of experiments: how many significant results are false alarms? (`code/ch04/04_pvalue_uniform.py`)

```
# ---------- (iii) a population of experiments ----------
```

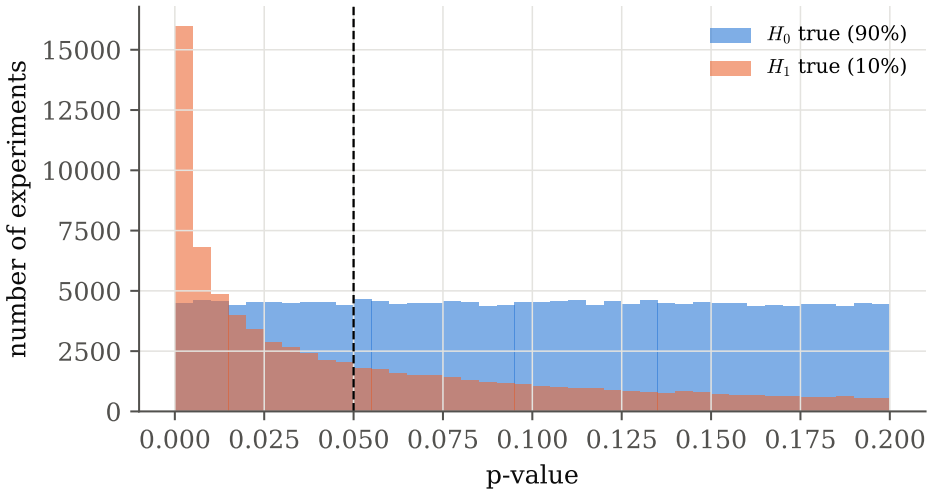

Figure 4.12: p-values from a population of experiments in which 90% of the nulls are true. The blue histogram (true nulls) is flat; the orange one (real effects) rises towards zero. Left of the dashed line at $p = 0.05$ both contribute, and just left of it the flat blue carpet is the larger.

```
pi0 = 0.9                                                    # fraction of experiments
    where H0 is true
mu_eff = 0.5                                                 # effect size when H0 is
    false
Mpop = 1_000_000
is_null = rng.random(Mpop) < pi0
mu = np.where(is_null, 0.0, mu_eff)
pp = stats.norm.sf(np.sqrt(n) * rng.normal(mu, sigma / np.sqrt(n)) / sigma)
power = np.mean(pp[~is_null] < 0.05)
sig = pp < 0.05
frac_null_sig = np.mean(is_null[sig])
band = (pp > 0.04) & (pp < 0.05)
frac_null_band = np.mean(is_null[band])
# the same, analytically: P(H0 | p in band) = pi0 P(band|H0) / [pi0 P(band|H0) + (1-pi0)
    P(band|H1)]
zlo, zhi = stats.norm.isf(0.05), stats.norm.isf(0.04)
d = np.sqrt(n) * mu_eff / sigma
PbandH1 = stats.norm.cdf(zhi - d) - stats.norm.cdf(zlo - d)
frac_null_band_th = pi0 * 0.01 / (pi0 * 0.01 + (1 - pi0) * PbandH1)
frac_null_sig_th = pi0 * 0.05 / (pi0 * 0.05 + (1 - pi0) * stats.norm.sf(zlo - d))
```

The code draws one Boolean per experiment, `is_null`, with probability π_0, and sets the true mean to 0 or 0.5 accordingly. It draws the sample mean directly from $\mathcal{N}(\mu, \sigma^2/n)$, which is its exact distribution, converts it to a p-value, and then simply counts: among the experiments with `pp < 0.05`, what fraction have `is_null`? The analytic lines below are (4.16) and its narrow-band version.

Watch out: p is not $\mathrm{P}(H_0 \mid \text{data})$

The p-value is computed assuming the null is true, so it cannot be the probability that the null is true. The fraction of significant results that are false alarms depends on the power and on how often nulls are true in the first place, neither of which enters p. In the example, $p < 0.05$ went with a 0.489 chance of a true null, and $0.04 < p < 0.05$ with a 0.681 chance. The inference direction is the subject of Chapter 5.

This does not make p-values useless. It makes them one ingredient. A small p-value says

the data are hard to produce by chance alone; whether that makes the alternative probable depends on how plausible it was to begin with. That is the logic behind the 5σ convention of Section 4.9, and it is exactly the prior-times-likelihood structure of Bayes' theorem.

4.5 Three workhorse tests: Wald, Student's t and permutation

A calorimeter is calibrated twice, a week apart, on the 661.7 keV gamma line of ^{137}Cs. The first run records 12 reconstructed peak positions, the second 15. The second run's mean is higher. Did the energy scale drift, or is this the scatter we expect from a detector with a resolution of a few keV? Situations like this, comparing two samples or comparing an estimate with a reference value, are the everyday business of testing. Most tests for them are one of three kinds.

1. The *Wald test*: divide the estimate's distance from the null value by its estimated standard error and compare with a normal distribution. It works for any estimator that is approximately normal.
2. The *t-test*: the same ratio, with the exact distribution that accounts for having estimated the standard error from few Gaussian readings.
3. The *permutation test*: no distributional assumption at all; the null distribution is built by shuffling the labels of the data.

Most powerful tests in the sense of Section 4.6 often do not exist for composite hypotheses, so these general-purpose tests carry most of the load [Wasserman p. 152].

4.5.1 The Wald test

Let $\hat\theta$ be an estimate of a scalar parameter θ with estimated standard error $\widehat{\mathrm{se}}$, and suppose $\hat\theta$ is approximately normal, as maximum-likelihood estimators are for large samples (Chapter 3). To test $H_0 : \theta = \theta_0$ against $H_1 : \theta \neq \theta_0$ we measure the distance in standard errors,

$$W = \frac{\hat\theta - \theta_0}{\widehat{\mathrm{se}}}, \qquad \text{reject } H_0 \text{ when } |W| > z_{\alpha/2} \tag{4.17}$$

[Wasserman Def. 10.3]. Under the null, W is approximately standard normal, so

$$\mathrm{P}_{\theta_0}\big(|W| > z_{\alpha/2}\big) \longrightarrow \mathrm{P}\big(|Z| > z_{\alpha/2}\big) = \alpha \qquad (n \to \infty), \tag{4.18}$$

which is [Wasserman Thm 10.4]: the Wald test has size α asymptotically. The p-value of an observed w is the two-sided normal tail [Wasserman (10.7)]:

$$p = \mathrm{P}_{\theta_0}\big(|W| > |w|\big) \approx \mathrm{P}\big(|Z| > |w|\big) = 2\Phi(-|w|). \tag{4.19}$$

The standard error may also be computed at the null value, se_0, in place of the estimate; both versions are valid [Wasserman Remark 10.5]. For a binomial proportion $\hat p$ tested against p_0, for instance, one may use $\mathrm{se}_0 = \sqrt{p_0(1-p_0)/n}$, which needs no estimate at all.

Example: comparing two means. Two independent samples $X_1, \dots, X_m$ and $Y_1, \dots, Y_n$ have means μ_1, μ_2. The null is $\delta = \mu_1 - \mu_2 = 0$, the estimate is $\hat\delta = \bar X - \bar Y$, and because the samples are independent the variances add [Wasserman Ex. 10.8]:

$$\widehat{\mathrm{se}} = \sqrt{\frac{s_1^2}{m} + \frac{s_2^2}{n}}, \qquad W = \frac{\bar X - \bar Y}{\sqrt{s_1^2/m + s_2^2/n}}, \tag{4.20}$$

with s_1^2, s_2^2 the two sample variances. In Wasserman's cholesterol data [Wasserman Ex. 10.15] the two group means are 216.2 and 195.3 with standard errors 5 and 2.4, so $W = (216.2 - 195.3)/\sqrt{5^2 + 2.4^2} = 20.9/5.55 \approx 3.78$ and $p = 2\Phi(-3.78) = 0.00016$, the quoted 0.0002. The same recipe works for medians, with the standard error of the difference of sample medians taken from the bootstrap of Chapter 3 [Wasserman Ex. 10.9]; there $W = 2.4$ and $p = 0.02$.

Example: two classifiers, and paired data. [Wasserman Ex. 10.7] compares two prediction algorithms, and the same logic compares two event classifiers. If each is run on its own test set, of sizes m and n, the error counts are independent binomials and (4.20) applies with $s_i^2 = \hat{p}_i(1 - \hat{p}_i)$. If both run on the *same* test set, the two error rates are correlated and the variances no longer add. The fix is to test the per-event difference: let $X_i = 1$ if the first classifier is right on event i, Y_i likewise for the second, and $D_i = X_i - Y_i$. Then $\hat{\delta} = \bar{D}$, $\widehat{\text{se}} = S_D/\sqrt{n}$ with S_D the sample standard deviation of the D_i, and $W = \bar{D}/\widehat{\text{se}}$. This **paired comparison** removes the event-to-event variation that both classifiers share, which is usually most of it.

4.5.2 Small samples: Student's t

The Wald test's guarantee is asymptotic. With few readings, the estimated standard error is itself noisy, and a too-small $\widehat{\text{se}}$ inflates $|W|$. We can see how badly by simulation: draw n readings from $\mathcal{N}(0,1)$, so the null $\mu = 0$ is true, compute $T = \sqrt{n}\,\bar{X}/S$ with S the sample standard deviation, and count how often $|T| > 1.96$. Figure 4.13 shows the answer: the false-alarm rate is 0.190 at $n = 3$, 0.122 at $n = 5$, 0.081 at $n = 10$ and 0.059 at $n = 30$, instead of 0.05.

For Gaussian data the exact distribution of T is known. Write

$$T = \frac{\sqrt{n}(\bar{X} - \mu_0)}{S} \overset{(1)}{=} \frac{\sqrt{n}(\bar{X} - \mu_0)/\sigma}{S/\sigma} \overset{(2)}{=} \frac{Z}{\sqrt{V/(n-1)}}, \qquad Z \sim \mathcal{N}(0,1), \quad V = \frac{(n-1)S^2}{\sigma^2} \sim \chi^2_{n-1}. \tag{4.21}$$

(1) Divide numerator and denominator by the unknown σ; the ratio is unchanged, so T does not depend on σ.

(2) Under the null the numerator is standard normal. In the denominator, $S/\sigma = \sqrt{V/(n-1)}$, and $(n-1)S^2/\sigma^2$ is χ^2_{n-1} and independent of $\bar{X}$ for Gaussian data (Chapter 3).

A standard normal divided by the square root of an independent χ^2_k/k is by definition a **Student t variable** with k degrees of freedom [a bell curve with heavier tails, because the denominator sometimes comes out small], with density [Wasserman p. 170]

$$f(t) = \frac{\Gamma\left(\frac{k+1}{2}\right)}{\sqrt{k\pi}\,\Gamma\left(\frac{k}{2}\right)}\left(1 + \frac{t^2}{k}\right)^{-(k+1)/2}. \tag{4.22}$$

For $k = 1$ it is the Cauchy distribution of Chapter 2, and as $k \to \infty$ it becomes the standard normal, because $(1 + t^2/k)^{-(k+1)/2} \to e^{-t^2/2}$ and $V/k \to 1$ by the law of large numbers. So $T \sim t_{n-1}$ exactly, and the **t-test** rejects when $|T| > t_{n-1,\alpha/2}$, the upper $\alpha/2$ quantile of t_{n-1}. The same fact lets us compute, not just simulate, how often the Wald test rejects a true null. The Wald test uses the normal cut 1.96, so its size is $\mathrm{P}(|t_{n-1}| > 1.96)$, which for $n = 3$ is 0.189, the solid line in Figure 4.13. The t-test's simulated size is 0.050 at $n = 3$ and 0.050 at $n = 10$. For moderately large n the two tests are the same test.

For two samples with possibly different variances, the ratio (4.20) is not exactly t-distributed. **Welch's t-test** uses a t distribution with an effective number of degrees of freedom computed from s_1, s_2, m, n; it is what `scipy.stats.ttest_ind(..., equal_var=False)` does.

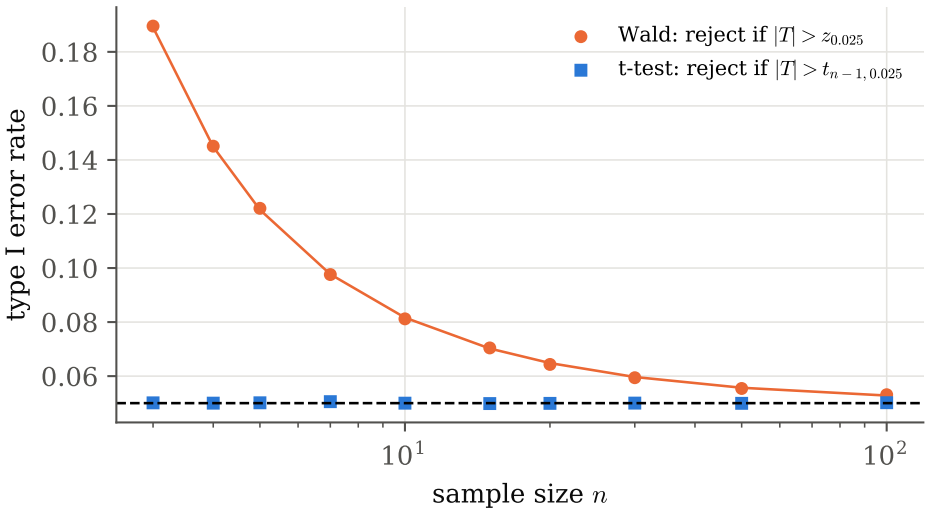

Figure 4.13: How often a test rejects a true null, as a function of the number of Gaussian readings. The Wald test, which uses the normal cut 1.96 with an estimated standard error, rejects too often for small samples (orange dots, with the exact curve as a line). The t-test, which uses the t quantile, stays on the dashed 0.05 line at every sample size (blue squares).

4.5.3 The permutation test

The t-test is exact only for Gaussian data. The **permutation test** is exact for any distribution, at the price of a computation [Wasserman §10.5]. The null it tests is that the two samples come from the same distribution, $H_0 : F_X = F_Y$. The key observation: if that is true, the labels "first sample" and "second sample" carry no information. Every way of splitting the pooled $N = m + n$ values into a group of m and a group of n was equally likely to have produced the data we saw. So we can build the null distribution of any statistic T by recomputing it for all $N!$ orderings of the pooled values, each with probability $1/N!$. That is the **permutation distribution**, and the p-value is the fraction of orderings with T larger than the observed value.

Example: the smallest possible permutation test. Take $(X_1, X_2, Y_1) = (1, 9, 3)$ and $T = \left|\bar{X} - \bar{Y}\right|$ [Wasserman Ex. 10.19]. The observed value is $|(1 + 9)/2 - 3| = 2$. The six orderings, with the first two entries playing the role of X:

ordering	T	probability
$(1,9,3), (9,1,3)$	$\lvert 5-3\rvert = 2$	$2/6$
$(1,3,9), (3,1,9)$	$\lvert 2-9\rvert = 7$	$2/6$
$(3,9,1), (9,3,1)$	$\lvert 6-1\rvert = 5$	$2/6$

Four of the six give $T > 2$, so $p = \mathrm{P}_0(T > 2) = 4/6 = 0.667$. The script enumerates the six orderings with `itertools.permutations` and gets the same number. (Some authors count $T \geq t_{\text{obs}}$, which includes the observed ordering itself; with continuous data and many orderings the difference is negligible.)

For real data $N!$ is astronomically large, so we sample orderings at random. The algorithm [Wasserman p. 163] is:

1. compute t_{obs} from the data as labelled;
2. shuffle the pooled data, split into groups of m and n, and recompute T;

3. repeat step 2 B times, giving $T_1, \dots, T_B$;
4. the p-value is approximately $\frac{1}{B}\sum_{j=1}^{B} I(T_j > t_{\text{obs}})$, with I the indicator (one if true, zero if false).

Why is this legitimate? Under the null the N values are exchangeable: their joint distribution does not change when we reorder them. Given the set of values that occurred, every assignment of labels is equally likely, so the shuffled statistics are draws from the exact conditional null distribution of T. No normality, no large-sample limit, no estimate of a standard error is involved. The permutation test is most useful when there are few samples and the statistic has no convenient formula for its distribution. Wasserman's gene-expression example is of this kind ([Wasserman Ex. 10.20]: ten patients, two tumour types, T the absolute difference of medians = 710, $p = 0.045$).

Example: the calorimeter calibration. Back to the two calibration runs. We simulate run 1 as 12 readings from $\mathcal{N}(661.7, 4^2)$ keV and run 2 as 15 readings with a true shift of 3.3 keV (script `05_wald_t_permutation.py`). The observed means are 662.07 and 665.67 keV with sample standard deviations 4.30 and 3.55 keV. By (4.20),

$$\begin{aligned} \hat{\delta} &= 665.67 - 662.07 = 3.60 \text{ keV}, \\ \widehat{\text{se}} &= \sqrt{4.30^2/12 + 3.55^2/15} = 1.54 \text{ keV}, \\ W &= 3.60/1.54 = 2.33, \end{aligned}$$

so the Wald p-value is $2\Phi(-2.33) = 0.0198$. Welch's t-test gives 0.0298, larger because it accounts for the uncertainty in the two standard deviations. The permutation test, with $B = 100\,000$ shuffles of the 27 values, gives 0.0251. Figure 4.14 shows the permutation distribution of $\bar{x}_2 - \bar{x}_1$ with the observed difference marked. The three p-values are close to one another: they ask the same question in three ways. None of them would convince a particle physicist of a new effect. Nor could they be expected to. With twelve and fifteen readings of 4 keV resolution, the true shift of 3.3 keV is only $3.3/\sqrt{4^2/12 + 4^2/15} \approx 2.1$ standard errors on average, and a single pair of runs can easily show much less or much more. This experiment is too small to find the shift reliably.

Listing 4.5: Wald, Welch and permutation tests for two calibration runs (`code/ch04/05_wald_t_permutation.py`)

```
m, n = 12, 15
run1 = rng.normal(661.7, 4.0, size=m)                    # Cs-137 line, keV, resolution 4 keV
run2 = rng.normal(665.0, 4.0, size=n)                    # a 3.3 keV scale shift in run 2
d_hat = run2.mean() - run1.mean()
se_hat = np.sqrt(run1.var(ddof=1) / m + run2.var(ddof=1) / n)
W = d_hat / se_hat
p_wald = 2 * stats.norm.sf(abs(W))
p_welch = stats.ttest_ind(run2, run1, equal_var=False).pvalue
pooled = np.concatenate([run1, run2])
B = 100_000
Tperm = np.empty(B)
for j in range(B):
    perm = rng.permutation(pooled)
    Tperm[j] = perm[m:].mean() - perm[:m].mean()
p_perm = np.mean(np.abs(Tperm) >= abs(d_hat))
p_perm_scipy = stats.permutation_test((run2, run1), lambda a, b: a.mean() - b.mean(),
                                      n_resamples=20_000, alternative="two-sided",
                                      random_state=rng).pvalue
```

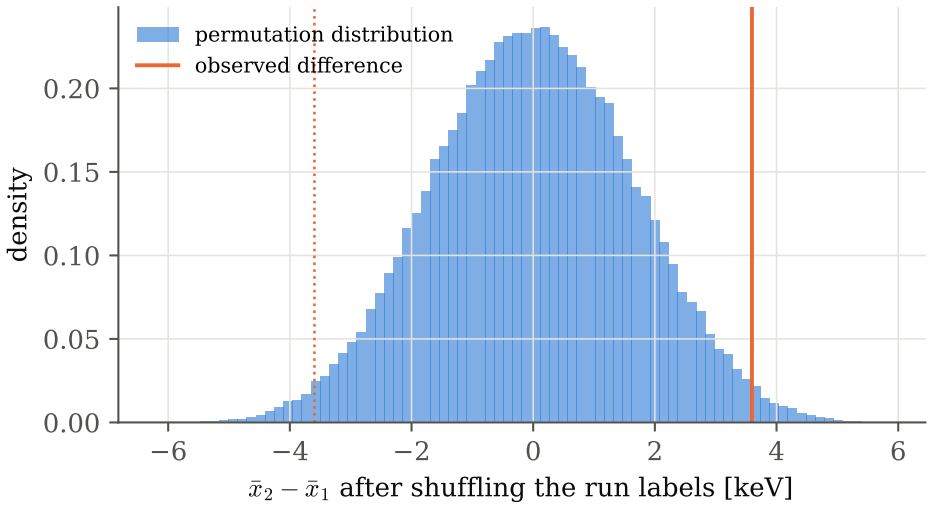

Figure 4.14: The permutation distribution for the calibration example: the difference of the two run means after randomly reassigning the 27 readings to the two runs, 100 000 times. The solid orange line is the observed difference and the dotted one its mirror image; the fraction of shuffles beyond either line is the two-sided p-value.

The loop is the algorithm above, line for line: `rng.permutation` shuffles the pooled readings, the first m play run 1 and the rest run 2, and the difference of means is stored. The p-value counts shuffles with $|T_j| \geq |t_{\text{obs}}|$ (two-sided). As a cross-check the script calls `scipy.stats.permutation_test` with 20 000 resamples, which returns 0.0273. Both numbers are Monte Carlo estimates, so they carry a random error. For the shorter run of 20 000 resamples that error is $\sqrt{p(1-p)/20\,000}$, a few thousandths at most. The two estimates differ by 1.8 times their combined error; more shuffles would bring them together. In large samples the permutation test usually agrees with the asymptotic tests, and it is most valuable for small samples [Wasserman p. 164].

Tests and intervals are two views of one object. There is a simple link between the Wald test and the familiar interval $\hat{\theta} \pm z_{\alpha/2}\widehat{\text{se}}$. By (4.17), $|\hat{\theta} - \theta_0| > z_{\alpha/2}\widehat{\text{se}}$ says precisely that θ_0 lies outside that interval. So the size-α Wald test rejects θ_0 if and only if θ_0 is outside the $1-\alpha$ interval [Wasserman Thm 10.10]. The second part of the chapter turns that observation into a general machine for building confidence intervals from tests.

4.6 The best test: the Neyman–Pearson lemma

A trigger has to decide, event by event, whether a collision looks like signal or like background. Each event comes with several measured quantities: energies, angles, isolation variables. Any selection keeps some signal and some background. At a fixed signal efficiency, say 90%, one selection keeps less background than another, and we would like the best one. Put as a question about tests: among all tests with the same size α, which has the largest power? For two simple hypotheses there is a complete answer, and it is one of the few genuinely optimal results in statistics.

The question in words.

1. We have a fixed budget α of false-alarm probability. Which outcomes should we spend it

on?

2. Does the answer depend on the particular alternative, or is one test best against a whole family of alternatives?

3. What do we do when the densities are only available as simulated events in many dimensions?

4.6.1 Spending a false-alarm budget

Take a simple null and a simple alternative, $H_0 : \theta = \theta_0$ versus $H_1 : \theta = \theta_1$, with densities $f_0(\boldsymbol{x}) = f(\boldsymbol{x} \mid \theta_0)$ and $f_1(\boldsymbol{x}) = f(\boldsymbol{x} \mid \theta_1)$ for the whole data set. A test is a choice of rejection region R. Its size and power are

$$\alpha = \int_R f_0(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}, \qquad \beta(\theta_1) = \int_R f_1(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x}.$$

Think of each small cell $\mathrm{d}\boldsymbol{x}$ of data space as an item we can put into R. It costs $f_0\,\mathrm{d}\boldsymbol{x}$ of the false-alarm budget and buys $f_1\,\mathrm{d}\boldsymbol{x}$ of power. The budget is fixed. To buy as much power as possible we should take the items with the best value for money first, the cells where the ratio f_1/f_0 is largest, and keep taking them in order of decreasing ratio until the budget is spent. The region we end up with is $R = \{\boldsymbol{x} : \ f_1(\boldsymbol{x})/f_0(\boldsymbol{x}) > k\}$, with the threshold k fixed by the budget.

The same answer comes out of the Lagrange-multiplier method familiar from mechanics. We maximise $\int_R f_1$ subject to $\int_R f_0 = \alpha$, so we maximise $\int_R (f_1 - k f_0)\,\mathrm{d}\boldsymbol{x}$ for a multiplier k. The integrand can be positive or negative, and the integral over R is largest when R contains every point where $f_1 - k f_0 > 0$ and no point where it is negative. The multiplier is the exchange rate between power and size.

Key idea: Neyman–Pearson lemma

For testing a simple $H_0 : \theta = \theta_0$ against a simple $H_1 : \theta = \theta_1$, the test that rejects when the **likelihood ratio**

$$\Lambda(\boldsymbol{x}) = \frac{f(\boldsymbol{x} \mid \theta_1)}{f(\boldsymbol{x} \mid \theta_0)} = \frac{\mathcal{L}(\theta_1)}{\mathcal{L}(\theta_0)}$$

exceeds a constant k, with k chosen so that $\mathrm{P}_{\theta_0}(\Lambda > k) = \alpha$, has the largest power of all tests of level α [Wasserman Thm 10.30], [CasellaBerger Thm 8.3.12], [Cowan (4.12)]. The ratio collapses any number of measured variables into one number, and no other function of the data does better.

Why it is true. The budget argument is the proof in disguise. To make it exact, describe a test by its **test function** $\phi(\boldsymbol{x})$ [one where the test rejects, zero where it retains], so that size and power are $\int \phi f_0$ and $\int \phi f_1$. Let ϕ be the likelihood-ratio test and ϕ' any other test of level α, with power functions β and β'. At every point, $[\phi(\boldsymbol{x}) - \phi'(\boldsymbol{x})][f_1(\boldsymbol{x}) - k f_0(\boldsymbol{x})] \geq 0$: where $f_1 > k f_0$ we have $\phi = 1 \geq \phi'$, and where $f_1 < k f_0$ we have $\phi = 0 \leq \phi'$, so the two factors never have opposite signs. Integrating,

$$\begin{aligned} 0 &\overset{(1)}{\leq} \int \big[\phi(\boldsymbol{x}) - \phi'(\boldsymbol{x})\big]\big[f_1(\boldsymbol{x}) - k f_0(\boldsymbol{x})\big]\mathrm{d}\boldsymbol{x} \\ &\overset{(2)}{=} \big[\beta(\theta_1) - \beta'(\theta_1)\big] - k\big[\beta(\theta_0) - \beta'(\theta_0)\big] \\ &\overset{(3)}{\leq} \beta(\theta_1) - \beta'(\theta_1). \end{aligned} \tag{4.23}$$

(1) The integrand is non-negative at every point, as just argued.
(2) Multiply out: $\int \phi f_1 = \beta(\theta_1)$, $\int \phi f_0 = \beta(\theta_0)$, and likewise for ϕ'.
(3) $\beta(\theta_0) = \alpha$ for the likelihood-ratio test, and $\beta'(\theta_0) \le \alpha$ because ϕ' has level α; so the bracket multiplying $k \ge 0$ is non-negative, and dropping it can only increase the right-hand side.

So $\beta(\theta_1) \ge \beta'(\theta_1)$: no level-$\alpha$ test beats the likelihood ratio [CasellaBerger p. 315]. For discrete data replace integrals by sums. Notice what the proof used: nothing about the shape of the densities, the dimension of $\boldsymbol{x}$, or large samples. The lemma is exact.

Example: the Gaussian mean, and a uniformly best test. Let $X_1, \dots, X_n \overset{\text{iid}}{\sim} \mathcal{N}(\mu, \sigma^2)$, σ known, and test $\mu = 0$ against a single $\mu = \mu_1 > 0$. The log of the likelihood ratio is

$$\begin{aligned} \ln \Lambda &\overset{(1)}{=} \sum_{i=1}^{n} \Big[-\frac{(x_i - \mu_1)^2}{2\sigma^2} + \frac{x_i^2}{2\sigma^2} \Big] \\ &\overset{(2)}{=} \sum_{i=1}^{n} \frac{2\mu_1 x_i - \mu_1^2}{2\sigma^2} \overset{(3)}{=} \frac{n\mu_1}{\sigma^2}\,\bar{x} - \frac{n\mu_1^2}{2\sigma^2}. \end{aligned} \tag{4.24}$$

(1) The likelihood is a product of Gaussians; its log is a sum. The normalisations $1/\sqrt{2\pi\sigma^2}$ are the same under both hypotheses and cancel.
(2) Expand $(x_i - \mu_1)^2 = x_i^2 - 2\mu_1 x_i + \mu_1^2$; the x_i^2 terms cancel.
(3) $\sum_i x_i = n\bar{x}$.

Because $\mu_1 > 0$, $\ln \Lambda$ increases with $\bar{x}$, so "$\Lambda > k$" is the same event as "$\bar{x} > c$" for some c. The most powerful test is the one-sided test of Section 4.3.2, with $c = \sigma z_\alpha / \sqrt{n}$ to give size α [CasellaBerger Ex. 8.3.15].

The value of μ_1 has disappeared from the rejection region. Neither the event $\bar{x} > c$ nor the cut $c = \sigma z_\alpha / \sqrt{n}$ mentions it. So the same region is most powerful against *every* $\mu_1 > 0$. A test with this property is **uniformly most powerful**. Such tests exist when the likelihood ratio is monotone in one statistic, as for one-sided problems in exponential families. For two-sided alternatives they usually do not: the best test against $\mu_1 > 0$ rejects for large $\bar{x}$, the best against $\mu_1 < 0$ rejects for small $\bar{x}$, and no single region is best against both [Wasserman p. 152].

Example: discreteness restricts the available sizes. Let $X \sim \text{Binomial}(2, \theta)$, testing $\theta = \frac{1}{2}$ against $\theta = \frac{3}{4}$ [CasellaBerger Ex. 8.3.14]. The pmfs are $\binom{2}{x}\theta^x(1-\theta)^{2-x}$, giving $(\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$ and $(\frac{1}{16}, \frac{6}{16}, \frac{9}{16})$ for $x = 0, 1, 2$, so the ratios are

$$\Lambda(0) = \frac{1/16}{1/4} = \frac{1}{4}, \qquad \Lambda(1) = \frac{6/16}{1/2} = \frac{3}{4}, \qquad \Lambda(2) = \frac{9/16}{1/4} = \frac{9}{4}.$$

Ranking the outcomes by Λ and filling the budget: rejecting on $\{2\}$ is the most powerful test of size $\mathrm{P}_{1/2}(X = 2) = \frac{1}{4}$; rejecting on $\{1, 2\}$ is the most powerful test of size $\frac{3}{4}$. No non-randomised test has size 0.05 except the one that never rejects. With discrete data the lemma still says what to do, but only certain sizes can be achieved, as we saw for the Poisson counts in Section 4.3.3.

4.6.2 Selecting particles: efficiency, purity and the ratio

Selecting events is a test, and the lemma tells us how to do it best. [Cowan §4.2] takes a charged particle of known momentum whose ionisation t is measured. Electrons and pions deposit different amounts on average, so t has density $g(t \mid e)$ for electrons and $g(t \mid \pi)$ for pions.

Selecting electron candidates with a cut $t < t_{\text{cut}}$ defines two efficiencies [Cowan (4.3)–(4.4)],

$$\varepsilon_e = \int_{-\infty}^{t_{\text{cut}}} g(t \mid e)\,\mathrm{d}t = 1 - \alpha, \qquad \varepsilon_\pi = \int_{-\infty}^{t_{\text{cut}}} g(t \mid \pi)\,\mathrm{d}t = \beta_{\text{II}}.$$

Here the *signal* plays the role of the null: rejecting "it is an electron" when it is one loses signal, with probability α, and keeping a pion is a type II error. The purity of the selected sample follows from Bayes' theorem with the particle fractions a_e and $a_\pi = 1 - a_e$ as prior probabilities [Cowan (4.8)–(4.11)]:

$$P_e = \frac{\text{electrons kept}}{\text{particles kept}} = \frac{a_e\,\varepsilon_e}{a_e\,\varepsilon_e + a_\pi\,\varepsilon_\pi}. \tag{4.25}$$

This is the same structure as (4.16): the purity of a selection, like the fraction of true discoveries, needs the prior fractions. At fixed efficiency ε_e the purity is largest when ε_π is smallest, which is the Neyman–Pearson problem. With one variable and a monotone ratio a single cut is automatically optimal. With a vector of variables $\boldsymbol{x}$ the lemma says to keep the events with $g(\boldsymbol{x} \mid e)/g(\boldsymbol{x} \mid \pi) > c$ [Cowan (4.12)–(4.13)].

In practice $g(\boldsymbol{x} \mid H)$ is known only through simulated events. With M histogram bins per variable and n variables there are M^n bins to fill, which becomes impossible beyond a few variables [Cowan p. 51]. One retreat is a linear statistic $t = \boldsymbol{a}^{\mathsf{T}}\boldsymbol{x}$. Fisher chose the direction $\boldsymbol{a}$ that maximises the separation of the two class means relative to the spread within the classes, $(\tau_0 - \tau_1)^2/(\Sigma_0^2 + \Sigma_1^2)$, and found [Cowan (4.23)]

$$\boldsymbol{a} \propto \boldsymbol{W}^{-1}(\boldsymbol{\mu}_0 - \boldsymbol{\mu}_1), \qquad \boldsymbol{W} = \boldsymbol{V}_0 + \boldsymbol{V}_1, \tag{4.26}$$

with $\boldsymbol{\mu}_k$ and $\boldsymbol{V}_k$ the mean vector and covariance matrix of $\boldsymbol{x}$ under hypothesis k. When both classes are Gaussian with the *same* covariance $\boldsymbol{V}$, Fisher's discriminant is exactly the log likelihood ratio. Writing $Q_k = (\boldsymbol{x} - \boldsymbol{\mu}_k)^{\mathsf{T}}\boldsymbol{V}^{-1}(\boldsymbol{x} - \boldsymbol{\mu}_k)$ for the quadratic form in each Gaussian exponent,

$$\begin{aligned} \ln \frac{\mathcal{N}(\boldsymbol{x}; \boldsymbol{\mu}_0, \boldsymbol{V})}{\mathcal{N}(\boldsymbol{x}; \boldsymbol{\mu}_1, \boldsymbol{V})} &\overset{(1)}{=} -\tfrac{1}{2}Q_0 + \tfrac{1}{2}Q_1 \\ &\overset{(2)}{=} (\boldsymbol{\mu}_0 - \boldsymbol{\mu}_1)^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{x} - \tfrac{1}{2}\big(\boldsymbol{\mu}_0^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{\mu}_0 - \boldsymbol{\mu}_1^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{\mu}_1\big). \end{aligned} \tag{4.27}$$

(1) The normalisations $(2\pi)^{-n/2}\det \boldsymbol{V}^{-1/2}$ are equal and cancel.

(2) Expand $Q_k = \boldsymbol{x}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{x} - 2\boldsymbol{\mu}_k^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{x} + \boldsymbol{\mu}_k^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{\mu}_k$ (using the symmetry of $\boldsymbol{V}^{-1}$). The quadratic term in $\boldsymbol{x}$ is the same for both and cancels, leaving a linear function of $\boldsymbol{x}$.

The coefficient vector is $\boldsymbol{V}^{-1}(\boldsymbol{\mu}_0 - \boldsymbol{\mu}_1)$, proportional to Fisher's with $\boldsymbol{W} = 2\boldsymbol{V}$ [Cowan (4.27)–(4.28)]. When the covariances differ, the $\boldsymbol{x}^{\mathsf{T}}\boldsymbol{V}_k^{-1}\boldsymbol{x}$ terms no longer cancel, the optimal boundary is curved, and a linear statistic loses power. Nonlinear methods, neural networks and boosted trees, are in this light approximations to the likelihood ratio learned from simulated events [Cowan §4.4.2]: a classifier trained to separate two classes outputs, at best, a monotone function of $g(\boldsymbol{x} \mid H_0)/g(\boldsymbol{x} \mid H_1)$.

Example: three selections, and three hundred random ones. We make signal and background Gaussian in two variables (script `06_neyman_pearson.py`), with different means and different covariance matrices, and compare three selections at a signal efficiency of 90%: a cut on x_1 alone, Fisher's linear discriminant (4.26) trained on 20 000 events of each class, and the exact log likelihood ratio. Figure 4.15 shows the events and the three decision boundaries. The fractions of background kept are 0.397 for the x_1 cut, 0.256 for Fisher and 0.177 for the likelihood ratio.

The lemma claims that no selection does better than the likelihood ratio. To check this, the script also draws 300 random quadratic selections $g(\boldsymbol{x}) = \boldsymbol{x}^{\mathsf{T}}\boldsymbol{A}\boldsymbol{x} + \boldsymbol{v}^{\mathsf{T}}\boldsymbol{x} > c$, each tuned to keep

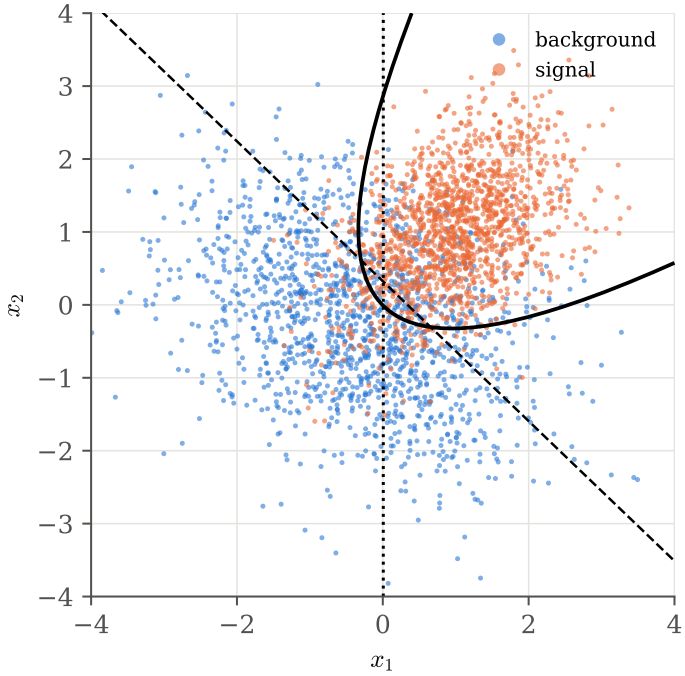

Figure 4.15: Signal (orange) and background (blue) events in two measured variables, with three boundaries that each keep 90% of the signal: a cut on x_1 alone (dotted), Fisher's straight line (dashed), and the curved contour of constant likelihood ratio (solid). The curved boundary follows the shape of the two clouds, which have different orientations, and so admits the least background.

90% of the signal. The best of them keeps a background fraction 0.199, above the likelihood ratio's 0.177. (Because the true ratio here is itself quadratic, a random quadratic can come close, but it cannot win.) Figure 4.16 shows the whole trade-off as a **ROC curve** [background efficiency against signal efficiency, as the cut is varied]. The likelihood-ratio curve lies below the others at every signal efficiency.

Listing 4.6: Three selections compared at equal signal efficiency (code/ch04/06_neyman_pearson.py)

```
def lnr(x):                          # log likelihood ratio  ln[ f(x|signal) / f(x|background) ]
    return S.logpdf(x) - Bk.logpdf(x)

# Fisher linear discriminant from training samples: a proportional to (W_s + W_b)^{-1}
    (mu_s - mu_b)
tr_s, tr_b = xs[:20000], xb[:20000]
Wsum = np.cov(tr_s.T) + np.cov(tr_b.T)
a_fish = np.linalg.solve(Wsum, tr_s.mean(0) - tr_b.mean(0))

stats_s = {"cut on $x_1$ alone": xs[:, 0], "Fisher linear": xs @ a_fish, "likelihood
    ratio": lnr(xs)}
stats_b = {"cut on $x_1$ alone": xb[:, 0], "Fisher linear": xb @ a_fish, "likelihood
    ratio": lnr(xb)}

eff_s = np.linspace(0.01, 0.99, 99)
roc = {}
for name in stats_s:
    thr = np.quantile(stats_s[name], 1 - eff_s)                # keep events with
    statistic > thr
    sb = np.sort(stats_b[name])
    roc[name] = 1 - np.searchsorted(sb, thr) / M              # background efficiency
i90 = np.argmin(np.abs(eff_s - 0.90))
bkg90 = {k: v[i90] for k, v in roc.items()}
```

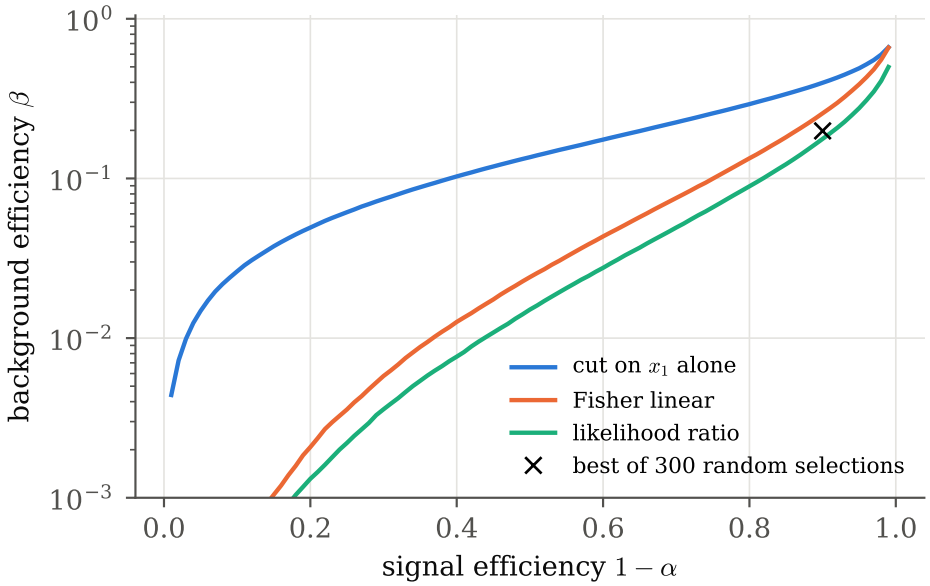

Figure 4.16: Background kept versus signal kept, as the threshold of each selection is varied. Lower is better. The likelihood ratio (green) is lowest everywhere, Fisher's linear discriminant (orange) is next, a cut on one variable (blue) is worst, and the cross marks the best of 300 random quadratic selections at 90% signal efficiency, which still lies above the green curve.

The function `lnr` is the log likelihood ratio, evaluated with the exact densities because we generated the data; in a real analysis they would come from simulation or be learned. Fisher's coefficients come from one line of linear algebra, `np.linalg.solve(Wsum, tr_s.mean(0) - tr_b.mean(0))`, which is (4.26) without forming an inverse. For each statistic the threshold for a given signal efficiency is a quantile of its signal distribution (`np.quantile`), and the background efficiency is the fraction of background above it, found by sorting.

Watch out: Most powerful for one alternative only

The Neyman–Pearson lemma is about *two* completely specified hypotheses. Real alternatives have free parameters: an unknown mass, an unknown coupling. A test tuned to one mass hypothesis can be poor for another, and a uniformly most powerful test rarely exists. The generalisation that handles free parameters, by fitting them, is the likelihood-ratio test of the next section; it is not guaranteed optimal, but it inherits the lemma's logic and is the standard tool.

4.7 Likelihood-ratio tests and Wilks' theorem

The Neyman–Pearson lemma needs two completely specified hypotheses. A real search never has them. In the diphoton bump the background normalisation is known only roughly, the signal strength is unknown, and even the null "no signal" leaves the background level free. Such unknown parameters, which we must allow for but do not want to report, are **nuisance parameters** [parameters of the model that are not the question, like a background level or a calibration constant]. We need a test that works with composite hypotheses, and a way to get its null distribution without simulating every possible value of the nuisance parameters.

The recipe is the natural generalisation of the lemma: in the ratio of likelihoods, give each

hypothesis its best shot by maximising over its free parameters. The surprise, due to Wilks [22], is that the resulting statistic has, for large samples, a null distribution that does not depend on the model at all.

The question in words.

1. How much better does the data fit if we free the parameters that the null fixes?
2. How large must that improvement be before it is surprising, if the null is true?
3. When does the universal answer fail, and what do we do then?

4.7.1 The likelihood-ratio statistic

Let $\mathcal{L}(\boldsymbol{\theta})$ be the likelihood of the data as a function of all parameters $\boldsymbol{\theta} \in \Theta$ (Chapter 3), and let the null restrict them to $\Theta_0 \subset \Theta$. The **likelihood ratio** is

$$\lambda(\boldsymbol{x}) = \frac{\sup_{\boldsymbol{\theta}\in\Theta_0} \mathcal{L}(\boldsymbol{\theta})}{\sup_{\boldsymbol{\theta}\in\Theta} \mathcal{L}(\boldsymbol{\theta})} = \frac{\mathcal{L}(\hat{\boldsymbol{\theta}}_0)}{\mathcal{L}(\hat{\boldsymbol{\theta}})}, \qquad -2\ln\lambda = 2\big[\ln\mathcal{L}(\hat{\boldsymbol{\theta}}) - \ln\mathcal{L}(\hat{\boldsymbol{\theta}}_0)\big], \tag{4.28}$$

where $\hat{\boldsymbol{\theta}}$ is the maximum-likelihood estimate over all of Θ and $\hat{\boldsymbol{\theta}}_0$ the one restricted to Θ_0. Because Θ_0 is part of Θ, the restricted maximum can never be higher, so $0 < \lambda \le 1$ and $-2\ln\lambda \ge 0$. It is zero when the null fits as well as anything, and grows as the unrestricted fit pulls away. We reject for large $-2\ln\lambda$.

Two conventions need a word. First, [Wasserman Def. 10.21] calls the quantity $2\ln[\mathcal{L}(\hat{\boldsymbol{\theta}})/\mathcal{L}(\hat{\boldsymbol{\theta}}_0)]$ itself "λ", so Wasserman's λ is our $-2\ln\lambda$. Second, the denominator maximises over all of Θ rather than over the alternative alone, $\Theta \setminus \Theta_0$. This changes the statistic very little and makes its theory much simpler [Wasserman p. 164].

Key idea: Wilks' theorem

Let $\boldsymbol{\theta}$ have r free parameters and the null fix $r - q$ of them, leaving q free. If the null is true, the model is regular and the true value lies in the interior of Θ_0, then for large samples

$$-2\ln\lambda \;\sim\; \chi^2_{r-q}$$

[the degrees of freedom are the number of parameters the null fixes], whatever the model [Wasserman Thm 10.22], [CasellaBerger Thm 10.3.3]. The p-value is $\mathrm{P}(\chi^2_{r-q} > -2\ln\lambda_{\mathrm{obs}})$.

For example, with five parameters and the null $\theta_4 = \theta_5 = 0$, the statistic is asymptotically $\chi^2_{5-3} = \chi^2_2$ [Wasserman p. 164]. The nuisance parameters, the ones left free under both hypotheses, cost nothing in degrees of freedom: they are refitted in numerator and denominator.

4.7.2 Why the answer is χ^2

Take one parameter, θ, and a simple null $\theta = \theta_0$, so $r - q = 1$. Write $\ell(\theta) = \ln\mathcal{L}(\theta)$ and expand it around its maximum $\hat{\theta}$ [CasellaBerger p. 395]:

$$\begin{aligned} -2\ln\lambda &\overset{(1)}{=} 2\big[\ell(\hat{\theta}) - \ell(\theta_0)\big] \\ &\overset{(2)}{=} 2\Big[\ell(\hat{\theta}) - \Big(\ell(\hat{\theta}) + \ell'(\hat{\theta})(\theta_0 - \hat{\theta}) + \tfrac{1}{2}\ell''(\hat{\theta})(\theta_0 - \hat{\theta})^2 + \dots\Big)\Big] \\ &\overset{(3)}{=} -\ell''(\hat{\theta})\,(\hat{\theta} - \theta_0)^2 + \dots \end{aligned}$$

$$\overset{(4)}{=} \left(\frac{\hat\theta - \theta_0}{\widehat{\mathrm{se}}}\right)^2 + \dots . \tag{4.29}$$

(1) Definition (4.28) with $\hat\theta_0 = \theta_0$.
(2) Taylor expansion of $\ell(\theta_0)$ about $\hat\theta$.
(3) $\ell'(\hat\theta) = 0$ at the maximum, and the $\ell(\hat\theta)$ terms cancel.
(4) The curvature of the log likelihood at its peak is the observed information, and its inverse is the variance of the estimate: $-\ell''(\hat\theta) = 1/\widehat{\mathrm{se}}^{\,2}$ (Chapter 3).

For a large sample, $\hat\theta$ is approximately normal about the true value with standard deviation se. Under the null the true value is θ_0, so the bracket in the last line is approximately a standard normal Z, and $-2\ln\lambda \approx Z^2 \sim \chi^2_1$. The dropped terms are of higher order in $\hat\theta - \theta_0$, which shrinks as $1/\sqrt{n}$. In words: near its peak, every smooth log likelihood is a parabola, the likelihood-ratio statistic is the drop of that parabola between $\hat\theta$ and θ_0, and the drop is the square of the Wald statistic of Section 4.5. With k fixed parameters the same expansion gives a quadratic form in a k-dimensional normal vector weighted by its inverse covariance, which is a sum of k squared independent standard normals: χ^2_k.

The linear-Gaussian case, where Wilks is exact. If the data are $y_i = \mu_i(\boldsymbol\theta) + \epsilon_i$ with known Gaussian errors σ_i, then $-2\ln\mathcal{L}(\boldsymbol\theta) = \chi^2(\boldsymbol\theta) + \text{const}$ with $\chi^2(\boldsymbol\theta) = \sum_i (y_i - \mu_i(\boldsymbol\theta))^2/\sigma_i^2$ (Chapter 3), and

$$-2\ln\lambda \overset{(1)}{=} -2\ln\mathcal{L}(\hat{\boldsymbol\theta}_0) + 2\ln\mathcal{L}(\hat{\boldsymbol\theta}) \overset{(2)}{=} \chi^2_{\min}(H_0) - \chi^2_{\min}(H_1) \equiv \Delta\chi^2. \tag{4.30}$$

(1) Definition (4.28).
(2) Maximising the likelihood is minimising χ^2, and the constants cancel in the difference.

When the model is linear in the parameters, $\Delta\chi^2$ is exactly χ^2_{r-q} for any sample size. Here is the geometric reason. Divide each residual by its σ_i; the noise vector $\boldsymbol\epsilon/\boldsymbol\sigma$ is then an isotropic Gaussian in N dimensions. A least-squares fit with r linear parameters is the orthogonal projection of the data onto an r-dimensional subspace; the null's fit projects onto a q-dimensional subspace inside it. Under the null, the difference of the two squared residual lengths is the squared length of the noise projected onto the $(r-q)$-dimensional part of the big subspace orthogonal to the small one. An isotropic Gaussian projected onto any k-dimensional subspace is an isotropic Gaussian in k dimensions, and its squared length is χ^2_k.

Example: the Poisson rate. With $X_1, \dots, X_n \overset{\text{iid}}{\sim} \mathrm{Pois}(\lambda)$ and $H_0 : \lambda = \lambda_0$ [CasellaBerger Ex. 10.3.2], the log likelihood is $\ell(\lambda) = -n\lambda + S\ln\lambda + \text{const}$ with $S = \sum_i X_i$, and its maximum is at $\hat\lambda = S/n$. Then

$$\begin{aligned} -2\ln\lambda &\overset{(1)}{=} 2\big[\ell(\hat\lambda) - \ell(\lambda_0)\big] \overset{(2)}{=} 2\big[-n\hat\lambda + S\ln\hat\lambda + n\lambda_0 - S\ln\lambda_0\big] \\ &\overset{(3)}{=} 2n\left[(\lambda_0 - \hat\lambda) - \hat\lambda\ln\frac{\lambda_0}{\hat\lambda}\right]. \end{aligned} \tag{4.31}$$

(1) Definition, with a simple null.
(2) Insert ℓ; the $\ln X_i!$ terms in the constant cancel.
(3) Use $S = n\hat\lambda$ and $\ln\hat\lambda - \ln\lambda_0 = -\ln(\lambda_0/\hat\lambda)$.

Casella and Berger simulate it for $\lambda_0 = 5$ and $n = 25$. Our 100 000 simulated experiments give the percentiles below; they sit close to those of χ^2_1 already at this modest sample size (their own table has 1.630, 2.726, 3.744 and 6.304 from 10 000 experiments).

percentile	0.80	0.90	0.95	0.99
simulated $-2\ln\lambda$	1.630	2.726	3.757	6.685
χ^2_1	1.642	2.706	3.841	6.635

Example: is there a quadratic term? Twenty points y_i at $x_i \in [-1, 1]$ carry Gaussian noise of known $\sigma = 0.5$, and the truth is a constant. We fit a constant, a straight line and a parabola $a + bx + cx^2$, and form $\Delta\chi^2$ for two nulls: $c = 0$ (one constraint) and $b = c = 0$ (two constraints). Over 100 000 simulated data sets the first has mean 1.002 and variance 2.011, the second mean 2.003 and variance 3.995, matching χ^2_1 (mean 1, variance 2) and χ^2_2 (mean 2, variance 4). Figure 4.17 shows both examples.

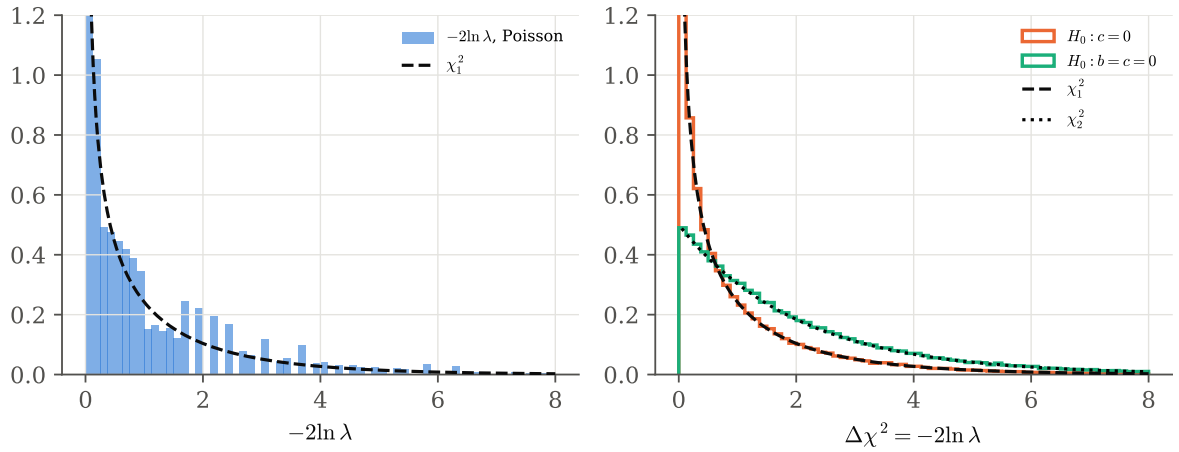

Figure 4.17: Wilks' theorem checked twice. Left: the likelihood-ratio statistic for a Poisson rate (25 counts, $\lambda_0 = 5$) follows the χ^2_1 density (dashed) closely. Right: $\Delta\chi^2$ between nested polynomial fits with Gaussian noise follows χ^2_1 when one coefficient is tested (orange) and χ^2_2 when two are (green, with the dotted density). For linear models the agreement is exact, not only asymptotic.

Example: Mendel's peas by likelihood ratio. Mendel counted $X = (315, 101, 108, 32)$ peas in four classes, $n = 556$, where his theory predicts probabilities $p_0 = (\frac{9}{16}, \frac{3}{16}, \frac{3}{16}, \frac{1}{16})$ [Wasserman Ex. 10.18]. The multinomial likelihood is $\prod_j p_j^{X_j}$, maximised at $\hat{p}_j = X_j/n$, so

$$-2\ln\lambda = 2\sum_{j=1}^{4} X_j \ln\frac{X_j/n}{p_{0j}}$$
$$= 2\left[315\ln\frac{315/556}{9/16} + 101\ln\frac{101/556}{3/16} + 108\ln\frac{108/556}{3/16} + 32\ln\frac{32/556}{1/16}\right] = 0.48$$

[Wasserman Ex. 10.23]. The unrestricted model has three free probabilities (four that sum to one), the null none, so the reference is χ^2_3 and the p-value is about 0.92. The Pearson statistic of Section 4.8 gives 0.47 on the same data: for large counts the two statistics agree to second order.

4.7.3 When the null sits on a boundary: $Z = \sqrt{q_0}$

When the null value sits on the edge of the allowed region, Wilks' theorem needs a correction, and the corrected answer is very simple. The case that matters is the counting experiment of Section 4.3.3: a count $N \sim \text{Pois}(s + b)$, with known expected background b, unknown expected

signal s, and the physical constraint $s \geq 0$. The null $s = 0$ sits on the *edge* of the allowed region, which breaks the interior condition of Wilks' theorem.

The fit. The log likelihood is $\ell(s) = N \ln(s+b) - (s+b) + \text{const}$. Its maximum is at $s = N - b$ if that is allowed, and at the boundary $s = 0$ otherwise, so $\hat{s} = \max(N - b, 0)$.

The statistic. The discovery statistic is the likelihood-ratio statistic (4.28) for the null $s = 0$:

$$q_0 = -2 \ln \frac{\mathcal{L}(0)}{\mathcal{L}(\hat{s})} \overset{(1)}{=} 2\big[N \ln(\hat{s}+b) - (\hat{s}+b) - N \ln b + b\big] \overset{(2)}{=} \begin{cases} 2\big[N \ln(N/b) - (N-b)\big], & N > b, \\ 0, & N \leq b. \end{cases} \tag{4.32}$$

(1) Insert ℓ at $\hat{s}$ and at 0.
(2) For $N > b$, $\hat{s} + b = N$. For $N \leq b$ the best allowed fit is $\hat{s} = 0$, the same as the null, and the ratio is one. A deficit is never evidence for a signal.

Its null distribution. For a large background, N is nearly Gaussian about b and falls below it half of the time; then $q_0 = 0$. In the other half, the unconstrained Wilks argument applies and q_0 is χ^2_1. So the null distribution is the mixture $\frac{1}{2}\delta(q_0) + \frac{1}{2}\chi^2_1$, a result that goes back to Chernoff. Its tail is

$$\mathrm{P}(q_0 \geq Z^2 \,|\, H_0) \overset{(1)}{=} \tfrac{1}{2}\,\mathrm{P}\big(\chi^2_1 \geq Z^2\big) \overset{(2)}{=} \tfrac{1}{2}\,\mathrm{P}\big(|Z'| \geq Z\big) \overset{(3)}{=} \Phi(-Z), \qquad Z' \sim \mathcal{N}(0,1), \tag{4.33}$$

(1) For $Z > 0$ only the χ^2_1 half contributes, with weight $\frac{1}{2}$.
(2) A χ^2_1 variable is the square of a standard normal.
(3) The two tails of Z' are equal, $\mathrm{P}(|Z'| \geq Z) = 2\Phi(-Z)$.

so the significance of an observation is simply $Z = \sqrt{q_0}$ standard deviations [27]. The same half-χ^2, and $Z = \sqrt{q_0}$, survive when the background and calibrations are nuisance parameters profiled in q_0, as the second part of the chapter shows in its section on discovery and exclusion with nuisance parameters. Figure 4.18 tests this with two million background-only toys at $b = 3.2$ and at $b = 100$. The fraction with $q_0 = 0$ is 0.603 and 0.527, above one half because the Poisson puts extra probability at and just below its mean. The fraction with $q_0 \geq 9$, that is $Z \geq 3$, is 0.001769 and 0.001262, against the asymptotic 0.00135: the formula is good to about 7% at $b = 100$ and to about 30% at $b = 3.2$. For Cowan's peak, 11 events on 3.2, $Z = \sqrt{q_0} = 3.40$, while the exact Poisson tail corresponds to 3.29.

Listing 4.7: The discovery statistic for a counting experiment (`code/ch04/07_wilks.py`)

```
# ---------- (iii) counting experiment with s >= 0 ----------
def q0(nobs, b):
    nobs = np.asarray(nobs, float)
    with np.errstate(divide="ignore", invalid="ignore"):
        q = 2 * (nobs * np.log(nobs / b) - (nobs - b))
    return np.where(nobs > b, q, 0.0)
```

The function is (4.32) verbatim: the `np.where` enforces $\hat{s} \geq 0$, and the `errstate` guard silences the harmless warnings from $\ln 0$ in the branch that is discarded.

Example: the expected significance, and when $s/\sqrt{b}$ is enough. Before an experiment we want its *median* significance if a signal s is present. We can get it without simulation [27]:

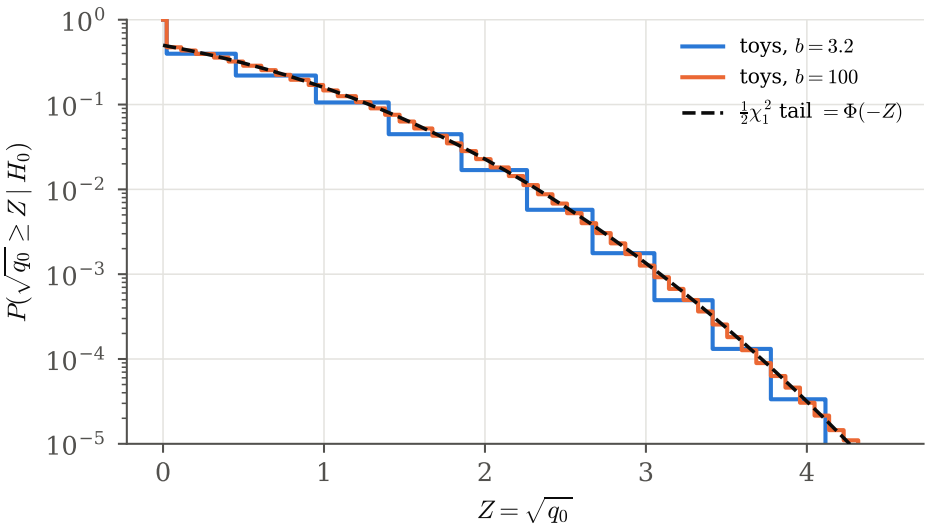

Figure 4.18: The probability that background alone reaches a significance $Z = \sqrt{q_0}$ or more, from toys with $b = 3.2$ (blue) and $b = 100$ (orange), compared with the asymptotic half-χ^2_1 prediction $\Phi(-Z)$ (dashed). The large-background staircase follows the prediction closely; the small-background one jumps in coarse steps because only integer counts are possible, and wanders above and below the line.

evaluate q_0 on the "Asimov" data set, in which N is replaced by its expectation $s + b$. Then

$$\begin{aligned} Z_A^2 = q_0\big(N = s+b\big) &\overset{(1)}{=} 2\left[(s+b)\ln\frac{s+b}{b} - s\right] \overset{(2)}{=} 2\left[(s+b)\ln\left(1+\frac{s}{b}\right) - s\right] \\ &\overset{(3)}{=} 2\left[(s+b)\left(\frac{s}{b} - \frac{s^2}{2b^2} + \frac{s^3}{3b^3} - \dots\right) - s\right] \\ &\overset{(4)}{=} \frac{s^2}{b}\left[1 - \frac{s}{3b} + \dots\right]. \end{aligned} \tag{4.34}$$

(1) (4.32) with $N = s + b > b$; $N - b = s$.

(2) $(s + b)/b = 1 + s/b$.

(3) $\ln(1 + u) = u - u^2/2 + u^3/3 - \dots$ with $u = s/b$.

(4) Multiply out: $(s + b)(s/b) = s^2/b + s$, whose s cancels the $-s$; $(s + b)(-s^2/2b^2) = -s^2/2b - s^3/2b^2$; $(s + b)(s^3/3b^3) = s^3/3b^2 + \dots$. Collecting, $s^2/b - s^2/2b = s^2/2b$ and $-s^3/2b^2 + s^3/3b^2 = -s^3/6b^2$; the factor 2 gives $s^2/b - s^3/3b^2$.

So for $s \ll b$ the familiar $Z \approx s/\sqrt{b}$ is recovered, and the first correction shows it *overestimates* the significance. With $s = 10$ on $b = 100$, $Z_A = 0.984$, $s/\sqrt{b} = 1.000$, and the median of toy significances is 0.984. With $s = 5$ on $b = 3.2$ the shortcut fails badly: $Z_A = 2.33$ against $s/\sqrt{b} = 2.80$.

How this is used in real research: Profile likelihood ratios at the LHC

The discovery of the Higgs boson and most searches since use exactly this statistic, with many nuisance parameters for backgrounds, luminosity and energy scales. Each is "profiled": maximised separately in numerator and denominator of λ. The asymptotic formulae, $Z = \sqrt{q_0}$ and the Asimov median, are derived for this general case in [27]. Our toys *verify* them against an analytic answer. In research the same toys are the *instrument*: where counts are small, parameters sit on boundaries or the signal mass is scanned, the null distribution of q_0 is generated by simulation, and the asymptotic formula serves only as a cross-check.

Where Wilks does not apply. Three conditions carried the derivation, and each fails somewhere in physics. The parameter must be in the interior (the boundary gives the half-χ^2 above). The hypotheses must be nested, one a special case of the other. And every parameter of the alternative must mean something under the null. The last condition fails in a bump hunt: the signal mass is meaningless when the signal strength is zero, and maximising over it inflates q_0 beyond any χ^2. That is the look-elsewhere effect in its likelihood form [15], and it leads to the trials factor treated in the second part of the chapter.

4.8 Goodness of fit: Pearson's χ^2 and Kolmogorov–Smirnov

So far the null has always been tested against a definite direction: a signal in a window, a bias of a coin, a shift of a calibration. Often we want something vaguer. Here is the background model for the whole mass spectrum, thirty bins of it; does it describe the data *at all*? No particular alternative is in mind, just "something else". This is a **goodness-of-fit** test [Cowan §4.5]: the test statistic itself measures the disagreement between data and model, and its large values are the extreme direction.

The question in words.

1. How do we add up the disagreement of many bins into one number with a known null distribution?
2. What changes when the total is fixed, when parameters were fitted to the same data, and when counts are small?
3. Can we avoid binning altogether?

4.8.1 The χ^2 distribution, recalled

If $Z_1, \dots, Z_k$ are independent standard normals, $V = \sum_{i=1}^{k} Z_i^2$ has the χ^2 distribution with k degrees of freedom (Chapter 2), with density, mean and variance [Wasserman p. 159]

$$f(v) = \frac{v^{k/2-1} e^{-v/2}}{2^{k/2}\Gamma(k/2)} \quad (v > 0), \qquad \mathbb{E}\, V = k, \qquad \operatorname{Var} V = 2k. \tag{4.35}$$

The mean is immediate, $\mathbb{E}\, Z_i^2 = 1$ for each term, and the variance follows from $\mathbb{E}\, Z^4 = 3$: $\operatorname{Var} Z_i^2 = 3 - 1 = 2$ per term. Its upper quantile $\chi^2_{k,\alpha}$ is defined by $\mathrm{P}(\chi^2_k > \chi^2_{k,\alpha}) = \alpha$, and a p-value is the upper tail beyond the observed value. For large k the distribution is close to $\mathcal{N}(k, 2k)$.

4.8.2 Pearson's statistic

A histogram has N bins with observed counts n_i and expected counts ν_i under the model. If the counts are independent Poisson variables and none of the ν_i is small, each n_i is approximately Gaussian with mean ν_i and variance ν_i, so $(n_i - \nu_i)/\sqrt{\nu_i}$ is approximately a standard normal. Adding the squares [Cowan (4.39)],

$$\chi^2 = \sum_{i=1}^{N} \frac{(n_i - \nu_i)^2}{\nu_i} \;\sim\; \chi^2_N \qquad \text{(approximately, for } \nu_i \gtrsim 5\text{)}. \tag{4.36}$$

The approximation does not care what physical variable was histogrammed or what shape the model has; the test is **distribution free**. Each term is the squared deviation in units of its own standard deviation, so χ^2 is the total disagreement counted in "sigmas squared".

If instead the total $n = \sum_i n_i$ is fixed, the counts are multinomial with cell probabilities p_{0i} and expected counts $E_i = np_{0i}$, and Pearson's statistic is [Wasserman Def. 10.16], [Cowan (4.41)]

$$T = \sum_{j=1}^{k} \frac{(X_j - E_j)^2}{E_j} \;\sim\; \chi^2_{k-1} \tag{4.37}$$

under the null, asymptotically [Wasserman Thm 10.17]. The one lost degree of freedom is the constraint $\sum_j (X_j - E_j) = 0$: the deviations are not independent, because an excess in one cell must be paid for by deficits elsewhere. The case $k = 2$ shows the mechanism exactly. With cell probabilities p and $1-p$, $X_2 - n(1-p) = -(X_1 - np)$, so

$$\begin{aligned} T &\overset{(1)}{=} \frac{(X_1 - np)^2}{np} + \frac{(X_1 - np)^2}{n(1-p)} \\ &\overset{(2)}{=} (X_1 - np)^2 \,\frac{(1-p) + p}{np(1-p)} \overset{(3)}{=} \left(\frac{X_1 - np}{\sqrt{np(1-p)}} \right)^2 . \end{aligned} \tag{4.38}$$

(1) The second deviation is minus the first, and its square is the same.
(2) Common denominator.
(3) $(1-p) + p = 1$.

The bracket is the binomial count standardised by its own mean np and standard deviation $\sqrt{np(1-p)}$, which by the de Moivre–Laplace theorem of Chapter 2 is approximately standard normal. So $T \approx Z^2 \sim \chi^2_1$: two cells, one degree of freedom. For k cells the same happens in $k-1$ dimensions: the constraint confines the standardised deviation vector to a hyperplane, and its squared length is a sum of $k-1$ independent squared normals.

Example: Mendel's peas. Mendel crossed peas and counted $X = (315, 101, 108, 32)$ progeny of four types, $n = 556$; his theory predicts $p_0 = (\frac{9}{16}, \frac{3}{16}, \frac{3}{16}, \frac{1}{16})$ [Wasserman Ex. 10.18]. The expected counts are $E = (312.75, 104.25, 104.25, 34.75)$ and

$$\begin{aligned} T &= \frac{(315-312.75)^2}{312.75} + \frac{(101-104.25)^2}{104.25} + \frac{(108-104.25)^2}{104.25} + \frac{(32-34.75)^2}{34.75} \\ &= 0.016 + 0.101 + 0.135 + 0.218 = 0.470. \end{aligned}$$

With $k - 1 = 3$ degrees of freedom the 5% critical value is 7.815, far above, and the p-value is $\mathrm{P}(\chi^2_3 > 0.470) = 0.925$. So the data do not contradict Mendel's theory. They do not prove it either. A test like this can show evidence to reject the null, but it cannot prove the null [Wasserman p. 161], because a failure to reject may come from a true null or from low power. (A footnote there recalls that Mendel's results have been suspected of fitting *too* well. A p-value very close to one is also improbable under the null.)

Watch out: χ^2/ν near one is not enough

It is common to quote χ^2 divided by the number of degrees of freedom and call anything near one a good fit. The ratio hides the scale: the spread of χ^2_ν/ν is $\sqrt{2/\nu}$, which shrinks with ν. For $\chi^2 = 15$ on 10 degrees of freedom the p-value is 0.13, perfectly fine; for $\chi^2 = 150$ on 100, the same ratio, it is 9.0×10^{-4} [Cowan p. 62]. Always quote χ^2 and ν separately, or the p-value.

4.8.3 Fitted parameters and small counts

Usually the model has parameters, such as a background slope, that are estimated from the same histogram. The fit pulls the expectation towards the data and makes χ^2 smaller than it would be at the true parameters. If s parameters are estimated by maximising the multinomial likelihood of the binned counts, $Q(\boldsymbol{\theta}) = \prod_j p_j(\boldsymbol{\theta})^{N_j}$, then [Wasserman Thm 10.29]

$$Q = \sum_{j=1}^{k} \frac{\big(N_j - n p_j(\hat{\boldsymbol{\theta}})\big)^2}{n p_j(\hat{\boldsymbol{\theta}})} \;\sim\; \chi^2_{k-1-s} : \tag{4.39}$$

each fitted parameter removes one degree of freedom, for the same geometric reason as in Wilks' theorem (Section 4.7.2): the fit projects the deviations onto a smaller subspace. This count holds only when the parameters are fitted to the binned counts. If they are estimated instead from the *unbinned* data, which is often more natural, the distribution of Q is no longer χ^2_{k-1-s}; a theorem of Chernoff and Lehmann puts it between χ^2_{k-1-s} and χ^2_{k-1} [Wasserman p. 169]. The reason is that the unbinned estimate is not tuned to the bins, so it removes less of the disagreement.

Example: fitting a decay length. The script `code/ch04/08_goodness_of_fit.py` draws 400 decay times with mean $\tau = 2$, histograms them in $k = 8$ bins, $[0,1), [1,2), \ldots, [7,\infty)$, and fits τ two ways: by maximising the binned multinomial likelihood, and by the unbinned maximum-likelihood estimate $\hat{\tau} = \bar{t}$. Over 4000 repetitions the mean of Q is 6.01 with the binned fit, as $\chi^2_{k-2} = \chi^2_6$ predicts, and 6.06 with the unbinned one; each mean carries a random error of about 0.05. Both fits see the same histograms, so their difference is measured much better: the unbinned fit leaves Q larger by 0.051 ± 0.002 on average, which puts it between χ^2_6 and χ^2_7, as Chernoff–Lehmann says (Figure 4.19, right). Here the difference is small; it matters more when the bins are few and the parameters many.

Example: when the bins are sparse. The χ^2_N approximation needs every ν_i to be reasonably large. With a few counts per bin, $(n_i - \nu_i)^2/\nu_i$ is far from a squared Gaussian: a Poisson with small mean is skewed, and a single count of 5 where 1 was expected contributes 16. [Cowan p. 63] finds $\chi^2 = 29.8$ for 20 bins of his bump histogram, where most bins have fewer than five entries, and shows that the χ^2_{20} tail (0.073) understates the true p-value (0.11, from Monte Carlo). Our version uses 20 Poisson bins with expected counts between about 1 and 4. Simulating 200 000 histograms under the null, the 95% point of Pearson's statistic is 33.5, against 31.4 for χ^2_{20}. For an observed value of 30 the simulated p-value is 0.091 and the χ^2 formula would give 0.070. With 25 times more data in the same shape the simulated 95% point becomes 31.4, on the χ^2 value (Figure 4.19, left). The remedy is Cowan's: when counts are small, simulate the null distribution of the statistic you computed.

Binning is a choice, and different choices give different p-values [Cowan p. 63]. Bins must be wide enough for the approximation, yet wide bins throw away where in the bin each event fell. Simulating the null distribution relaxes the first constraint. Avoiding bins altogether removes the choice.

4.8.4 The Kolmogorov–Smirnov test

For n individual measurements $x_1, \ldots, x_n$ we can compare the data with a hypothesised continuous CDF F directly. The **empirical CDF** [the fraction of the data at or below x]

$$F_n(x) = \frac{1}{n} \#\{i : \; x_i \le x\}$$

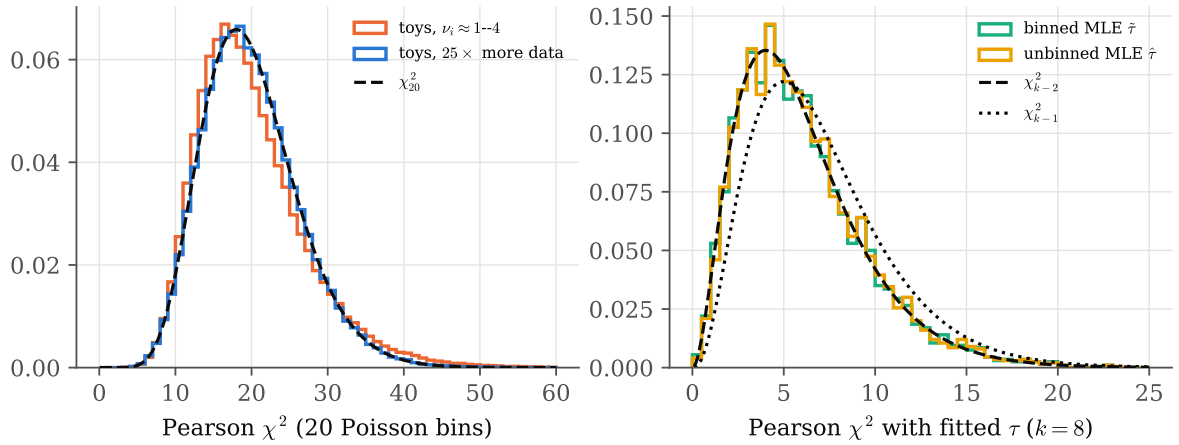

Figure 4.19: Left: the null distribution of Pearson's χ^2 for 20 Poisson bins. With one to four expected counts per bin (orange) it has a longer tail than χ^2_{20} (dashed); with 25 times more data (blue) it lies on the curve. Right: after fitting a decay length, Pearson's statistic follows χ^2_{k-2} when the fit uses the binned counts (green) and sits slightly towards χ^2_{k-1} (dotted) when the fit uses the unbinned decay times (yellow).

is a staircase that climbs by $1/n$ at each data point. The **Kolmogorov–Smirnov statistic** is its largest vertical distance from the model,

$$D_n = \sup_x |F_n(x) - F(x)| \,. \tag{4.40}$$

The supremum over all x reduces to a check at the data points. Sort them, $x_{(1)} \le \cdots \le x_{(n)}$. Between two data points F_n is flat and F increases, so the gap $F_n - F$ is largest just after a jump and $F - F_n$ is largest just before one. At $x_{(i)}$ the staircase jumps from $(i-1)/n$ to i/n, hence

$$D_n = \max\bigl(D_n^+, D_n^-\bigr), \qquad D_n^+ = \max_i\Bigl(\frac{i}{n} - F(x_{(i)})\Bigr), \qquad D_n^- = \max_i\Bigl(F(x_{(i)}) - \frac{i-1}{n}\Bigr). \tag{4.41}$$

Why is the null distribution of D_n the same for every continuous F? Set $u_i = F(x_i)$. Under the null the u_i are uniform on $(0,1)$ by the probability integral transform of Section 4.4.2, and because F is increasing, "$x_i \le x$" is the same as "$u_i \le F(x)$". Writing $u = F(x)$,

$$|F_n(x) - F(x)| \overset{(1)}{=} \Bigl|\frac{1}{n}\#\{i : u_i \le u\} - u\Bigr| \overset{(2)}{=} |G_n(u) - u| \,, \tag{4.42}$$

(1) Replace each event $x_i \le x$ by the equivalent $u_i \le u$.
(2) G_n is the empirical CDF of the uniform sample $u_1, \dots, u_n$.

so D_n is the Kolmogorov–Smirnov distance of a uniform sample from the uniform CDF, whatever F was. Its distribution can be tabulated once; for large n, Kolmogorov showed that $\sqrt{n}D_n$ converges to a limiting distribution with tail $\mathrm{P}(K > x) = 2\sum_{j\ge1}(-1)^{j-1}e^{-2j^2x^2}$.

Example: a decay length that is not what we thought. Fifty decay times are drawn with mean 1.3, and we test the null that the mean is 1, $F(x) = 1 - e^{-x}$. Figure 4.20 (left) shows the empirical staircase below the model curve over most of the range, since longer lifetimes make small times rarer. Our own implementation of (4.41) finds $D_{50} = 0.1790$, so $\sqrt{n}D_n = 1.266$. The exact p-value from `scipy.stats.kstest` (which also returns $D = 0.1790$) is 0.0714; the Kolmogorov limit gives 0.0812; and 40 000 simulated null samples of size 50 give 0.0726. With only fifty events, a 30% change of lifetime gives modest evidence against the null at best, and another fifty decays could easily give a much larger p-value.

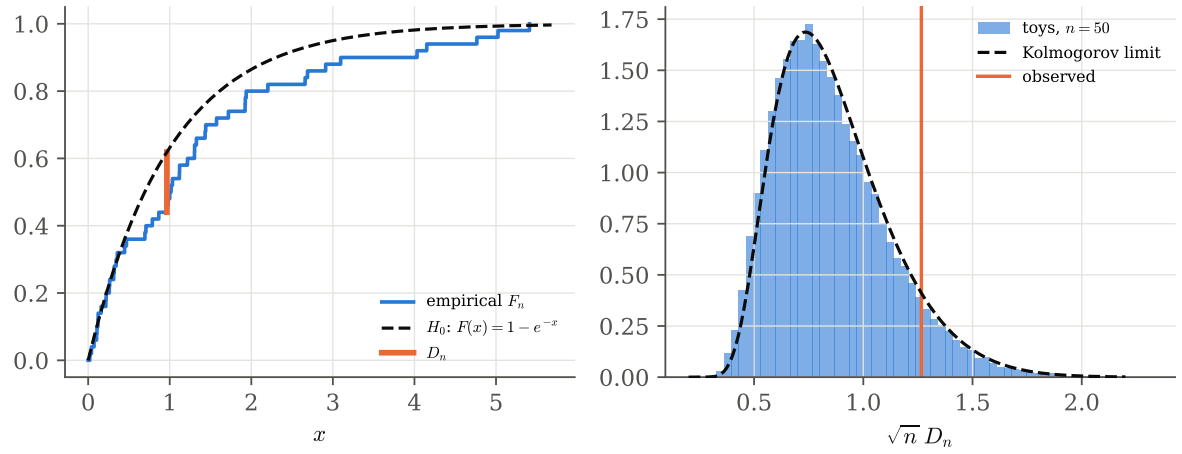

Figure 4.20: Left: the empirical CDF of fifty decay times (blue staircase) and the null model's CDF (dashed). The orange bar marks the largest vertical gap, D_n. Right: the null distribution of $\sqrt{n}\, D_n$ for samples of fifty, from simulation (histogram) and Kolmogorov's large-n limit (dashed), with the observed value marked.

Listing 4.8: The Kolmogorov–Smirnov statistic from scratch (`code/ch04/08_goodness_of_fit.py`)

```
# ---------- (iv) Kolmogorov-Smirnov from scratch ----------
def ks_stat(sample, cdf):
    """D_n = sup_x |F_n(x) - F(x)|; the sup is attained just before or at a data point."""
    xs = np.sort(sample); n = xs.size
    F = cdf(xs)
    d_plus = np.max(np.arange(1, n + 1) / n - F)   # F_n jumps up to i/n at x_(i)
    d_minus = np.max(F - np.arange(0, n) / n)      # just before the jump F_n = (i-1)/n
```

The function sorts the sample, evaluates the model CDF at each point, and takes the two maxima of (4.41) with the vectors `np.arange(1, n+1)/n` (the tops of the steps) and `np.arange(0, n)/n` (the bottoms). It agrees with scipy to every digit printed. The Monte Carlo p-value calls the same function on samples drawn from the null.

Two cautions. The distribution-free property holds only when F is fully specified in advance. If its parameters are estimated from the same data, the fitted CDF hugs the data and D_n is typically smaller, so the tabulated p-values are too large; the null distribution must then be simulated, fitting the parameters afresh on each simulated sample. And like every goodness-of-fit test, a large p-value does not certify the model: it may only mean the test has little power against the departure that is actually present [Wasserman p. 169]. Relatives of KS that weight the whole curve rather than its largest gap, such as the Cramér–von Mises statistic, are often more powerful [Cowan p. 63].

4.9 From p to $Z\sigma$, and why a discovery needs 5σ

Particle physicists rarely quote p-values. They say that an excess is "a 2.6σ fluctuation", that 3σ counts as evidence, and that a discovery needs 5σ. The language comes from Gaussian error bars, but it is used for every kind of test statistic, including Poisson counts and likelihood ratios that are nothing like Gaussian. So "Z sigma" must be a relabelling of the p-value, and it is: a precise one-to-one translation. Once we have it, we can ask why particle physics sets the bar so high, when other fields are content with $p < 0.05$.

The question in words.

1. What exactly does "Z sigma" mean for a test statistic that is not Gaussian?
2. How small is the p-value of a 5σ result, and how does it compare with 3σ?
3. What goes wrong with a lower threshold, given many searches, imperfect backgrounds and new physics that is rare?

4.9.1 The translation

The **significance** Z of a p-value is the number of standard deviations above the mean at which a standard normal variable has the same upper-tail probability [27]:

$$p = \int_Z^\infty \frac{e^{-t^2/2}}{\sqrt{2\pi}}\,\mathrm{d}t = 1 - \Phi(Z) = \Phi(-Z), \qquad Z = \Phi^{-1}(1-p). \tag{4.43}$$

The definition says nothing about the distribution of the actual statistic. A Poisson count, a χ^2, a permutation statistic: whatever gave the p-value, Z is only a relabelling of it on a scale that physicists find intuitive. For the bump of Section 4.1, $p = 0.005172$ becomes $Z = 2.56$. Some authors use the two-sided convention $p = 2\Phi(-Z)$, which corresponds to $|\text{Gaussian}| \geq Z$; discovery claims use the one-sided version, because only an excess counts. The table from `code/ch04/09_p_to_z.py`:

Z	one-sided $\Phi(-Z)$	two-sided $2\Phi(-Z)$
1	0.1587	0.3173
2	0.02275	0.0455
3	0.00135	0.0027
4	3.167×10^{-5}	6.334×10^{-5}
5	2.867×10^{-7}	5.733×10^{-7}
6	9.866×10^{-10}	1.973×10^{-9}

In the other direction, $p = 0.05$ corresponds to $Z = 1.645$ one-sided and 1.960 two-sided. The usual 5% threshold of the life sciences is a 1.6 to 2σ effect, and a 5σ result has a p-value about 170 000 times smaller.

Example: reading the scale in both directions. A search reports a one-sided p-value of 2.5×10^{-4}. Then $Z = \Phi^{-1}(1 - 2.5 \times 10^{-4}) = 3.48$, a little above the 3σ line of "evidence" and well short of 5σ. Had the same number been a two-sided p-value, the one-sided tail would be half of it, 1.25×10^{-4}, and $Z = 3.66$; quoting Z without saying which convention is in use can move the claim by a fifth of a sigma. In the other direction, an analysis planned to reach $Z = 4.2$ must see a background-only tail no bigger than $\Phi(-4.2) = 1.3 \times 10^{-5}$, about one chance in 75 000.

How fast the tail falls. For large Z there is a simple estimate of the tail, useful for checking orders of magnitude without a table. Write $\varphi(t) = e^{-t^2/2}/\sqrt{2\pi}$ and note that $\varphi'(t) = -t\varphi(t)$. Integrating by parts,

$$\begin{aligned}\Phi(-Z) = \int_Z^\infty \varphi(t)\,\mathrm{d}t &\overset{(1)}{=} \int_Z^\infty \frac{1}{t}\,\big(t\varphi(t)\big)\,\mathrm{d}t \overset{(2)}{=} \Big[-\frac{\varphi(t)}{t}\Big]_Z^\infty - \int_Z^\infty \frac{\varphi(t)}{t^2}\,\mathrm{d}t \\ &\overset{(3)}{=} \frac{\varphi(Z)}{Z} - \int_Z^\infty \frac{\varphi(t)}{t^2}\,\mathrm{d}t \overset{(4)}{\approx} \frac{\varphi(Z)}{Z}\Big(1 - \frac{1}{Z^2}\Big).\end{aligned} \tag{4.44}$$

(1) Multiply and divide by t.

(2) Parts, with $u = 1/t$ and $\mathrm{d}v = t\varphi(t)\,\mathrm{d}t$, so $v = -\varphi(t)$ and $\mathrm{d}u = -\mathrm{d}t/t^2$.
(3) The boundary term vanishes at infinity.
(4) The remaining integral is smaller by a factor of about $1/Z^2$; the same trick applied to it gives the correction shown.

At $Z = 5$, $\varphi(5) = e^{-12.5}/\sqrt{2\pi} = 1.49 \times 10^{-6}$, so the estimate is $1.49 \times 10^{-6} \times 0.96/5 = 2.85 \times 10^{-7}$, against the exact 2.867×10^{-7}. The factor $e^{-Z^2/2}$ dominates: each extra sigma near $Z = 5$ costs a factor of $e^{-(Z+1)^2/2+Z^2/2} = e^{-Z-1/2} \approx 250$ in probability.

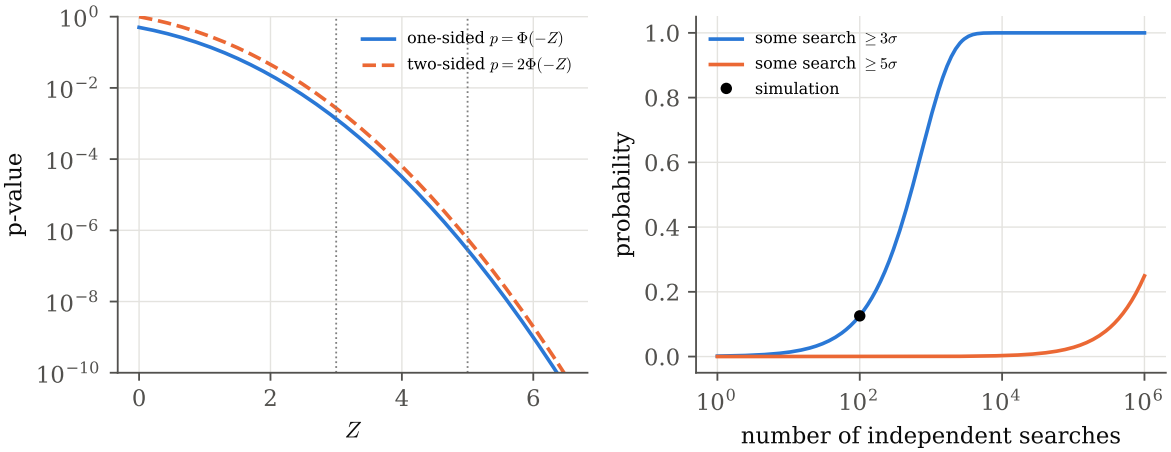

Figure 4.21: Left: the p-value that corresponds to a significance Z, one-sided (solid) and two-sided (dashed), on a log scale; the dotted lines mark 3σ and 5σ. Right: the probability that at least one of many independent background-only searches reaches 3σ (blue) or 5σ (orange). With a hundred searches the chance of a 3σ fluctuation somewhere is already about one in eight; the black dot is a direct simulation.

4.9.2 Why five

Three separate arguments each call for a threshold far stricter than $p < 0.05$: there are many searches, the backgrounds are imperfect, and new physics is rare. We take them one at a time.

Many searches. A laboratory does not run one test. It scans masses, channels, final states, and every analysis group does the same. If N independent searches each have probability p_1 of a false alarm, the probability that at least one of them fires is

$$\mathrm{P}(\text{at least one}) \overset{(1)}{=} 1 - \mathrm{P}(\text{none}) \overset{(2)}{=} 1 - (1 - p_1)^N \overset{(3)}{\approx} N p_1 \quad (N p_1 \ll 1). \tag{4.45}$$

(1) Complement.
(2) Independence: the probability that all N stay quiet is the product.
(3) $(1 - p_1)^N \approx 1 - N p_1$ to first order.

With $N = 100$ and a 3σ threshold, $p_1 = 0.00135$ gives 0.126, and a simulation of the maximum of 100 standard normals over 200 000 trials gives 0.126. One lab in eight would see a 3σ effect from nothing. At 5σ the same number is 2.866×10^{-5}. This is Kruschke's two coins of Section 4.2.2 on a larger scale, and it is the look-elsewhere effect that the second part of the chapter quantifies properly for scans over a mass.

Imperfect backgrounds. The p-value is computed from the null model alone, so an error in the null model goes straight into it. In Section 4.1.4 moving the background from 0.5 to 0.8

events changed the p-value of five events by a factor of about eight. Real detectors also have tails in their resolution functions that no Gaussian captures. A 5σ threshold leaves a margin: an effect that survives it is unlikely to be an artefact of a background that is off by a modest amount. A 3σ effect is not so robust.

New physics is rare. The third argument is the population argument of Section 4.4.4, and it needs Bayes' theorem. *The event* is "the search crossed the threshold". *The question* is what produced it: a real effect, or a false alarm on a null. Suppose that of all the hypotheses that searches test, only a fraction $\pi_1 = 10^{-3}$ are real. *Each route in turn:* when an effect is real, the search reaches the threshold half the time, so the power is 0.5; when the null is true, it reaches it with the false-alarm probability p_{thr} of the threshold. Figure 4.22 draws the probability tree. *Only then the numbers.* The fraction of threshold crossings that are real, the *purity* of the discoveries, is

$$\mathrm{P}(\text{real} \,|\, \text{crossed}) \overset{(1)}{=} \frac{\pi_1 \times 0.5}{\pi_1 \times 0.5 + (1-\pi_1)\, p_{\text{thr}}}, \tag{4.46}$$

(1) Bayes' theorem on the tree: the two branches that end in "crossed" are "real, then detected" and "null, then false alarm".

exactly the purity formula (4.25) of event selection, with hypotheses in place of particles. With $p_{\text{thr}} = 0.00135$ (3σ) the purity is 0.270: nearly three quarters of the "discoveries" would be false. With $p_{\text{thr}} = 2.867 \times 10^{-7}$ (5σ) it is 0.9994. The numbers π_1 and the power are illustrative, and a frequentist cannot even write π_1 into the p-value. But the lesson is robust: when true effects are rare, the threshold must be far smaller than π_1 for a crossing to mean what we want it to mean. Extraordinary claims need extraordinary evidence, and 5σ is how particle physics encodes that without writing down a prior. Chapter 5 writes it down.

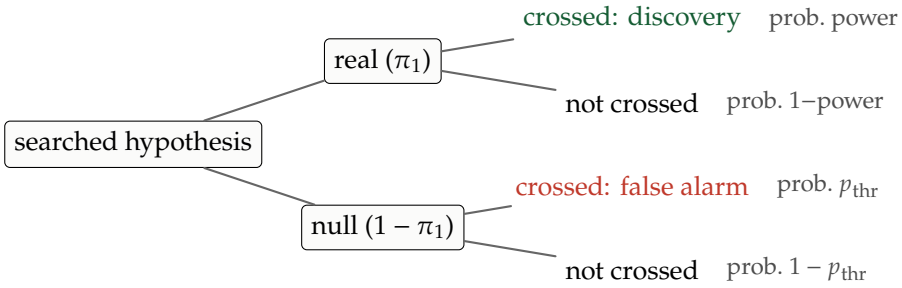

Figure 4.22: The probability tree behind the 5σ convention. First nature decides whether the hypothesis being searched for is real, with a small probability π_1; then the experiment either crosses the threshold or not. Among all crossings, the false alarms (red) come from the heavily populated null branch, the discoveries (green) from the thin real branch. Only a tiny false-alarm probability keeps the red leaf smaller than the green one.

What 5σ does not say. A 5σ result has $p = 2.867 \times 10^{-7}$. It does not follow that the probability of the null is 2.867×10^{-7}, nor that the new particle exists with probability $1 - 2.867 \times 10^{-7}$. As in Section 4.4.4, those are inference-direction statements and need a prior. The convention in particle physics is to call 3σ "evidence" and 5σ an "observation", to report the p-value (or Z) together with the expected significance of the experiment, and to leave the probability of the hypothesis to a Bayesian analysis.

Recap

- The null hypothesis is the one whose sampling distribution we know: "it happened by chance". A test runs in the prediction direction, from H_0 to the outcomes it produces.
- The p-value is the probability, under H_0, of a test statistic at least as extreme as observed, in the direction the alternative predicts. The direction, and the experimental plan (stopping rule, number of places looked), are part of the question.
- A test has size α (false-alarm rate) and a power function $\beta(\theta)$ (rejection rate under the truth). Power grows with effect size and with $\sqrt{n}$; experiment planning is a power calculation.
- Under a continuous null the p-value is uniform, so "reject if $p \le \alpha$" has size α. For discrete data it is valid: $\mathrm{P}(p \le \alpha) \le \alpha$.
- A p-value is not $\mathrm{P}(H_0 \mid \text{data})$: that needs the prior frequency of true nulls and the power (Bayes).
- Wald, t and permutation tests cover most everyday comparisons; the t-test is exact for small Gaussian samples, the permutation test for any distribution.
- Neyman–Pearson: for simple hypotheses the likelihood ratio is the most powerful statistic. With free parameters, $-2\ln\lambda$ is asymptotically χ^2 with as many degrees of freedom as the null fixes (Wilks); on a boundary it is half χ^2_1 and $Z = \sqrt{q_0}$.
- Pearson's χ^2 and Kolmogorov–Smirnov test a whole model; fitted parameters, small counts and estimated CDFs change their null distributions, which can always be simulated.
- $Z = \Phi^{-1}(1-p)$. Discovery needs 5σ because of many searches, imperfect backgrounds and the rarity of real effects.

4.10 From a test to an interval: the values we cannot reject

A new muon trigger is being commissioned. *What happened:* in a test run, 24 muons that we know passed through the detector are sent in, and the trigger fires on 7 of them. (The numbers are those of Kruschke's coin, $z = 7$ heads in $N = 24$ flips [Kruschke §11.3.1]; a trigger efficiency θ, the probability that the trigger fires on a muon, is a heads probability with a different name.) The design goal was an efficiency of one half. A test of $H_0 : \theta = 0.5$ answers one narrow question: do the data contradict the design value? They do not, quite: the two-sided p-value is 0.064, just above 0.05. But the engineer who must decide whether to rebuild the trigger has a different question. *Which efficiencies are compatible with* 7 *firings out of* 24*?* Is 0.4 still possible? Is 0.2? What about 0.6?

The tools of the first part of the chapter already answer this. Each candidate value θ_0 defines its own null hypothesis, $H_0 : \theta = \theta_0$, and we can test each one at level α. Some candidates are rejected; the rest survive. The set of survivors is a confidence interval. So a p-value asks how surprising the data are under one hypothesis, and a confidence interval asks the same question of every hypothesis at once and lists the ones that pass.

The question in words.

1. What property should a reported range $[a, b]$ have, so that quoting it is an honest summary of an experiment, whatever the true θ is?
2. How do we build a range with that property from tests we already know?
3. What does the range say, and what does it not say?

4.10.1 What a confidence interval promises

An interval estimate is a pair of numbers $a(\boldsymbol{X})$ and $b(\boldsymbol{X})$ computed from the data $\boldsymbol{X}$, with $a \le b$, together with the claim "$a \le \theta \le b$" [CasellaBerger Def. 9.1.1]. The data are random, so a and b are random too: rerun the experiment and the interval moves. The parameter does not move. It has one fixed value, which we do not know. So the one thing we can ask of a recipe for intervals is this: over repeated runs of the experiment, how often does the moving interval land on the fixed parameter?

Working definition 4.3 (confidence interval, coverage)

A $1-\alpha$ **confidence interval** for θ is a pair of statistics $a(\boldsymbol{X}) \le b(\boldsymbol{X})$ [functions of the data only, no unknown parameter inside] such that [Wasserman (6.9)]

$$\mathrm{P}_\theta\big(a(\boldsymbol{X}) \le \theta \le b(\boldsymbol{X})\big) \;\ge\; 1-\alpha \qquad \text{for every } \theta \in \Theta.$$

The left side, read as a function of θ, is the **coverage probability** [the fraction of repeated experiments, generated with this θ, whose interval contains it] [CasellaBerger Def. 9.1.4]. Its smallest value over θ is the **confidence coefficient** [CasellaBerger Def. 9.1.5]. *Operational test:* simulate many experiments at a fixed θ, build the interval each time, count the hits; repeat for other θ.

Three words in the definition carry the weight. "Every" θ: we do not know the truth, so the guarantee must hold whatever it is. "At least": for discrete data an exact $1-\alpha$ is impossible, and we then accept intervals that cover more often. "Repeated experiments": the probability is about the recipe, not about the one interval we computed. For a parameter vector the same definition applies to a region (an ellipse, say) instead of an interval, and we speak of a **confidence set**.

We do not need to imagine one experiment repeated forever for this to be useful [Wasserman p. 92]. On day one we measure one quantity and quote a 95% interval. On day two we measure a completely different quantity, on day three another. If every one of those intervals comes from a recipe with 95% coverage, then over a career 95% of the quoted intervals contain their true values, even though no two of them are about the same parameter. The pollster who writes "83% in favour, accurate to within 4 points 95 percent of the time" makes exactly this promise about a lifetime of different questions [Wasserman Ex. 6.13].

4.10.2 Inverting a family of tests

A level-α test of $H_0 : \theta = \theta_0$ has an **acceptance region** $A(\theta_0)$ [the set of data sets for which that null is retained], with

$$\mathrm{P}_{\theta_0}\big(\boldsymbol{X} \in A(\theta_0)\big) \;\ge\; 1-\alpha. \tag{4.47}$$

The acceptance region lives in the space of *data*. We now define a set in the space of *parameters*, one for each observed data set $\boldsymbol{x}$:

$$C(\boldsymbol{x}) = \big\{\theta_0 :\; \boldsymbol{x} \in A(\theta_0)\big\}, \tag{4.48}$$

the set of null values that the data $\boldsymbol{x}$ fail to reject. The two sets are tied together by a statement that is true by definition [CasellaBerger p. 340]:

$$\boldsymbol{x} \in A(\theta_0) \quad \Longleftrightarrow \quad \theta_0 \in C(\boldsymbol{x}). \tag{4.49}$$

Key idea: Test inversion

If $A(\theta_0)$ is the acceptance region of a level-α test of $\theta = \theta_0$, for every θ_0, then the set of values not rejected, $C(\boldsymbol{X}) = \{\theta_0 : \boldsymbol{X} \in A(\theta_0)\}$, is a $1-\alpha$ confidence set. Conversely, from any $1-\alpha$ confidence set, $A(\theta_0) = \{\boldsymbol{x} : \theta_0 \in C(\boldsymbol{x})\}$ is the acceptance region of a level-α test [CasellaBerger Thm. 9.2.2]. Tests and intervals are the same object read in two directions.

The proof is short, and it shows where "for every θ" comes from. Let θ be the true value, whatever it is. We ask: how often does the set of survivors $C(\boldsymbol{X})$ contain it? Then

$$\mathrm{P}_\theta\big(\theta \in C(\boldsymbol{X})\big) \overset{(1)}{=} \mathrm{P}_\theta\big(\boldsymbol{X} \in A(\theta)\big) \overset{(2)}{\geq} 1-\alpha. \tag{4.50}$$

(1) The event "the random set $C(\boldsymbol{X})$ contains θ" is, by (4.49) with $\theta_0 = \theta$, the same event as "the random data fall in the acceptance region of the test of the true value". Same event, same probability.

(2) The test of $\theta_0 = \theta$ has level α, (4.47), and this holds for the true value like for any other.

We never needed to know which θ is true. We built a test for *every* candidate. Whichever candidate is true, its own test decides whether the interval covers it. That test wrongly rejects with probability at most α, so the interval misses with probability at most α. The converse runs the same chain backwards: $\mathrm{P}_{\theta_0}(\boldsymbol{X} \notin A(\theta_0)) = \mathrm{P}_{\theta_0}(\theta_0 \notin C(\boldsymbol{X})) \leq \alpha$.

In practice we use the first direction. Building a level-α test is easy: choose a statistic and a tail, as in the first part of the chapter. Guessing the right shape of an interval is hard. Inversion solves the hard problem with the easy one, and every property of the test carries over to the interval: one-sided tests give one-sided intervals (limits), two-sided tests give two-sided intervals, a test based on a sufficient statistic gives an interval based on it, and a strangely shaped acceptance region gives a strangely shaped set, which need not even be an interval [CasellaBerger p. 341].

Example: the Gaussian mean. Take $X_1, \ldots, X_n$ independent, each $\mathcal{N}(\mu, \sigma^2)$ with σ known, and the two-sided test of $\mu = \mu_0$ that retains when the sample mean $\bar{x}$ is within $z_{\alpha/2}\sigma/\sqrt{n}$ of μ_0, where $z_{\alpha/2} = \Phi^{-1}(1-\alpha/2)$ is the standard normal quantile (1.96 for $\alpha = 0.05$) [CasellaBerger Ex. 9.2.1]. Then

$$\begin{aligned} \boldsymbol{x} \in A(\mu_0) &\overset{(1)}{\Longleftrightarrow} |\bar{x} - \mu_0| \leq z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \\ &\overset{(2)}{\Longleftrightarrow} -z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \leq \bar{x} - \mu_0 \leq z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \\ &\overset{(3)}{\Longleftrightarrow} \bar{x} - z_{\alpha/2}\frac{\sigma}{\sqrt{n}} \leq \mu_0 \leq \bar{x} + z_{\alpha/2}\frac{\sigma}{\sqrt{n}}. \end{aligned} \tag{4.51}$$

(1) Definition of the acceptance region of this test.

(2) An absolute value is at most c exactly when the quantity lies between $-c$ and c.

(3) Subtract $\bar{x}$ throughout and multiply by -1, which reverses both inequalities; then read the result as a condition on μ_0.

The last line is $C(\boldsymbol{x})$: the familiar $\bar{x} \pm z_{\alpha/2}\sigma/\sqrt{n}$. Figure 4.23 draws it. In the plane of (data, parameter), the test keeps the band between two parallel lines. Reading the band horizontally,

at fixed μ_0, gives the acceptance region, a range of $\bar{x}$. Reading it vertically, at the observed $\bar{x}$, gives the confidence interval, a range of μ. The test fixes the parameter and asks which data are consistent with it; the interval fixes the data and asks which parameters are consistent with them.

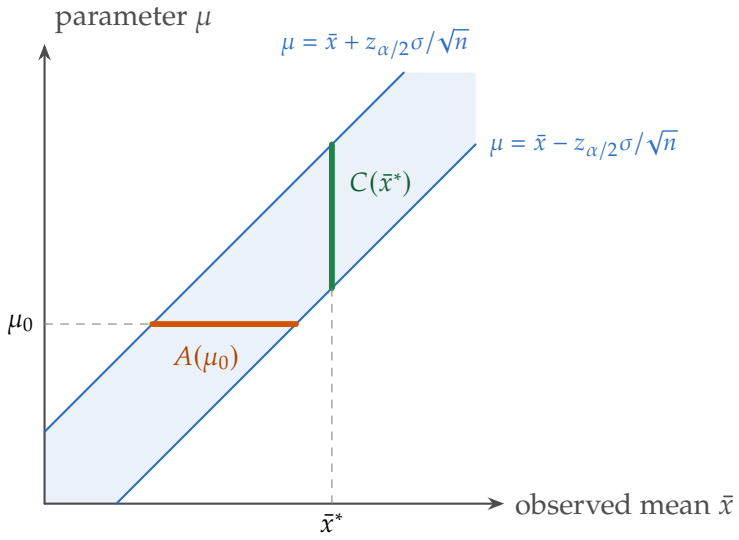

Figure 4.23: The Gaussian test and its interval are one band. The shaded band holds the pairs (observed mean, parameter) that the level-α test does not reject. A horizontal cut at a hypothesised μ_0 gives the range of data the test accepts (orange). A vertical cut at the mean actually observed gives the range of parameters the data do not reject (green): the confidence interval.

Example: the trigger efficiency, exactly. Back to the trigger: $N = 24$ muons, of which $z = 7$ fired it. The number of firings Z is binomial, Binomial(N, θ). *The question:* which θ_0 does a two-sided test at level α fail to reject? The test splits α equally between the two tails, so a candidate can fail in two ways.

- It is too *small* if, under θ_0, seeing z or more firings has probability at most $\alpha/2$.
- It is too *large* if, under θ_0, seeing z or fewer firings has probability at most $\alpha/2$.

The survivors are the θ_0 that fail neither way:

$$\mathrm{P}(Z \geq z \mid \theta_0) > \frac{\alpha}{2} \qquad \text{and} \qquad \mathrm{P}(Z \leq z \mid \theta_0) > \frac{\alpha}{2}. \tag{4.52}$$

As θ_0 grows, each muon is more likely to fire the trigger, so the first tail grows and the second shrinks. The first condition therefore cuts off small θ_0, the second cuts off large θ_0, and the survivors form an interval $[\theta_L, \theta_U]$, whose ends solve $\mathrm{P}(Z \geq z \mid \theta_L) = \alpha/2$ and $\mathrm{P}(Z \leq z \mid \theta_U) = \alpha/2$. This is the **Clopper–Pearson** interval [CasellaBerger Ex. 9.2.5]. For our trigger it is

$$\theta \in [0.126,\ 0.511] \qquad (95\%),$$

the numbers Kruschke finds for the same data [Kruschke p. 321]. The design value 0.5 is inside, which is the interval version of $p = 0.064 > 0.05$. So is 0.2, and so is every efficiency from about 0.13 to about 0.51. That answers the engineer: 0.2 and 0.4 are still possible, 0.6 is not. Seven firings in twenty-four is weak information.

Figure 4.24 shows the whole family of tests at once. For every θ_0 on the horizontal axis we plot the two-sided p-value of $H_0 : \theta = \theta_0$. This **p-value function** is largest near the observed

fraction $\hat{\theta} = 0.292$ and falls off on both sides; the confidence interval is the set where it stays above α. The curve is not a probability density for θ: its height at θ_0 is a tail probability of the data, and the area under it has no meaning (it need not be one) [Kruschke p. 323].

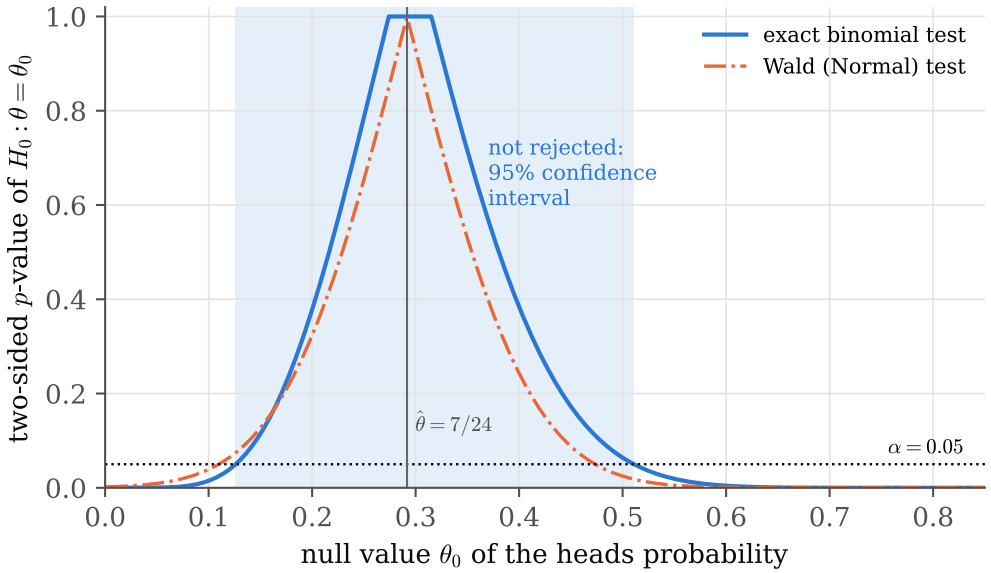

Figure 4.24: The two-sided p-value of $\theta = \theta_0$ for 7 successes in 24 trials, as a function of the hypothesised θ_0. The solid curve uses the exact binomial tails, the dash-dotted one the Normal (Wald) approximation. Where a curve stays above the dotted line at $\alpha = 0.05$, the null value survives; the shaded strip is the exact 95% confidence interval. The Wald curve is symmetric about $\hat{\theta}$ and shifted to the left of the exact one.

Two cheaper intervals for the same data. The exact interval needs a root finder. Two shortcuts avoid it. The first, the Normal (Wald) interval, treats the observed fraction $\hat{\theta} = z/N$ as Gaussian with mean θ and estimated standard error $\widehat{\mathrm{se}} = \sqrt{\hat{\theta}(1-\hat{\theta})/N}$. Its coverage is right only in the large-sample limit [Wasserman Thm. 6.16]. To see why, write $\hat{\theta}_n$ for the estimate from n trials and suppose $(\hat{\theta}_n - \theta)/\widehat{\mathrm{se}}$ tends in distribution to $Z \sim \mathcal{N}(0,1)$ (here Z is a standard normal variable, not the count). Then

$$\begin{aligned} \mathrm{P}_\theta\big(\hat{\theta}_n - z_{\alpha/2}\widehat{\mathrm{se}} < \theta < \hat{\theta}_n + z_{\alpha/2}\widehat{\mathrm{se}}\big) &\overset{(1)}{=} \mathrm{P}_\theta\Big(-z_{\alpha/2} < \frac{\hat{\theta}_n - \theta}{\widehat{\mathrm{se}}} < z_{\alpha/2}\Big) \\ &\xrightarrow{(2)} \mathrm{P}\big(-z_{\alpha/2} < Z < z_{\alpha/2}\big) \overset{(3)}{=} 1 - \alpha. \end{aligned} \tag{4.53}$$

(1) The same rearrangement of inequalities as in (4.51), now with $\hat{\theta}_n$ and $\widehat{\mathrm{se}}$.
(2) Convergence in distribution: probabilities of intervals converge to those of the limit.
(3) The definition of $z_{\alpha/2}$ puts $\alpha/2$ in each tail.

For the trigger, $\widehat{\mathrm{se}} = 0.0928$ and the interval is $[0.110, 0.474]$. It is symmetric about $\hat{\theta}$, while the exact one reaches further up, because a binomial with θ below one half has a longer right tail. The second shortcut, from Hoeffding's inequality, gives a third interval, $\hat{\theta} \pm \epsilon_N$ with $\epsilon_N^2 = \ln(2/\alpha)/(2N)$, which covers with probability at least $1 - \alpha$ for *every* N, not just in the limit [Wasserman Ex. 6.15]. Here $\epsilon_N = 0.277$ and the interval is $[0.014, 0.569]$, almost twice as long. That is the price of a guarantee that uses nothing about the binomial except that each trial is between 0 and 1. So the trade is: the Normal interval is shorter, but its coverage is only approximately right [Wasserman Ex. 6.17]. How far off it is, we measure in Section 4.12.

Example: inverting a likelihood-ratio test. Test inversion works with any test, including the likelihood-ratio test. Casella and Berger take n lifetimes from an exponential distribution with mean λ [CasellaBerger Ex. 9.2.3]. The likelihood is $\lambda^{-n}e^{-\sum x_i/\lambda}$, it is largest at $\hat{\lambda} = \sum x_i/n$, and the ratio of the likelihood at λ_0 to its maximum is

$$\frac{\lambda_0^{-n}e^{-\sum x_i/\lambda_0}}{\hat{\lambda}^{-n}e^{-n}} \overset{(1)}{=} \left(\frac{\sum x_i}{n\lambda_0}\right)^n e^{\,n}\, e^{-\sum x_i/\lambda_0}. \tag{4.54}$$

(1) Insert $\hat{\lambda} = \sum x_i/n$ in the denominator, so that $e^{-\sum x_i/\hat{\lambda}} = e^{-n}$, and collect powers.

The test retains λ_0 when this ratio is large, above some threshold k. Write $T = \sum x_i/\lambda_0$. Then the ratio is $(T/n)^n e^n e^{-T}$, so the condition is $T^n e^{-T} \geq k^*$, where the constant n^n/e^n has been moved into the new threshold $k^* = kn^n/e^n$. The function $T^n e^{-T}$ rises and then falls, so it is above a level exactly on a stretch $b \leq T \leq a$ whose ends have equal height, $a^n e^{-a} = b^n e^{-b}$. Solving $b \leq \sum x_i/\lambda_0 \leq a$ for λ_0 gives the interval $\sum x_i/a \leq \lambda \leq \sum x_i/b$.

Its coverage. The interval covers the true λ exactly when $T = \sum X_i/\lambda$ lies between b and a. Each X_i/λ is exponential with mean one, whatever λ is, so T is a sum of n exponentials of mean one, a Gamma$(n, 1)$ variable, with the same distribution for every λ. For $n = 2$ its density is te^{-t}, and

$$\mathrm{P}(b \leq T \leq a) \overset{(1)}{=} \int_b^a te^{-t}\,\mathrm{d}t \overset{(2)}{=} \left[-te^{-t}\right]_b^a + \int_b^a e^{-t}\,\mathrm{d}t \overset{(3)}{=} e^{-b}(b+1) - e^{-a}(a+1). \tag{4.55}$$

(1) The Gamma$(2, 1)$ density.
(2) Integration by parts with $u = t$, $\mathrm{d}v = e^{-t}\mathrm{d}t$.
(3) Evaluate both terms and collect.

Requiring 0.90 and $a^2e^{-a} = b^2e^{-b}$ at the same time gives $a = 5.480$, $b = 0.441$ and a confidence coefficient of 0.90006. As a check: $e^{-0.441} \times 1.441 = 0.9272$ and $e^{-5.480} \times 6.480 = 0.0270$, whose difference is 0.900; and $5.480^2e^{-5.480} = 0.125 = 0.441^2e^{-0.441}$. The interval for two lifetimes is $[\sum x_i/5.48,\ \sum x_i/0.441]$, a factor of twelve wide.

The exponential example worked so smoothly because $T = \sum X_i/\lambda$ has a distribution that does not depend on λ. Such a function of data and parameter is called a **pivot** [CasellaBerger Def. 9.2.6]. $(\bar{X} - \mu)/(\sigma/\sqrt{n})$ is a pivot for a Gaussian mean, and $(\bar{X} - \mu)/(S/\sqrt{n})$, with the sample standard deviation S, is a pivot with a Student t_{n-1} distribution when σ is unknown. A pivot gives an interval whose coverage is the same for every parameter value, and the coverage can be computed once. Without a pivot, as for the binomial, coverage depends on θ, and we have to check it everywhere (Section 4.12).

One-sided limits. Inverting one-sided tests gives one-sided intervals. To get an *upper* bound for a Gaussian mean with unknown σ, test $\mu = \mu_0$ against $\mu < \mu_0$. The level-α test rejects when $(\bar{x} - \mu_0)/(s/\sqrt{n}) < -t_{n-1,\alpha}$, so it retains when $\mu_0 \leq \bar{x} + t_{n-1,\alpha}s/\sqrt{n}$, and the survivors form $(-\infty,\ \bar{x} + t_{n-1,\alpha}s/\sqrt{n}]$ [CasellaBerger Ex. 9.2.4]. The alternative decides the shape: an alternative of *small* values rejects large μ_0, and what survives is everything below a bound. Upper limits on signal rates in searches are built this way (Section 4.13).

4.10.3 Tests and intervals give the same verdict

Wasserman states the special case of test inversion that practitioners use every day [Wasserman Thm. 10.10]: the size-α Wald test rejects $\theta = \theta_0$ exactly when θ_0 lies outside $\hat{\theta} \pm z_{\alpha/2}\widehat{\mathrm{se}}$. It is (4.51) with $\widehat{\mathrm{se}}$ in place of $\sigma/\sqrt{n}$. Checking whether a null value is inside a 95% interval *is* a test at the 5% level.

The interval carries more information than the verdict, and that answers a common confusion between statistical and scientific significance [Wasserman p. 155]. Figure 4.25 shows two intervals that both exclude θ_0, so both tests reject. In the first, the whole interval sits close to θ_0: the effect is real but tiny, perhaps too small to matter. In the second, the interval is far away: the effect is large. A p-value alone cannot tell these apart; the interval can. A 3×10^{-4} shift in a calibration constant can be "highly significant" with enough data and still irrelevant to every physics result that uses the constant.

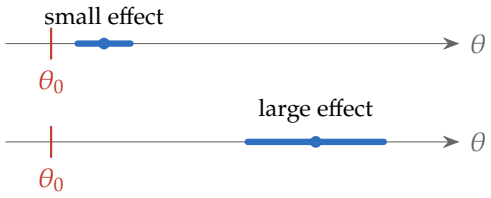

Figure 4.25: Statistical versus scientific significance. Both 95% intervals (blue bars, dots at the estimates) exclude the null value θ_0, so both data sets reject H_0 at the 5% level. In the top row the effect is close to θ_0 and may not matter in practice; in the bottom row it is large. The interval reports the size of the effect; the test only reports that it is not zero.

4.10.4 The interval inherits the test's intentions

The first part of the chapter found that a p-value depends on the stopping rule: the same 7 heads in 24 flips gave different p-values when the experimenter meant to stop at $N = 24$, at $z = 7$, or when time ran out. An interval built from those tests inherits the dependence. Kruschke works out the 95% intervals for the four intentions [Kruschke pp. 318–321]:

intention of the experimenter	95% confidence interval for θ
stop after $N = 24$ trials	[0.126, 0.511]
stop after $z = 7$ successes	[0.126, 0.484]
stop when the time is up	[0.135, 0.497]
test two coins, each with fixed N	[0.110, 0.539]

The data are identical in all four rows. What differs is the cloud of experiments that *could* have happened, and a confidence interval, like a p-value, is a statement about that cloud. For a trigger test this is not academic. A run stopped "when the beam went down" has a random N, and strictly its interval must be computed for that plan. Section 4.17 returns to this point: the Bayesian interval depends on the data only through the likelihood and does not care why the experimenter stopped.

Python. The inversion for the trigger is a few lines of `code/ch04/11_test_inversion.py`.

Listing 4.9: The exact binomial interval by test inversion (`code/ch04/11_test_inversion.py`)

```
# ---------- exact p-value function: two tails, each compared with alpha/2 ----------
def p_lower_tail(t):          # P(Z <= z | theta = t): small when t is too large
    return stats.binom.cdf(z, N, t)

def p_upper_tail(t):          # P(Z >= z | theta = t): small when t is too small
    return stats.binom.sf(z - 1, N, t)

def p_two_sided(t):
    return np.minimum(1.0, 2 * np.minimum(p_lower_tail(t), p_upper_tail(t)))

```

```
# the interval ends are where each one-sided tail equals alpha/2
lo = optimize.brentq(lambda t: p_upper_tail(t) - alpha / 2, 1e-6, z / N)
hi = optimize.brentq(lambda t: p_lower_tail(t) - alpha / 2, z / N, 1 - 1e-6)
# the same numbers from the binomial-beta identity (a check)
lo_beta = stats.beta.ppf(alpha / 2, z, N - z + 1)
hi_beta = stats.beta.ppf(1 - alpha / 2, z + 1, N - z)
assert abs(lo - lo_beta) < 1e-6 and abs(hi - hi_beta) < 1e-6
```

The two functions are the tails in (4.52): `binom.cdf(z, N, t)` is $P(Z \le z)$ and `binom.sf(z - 1, N, t)` is $P(Z \ge z)$ (the survival function is a strict inequality, hence the $z-1$). The p-value function is twice the smaller tail, capped at one. The interval ends come from a root finder: `brentq` solves "tail = $\alpha/2$" on the side of $\hat{\theta}$ where that tail is the one that shrinks. The last lines check the result against a closed form. Integrating the beta density by parts z times shows that $P(Z \ge z \mid \theta)$ equals the probability that a Beta$(z, N-z+1)$ variable is below θ, so θ_L is a beta quantile, and similarly for θ_U; the assertion confirms that the root finder and the identity agree to 10^{-6}.

Watch out: "The parameter is in the interval with probability 95%"

After the experiment the interval is two numbers, $[0.126, 0.511]$, and the efficiency is one number. Either it is inside or it is not; in the frequentist framework the probability is 0 or 1, and we do not know which [Cowan p. 123]. The 95% belongs to the recipe that produced the two numbers. Saying "the efficiency lies in $[0.126, 0.511]$ with probability 95%" is a statement about θ given the data, an inference-direction statement, and it needs a prior (Section 4.17, Chapter 5).

4.11 The Neyman construction: a belt of acceptance regions

A calorimeter measures the energy of a jet. The estimate $\hat{\theta}$ it returns is not Gaussian: at low energy the response is skewed, at high energy it is wider, and the shape of the scatter changes with the true energy θ. From test beams or simulation we know, for every true θ, the distribution $g(\hat{\theta}; \theta)$ of the estimate. We see one number, $\hat{\theta}_{\text{obs}}$, and want an interval for θ that covers the true energy in, say, 68.3% of repeated measurements, whatever that energy is.

Test inversion (Section 4.10.2) already tells us what to do. For every θ, choose a set of $\hat{\theta}$ values that has probability $1-\alpha$ under $g(\cdot; \theta)$. Then collect the θ whose set contains the observation. Drawing all those sets at once on one graph is Neyman's construction of 1937 [Cowan §9.2], [28]. Every other frequentist interval in this chapter is a special case of it, or a shortcut to it.

The question in words. Given only the family of sampling distributions $g(\hat{\theta}; \theta)$: how do we draw a region in the (data, parameter) plane that yields, for any observed $\hat{\theta}$, an interval with guaranteed coverage? And how does the recipe look for the two workhorses, a Gaussian estimate and a Poisson count?

4.11.1 The construction, step by step

We use the convention of Feldman and Cousins: the measured quantity on the horizontal axis, the parameter on the vertical axis [28].

Step 1. *For one hypothetical θ, pick an acceptance interval.* Along the horizontal line at height θ, choose $[v_\beta(\theta), u_\alpha(\theta)]$ such that the estimate falls above u_α with probability α and

below v_β with probability β [Cowan (9.1)–(9.2)]:

$$\alpha = \int_{u_\alpha(\theta)}^{\infty} g(\hat{\theta};\theta)\,\mathrm{d}\hat{\theta}, \qquad \beta = \int_{-\infty}^{v_\beta(\theta)} g(\hat{\theta};\theta)\,\mathrm{d}\hat{\theta}. \tag{4.56}$$

Why legitimate? We only used $g(\cdot;\theta)$, which we know for every θ by assumption. The data play no role yet.

Step 2. *Repeat for every θ.* The horizontal intervals sweep out a region, the **confidence belt**, bounded by the curves $v_\beta(\theta)$ on the left and $u_\alpha(\theta)$ on the right. For every θ, by construction, $\mathrm{P}\big(v_\beta(\theta) \le \hat{\theta} \le u_\alpha(\theta)\big) = 1 - \alpha - \beta$ [Cowan (9.3)].

Step 3. *Do the experiment, draw a vertical line at $\hat{\theta}_{\text{obs}}$.* The confidence interval $[a, b]$ is the set of θ whose horizontal interval is cut by the line. *Why legitimate?* This is (4.48): the horizontal interval at θ is the acceptance region of a test of θ, and the vertical cut collects the values not rejected.

Why does the result cover? Figure 4.26 shows it. Suppose the truth is θ_{true}, a height on the graph that we do not know.

- The interval contains θ_{true} exactly when the vertical line at $\hat{\theta}_{\text{obs}}$ cuts the horizontal segment at height θ_{true}.
- That happens exactly when $\hat{\theta}_{\text{obs}}$ falls inside that segment.
- By Step 1, the estimate falls inside the segment at the true height with probability $1 - \alpha - \beta$.

So the coverage equals the probability inside the horizontal segment at the true value. We made that $1 - \alpha - \beta$ at every height, so it holds whatever the truth is.

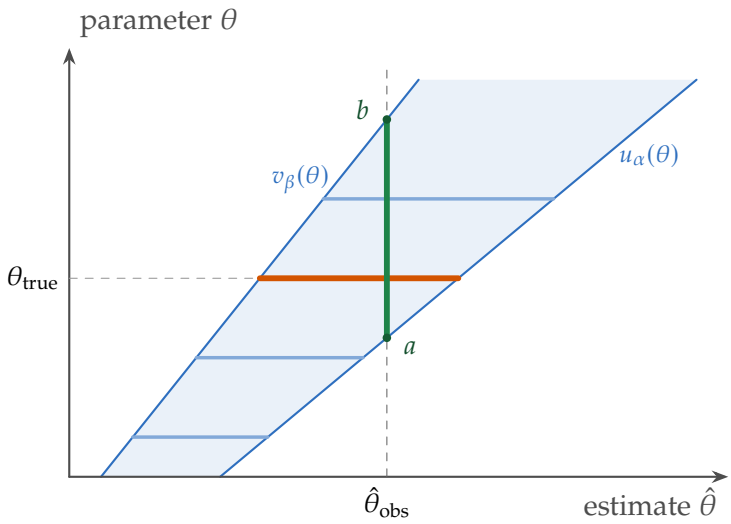

Figure 4.26: A confidence belt. For each hypothetical θ (vertical axis) the horizontal segment holds the estimates that are accepted, with probability $1 - \alpha - \beta$; a few are drawn, and the one at the true value is orange. The vertical line at the observed estimate cuts the belt between a and b (green): that is the confidence interval. The lower end a comes from the right edge of the belt, the upper end b from the left edge. The green interval contains θ_{true} exactly when the observed estimate lies on the orange segment.

Working definition 4.4 (confidence belt)

For each parameter value θ an **acceptance interval** $[v_\beta(\theta), u_\alpha(\theta)]$ of the estimate, with probability $1-\alpha-\beta$ under $g(\hat{\theta};\theta)$. The union over θ is the **confidence belt**. The interval for an observation is the vertical cut of the belt at $\hat{\theta}_{\text{obs}}$. *Operational recipe:* on a grid of θ, compute the acceptance interval from the known (or simulated) distribution of the estimate; for the observed value, keep every grid point whose interval contains it.

The same thing with inverse functions. If the estimator is a good one, both edges increase with θ: a larger true value gives larger estimates. Then they can be inverted, $a(\hat{\theta}) \equiv u_\alpha^{-1}(\hat{\theta})$ and $b(\hat{\theta}) \equiv v_\beta^{-1}(\hat{\theta})$ [Cowan (9.4)], and the coverage follows in two lines. Fix the true θ. Then

$$\mathrm{P}\big(a(\hat{\theta}) \geq \theta\big) \overset{(1)}{=} \mathrm{P}\big(\hat{\theta} \geq u_\alpha(\theta)\big) \overset{(2)}{=} \alpha, \qquad \mathrm{P}\big(b(\hat{\theta}) \leq \theta\big) \overset{(3)}{=} \mathrm{P}\big(\hat{\theta} \leq v_\beta(\theta)\big) \overset{(4)}{=} \beta,$$
$$\mathrm{P}\big(a(\hat{\theta}) < \theta < b(\hat{\theta})\big) \overset{(5)}{=} 1-\alpha-\beta. \tag{4.57}$$

(1) u_α is increasing, so applying it to both sides of $a(\hat{\theta}) \geq \theta$ preserves the inequality, and $u_\alpha(a(\hat{\theta})) = \hat{\theta}$ by the definition of the inverse.
(2) The definition of u_α in (4.56).
(3) The same step for v_β and b.
(4) The definition of v_β.
(5) The two "miss" events cannot happen together, because $a < b$ (the right edge of the belt lies to the right of the left edge), so the probability of a hit is one minus the sum of the two.

The random quantities are a and b: they depend on $\hat{\theta}$. Repeated experiments give different intervals, and a fraction $1-\alpha-\beta$ of them contain the fixed θ [Cowan p. 121].

In practice we find a and b without drawing the belt. By the definition of the inverses, $u_\alpha(a) = \hat{\theta}_{\text{obs}}$ and $v_\beta(b) = \hat{\theta}_{\text{obs}}$. Putting these into (4.56), at $\theta = a$ for the first integral and $\theta = b$ for the second, gives [Cowan (9.9)]

$$\alpha = \int_{\hat{\theta}_{\text{obs}}}^{\infty} g(\hat{\theta}; a)\,\mathrm{d}\hat{\theta}, \qquad \beta = \int_{-\infty}^{\hat{\theta}_{\text{obs}}} g(\hat{\theta}; b)\,\mathrm{d}\hat{\theta}. \tag{4.58}$$

In words: the lower end a is the parameter value for which an estimate as large as the one observed, or larger, would occur with probability α; the upper end b is the value for which an estimate this small or smaller would occur with probability β. Each end is a one-sided test with p-value exactly α (or β). Beware of the names here. The p-value of the test of $\theta = a$ is α, a small number. The confidence level of the limit $\theta \geq a$ is $1-\alpha$, a large one. To keep them apart we say "confidence level" only for the coverage of an interval and "p-value" only for tests [Cowan pp. 122–123].

Central and one-sided. The recipe leaves one choice free: how to split the excluded probability between the two sides. If the total excluded probability is γ, then $\alpha = \beta = \gamma/2$ gives a **central** interval of level $1-\gamma$. $\beta = 0$ gives a lower limit, $\alpha = 0$ an upper limit. A central interval has equal probabilities of missing on either side; it need not be symmetric about the estimate. And the choice must be made *before* looking at the data. Section 4.13 shows what goes wrong when the data decide it.

4.11.2 Gaussian estimate: the error bar is a 68.3% interval

When $g(\hat{\theta};\theta)$ is Gaussian with mean θ and known standard deviation $\sigma_{\hat{\theta}}$, the cumulative distribution is $G(\hat{\theta};\theta) = \Phi\big((\hat{\theta}-\theta)/\sigma_{\hat{\theta}}\big)$ [Cowan (9.10)]. Then (4.58) can be solved in closed form:

$$\alpha \overset{(1)}{=} 1 - \Phi\Big(\frac{\hat{\theta}_{\text{obs}} - a}{\sigma_{\hat{\theta}}}\Big) \implies a \overset{(2)}{=} \hat{\theta}_{\text{obs}} - \sigma_{\hat{\theta}}\,\Phi^{-1}(1-\alpha),$$
$$\beta \overset{(3)}{=} \Phi\Big(\frac{\hat{\theta}_{\text{obs}} - b}{\sigma_{\hat{\theta}}}\Big) \implies b \overset{(4)}{=} \hat{\theta}_{\text{obs}} - \sigma_{\hat{\theta}}\,\Phi^{-1}(\beta) \overset{(5)}{=} \hat{\theta}_{\text{obs}} + \sigma_{\hat{\theta}}\,\Phi^{-1}(1-\beta). \tag{4.59}$$

(1) The upper tail beyond $\hat{\theta}_{\text{obs}}$ of a Gaussian centred on a.
(2) Solve: $\Phi\big((\hat{\theta}_{\text{obs}} - a)/\sigma\big) = 1-\alpha$, apply Φ^{-1} and rearrange.
(3) The lower tail below $\hat{\theta}_{\text{obs}}$ of a Gaussian centred on b.
(4) Apply Φ^{-1} and rearrange.
(5) Symmetry of the Gaussian: $\Phi^{-1}(\beta) = -\Phi^{-1}(1-\beta)$.

With $\alpha = \beta = 0.1587$, $\Phi^{-1}(1-\alpha) = 1$ and the 68.3% central interval is $\hat{\theta}_{\text{obs}} \pm \sigma_{\hat{\theta}}$ [Cowan (9.13)]. This is the precise sense in which a "one-sigma error bar" is a confidence interval. The standard quantiles, which every physicist ends up knowing by heart [Cowan Tables 9.1–9.2]:

central, $1-\gamma$		one-sided, $1-\alpha$	
$\Phi^{-1}(1-\gamma/2)$	$1-\gamma$	$\Phi^{-1}(1-\alpha)$	$1-\alpha$
1	0.6827	1	0.8413
2	0.9544	2	0.9772
3	0.9973	3	0.9987
1.645	0.90	1.282	0.90
1.960	0.95	1.645	0.95
2.576	0.99	2.326	0.99

The number 1.645 appears twice: it is the central 90% quantile and the one-sided 95% one. This coincidence matters when a parameter sits at a physical boundary (Section 4.13).

Physicists use the same convention, the 68.3% central interval, for error bars even when g is not Gaussian. The interval is then no longer symmetric, and the result is quoted as $\hat{\theta}^{+d}_{-c}$, meaning $a = \hat{\theta} - c$ and $b = \hat{\theta} + d$. For example, $5.79^{+0.32}_{-0.25}$ means: the recipe that produced $[5.54, 6.11]$ covers the true value in 68.3% of repeated experiments, with equal chances of missing high and low. It does not mean that θ lies in $[5.54, 6.11]$ with probability 68.3% [Cowan p. 123]. When $\sigma_{\hat{\theta}}$ is itself estimated from the data, the pivot becomes Student's t; for large samples the Gaussian recipe with the estimated $\hat{\sigma}$ is fine, for small ones it is not, and Section 4.12 measures by how much.

4.11.3 Poisson counts: a belt with steps

A count n of rare events is Poisson with mean ν, and the estimate is $\hat{\nu} = n$ [Cowan (9.14)]. *What changes:* the estimate now takes only integer values. So (4.56) cannot be satisfied exactly. The tail probability beyond an integer changes in jumps from one integer to the next, and for a given α there is usually no integer $u_\alpha(\nu)$ whose tail is exactly α. *The fix:* keep the end conditions (4.58), and count the observed value as part of each tail [Cowan (9.15)–(9.16)]:

$$\alpha = \mathrm{P}(n \geq n_{\text{obs}}; a) = 1 - \sum_{n=0}^{n_{\text{obs}}-1} \frac{a^n}{n!} e^{-a}, \qquad \beta = \mathrm{P}(n \leq n_{\text{obs}}; b) = \sum_{n=0}^{n_{\text{obs}}} \frac{b^n}{n!} e^{-b}. \tag{4.60}$$

These can be solved numerically. There is also a closed form, because the Poisson cumulative sum is a χ^2 tail [Cowan (9.17)]:

$$\sum_{n=0}^{k} \frac{\nu^n}{n!} e^{-\nu} = \int_{2\nu}^{\infty} f_{\chi^2}\big(z;\, 2(k+1)\big)\, \mathrm{d}z, \qquad f_{\chi^2}(z;m) = \frac{z^{m/2-1} e^{-z/2}}{2^{m/2}\,\Gamma(m/2)}. \tag{4.61}$$

To prove the identity, we show that the two sides start at the same value and change at the same rate. Call the left side $F(\nu)$ and the right side $H(\nu)$. Both equal one at $\nu = 0$: on the left only the $n = 0$ term survives, and on the right the whole χ^2 density is integrated. Their derivatives are

$$\begin{aligned} F'(\nu) &\overset{(1)}{=} \sum_{n=0}^{k} \Big(\frac{n\nu^{n-1}}{n!} - \frac{\nu^n}{n!} \Big) e^{-\nu} \overset{(2)}{=} \sum_{n=1}^{k} \frac{\nu^{n-1}}{(n-1)!} e^{-\nu} - \sum_{n=0}^{k} \frac{\nu^n}{n!} e^{-\nu} \overset{(3)}{=} -\frac{\nu^k}{k!} e^{-\nu}, \\ H'(\nu) &\overset{(4)}{=} -2\, f_{\chi^2}\big(2\nu;\, 2k+2\big) \overset{(5)}{=} -2\, \frac{(2\nu)^k e^{-\nu}}{2^{k+1}\, k!} \overset{(6)}{=} -\frac{\nu^k}{k!} e^{-\nu}. \end{aligned} \tag{4.62}$$

(1) Product rule on $\nu^n e^{-\nu}$.
(2) Cancel n against $n!$ in the first sum; its $n = 0$ term is zero.
(3) Shift $n - 1 \to n$ in the first sum: it becomes the second sum without its last term, so everything cancels except $-\nu^k e^{-\nu}/k!$.
(4) Fundamental theorem of calculus, with the lower limit 2ν whose derivative is 2.
(5) Insert the density with $m = 2k + 2$: $z^{m/2-1} = (2\nu)^k$, $e^{-z/2} = e^{-\nu}$, $2^{m/2} = 2^{k+1}$, $\Gamma(k+1) = k!$.
(6) Simplify $2 \cdot 2^k / 2^{k+1} = 1$.

The two functions are equal at $\nu = 0$ and have equal derivatives everywhere, so they are equal for every ν. Applying the identity to the two conditions in (4.60) (with $k = n_{\text{obs}} - 1$ for a and $k = n_{\text{obs}}$ for b) turns each into a χ^2 probability up to $2a$ or beyond $2b$, so the limits are quantiles of χ^2 distributions [Cowan (9.18)]:

$$a = \tfrac{1}{2} F^{-1}_{\chi^2}(\alpha;\, 2n_{\text{obs}}), \qquad b = \tfrac{1}{2} F^{-1}_{\chi^2}(1-\beta;\, 2(n_{\text{obs}}+1)), \tag{4.63}$$

where $F^{-1}_{\chi^2}(p;m)$ is the p quantile with m degrees of freedom. These are Garwood's intervals of 1936 [CasellaBerger Ex. 9.2.15]. For n independent Poisson observations of rate λ the sum is Poisson$(n\lambda)$, and the interval for λ is (4.63) divided by n; with $n = 10$ observations summing to 6, the 90% interval is $[0.261,\ 1.184]$.[1]

Example: zero events. If nothing is seen, $n_{\text{obs}} = 0$, there is no lower limit and the upper limit solves $\beta = e^{-b}$, so $b = -\ln\beta$ [Cowan (9.20)]. At 95%, $b = -\ln 0.05 = 2.996 \approx 3$: if the mean were 3, seeing nothing would happen 5% of the time. This "rule of three" is how a search that sees no candidate events quotes its sensitivity. At 90% it is 2.303.

Example: the 90% **table.** Script `code/ch04/12_neyman_poisson_belt.py` builds the belt by brute force (for each ν on a grid, keep the counts whose two tails both exceed 5%), reads off the intervals, and checks them against (4.63):

n_{obs}	0	1	2	3	4	5	6	7	8	9	10
a	0.00	0.05	0.36	0.82	1.37	1.97	2.61	3.29	3.98	4.70	5.43
b	3.00	4.74	6.30	7.75	9.15	10.51	11.84	13.15	14.43	15.71	16.96

[1] Casella and Berger print 0.262 for the lower end; $F^{-1}_{\chi^2}(0.05;12)/20 = 5.226/20 = 0.2613$.

These are the $\alpha = 0.05$ and $\beta = 0.05$ columns of Cowan's Table 9.3. The belt is in Figure 4.27. Two features distinguish it from the Gaussian one. The edges are staircases, because the acceptance set at each ν is a set of integers. And the probability inside each horizontal set is not 0.90 but somewhere between 0.9002 and 0.9995, depending on ν: adding the observed count to each tail makes each tail at most 5%, so the interval covers at least 90% [Cowan (9.19)]. Discreteness buys safety at the price of intervals that are longer than they need to be for most ν; Section 4.12 maps the over-coverage exactly.

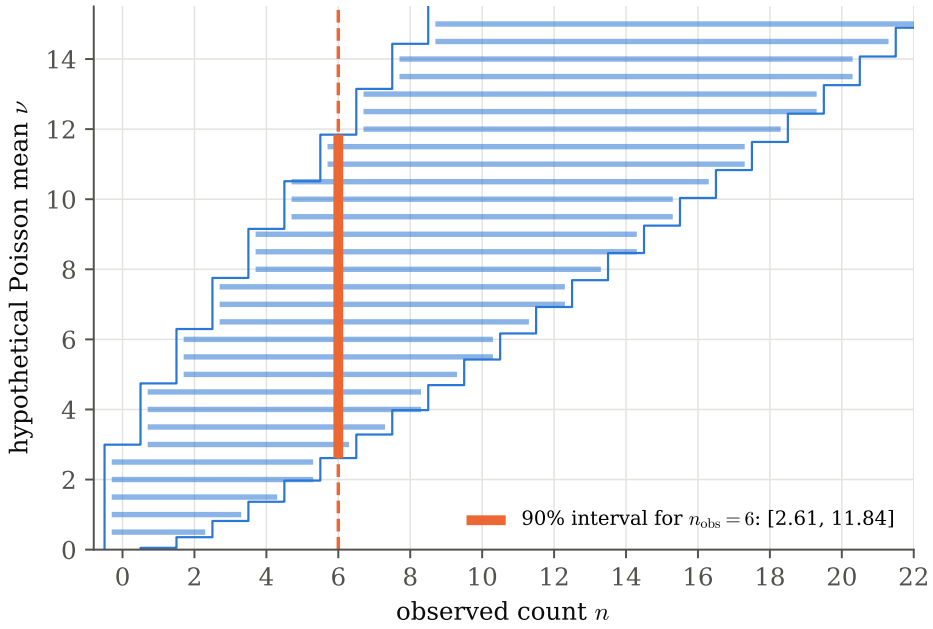

Figure 4.27: The 90% central confidence belt for a Poisson mean, built by brute force. Each horizontal bar is the set of counts accepted at one hypothetical mean ν (bars drawn every 0.5); the thin staircases are the edges of the belt on the fine grid. The dashed vertical line at $n = 6$ cuts the belt between the two ends of the orange bar, the 90% interval for six observed events.

Python. The heart of the brute-force construction:

Listing 4.10: The Poisson belt and its inversion (`code/ch04/12_neyman_poisson_belt.py`)

```
# ---------- the construction: one horizontal acceptance set per hypothetical nu ----------
nu_grid = np.arange(0.0005, 20.0, 0.0005)
n_max = 60
n = np.arange(n_max + 1)
cdf = stats.poisson.cdf(n[None, :], nu_grid[:, None])        # P(N <= n | nu)
sf = 1 - cdf + stats.poisson.pmf(n[None, :], nu_grid[:, None])  # P(N >= n | nu)
# n1(nu): the smallest n with P(N < n) <= a_tail AND P(N < n+1) > a_tail, i.e. the lowest
# count we keep.  Keep n if P(N <= n) > a_tail  and  P(N >= n) > a_tail  (both tails "not too small").
keep = (cdf > a_tail) & (sf > a_tail)
n1 = np.array([n[k].min() for k in keep])
n2 = np.array([n[k].max() for k in keep])
acc_prob = np.array([stats.poisson.pmf(n[k], nu).sum() for k, nu in zip(keep, nu_grid)])

# ---------- the inversion: the interval for n_obs collects every nu whose set contains n_obs ----------
def interval_from_belt(n_obs):
    inside = (n1 <= n_obs) & (n_obs <= n2)
    nus = nu_grid[inside]
    lo = 0.0 if n_obs == 0 else nus.min()
```

```
    return lo, nus.max()
```

`cdf` and `sf` are matrices, one row per hypothetical ν and one column per count, holding $P(N \le n)$ and $P(N \ge n)$. The boolean matrix `keep` marks the counts whose two tails are both larger than 5%: each row is one horizontal acceptance set. Inverting is then a vertical read: `interval_from_belt` collects every ν whose row contains the observed count. The script then asserts that the brute-force interval equals Garwood's formula to within the grid spacing, for $n_{\text{obs}} = 0, \ldots, 10$.

4.11.4 When the estimate is not Gaussian: transform first

For a non-Gaussian estimator we can always build the full belt. Sometimes a change of variables makes that unnecessary. The textbook case is the correlation coefficient r of n pairs from a two-dimensional Gaussian [Cowan §9.5]. Its distribution is skewed, the more so the closer the true ρ is to ± 1, and it is Gaussian only for very large n (Cowan quotes $n \gtrsim 500$).

The trouble is that the spread of r depends on the unknown ρ. Fisher's idea is to transform r so that it does not: a **variance-stabilising transformation** [a function g chosen so that the variance of $g(r)$ no longer depends on ρ]. The variance of r is approximately $(1-\rho^2)^2/n$ [Cowan (5.17)]. The delta method of Chapter 3 (a smooth function of an estimate has variance g'^2 times the estimate's variance) gives $\operatorname{Var} g(r) \approx g'(\rho)^2(1-\rho^2)^2/n$. This is independent of ρ if $g'(\rho) = 1/(1-\rho^2)$:

$$g(\rho) \overset{(1)}{=} \int \frac{\mathrm{d}\rho}{1-\rho^2} \overset{(2)}{=} \frac{1}{2}\int \left(\frac{1}{1+\rho} + \frac{1}{1-\rho}\right)\mathrm{d}\rho \overset{(3)}{=} \frac{1}{2}\ln\frac{1+\rho}{1-\rho} \overset{(4)}{=} \tanh^{-1}\rho. \tag{4.64}$$

(1) Integrate the required derivative.
(2) Partial fractions: $1/(1-\rho^2) = \frac{1}{2}[1/(1+\rho) + 1/(1-\rho)]$.
(3) $\int \mathrm{d}\rho/(1\pm\rho) = \pm\ln(1\pm\rho)$; choose the constant so that $g(0) = 0$.
(4) The standard form of the inverse hyperbolic tangent.

So $z = \tanh^{-1} r$ has variance close to $1/n$; a finer calculation gives $1/(n-3)$ [Cowan (9.22)–(9.25)], and z is close to Gaussian much sooner than r. The recipe: transform, build the Gaussian interval for $\zeta = \tanh^{-1}\rho$, transform the ends back with tanh.

Example: $r = 0.5$ from 20 pairs. The point first: the naive Gaussian interval claims a correlation, and the transformed one does not. *Naive.* The naive error $\hat{\sigma}_r = (1-r^2)/\sqrt{n} = 0.168$ makes r look like a three-sigma effect, and the naive 99% interval $[0.068, 0.932]$ excludes zero. *Transformed.* Now $z = \tanh^{-1} 0.5 = 0.549$ and $\sigma_z = 1/\sqrt{n-3} = 1/\sqrt{17} = 0.243$. The 99% interval for ζ is $[-0.075, 1.174]$, and applying tanh to its ends gives $[-0.075, 0.826]$ for ρ: zero is inside [Cowan p. 130]. The evidence for a correlation is much weaker than the naive error suggests. Under $\rho = 0$ the naive Gaussian gives a one-sided probability of 0.14% for $r \ge 0.5$, the z transformation gives 1.2%, and the exact calculation (under $\rho = 0$, $r\sqrt{n-2}/\sqrt{1-r^2}$ is Student t with $n-2$ degrees of freedom, here $t = 2.45$) gives 1.2%.[2] Which interval should we trust? A simulation of 10^5 samples of 20 pairs settles it. At $\rho = 0.5$ the naive 99% interval covers only 0.951 of the time, the Fisher interval 0.989; at $\rho = 0.8$, 0.941 against 0.989.

[2] Cowan quotes 2.3% for the z transformation. We find 1.2% for the one-sided tail, in agreement with the exact t calculation; 2.3% is close to the two-sided value.

4.11.5 Intervals from the likelihood function

The most widely used interval in physics needs no belt at all. In the large sample limit, the maximum-likelihood estimator is Gaussian around the true value with standard deviation $\sigma_{\hat\theta}$, and the likelihood itself becomes a Gaussian function of θ around $\hat\theta$ with the same width [Cowan (9.26)–(9.27)]; the equality of the two widths is the Cramér–Rao bound becoming an equality (Chapter 3). Then

$$\ln \mathcal{L}(\hat\theta \pm N\sigma_{\hat\theta}) \overset{(1)}{=} \ln \mathcal{L}_{\max} - \frac{(N\sigma_{\hat\theta})^2}{2\sigma^2_{\hat\theta}} \overset{(2)}{=} \ln \mathcal{L}_{\max} - \frac{N^2}{2}. \tag{4.65}$$

(1) $\ln \mathcal{L}(\theta) = \ln \mathcal{L}_{\max} - (\theta - \hat\theta)^2/2\sigma^2_{\hat\theta}$ for a Gaussian likelihood, evaluated at $\theta - \hat\theta = \pm N\sigma_{\hat\theta}$.

(2) Cancel $\sigma^2_{\hat\theta}$.

So the 68.3% interval is where $\ln \mathcal{L}$ has dropped by $1/2$ from its maximum, the 95.4% interval where it has dropped by 2, and in a least-squares fit, where $\ln \mathcal{L} = -\chi^2/2$, where χ^2 has risen by N^2 [Cowan (9.28)–(9.30)]:

$$\ln \mathcal{L}\big(\hat\theta^{+d}_{-c}\big) = \ln \mathcal{L}_{\max} - \frac{N^2}{2}, \qquad \chi^2\big(\hat\theta^{+d}_{-c}\big) = \chi^2_{\min} + N^2. \tag{4.66}$$

This prescription is used, and works well, even when $\ln \mathcal{L}$ is not a parabola. *Why?* The reason is that the likelihood does not care how we label the parameter. Suppose some monotone reparametrisation $\eta = h(\theta)$ makes the likelihood Gaussian in η. The likelihood is a function on parameter space, and its *values* do not change when we relabel the points: $\mathcal{L}$ at the point called θ equals $\mathcal{L}$ at the same point called $\eta = h(\theta)$. So the points where $\ln \mathcal{L}$ has dropped by $1/2$ are the same points in either labelling. In the η labelling they bound an exact 68.3% interval; mapped back, they bound an asymmetric interval in θ with the same coverage. So the recipe uses the good parametrisation without our having to find it. But it is only as good as the assumption that such an h exists, and that is guaranteed only for large samples. That is why the result is called a *likelihood interval*: it approximates the confidence interval, and is not one exactly [Cowan p. 131].

Example: five lifetimes. Take n decay times t_i from an exponential with mean τ. With $\hat\tau = \bar t$ and $u = \hat\tau/\tau$,

$$\ln \mathcal{L}(\tau) - \ln \mathcal{L}_{\max} \overset{(1)}{=} \left(-n\ln\tau - \frac{n\hat\tau}{\tau}\right) - \left(-n\ln\hat\tau - n\right) \overset{(2)}{=} n\left(\ln\frac{\hat\tau}{\tau} - \frac{\hat\tau}{\tau} + 1\right) \overset{(3)}{=} n\,(\ln u - u + 1). \tag{4.67}$$

(1) $\ln \mathcal{L} = \sum_i \ln(\tau^{-1}e^{-t_i/\tau}) = -n\ln\tau - \sum_i t_i/\tau$, and $\sum_i t_i = n\hat\tau$; at the maximum $\tau = \hat\tau$ the second term is $-n$.

(2) Collect the logarithms.

(3) Definition of u.

The drop depends on the data only through u, so the two roots of $n(\ln u - u + 1) = -\frac{1}{2}$ are fixed numbers for each n: for $n = 5$, $u = 0.617$ and $u = 1.516$. The likelihood interval is $[\hat\tau/1.516,\ \hat\tau/0.617]$ for *every* sample of five. For the sample simulated in `code/ch04/14_likelihood_intervals.py` with true $\tau = 1$, $\hat\tau = 1.58$ and the interval is $[1.04, 2.56]$, that is $\hat\tau = 1.58^{+0.98}_{-0.54}$ (Figure 4.28, left). Cowan's own sample gives $0.85^{+0.52}_{-0.30}$ [Cowan Fig. 9.6], the same ratios 1.61 and 0.65 to $\hat\tau$, as the invariance predicts.

Because $u = \hat\tau/\tau$ is a pivot (it is a mean of five exponentials of mean one, a Gamma$(5, 1/5)$ variable, whatever τ is), the coverage of the likelihood interval can be computed exactly: it is

$\mathrm{P}(0.617 \le U \le 1.516) = 0.675$, against a nominal 0.683; a Monte Carlo of 2×10^5 experiments gives 0.674. The exact central interval for our sample, from the pivot $2n\hat{\tau}/\tau \sim \chi^2_{2n}$, is $[1.10, 2.78]$. The symmetric interval $\hat{\tau} \pm \hat{\tau}/\sqrt{n}$ happens to have about the right total coverage at $n = 5$ (0.680), but it distributes its misses badly: it lies entirely below the truth in 0.266 of experiments and entirely above it in 0.053, where a central interval would have 0.159 on each side. The likelihood interval splits them as 0.199 and 0.126. Figure 4.28 (right) shows how both approach the nominal coverage as n grows. With $n = 50$ Cowan's symmetric 1.06 ± 0.15 is fine; with $n = 5$ the asymmetric likelihood interval is the honest summary.

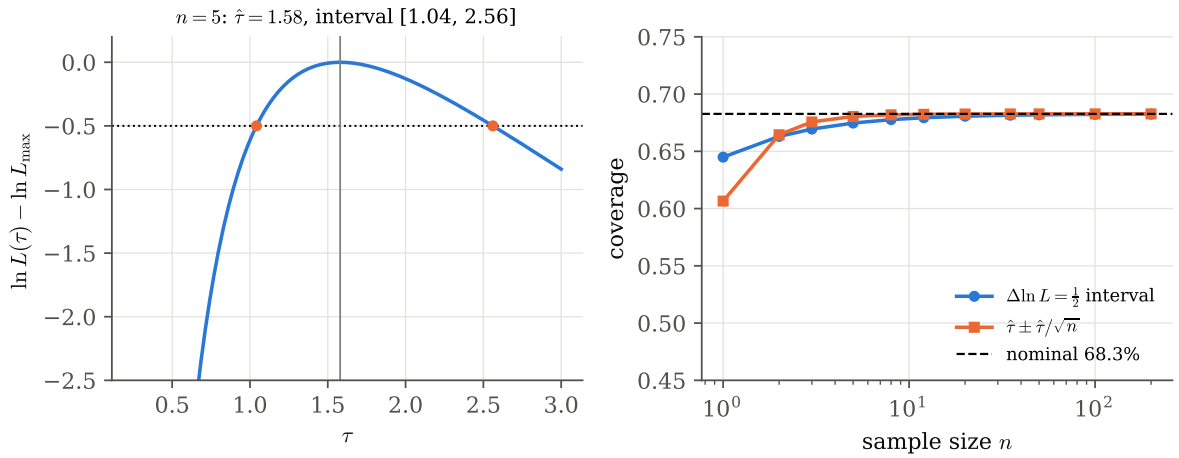

Figure 4.28: Left: the log-likelihood of five simulated decay times, relative to its maximum, as a function of the mean lifetime τ. It is not a parabola: it falls steeply towards small τ and slowly towards large τ. The dotted line is the drop by $1/2$; its two crossings (orange) are the ends of the likelihood interval. Right: the exact coverage of the $\Delta \ln \mathcal{L} = \frac{1}{2}$ interval and of the symmetric $\hat{\tau} \pm \hat{\tau}/\sqrt{n}$, as a function of the sample size; both approach 68.3%.

4.11.6 Several parameters: confidence regions

With m parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$, the large-sample estimators are jointly Gaussian with covariance $\mathbf{C}$, and the likelihood is a Gaussian function of $\boldsymbol{\theta}$ with the same $\mathbf{C}$ [Cowan (9.31)–(9.33)]. Both are governed by the quadratic form

$$Q(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}) = (\hat{\boldsymbol{\theta}} - \boldsymbol{\theta})^{\mathsf{T}} \mathbf{C}^{-1} (\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}), \tag{4.68}$$

which is symmetric in its two arguments. The argument for a confidence region takes three steps.

- *Two readings of one form.* As a function of the estimate at fixed truth, the level sets of Q are the ellipses of equal sampling density. As a function of the parameters at fixed estimate, they are the contours of equal likelihood.
- *Its distribution.* At the true $\boldsymbol{\theta}$, Q has a χ^2_m distribution (Chapter 2): whitening the Gaussian vector turns Q into a sum of m squared independent standard normals. So $\mathrm{P}(Q \le Q_\gamma) = 1 - \gamma$ when $Q_\gamma = F^{-1}_{\chi^2}(1 - \gamma; m)$, the $1 - \gamma$ quantile.
- *The symmetry.* "The estimate is within Q_γ of the truth" and "the truth is within Q_γ of the estimate" are the same event.

So the region $\{\boldsymbol{\theta} : Q(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}) \le Q_\gamma\}$ contains the truth with probability $1-\gamma$: it is a $1-\gamma$ confidence region. In practice it is found as the contour [Cowan (9.34)–(9.37)]

$$\ln \mathcal{L}(\boldsymbol{\theta}) = \ln \mathcal{L}_{\max} - \frac{Q_\gamma}{2} \qquad \text{or} \qquad \chi^2(\boldsymbol{\theta}) = \chi^2_{\min} + Q_\gamma . \tag{4.69}$$

The thresholds grow with the number of parameters [Cowan Tables 9.4–9.5]:

$1-\gamma$	$m=1$	$m=2$	$m=3$	$m=4$	$m=5$
0.683	1.00	2.30	3.53	4.72	5.89
0.90	2.71	4.61	6.25	7.78	9.24
0.95	3.84	5.99	7.82	9.49	11.1
0.99	6.63	9.21	11.3	13.3	15.1

For $m=1$, $Q_\gamma = N^2$ and the recipe is (4.66). For $m=2$ the familiar threshold no longer works. The $\Delta\chi^2 = 1$ contour, which many plots label "1σ", contains the truth only 39.3% of the time; the 68.3% region needs $\Delta\chi^2 = 2.30$. Figure 4.29 checks this with a straight-line fit to ten points, repeated 2×10^5 times: the truth falls inside the $\Delta\chi^2 = 1$ ellipse in 0.395 of the experiments and inside the $\Delta\chi^2 = 2.30$ ellipse in 0.683. The interval for the slope *alone*, $\hat\theta_2 \pm \sqrt{C_{22}}$, still covers 0.682: a one-parameter question keeps its one-parameter threshold. This is how cosmological constraints are drawn: the 68% and 95% contours in a plane of two parameters, and one-dimensional intervals from the marginal or profile of each (Chapters 9 and 10).

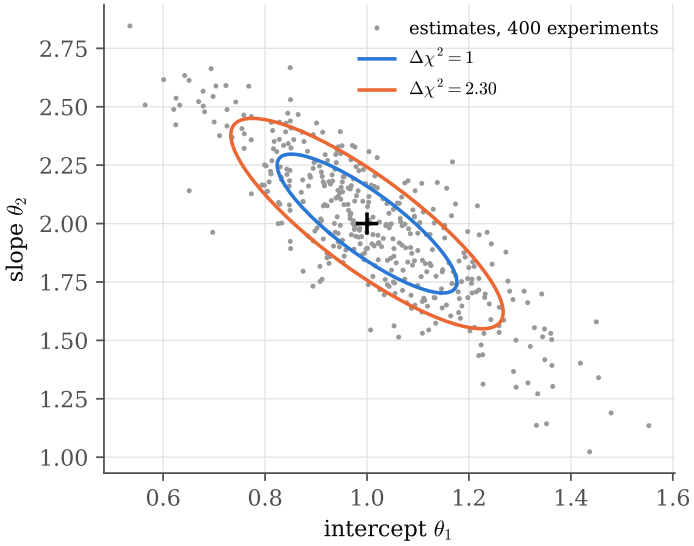

Figure 4.29: Two-parameter confidence regions for a straight-line fit. Grey dots: the fitted (intercept, slope) from 400 simulated experiments with the same true line (cross). The negative tilt is the correlation of the two estimates (correlation coefficient −0.84). The inner ellipse, $\Delta\chi^2 = 1$, holds about 39% of the dots, the outer, $\Delta\chi^2 = 2.30$, about 68%. The same ellipses drawn around any one estimate are its confidence regions.

As in one dimension, the region is random and the parameters are fixed [Cowan p. 135]. And as in one dimension, the χ^2_m calibration is only asymptotic. For strongly non-Gaussian likelihoods the coverage of (4.69) must be checked by simulation, as in Section 4.12.

4.12 Coverage is a property of the procedure

A hundred groups around the world measure the same Gaussian mean, each with $n = 10$ readings of known resolution, and each quotes the 95% interval $\bar{x} \pm 1.96\,\sigma/\sqrt{n}$. Figure 4.30 shows what happens in a simulation where we know the truth. The intervals jump up and down with the data; the true value, the dashed line, stays put; and 5 of the hundred intervals miss it. None of the hundred groups can tell from its own interval whether it is one of the unlucky ones. The 95% is a property of the whole ladder, not of any rung.

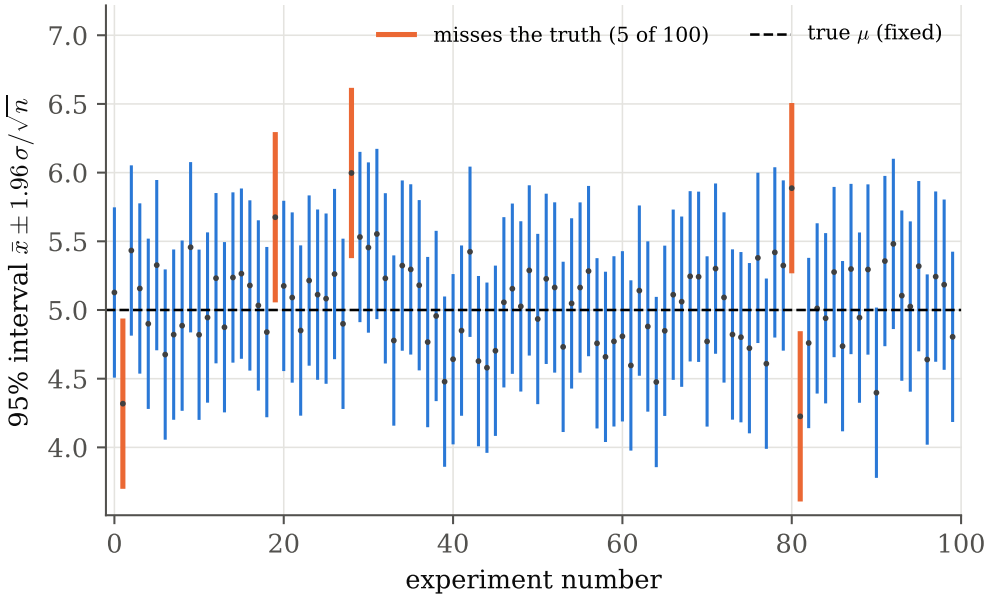

Figure 4.30: A hundred simulated experiments, each quoting a 95% interval for the same Gaussian mean. The vertical bars are the intervals, the dots the sample means, the dashed line the true value. The intervals move from experiment to experiment; the truth does not. The orange bars are the intervals that miss it.

A confidence level is a promise about a *recipe*: apply it to data generated with any θ, and it will contain that θ with the stated probability. We can check by simulation whether a recipe keeps the promise. The check finds three kinds of fault: recipes that cover less often than they claim, recipes that cover more often than needed and so are too wide, and, less obviously, recipes that are right on average but wrong in situations we can recognise from the data.

The question in words.

1. For a given recipe, how does the coverage depend on the true parameter, and what is its worst case?
2. Which common recipes undercover, which overcover, and why?
3. Is the long-run coverage the right thing to know about the one interval we actually hold?

4.12.1 The coverage function

For a recipe $x \mapsto [a(x), b(x)]$ the **coverage function** is $C(\theta) = \mathrm{P}_\theta\big(a(\boldsymbol{X}) \le \theta \le b(\boldsymbol{X})\big)$. For continuous data it is an integral, for counts a sum:

$$C(\theta) = \int \mathbb{1}\big[a(x) \le \theta \le b(x)\big]\, p(x \mid \theta)\, \mathrm{d}x, \qquad C(\nu) = \sum_{n=0}^{\infty} \mathrm{P}(n \mid \nu)\, \mathbb{1}\big[a(n) \le \nu \le b(n)\big]. \tag{4.70}$$

The indicator $\mathbb{1}[\cdot]$ is one when the interval computed from x contains θ and zero otherwise. A recipe is *exact* if $C(\theta) = 1 - \alpha$ everywhere, it **undercovers** where $C(\theta) < 1 - \alpha$ and **overcovers** where $C(\theta) > 1 - \alpha$. A recipe that overcovers somewhere and undercovers nowhere is called **conservative** [28]. The confidence coefficient of Section 4.10.1 is $\inf_\theta C(\theta)$.

Working definition 4.5 (checking coverage)

Operational recipe: choose a grid of true values θ. For each, simulate M experiments, apply the interval recipe to each, and record the fraction $\hat{C}(\theta)$ that contain θ; its Monte Carlo error is $\sqrt{\hat{C}(1-\hat{C})/M}$. For discrete data with a finite number of outcomes, evaluate the sum (4.70) exactly instead. A recipe is acceptable for a claimed level $1 - \alpha$ if $\hat{C}(\theta) \ge 1 - \alpha$ (within errors) at every θ that physics allows.

The simplest case is a Gaussian mean [CasellaBerger Ex. 9.1.3]. Take four readings from $\mathcal{N}(\mu, 1)$ and the interval $[\bar{X} - 1, \bar{X} + 1]$. *The question:* how often does it contain μ? The mean of four readings has variance $1/4$, so $\bar{X} \sim \mathcal{N}(\mu, 1/4)$, and

$$C(\mu) \overset{(1)}{=} \mathrm{P}(-1 \le \bar{X} - \mu \le 1) \overset{(2)}{=} \mathrm{P}\Big(-2 \le \frac{\bar{X} - \mu}{\sqrt{1/4}} \le 2\Big) \overset{(3)}{=} \mathrm{P}(-2 \le Z \le 2) = 0.9544. \tag{4.71}$$

(1) Rearrange $\bar{X} - 1 \le \mu \le \bar{X} + 1$.
(2) Divide by the standard deviation $\sqrt{1/4} = 1/2$.
(3) The standardised mean is standard normal whatever μ is.

The coverage is the same for every μ because $\bar{X} - \mu$ is a pivot: its distribution does not depend on μ (Section 4.10.2). Most recipes have no pivot, and then the coverage depends on the parameter.

Example: two intervals for a uniform endpoint. Let $X_1, \dots, X_n$ be uniform on $[0, \theta]$ and $Y = \max X_i$ [CasellaBerger Ex. 9.1.6]. Since $Y \le y$ exactly when every $X_i \le y$, $\mathrm{P}(Y \le y) = (y/\theta)^n$, and $T = Y/\theta$ has density $n t^{n-1}$ on $[0, 1]$, whatever θ is. Compare two recipes, $[aY, bY]$ with $1 \le a < b$ and $[Y + c, Y + d]$ with $0 \le c < d$:

$$\begin{aligned} \mathrm{P}_\theta(aY \le \theta \le bY) &\overset{(1)}{=} \mathrm{P}\Big(\frac{1}{b} \le T \le \frac{1}{a}\Big) \overset{(2)}{=} \int_{1/b}^{1/a} n t^{n-1}\, \mathrm{d}t = \Big(\frac{1}{a}\Big)^n - \Big(\frac{1}{b}\Big)^n, \\ \mathrm{P}_\theta(Y + c \le \theta \le Y + d) &\overset{(3)}{=} \mathrm{P}\Big(1 - \frac{d}{\theta} \le T \le 1 - \frac{c}{\theta}\Big) \overset{(4)}{=} \Big(1 - \frac{c}{\theta}\Big)^n - \Big(1 - \frac{d}{\theta}\Big)^n \xrightarrow{\theta \to \infty} 0. \end{aligned} \tag{4.72}$$

(1) Divide $aY \le \theta \le bY$ by θ and invert: $1/b \le Y/\theta \le 1/a$.
(2) The density of T.
(3) Subtract Y and divide by θ (for $\theta \ge d$).
(4) Same integral with the new limits.

The scale recipe has the same coverage for every θ, because $T = Y/\theta$ is a pivot. The shift recipe does not. Its coverage depends on θ and tends to zero for large θ, because a fixed shift becomes

negligible when the endpoint is large. So its worst-case coverage, the confidence coefficient, is zero. Used for, say, the maximum energy of a spectrum, it would be a disastrous recipe, even though for some θ it looks fine.

4.12.2 The Gaussian mean, with and without a known σ

Simulating 200000 experiments of the kind in Figure 4.30 gives a coverage of 0.9498 ± 0.0005 for the 95% interval and 0.6814 for $\bar{x} \pm \sigma/\sqrt{n}$, as it must: this recipe is exact. Things go wrong when σ is not known and is replaced by the sample standard deviation s. The Normal quantile 1.96 assumes the scale is fixed, but s fluctuates from sample to sample. The quantity that does have a fixed distribution is $(\bar{x} - \mu)/(s/\sqrt{n})$, which follows Student's t_{n-1} (from the first part of the chapter). The simulation measures how much the Normal quantile loses:

readings n	3	5	10	30
$\bar{x} \pm 1.96\, s/\sqrt{n}$	0.810	0.879	0.918	0.941
$\bar{x} \pm t_{n-1,0.025}\, s/\sqrt{n}$	0.949	0.951	0.950	0.951

With three readings the "95%" interval covers only 81% of the time; the t quantile restores 95% at every n. The failure is systematic, not a fluctuation, and it is invisible in any single experiment. A calibration run with three repeated measurements, quoted with a Normal quantile, claims more precision than it has.

4.12.3 Counts: over-coverage and a saw-tooth

For a Poisson mean the sum in (4.70) can be done exactly on a fine grid of ν, and Figure 4.31 shows the result for two recipes: Garwood's interval (4.63) and the quick $n \pm z\sqrt{n}$ (the Wald interval for a count). Three things stand out.

First, Garwood's interval never undercovers. Its 90% version has coverage at least 0.903 and on average 0.939 over $0 < \nu < 15$; its 68.3% version has minimum 0.689 and mean 0.782. It is conservative, as (4.60) was designed to be. Feldman and Cousins insist that this is a defect, not a virtue: an interval that claims 68% and delivers 78% is wider than needed, and wider intervals mean less power to exclude false hypotheses [28]. With discrete data some over-coverage is unavoidable; the goal is to have as little of it as possible.

Second, the coverage is a saw-tooth. The reason is in the sum (4.70): count n contributes its probability only if its interval $[a(n), b(n)]$ contains ν. As ν increases past one of the interval ends, one count suddenly stops (or starts) contributing, and $C(\nu)$ jumps [CasellaBerger p. 352]. Between jumps the same counts contribute, and their probabilities change smoothly with ν. So every tooth sits at an entry of the table of interval ends.

Third, the quick recipe fails badly at small counts. At $\nu = 1$ its nominal 90% interval covers only 0.628 of the time (Garwood: 0.981), and as $\nu \to 0$ its coverage drops to 0.020. The reason is visible in the formula: $n = 0$ gives the interval $[0, 0]$, which contains no positive ν, and for small ν zero is the most likely count. The same mechanism ruins the Normal interval for a binomial proportion near 0 or 1.

The script `code/ch04/13_coverage.py` computes these curves with a matrix of Poisson probabilities:

Listing 4.11: Exact coverage of Poisson interval recipes (`code/ch04/13_coverage.py`)

```
def garwood(nobs, cl):
    a = (1 - cl) / 2
    lo = np.where(nobs == 0, 0.0, 0.5 * stats.chi2.ppf(a, 2 * np.maximum(nobs, 1)))
```

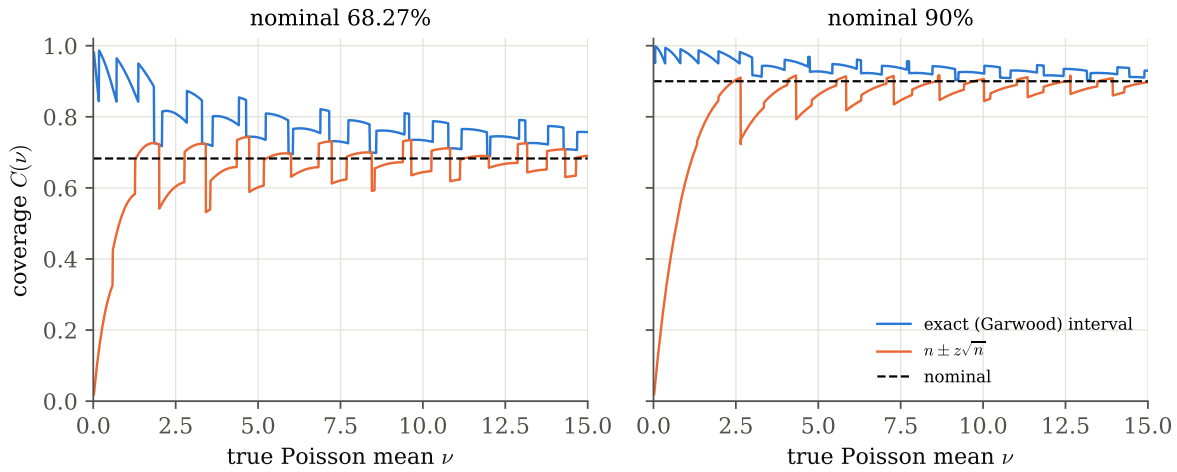

Figure 4.31: Exact coverage of two interval recipes for a Poisson mean, as a function of the true mean. Left: nominal 68.27%, right: nominal 90% (dashed lines). Garwood's exact interval (blue) always lies above the nominal level, with saw-tooth jumps where the true mean crosses an interval end. The quick interval $n \pm z\sqrt{n}$ (orange) undercovers, dramatically so below a mean of about two.

```
    hi = 0.5 * stats.chi2.ppf(1 - a, 2 * (nobs + 1))
    return lo, hi

def wald(nobs, cl):
    zq = stats.norm.isf((1 - cl) / 2)
    return nobs - zq * np.sqrt(nobs), nobs + zq * np.sqrt(nobs)

nmax = 80
nn_all = np.arange(nmax + 1)
nu = np.linspace(0.02, 15, 3000)
pmf = stats.poisson.pmf(nn_all[None, :], nu[:, None])

def coverage(method, cl):
    lo, hi = method(nn_all, cl)
    inside = (lo[None, :] <= nu[:, None]) & (nu[:, None] <= hi[None, :])
    return (pmf * inside).sum(1)

cov_g68, cov_g90 = coverage(garwood, 0.6827), coverage(garwood, 0.90)
cov_w68, cov_w90 = coverage(wald, 0.6827), coverage(wald, 0.90)
```

Each recipe returns the interval ends for all counts $0, \ldots, 80$ at once. The boolean matrix `inside` has one row per true ν and one column per count, and is true where that count's interval contains that ν. Multiplying by the Poisson probabilities and summing along each row is (4.70). A brute-force check at $\nu = 2.7$ draws 200000 counts, builds their intervals and counts hits: the Monte Carlo coverage 0.9796 agrees with the exact 0.9793 (and for the quick recipe the simulation gives 0.7442).

Pointwise versus uniform. The Poisson curve makes concrete a distinction between two meanings of "correct for large samples" [Wasserman §6.5]. Take the Normal interval for a proportion p from n trials, with estimate $\hat{p}$ and coverage $C(p)$. For each *fixed* p, $C(p)$ tends to $1 - \alpha$ as $n \to \infty$: the interval is *pointwise* asymptotic. But at any fixed n, a small enough p makes $\hat{p} = 0$ almost certain; the interval then collapses to $\{0\}$, and the coverage is near zero. So the worst case $\inf_p C(p)$ does not tend to $1 - \alpha$, and the interval is not *uniformly* asymptotic. "Large sample" has to be large compared with something, and near a boundary the something is the number of events, not the number of trials.

4.12.4 Right on average, wrong in a recognisable case

Coverage is an average over all possible data sets. Sometimes the data we hold tell us that we are in a subset of those data sets where the recipe is right much more often, or much less often, than the average. An example due to Berger and Wolpert shows this plainly [Wasserman Ex. 6.14]. Let θ be a fixed number, let X_1, X_2 be independent, each $+1$ or -1 with probability one half, and observe only $Y_i = \theta + X_i$. The "interval", a single point, is

$$C = \begin{cases} \{Y_1 - 1\} & \text{if } Y_1 = Y_2, \\ \{(Y_1 + Y_2)/2\} & \text{if } Y_1 \neq Y_2. \end{cases}$$

There are four equally likely cases:

$$\mathrm{P}_\theta(\theta \in C) \overset{(1)}{=} \tfrac{1}{4}\,\mathbb{1}[(\theta+1)-1=\theta] + \tfrac{1}{4}\,\mathbb{1}[(\theta-1)-1=\theta] + \tfrac{2}{4}\,\mathbb{1}[\tfrac{1}{2}(2\theta)=\theta] \overset{(2)}{=} \tfrac{1}{4} + 0 + \tfrac{1}{2} = \tfrac{3}{4}. \tag{4.73}$$

(1) $(X_1, X_2) = (+1, +1)$: both Y equal $\theta + 1$, and $C = \{\theta\}$. $(-1, -1)$: both equal $\theta - 1$, and $C = \{\theta - 2\}$. $(+1, -1)$ or $(-1, +1)$: the Y differ and their average is θ.
(2) Evaluate the indicators.

So C is a 75% confidence set for every θ.

What we observe. Now suppose the data are $Y_1 = 15$, $Y_2 = 17$. *The question.* Which of the four cases could have produced these data? The two Y differ, so $(+1, +1)$ and $(-1, -1)$ are ruled out; only the mixed cases remain, and in both of them the average of the Y is θ. So $C = \{16\}$ is *certainly* right. Had we instead seen $Y_1 = Y_2$, only the first two cases could have produced it, and the recipe is right in one of them and wrong in the other: right half the time. A simulation of 4×10^5 repetitions in `code/ch04/11_test_inversion.py` confirms it: overall coverage 0.7498, coverage 1.0000 when $Y_1 \neq Y_2$ (a fraction $1 - 0.5009$ of the time), and 0.5005 when $Y_1 = Y_2$.

The lesson: "75%" is a statement about the recipe, not about this data set. Calling $\{16\}$ a 75% confidence set is still correct, because that is what the recipe guarantees [Wasserman p. 93]. A probability statement about θ given these particular Y is a different kind of statement, the one Bayesian inference makes (Section 4.17). Frequentists handle the problem by *conditioning*: they compute the coverage only over data sets that share a feature of the observed one, a feature that carries no information about θ but does tell us how precise the experiment turned out to be (here, whether $Y_1 = Y_2$). In physics the classic case is a measurement whose resolution depends on an event-by-event quantity: the relevant error bar is the one for the resolution actually obtained.

How this is used in real research: Coverage studies: verification and research

A coverage simulation can play two different roles. When an analytic result exists, it *verifies*: the t interval must cover 95% at every n, the Garwood interval must never undercover, and a simulation that disagrees has a bug. When no analytic result exists, the same simulation *is* the method. Experiments at the LHC build Neyman belts from toy Monte Carlo when the test statistic has no known distribution; neutrino-oscillation fits construct Feldman–Cousins regions from millions of pseudo-experiments; cosmological analyses check whether a posterior interval from an MCMC chain (Chapter 9) covers the input parameters of simulated skies. In every case the recipe is (4.70) evaluated by brute force.

4.13 Upper limits near a physical boundary

The squared mass of a neutrino can be estimated from a measured energy and momentum as $\widehat{m^2} = E^2 - p^2$. The true m^2 cannot be negative, but the estimate can: both E^2 and p^2 carry measurement errors, and when the true mass is tiny, their difference comes out negative about half the time [Cowan §9.8]. The same happens to any parameter estimated as a difference, $\hat{\theta} = x - y$: a signal rate estimated as "counts minus expected background", a dark-matter cross-section, a tensor-to-scalar ratio. Physics says $\theta \geq 0$. The data, fluctuating, do not know that.

A search that sees nothing reports an *upper limit*. Near the boundary every recipe met so far runs into trouble. The interval can come out entirely in the forbidden region, or be empty, or be so short that it claims more than the experiment can know. Each fix trades one good property for another, and seeing what each one gives up shows what a limit really promises.

The question in words.

1. What does the classical recipe give when the estimate is negative, and is it wrong?
2. Which alternatives exist (shifting the estimate, a Bayesian prior on $\theta \geq 0$, Feldman and Cousins' ordering, CL_s), and what does each do to the coverage?
3. Why must the choice between "upper limit" and "two-sided interval" be made before the data are seen?

4.13.1 The classical limit can be negative

Let $\hat{\theta}$ be Gaussian with mean θ and known $\sigma_{\hat{\theta}}$, with $\theta \geq 0$ known a priori. The one-sided classical upper limit at confidence level $1 - \beta$ is, from (4.59),

$$\theta_{\mathrm{up}} = \hat{\theta}_{\mathrm{obs}} + \sigma_{\hat{\theta}}\, \Phi^{-1}(1 - \beta) \tag{4.74}$$

[Cowan (9.39)]. With $\sigma_{\hat{\theta}} = 1$ and $\hat{\theta}_{\mathrm{obs}} = -2$, the 95% limit is $-2 + 1.645 = -0.355$. The experiment "excludes" every physical value of θ, including zero.

Is the recipe wrong? No. It covers the true value in 95% of experiments, whatever that value is. If $\theta = 0$, an estimate below -1.645 happens 5% of the time, and those are exactly the experiments whose limit is negative. We have simply landed in the 5%. *Is the result useful?* Also no. We knew before the experiment that $\theta \geq 0$, and so certainly that $\theta > -0.355$. Two tempting repairs make it worse. Raising the confidence level to 99% moves the limit to 0.326, a limit three times smaller than the experiment's resolution, quoted at very high confidence; and choosing the level 97.725% gives $\theta_{\mathrm{up}} = 10^{-5}$, which is absurd [Cowan p. 137].

Whatever limit we quote, the first rule is to report the estimate itself, $\hat{\theta}_{\mathrm{obs}} \pm \sigma_{\hat{\theta}}$, even when it is negative. The reason is combination. Unbiased estimates from many experiments average to the truth only if the negative ones are kept; setting them to zero pushes every average upwards. When $\hat{\theta}$ is far from Gaussian, the whole likelihood function should be published so that others can combine it [Cowan p. 137].

4.13.2 Three repairs: shift, Bayes, and flip-flop

Shift the estimate to zero. A common practice replaces a negative estimate by zero before applying (4.74) [Cowan (9.40)]: $\theta_{\mathrm{up}} = \max(\hat{\theta}_{\mathrm{obs}}, 0) + \sigma_{\hat{\theta}}\Phi^{-1}(1 - \beta)$. At 95% the limit is then

never below $1.645\,\sigma_{\hat\theta}$ (1.645 for our example), so it is never smaller than about the resolution. The shifted limit is never below the classical one, so it contains the truth at least as often: it overcovers. In Figure 4.32 (right) its coverage is 1 for all $\theta \le 1.645$, because every experiment then quotes a limit above θ.

A Bayesian limit with a prior that knows $\theta \ge 0$. In the Bayesian approach the boundary is built in by a prior that vanishes for $\theta < 0$. With a flat prior on $\theta \ge 0$ [Cowan (9.41)–(9.44)] and $\sigma_{\hat\theta} = 1$, the posterior is the Gaussian likelihood cut off at zero and renormalised. Write $x = \hat\theta_{\text{obs}}$ and φ for the standard normal density. The upper limit solves

$$1-\beta \overset{(1)}{=} \frac{\int_0^{\theta_{\text{up}}} \varphi(\theta - x)\,\mathrm{d}\theta}{\int_0^{\infty} \varphi(\theta - x)\,\mathrm{d}\theta} \overset{(2)}{=} \frac{\Phi(\theta_{\text{up}}-x) - \Phi(-x)}{1-\Phi(-x)} \overset{(3)}{=} \frac{\Phi(\theta_{\text{up}}-x) - 1 + \Phi(x)}{\Phi(x)},$$

$$\Longrightarrow \quad \theta_{\text{up}} \overset{(4)}{=} x + \Phi^{-1}\big(1-\beta\,\Phi(x)\big). \tag{4.75}$$

(1) Bayes' theorem with a flat prior on $\theta \ge 0$: the posterior is the likelihood $\varphi(\theta - x)$ normalised over the physical region [Cowan (9.43)].
(2) Substitute $t = \theta - x$; the integrals are differences of the normal CDF.
(3) Symmetry, $\Phi(-x) = 1 - \Phi(x)$, in numerator and denominator.
(4) Multiply by $\Phi(x)$, solve for $\Phi(\theta_{\text{up}} - x) = 1 - \beta\Phi(x)$, and apply Φ^{-1}.

For $x = -2$ this gives $\theta_{\text{up}} = 1.05$. For large positive x, $\Phi(x) \to 1$ and the limit tends to the classical $x + 1.645$. The Bayesian limit is always positive and always above the classical one (Cowan's Fig. 9.8, our Figure 4.32, left).

It means something different. It is the value that θ exceeds with posterior probability 5%, given the prior. So it depends on the prior, and the flat prior has two weaknesses. First, it says that $0 < \theta < 1$ is as plausible before the experiment as $10^{40} < \theta < 10^{40} + 1$. Second, it changes when we relabel the parameter: a flat prior on m^2 is not flat on m. The prior $\pi(\theta) \propto 1/\theta$, flat in $\ln\theta$, gives limits invariant under $\theta \to \theta^k$, but the integrals diverge unless the likelihood vanishes at $\theta \to 0$, which a Gaussian likelihood does not [Cowan (9.45) and p. 139]. In practice the flat prior is the common choice, with its assumptions stated.

The Bayesian limit was not built to have coverage, but we can still measure its coverage. Figure 4.32 (right) shows that for this problem it overcovers near the boundary and approaches 95% from above for large θ (minimum 0.950).

Flip-flopping. Feldman and Cousins describe a third habit, common enough that they gave it a name [28]. Physicist X decides after seeing the data: "if the result is less than 3σ, I quote a 90% upper limit; if it is more, I quote a 90% central interval; and if it is negative, I pretend it was zero." Each of the two recipes alone covers 90%. The mixture does not. *The question:* take $\sigma = 1$ and a true mean $\mu = 2$; how often does the mixture contain 2? Here x is the measured value. Take the two branches one at a time.

- The upper-limit branch ($x < 3$) quotes $[0, \max(x, 0) + 1.28]$, which contains 2 when $x \ge 0.72$.
- The central branch ($x \ge 3$) quotes $[x - 1.645, x + 1.645]$, which contains 2 when $x \le 3.645$.

So

$$C(2) \overset{(1)}{=} \mathrm{P}(0.72 \le x < 3) + \mathrm{P}(3 \le x \le 3.645) \overset{(2)}{=} \mathrm{P}(-1.28 \le x - 2 \le 1.645)$$
$$\overset{(3)}{=} \Phi(1.645) - \Phi(-1.28) \overset{(4)}{=} 0.95 - 0.10 = 0.85. \tag{4.76}$$

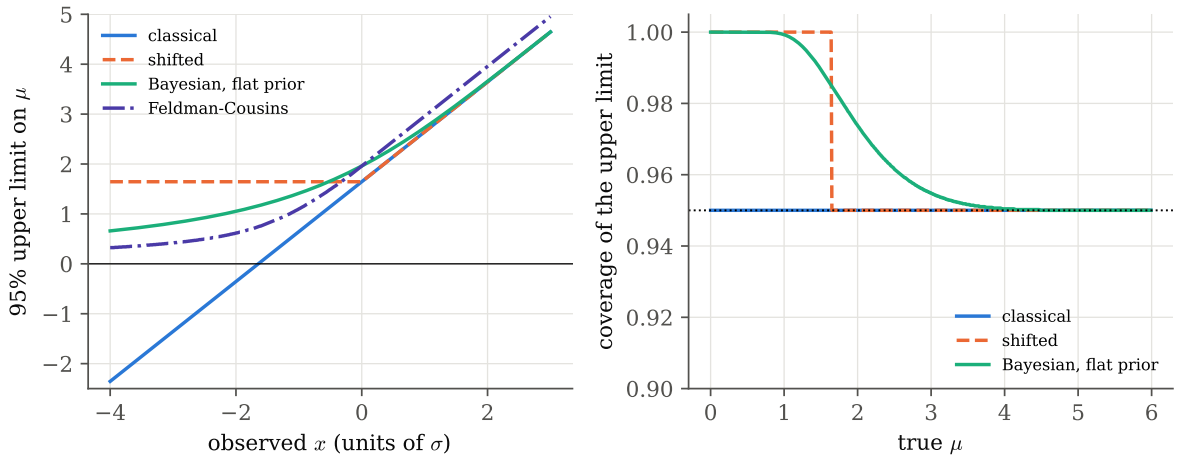

Figure 4.32: Left: 95% upper limits on a non-negative Gaussian mean as a function of the observed estimate, in units of the resolution. The classical limit (blue) goes negative for estimates below -1.645; the shifted limit (orange dashed) is flat at 1.645 for negative estimates; the flat-prior Bayesian limit (green) and the Feldman–Cousins upper end (violet) stay positive and fall slowly. All agree for large estimates. Right: the coverage of three of the recipes as a function of the true value. The classical limit covers exactly 95%, the other two more near the boundary.

(1) The two branches, each with its own condition for covering $\mu = 2$.
(2) The two ranges join into one; subtract the true value 2.
(3) $x - 2$ is standard normal.
(4) The standard quantiles of Section 4.11.2.

The quoted "90%" intervals cover 85% of the time. The missing 5% are the measurements above 3.645. The upper-limit recipe alone would have given them a limit above 2, but the switch hands them a central interval that misses. The script finds the same 0.850 at $\mu = 2$, and that this is the minimum; the coverage stays at 85% from $\mu \approx 1.3$ to $\mu \approx 4.3$ (Figure 4.35, left). In belt language (Figure 4.33, dashed), switching recipes at $x = 3$ bends the belt so that the horizontal acceptance intervals at intermediate μ hold only 85% of the probability.

Watch out: Deciding the form of the result after seeing the data

Choosing between an upper limit and a two-sided interval according to how the data came out destroys the coverage of both, even though each recipe is correct alone. The rule of the Neyman construction is that the acceptance regions are fixed before the measurement. If we want the result to switch automatically from a limit to an interval as the signal grows, the switch must be part of the construction itself, which is what the unified approach below does.

The strict alternative, always quoting the central interval, has its own problem. With $\sigma = 1$ and $x = -1.8$, the 90% central interval has upper end $x + 1.645 = -0.155$, so it contains no physical value at all. The interval is *empty* [28]. It is still a correct member of an ensemble with 90% coverage, but not one anybody wants to publish.

4.13.3 The unified approach of Feldman and Cousins

The Neyman construction (Section 4.11.1) leaves one choice open: *which* values of the measurement to put in the acceptance interval at each μ, so that it holds probability $1 - \alpha$. Central intervals leave out equal tails on both sides; upper limits leave out only the lowest values,

keeping everything above a cut. Feldman and Cousins choose by a likelihood ratio.

Key idea: Likelihood-ratio ordering

At each μ, rank the possible outcomes x by

$$R(x) = \frac{P(x \mid \mu)}{P(x \mid \mu_{\text{best}})},$$

where μ_{best} is the *physically allowed* value of μ that makes x most probable. Add outcomes to the acceptance interval in order of decreasing R until their total probability reaches $1 - \alpha$ [28, (4.1)]. Then build the belt and read the intervals as usual. The coverage is right by construction, the interval is never empty, and the result turns by itself from an upper limit into a two-sided interval as the data move away from the boundary.

Why this ordering? R compares how well μ explains x with how well the best physical value explains it. An outcome with R close to one is one that μ explains nearly as well as any allowed value could. Putting such outcomes in the acceptance set first means that we reject μ only for data that some other physical μ explains much better. This is the likelihood-ratio test of the first part of the chapter, with the physical boundary written into the maximisation, inverted into an interval.

Gaussian with $\mu \geq 0$. With $P(x \mid \mu) = \varphi(x - \mu)$, the best physical value is $\mu_{\text{best}} = \max(0, x)$. Then

$$R(x) \overset{(1)}{=} \begin{cases} \varphi(x-\mu)/\varphi(0) = e^{-(x-\mu)^2/2}, & x \geq 0, \\ \varphi(x-\mu)/\varphi(x) = e^{-(x-\mu)^2/2 + x^2/2} = e^{\,x\mu - \mu^2/2}, & x < 0, \end{cases} \tag{4.77}$$

(1) For $x \geq 0$, $\mu_{\text{best}} = x$ and $\varphi(0) = 1/\sqrt{2\pi}$; for $x < 0$, $\mu_{\text{best}} = 0$, and expanding $-(x-\mu)^2/2 + x^2/2 = x\mu - \mu^2/2$ [28, (4.2)–(4.3)].

For $x \geq 0$, R decreases with the distance from μ, so the acceptance interval is centred, as in a central interval. For $x < 0$, R decreases as x becomes more negative, but only linearly in the exponent, much more slowly than the Gaussian: negative outcomes are penalised less, because no physical μ explains them well. The acceptance interval $[x_1, x_2]$ at each μ is found numerically from $R(x_1) = R(x_2)$ and $\int_{x_1}^{x_2} \varphi(x - \mu)\mathrm{d}x = 1 - \alpha$ [28, (4.4)].

Where does the limit turn into a two-sided interval? The acceptance set at $\mu = 0$ decides it. There $R(x) = 1$ for all $x < 0$ and $R(x) = e^{-x^2/2}$ for $x \geq 0$, so every negative x is ranked first (probability $1/2$), followed by x from 0 upwards until the total is 0.90: $\Phi(x_2) = 0.90$, $x_2 = 1.28$. For an observation above 1.28, $\mu = 0$ is excluded and the interval is two-sided; below it, the interval starts at zero and is an upper limit. The brute-force belt in `code/ch04/15_feldman_cousins.py` reproduces Feldman and Cousins' Table X at 90%:

x_0	-2	-1	0	1	2	3
$[\mu_1, \mu_2]$	$[0.00, 0.40]$	$[0.00, 0.81]$	$[0.00, 1.64]$	$[0.00, 2.64]$	$[0.58, 3.64]$	$[1.37, 4.64]$

Here x_0 is the observed measurement and $[\mu_1, \mu_2]$ its interval. At $x_0 = 0$ the 90% upper limit is 1.64: the classical 95% limit rather than the 90% one (1.28). The reason is that at $\mu \approx 1.6$ the unified acceptance interval is already nearly central, so its left edge sits 1.645 below μ, and 1.645 is also the one-sided 95% quantile (Section 4.11.2). That is the price of repairing flip-flopping: near the boundary the unified limits are somewhat looser [28]. In exchange no interval is empty,

the limits for very negative x_0 shrink only slowly (as $1/|x_0|$), and the coverage is 90% for every μ (between 0.8998 and 0.9002 on our grid; Figure 4.35, left).

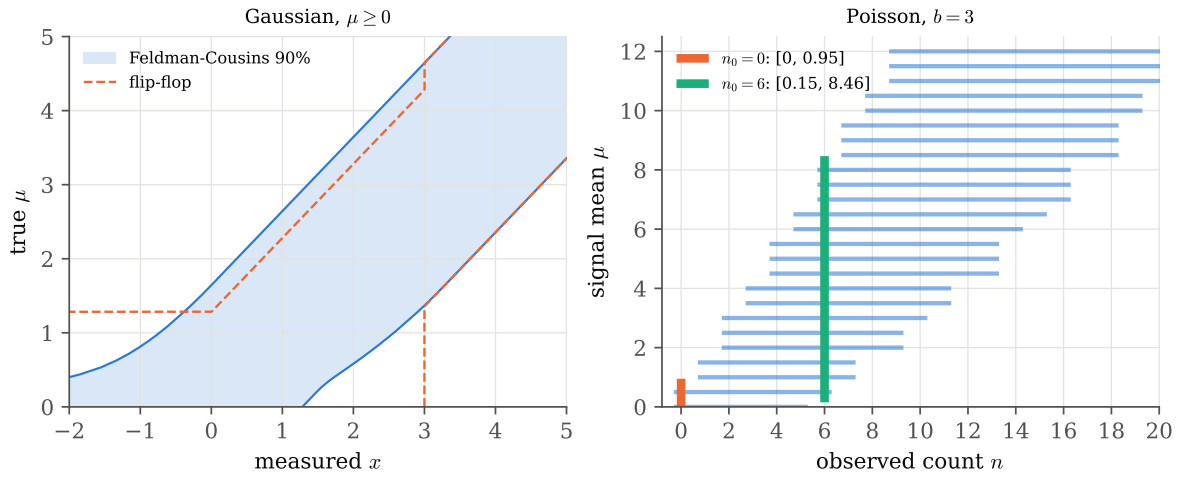

Figure 4.33: Left: the 90% Feldman–Cousins belt for a Gaussian measurement of a non-negative mean (shaded, solid edges) and the belt implied by flip-flopping (dashed). Below $x \approx 1.28$ the unified belt reaches down to $\mu = 0$, so the interval is an upper limit; above, it is two-sided. The flip-flop belt jumps at $x = 3$ where the recipe switches. Right: the Feldman–Cousins acceptance sets for a Poisson count on a known background $b = 3$ (bars every 0.5 in μ), with the intervals for $n_0 = 0$ (orange) and $n_0 = 6$ (green).

4.13.4 Counting on a known background

The most common version of the problem in particle physics is a count n of candidate events, of which a known mean b is expected from background and an unknown mean $\mu \geq 0$ from signal [Cowan §9.9]. The total is Poisson with mean $\mu + b$,

$$P(n \mid \mu) = \frac{(\mu + b)^n}{n!}\, e^{-(\mu+b)}, \tag{4.78}$$

and the naive estimate is $\hat{\mu} = n - b$, which is negative whenever fewer events than the expected background are seen [Cowan (9.47)–(9.48)]. The classical limits are the background-free ones shifted down by b [Cowan (9.50)]. For $b = 3$ and no events observed, the 90% upper limit is $2.303 - 3 = -0.70$: negative. The central 90% interval is $[0,\ 3.00 - 3]$, with an upper end -0.004 below zero: empty [28].

The ordering at one value of μ. Feldman and Cousins work one row of their construction by hand, $b = 3$ and $\mu = 0.5$ [28, Table I]. For each n the best physical signal is $\mu_{\text{best}} = \max(0, n - b)$, and $R = P(n \mid 0.5)/P(n \mid \mu_{\text{best}})$:

n	0	1	2	3	4	5	6	7	8	9	10
$P(n \mid \mu)$	0.030	0.106	0.185	0.216	0.189	0.132	0.077	0.039	0.017	0.007	0.002
μ_{best}	0	0	0	0	1	2	3	4	5	6	7
R	0.607	0.708	0.826	0.963	0.966	0.753	0.480	0.259	0.121	0.050	0.018
rank	6	5	3	2	1	4	7	8	9	10	11

Adding counts in the order of the last row, the total first reaches 0.90 with rank 7, so the acceptance set at $\mu = 0.5$ is $n \in [0, 6]$, with probability 0.935 (more than 0.90, because of

discreteness). Look at $n = 0$. Its probability under $\mu = 0.5$ is only 0.030. But no physical μ makes it much more probable: the best is $\mu = 0$, with 0.050. So $R = 0.607$, high in the ranking, and $n = 0$ is accepted. This is what keeps the interval for $n_0 = 0$ from being empty.

The intervals. Repeating the ranking on a grid of μ and reading vertically gives the Feldman–Cousins intervals; Figure 4.33 (right) shows the belt. The code is short:

Listing 4.12: The Feldman–Cousins acceptance sets for a Poisson count on background (`code/ch04/15_feldman_cousins.py`)

```
def fc_poisson_sets(mu_grid, b, cl=CL):
    """acceptance sets [n1, n2] for each mu, ranked by R = P(n|mu)/P(n|mu_best)."""
    mub = np.maximum(nn - b, 0.0)
    pbest = stats.poisson.pmf(nn, mub + b)
    n1 = np.empty(mu_grid.size, int); n2 = np.empty(mu_grid.size, int)
    for k, mu in enumerate(mu_grid):
        p = stats.poisson.pmf(nn, mu + b)
        order = np.argsort(-(p / pbest), kind="stable")
        cum = np.cumsum(p[order])
        keep = order[: np.searchsorted(cum, cl) + 1]
        n1[k], n2[k] = keep.min(), keep.max()
    return n1, n2
```

For every n the array `pbest` holds $P(n \mid \mu_{\text{best}})$; for each hypothetical μ the counts are sorted by decreasing R (`argsort` of $-R$), their probabilities accumulated, and the set cut where the running sum first reaches the confidence level. The minimum and maximum of the kept counts are the ends of the horizontal set. For $b = 3$ at 90%:

n_0	0	1	2	3	4	5	6	7	8	9	10
FC μ_1	0.00	0.00	0.00	0.00	0.00	0.00	0.15	0.90	1.51	1.88	2.64
FC μ_2	0.95*	1.88	3.04	4.42	5.59	6.99	8.46	9.53	10.99	12.29	13.50
classical	−0.70	0.89	2.32	3.68	4.99	6.27	7.53	8.77	9.99	11.21	12.41
CL_s	2.30	2.84	3.52	4.36	5.34	6.44	7.60	8.80	10.00	11.21	12.41

The first two rows agree with Feldman and Cousins' Table IV to the grid precision, with one exception marked *. For $n_0 = 0$ the raw construction gives 0.95; Feldman and Cousins publish 1.08. The difference is a deliberate correction: because n is discrete, the raw upper end is not always a decreasing function of b, and they lengthen intervals to make it so. Applying their rule (replace $\mu_2(b)$ by the largest value at any larger background) on a fine grid of b gives 1.07. For $n_0 \le 5$ the interval starts at zero: an upper limit. From $n_0 = 6$ on it is two-sided. The switch happens by itself.

CL_s and the Bayesian limit. The classical limit in the third row goes negative for small n_0. The reason: when the background fluctuates down, few events are seen, and every signal looks excluded. The LEP and Tevatron experiments adopted a modification designed against exactly this [27]. In a counting experiment, a small n is what argues against a signal, so the two relevant tail probabilities are those of seeing n_0 or fewer events, with and without the signal:

$$\text{CL}_{s+b}(\mu) = P(n \le n_0 \mid \mu + b), \qquad \text{CL}_b = P(n \le n_0 \mid b). \tag{4.79}$$

The classical recipe excludes μ when $\text{CL}_{s+b} < \alpha$.

Working definition 4.6 (CL_s)

The ratio $\mathrm{CL}_s(\mu) = \mathrm{CL}_{s+b}(\mu)/\mathrm{CL}_b$ (in the notation of [27], $p_{s+b}/(1-p_b)$). A signal μ is excluded at confidence level $1-\alpha$ if $\mathrm{CL}_s(\mu) < \alpha$. Dividing by $\mathrm{CL}_b \le 1$ makes exclusion harder exactly when the data look background-poor [when even background alone rarely gives so few events].

For $n_0 = 0$, $\mathrm{CL}_s = e^{-(\mu+b)}/e^{-b} = e^{-\mu}$, and the 90% limit is $\mu = \ln 10 = 2.30$ for *every* b. Seeing nothing on a background of three events excludes no more than seeing nothing on no background. That is the intended behaviour: an experiment should not get a better limit because its background fluctuated low. Figure 4.34 contrasts the three recipes as a function of b. The classical limit for $n_0 = 0$ falls as $2.30 - b$ and crosses zero at $b = 2.30$. The Feldman–Cousins limit also falls, from 2.44 at $b = 0$ towards about one: it is a correct confidence interval, and with a larger background, zero events really are rarer for every μ. CL_s stays at 2.30.

The CL_s limit is the flat-prior Bayesian limit of Cowan's (9.53)–(9.54). With a flat prior on $\mu \ge 0$, the posterior probability above μ is

$$\mathrm{P}(\mu_s > \mu \,|\, n_0) \overset{(1)}{=} \frac{\int_\mu^\infty (\mu'+b)^{n_0} e^{-(\mu'+b)}\,\mathrm{d}\mu'}{\int_0^\infty (\mu'+b)^{n_0} e^{-(\mu'+b)}\,\mathrm{d}\mu'} \overset{(2)}{=} \frac{\int_{\mu+b}^\infty t^{n_0} e^{-t}\,\mathrm{d}t/n_0!}{\int_b^\infty t^{n_0} e^{-t}\,\mathrm{d}t/n_0!}$$
$$\overset{(3)}{=} \frac{\sum_{n=0}^{n_0} (\mu+b)^n e^{-(\mu+b)}/n!}{\sum_{n=0}^{n_0} b^n e^{-b}/n!} \overset{(4)}{=} \mathrm{CL}_s(\mu). \tag{4.80}$$

(1) Posterior tail with the likelihood (4.78); the $1/n_0!$ cancels.
(2) Substitute $t = \mu' + b$, and divide top and bottom by $n_0!$.
(3) The gamma tail equals the Poisson cumulative sum, $\int_x^\infty t^k e^{-t}\mathrm{d}t/k! = \sum_{n=0}^k x^n e^{-x}/n!$: this is (4.61) with $z = 2t$, since $f_{\chi^2}(2t; 2k+2)\,\mathrm{d}(2t) = t^k e^{-t}\mathrm{d}t/k!$.
(4) Definition (4.79).

So setting the posterior tail to α and setting $\mathrm{CL}_s = \alpha$ give the same limit; the script finds the two limits equal to within 4.300×10^{-12}. For $b = 0$ both reduce to the classical limit [Cowan (9.55)], because then $\mathrm{CL}_b = 1$. So for a counting experiment without background the frequentist and the flat-prior Bayesian limits are the same number, and there is no choice to make [Cowan p. 142].

What each recipe does to the coverage. Figure 4.35 (right) shows the exact coverage for $b = 3$. All three recipes keep 90% as a minimum (Feldman–Cousins 0.900, classical 0.900, CL_s 0.901) and all have the Poisson saw-tooth. They differ in how much they overcover. The classical limit, negative values and all, is a correct 90% upper limit; its failures include every experiment that quotes a negative limit. CL_s overcovers most near $\mu = 0$, where it always covers, because it never excludes any μ below 2.30. It is conservative by design: not a confidence interval in the strict Neyman sense, but a limit with guaranteed coverage that a lucky downward fluctuation cannot improve. Feldman–Cousins is closest to exact.

Feldman and Cousins point out one more advantage of their construction [28, §IV.C]. The interval is never empty, even when the observation is improbable for *every* μ (say, no events at all on a background of fifteen). In that case a non-empty interval should not reassure anyone; the right response is a separate goodness-of-fit question, "how probable is so few events even for $\mu = 0$?". Their tables flag such entries. The interval answers "which μ are compatible with the data, given the model"; it does not test the model.

In practice the unified approach is standard for neutrino-oscillation results, CL_s for exclusion limits at the LHC, and in both communities the Bayesian flat-prior limit is quoted as a cross-check. Whatever the choice, it must be stated, and fixed before the data are looked at [Cowan p. 137].

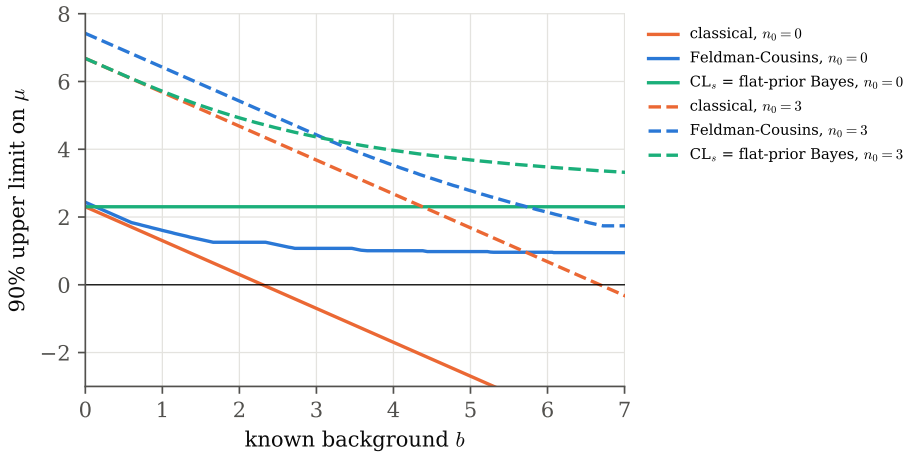

Figure 4.34: 90% upper limits on a signal mean for $n_0 = 0$ (solid) and $n_0 = 3$ (dashed) observed events, as a function of the known background. The classical limit (orange) falls linearly and becomes negative; the Feldman–Cousins limit (blue) falls but stays positive; CL$_s$, equal to the flat-prior Bayesian limit (green), does not improve when the background grows: for $n_0 = 0$ it is flat at 2.30.

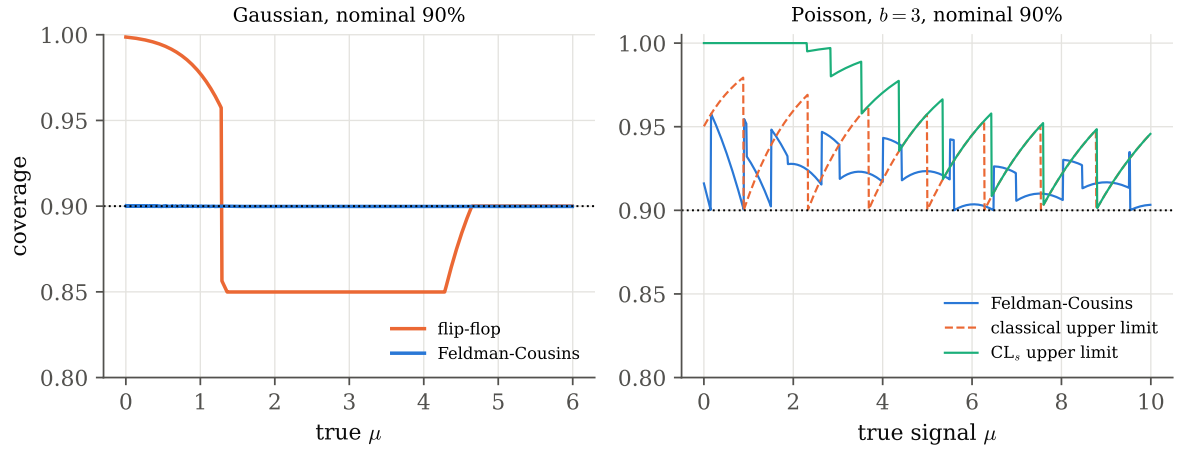

Figure 4.35: Coverage near a boundary. Left: Gaussian measurement of a non-negative mean, nominal 90%. The flip-flop recipe (orange) drops to 85% over a wide range of true values; the Feldman–Cousins intervals (blue, under the dotted line) cover 90% everywhere. Right: Poisson count on $b = 3$. Feldman–Cousins, classical upper limit and CL$_s$ all stay above 90%, with saw-tooth over-coverage; CL$_s$ overcovers most at small signals.

4.14 Many tests at once and the look-elsewhere effect

A microarray measures the activity of 2638 genes in two groups of patients, and for each gene we can test whether the two groups differ [Wasserman p. 165]. A particle search looks for a resonance at every mass between 105 and 155 GeV. A survey tests the isotropy of the sky in hundreds of patches. In all three cases each single test has a small false-alarm probability α. But there are many tests, so the chance that *some* test fires by luck is much larger. This is the **multiple testing** problem; in a particle search it is called the **look-elsewhere effect**. The first part of the chapter met it as one of the reasons for the 5σ convention. How much the false-alarm rate grows can be computed, and it can be kept under control.

The question in words.

1. If we run m tests, how likely is at least one false rejection, and how do we keep that under control?
2. When we expect some real effects among many tests, is "no false rejection at all" the right goal, or is "few false rejections among those we claim" better?
3. When the search is over a continuous parameter, like a mass, how many independent tests is it, and how do we convert the local p-value of the biggest bump into a global one?

4.14.1 The family-wise error rate and Bonferroni

Suppose we run c tests, all their null hypotheses are true, and the tests are independent, each with level α. *The question:* how likely is at least one false alarm? This probability, which Kruschke calls the *experimentwise* error rate [Kruschke §11.4.1], is

$$\alpha_{\text{EW}} \overset{(1)}{=} 1 - \text{P}(\text{no false alarm}) \overset{(2)}{=} 1 - (1-\alpha)^c. \tag{4.81}$$

(1) Complement.
(2) Independence: each test stays quiet with probability $1-\alpha$.

With nine groups there are $c = 9 \times 8/2 = 36$ pairwise comparisons, and at $\alpha = 0.05$ the chance of at least one false alarm is 0.84. An analyst who compares everything with everything is almost sure to find something.

The simplest cure is to make each test stricter. From here on we write m for the number of tests (the c above) and P_i for the p-value of test i. The **Bonferroni** method rejects null $H_{0,i}$ only if $P_i < \alpha/m$ [Wasserman p. 166]. Then, whatever the dependence between the tests, the probability of at least one false rejection, the **family-wise error rate**, is at most α [Wasserman Thm. 10.24]. Let R_i be the event "null i is true and falsely rejected", and R the event that at least one null is falsely rejected:

$$\text{P}(R) \overset{(1)}{=} \text{P}\Big(\bigcup_i R_i\Big) \overset{(2)}{\le} \sum_i \text{P}(R_i) \overset{(3)}{\le} \sum_{i=1}^{m} \frac{\alpha}{m} = \alpha. \tag{4.82}$$

(1) At least one false rejection means one of the R_i happened.
(2) The union bound: the probability of a union never exceeds the sum of the probabilities (overlaps are counted more than once on the right). No independence is needed.
(3) Under a true null the p-value is uniform (or, for discrete data, valid), so $\text{P}(P_i < \alpha/m) \le \alpha/m$; nulls that are false contribute no false rejections at all.

For the gene example, $0.05/2638 = 1.9 \times 10^{-5}$ is the threshold [Wasserman Ex. 10.25]. For the 36 comparisons the per-comparison level is 0.00139, and the actual family-wise rate for independent tests is $1-(1-0.00139)^{36} = 0.0488$, just below the target. The exact level for independent tests, $1-(1-\alpha)^{1/c} = 0.00142$ (the Šidák correction), is hardly different; Bonferroni's advantage is that it holds for any dependence.

The price is power. Bonferroni makes even one false rejection unlikely, and with thousands of tests the threshold becomes so small that real effects are missed. There is a second objection [Kruschke pp. 326–327]: the correction depends on how many comparisons the analyst *intended* to make, and on whether a comparison was planned or prompted by the data, so two analysts with the same data can reach different conclusions.

Watch out: The post hoc comparison

Comparing the two groups that happen to be furthest apart, after looking, is not one test: it is the largest of all possible comparisons, and its null distribution is that of a maximum. The same is true of the highest bin in a histogram, the best of several selection cuts, and the mass where a bump appeared. The p-value must be computed for the procedure actually followed, including the looking.

4.14.2 The false discovery rate and Benjamini–Hochberg

In a screening problem we *expect* some effects to be real. Then the useful promise is about the list of discoveries: most of what we claim should be true. To state this, sort the outcomes of the m tests into a table [Wasserman Table 10.2]:

	H_0 not rejected	H_0 rejected	total
H_0 true	U	V	m_0
H_0 false	T	S	m_1
total	$m - R$	R	m

V counts false discoveries, S true ones, $R = V + S$ all rejections. The **false discovery proportion** is FDP $= V/R$ (zero if $R = 0$), and the **false discovery rate** is its expectation, FDR $= \mathbb{E}(\text{FDP})$ [Wasserman p. 166]. Bonferroni controls $\mathrm{P}(V \geq 1)$; the FDR asks only that V be a small fraction of R on average.

The Benjamini–Hochberg procedure [Wasserman (10.8)]:

1. Sort the p-values, $P_{(1)} < \cdots < P_{(m)}$.
2. Find the largest i with $P_{(i)} < i\alpha/(C_m m)$, where $C_m = 1$ for independent tests and $C_m = \sum_{j=1}^{m} 1/j$ otherwise.
3. Reject every null with $P_i \leq P_{(i)}$ for that i.

Then FDR $\leq (m_0/m)\alpha \leq \alpha$, whatever the number of true nulls and whatever the distribution of the p-values of the false ones [Wasserman Thm. 10.26].

Why the sloping line $i\alpha/m$? Take the case $C_m = 1$, and follow the estimate of the false discovery proportion step by step.

- Suppose we reject every null whose p-value is below a threshold t.
- The m_0 true nulls have uniform p-values, so about $m_0 t$ of them fall below t. That is the expected number of false discoveries.
- If the threshold is the i-th smallest p-value, we make $R = i$ rejections, so the false discovery proportion is about $m_0 t/i$.
- We do not know m_0, so we replace it by its upper bound m. Requiring $mt/i \leq \alpha$ gives $t \leq i\alpha/m$: exactly the BH line.

So the procedure picks the most generous threshold whose estimated false discovery proportion is still at most α. The theorem shows that this heuristic holds exactly for the expectation.

Example: ten p-values. Wasserman's ten ordered p-values are 0.00017, 0.00448, 0.00671, 0.00907, 0.01220, 0.33626, 0.39341, 0.53882, 0.58125, 0.98617 [Wasserman Ex. 10.28]. At $\alpha = 0.05$, Bonferroni rejects below 0.005: the first 2. BH compares $P_{(i)}$ with $0.005\,i$: $0.00017 < 0.005$, $0.00448 < 0.010$, $0.00671 < 0.015$, $0.00907 < 0.020$, $0.01220 < 0.025$, but $0.33626 > 0.030$, and none of the later ones gets under the line. So BH rejects the first 5, the same as uncorrected testing here.

Example: a thousand tests. In `code/ch04/16_multiple_testing.py`, $m = 1000$ one-sided z-tests are run, of which $m_1 = 100$ have a real shift of 3 standard deviations, and the whole family is repeated 2000 times. On average:

procedure	true discoveries S	false discoveries V	FDR	$\mathrm{P}(V \geq 1)$
uncorrected, $P < 0.05$	91.2	45.1	0.330	1.000
Bonferroni	18.6	0.05	0.0024	0.045
Benjamini–Hochberg	60.5	3.0	0.0456	0.944

Each procedure buys something different. Uncorrected testing finds most real effects, but a third of its "discoveries" are false. Bonferroni makes almost no false discoveries and finds fewer than a fifth of the real effects. BH finds three times as many as Bonferroni, with a false discovery rate of 0.0456, at the bound $(m_0/m)\alpha = 0.045$ of the theorem. It almost always makes *some* false discovery, which it never promised not to do. When all nulls are true, $V = R$ and $\mathrm{FDR} = \mathrm{P}(V \geq 1)$, so BH controls the family-wise rate too: in 5000 all-null families it fired in 0.0462 of them, Bonferroni in 0.0456. Figure 4.36 shows the procedure on one family.

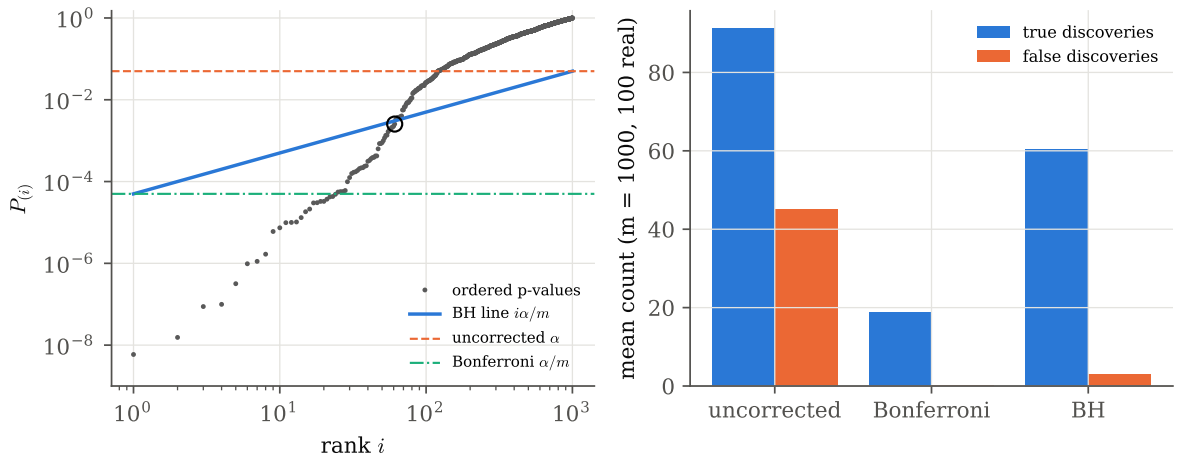

Figure 4.36: Left: the thousand p-values of one simulated family, sorted, on logarithmic axes. The real effects make the steep tail at small rank. The BH threshold is the last p-value below the sloping line $i\alpha/m$ (circled); the horizontal lines are the uncorrected and Bonferroni thresholds. Right: mean numbers of true and false discoveries of the three procedures over 2000 families.

Key idea: Two error rates for many tests

The family-wise error rate $\mathrm{P}(V \geq 1)$ is controlled by Bonferroni, $P_i < \alpha/m$, for any dependence. The false discovery rate $\mathbb{E}(V/R)$ is controlled by Benjamini–Hochberg, which rejects below the last crossing of the line $i\alpha/m$. Use the first when a single false claim is costly (a discovery), the second when a list of candidates will be followed up (a screening).

4.14.3 The look-elsewhere effect in a mass scan

A resonance search is a multiple test with a continuum of tests: one for every possible mass. (In this section m is a mass, no longer a number of tests.) *What is done.* We do not know the mass, so for every hypothesised mass m we fit a signal of that mass and compute the likelihood-ratio statistic $q_0(m)$ of the first part of the chapter. Its square root $Z(m) = \sqrt{q_0(m)}$ is the **local significance**, and $p_{\text{loc}} = \Phi(-Z)$ the **local p-value**. We then report the largest excess, $q_{\max} = \max_m q_0(m)$.

Why the usual theory fails. The mass exists only under the alternative: with no signal, the background does not depend on m, so the null hypothesis has no mass to fit. That is exactly the situation where Wilks' theorem does not apply to the maximum [15]. *The question* is then: under the background-only hypothesis, how is the maximum over the scan distributed?

Working definition 4.7 (local and global p-value, trials factor)

The **local p-value** of the biggest bump is the probability, under the background only, of an excess at least as large *at its mass*. The **global p-value** is the probability of an excess at least as large *anywhere in the search range*, $p_{\text{glob}} = \mathrm{P}(q_{\max} \geq q_{\text{obs}} \,|\, H_0)$. The **trials factor** is $p_{\text{glob}}/p_{\text{loc}}$. *Operational recipe:* simulate background-only data sets, scan each one exactly as the data were scanned, record $q_{\max}$; p_{glob} is the fraction with $q_{\max} \geq q_{\text{obs}}$.

A simulated search. The script `code/ch04/17_bump_scan.py` generates a diphoton-like spectrum of 3000 background events in sixty 1 GeV bins from 100 to 160 GeV, falling exponentially with decay length 30 GeV, and searches for a Gaussian peak of width $\sigma_m = 1.5$ GeV at 201 masses between 105 and 155 GeV in steps of 0.25 GeV. For simplicity the background shape and normalisation are taken as known; in the Gross–Vitells toy the normalisation is fitted, which changes the numbers, not the method. At each mass the signal strength $\hat{\mu} \geq 0$ maximises the binned Poisson likelihood, and

$$q_0(m) = 2\Big[\sum_i n_i \ln \frac{b_i + \hat{\mu} s_i(m)}{b_i} - \hat{\mu}\Big], \qquad \hat{\mu} \geq 0, \tag{4.83}$$

where $s_i(m)$ is the fraction of a unit signal at mass m falling in bin i, so that $\hat{\mu}$ counts signal events and $\sum_i s_i = 1$.

Listing 4.13: The scan: one-sided likelihood ratio at every mass, for many spectra at once (`code/ch04/17_bump_scan.py`)

```
def q0_scan(n):
    """n: (T, bins) counts.  Returns q0 (T, M) and mu_hat (T, M), one-sided (mu >= 0)."""
    n = n[:, None, :].astype(float)                    # (T, 1, bins)
    s = S[None, :, :]                                  # (1, M, bins)
    bb = b[None, None, :]
    g0 = (n * s / bb).sum(-1) - 1.0                    # d lnL / d mu at mu = 0 (sum s = 1)
    mu = np.maximum((s * (n - bb) / bb).sum(-1) / (s * s / bb).sum(-1), 0.0)   # linear start
    for _ in range(12):                                # Newton on a concave function
        lam = bb + mu[..., None] * s
        g = (n * s / lam).sum(-1) - 1.0
        h = -(n * s * s / lam**2).sum(-1)
        mu = np.maximum(mu - g / h, 0.0)
    mu = np.where(g0 > 0, mu, 0.0)
    lam = bb + mu[..., None] * s
    lnr = (n * np.log(lam / bb)).sum(-1) - mu          # lnL(mu) - lnL(0)
    return np.maximum(2 * lnr, 0.0), mu
```

The function takes a batch of spectra and returns q_0 at every mass for each of them. `g0` is the slope of $\ln \mathcal{L}$ at $\mu = 0$. If it is negative, the likelihood falls as soon as any signal is added, so the best non-negative signal is zero and $q_0 = 0$. Otherwise Newton's method climbs the log-likelihood, which is concave in μ, starting from the linear estimate $\sum s_i(n_i - b_i)/b_i \,/\, \sum s_i^2/b_i$; twelve iterations are plenty. Arrays of shape (spectra, masses, bins) let numpy do all 500×201 fits of a batch at once.

We took one background-only spectrum as "the data", choosing, among a hundred generated ones, the spectrum whose largest local excess was closest to 3σ. Figure 4.37 shows it. The best bump is at 142.50 GeV with $\hat{\mu} = 42$ events, $q_0 = 10.79$, local significance $Z_{\text{loc}} = 3.28$ and local p-value $p_{\text{loc}} = 5.10 \times 10^{-4}$. There is, of course, no particle.

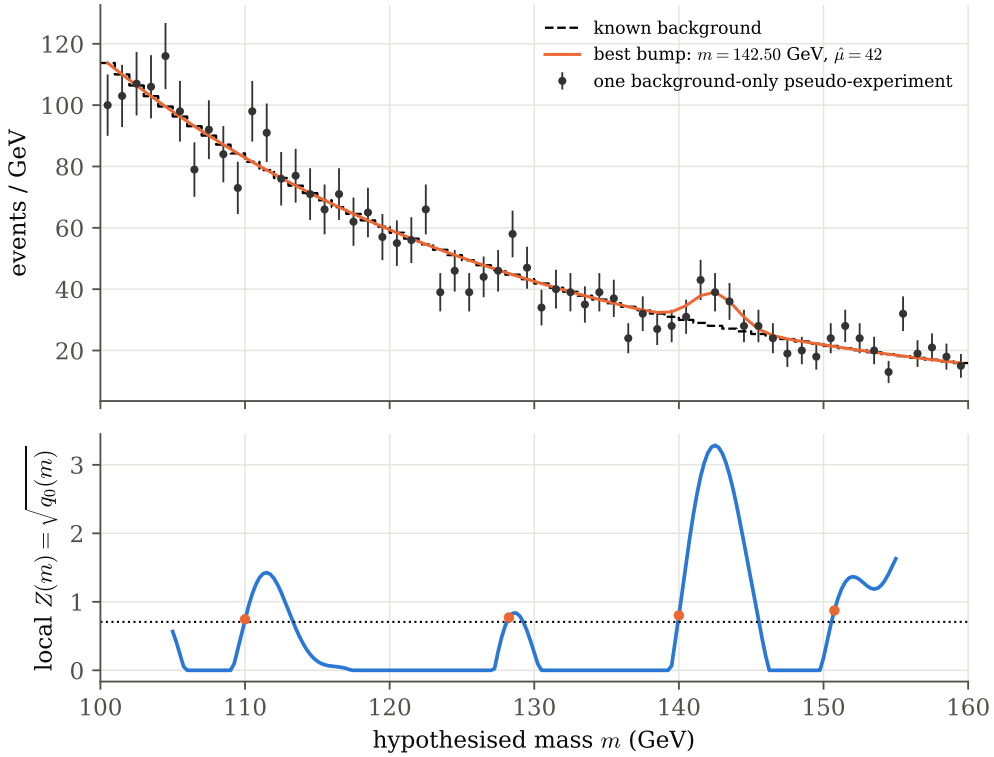

Figure 4.37: Top: a background-only pseudo-experiment (points), the known background (dashed) and the best fitted bump (orange). Bottom: the local significance $\sqrt{q_0}$ as a function of the hypothesised mass. It is zero wherever the data dip below the background, and the fluctuations are about as wide as the mass resolution. The dotted line is the reference level $\sqrt{0.5}$ used to count upcrossings (orange dots).

At one fixed mass the results of the first part of the chapter still hold. At 125 GeV, over 20000 background-only spectra, $q_0 = 0$ in 0.508 of them (the half-χ^2 spike at zero) and $\mathrm{P}(q_0 > 4) = 0.0234$, against $\Phi(-2) = 0.0228$. *Over all masses* the picture changes: a fraction 0.0159 ± 0.0009 of the background-only spectra have $q_{\max} \geq 10.79$. So

$$p_{\text{loc}} = 5.10 \times 10^{-4}\ (Z_{\text{loc}} = 3.28), \qquad p_{\text{glob}} = 0.0159\ (Z_{\text{glob}} = 2.15), \qquad \text{trials factor} \approx 31.3.$$

A "3.28σ bump" is a 2.15σ effect once we remember where we looked. A local 3σ excess somewhere in this range appears in 0.040 of background-only spectra, one in twenty-five.

4.14.4 The global p-value without a million toys

The simulation needed 20000 scans to measure a global p-value of 0.0159. For a 5σ claim, $p \approx 3\times10^{-7}$, it would need of order 10^7 scans, each a full fit [15]. Gross and Vitells, building on a bound by Davies, found a way around this.

The event. The largest excess is above some level c: $q_{\max} > c$. *How can it happen?* There are only two ways. Either q_0 is already above c at the lower end of the range, m_{lo}, or $q_0(m)$ crosses the level c upwards at least once somewhere in the scan. Call $N(c)$ the number of such **upcrossings**. Then

$$\mathrm{P}(q_{\max} > c) \overset{(1)}{\leq} \mathrm{P}\big(q_0(m_{\text{lo}}) > c\big) + \mathrm{P}\big(N(c) \geq 1\big) \overset{(2)}{\leq} p_{\text{loc}}(c) + \mathbb{E}[N(c)], \tag{4.84}$$

(1) The union bound over the two ways of exceeding c.
(2) $\mathrm{P}(N \geq 1) = \sum_{k\geq1} \mathrm{P}(N=k) \leq \sum_k k\,\mathrm{P}(N=k) = \mathbb{E}\,N$; the first term is the local p-value at a fixed mass.

and for large c the bound becomes an equality, since two upcrossings of a high level are rare [15, (1)]. *The remaining question:* how does $\mathbb{E}[N(c)]$ depend on c? Treat $Z(m)$ as a smooth Gaussian process of unit variance, a random curve along the mass axis. The rate at which it crosses a level u upwards is proportional to the density of Z at u, that is to $e^{-u^2/2}$ (Rice's formula). The proportionality constant depends on how quickly $Z(m)$ forgets its value as m changes, here on the mass resolution, but not on u. With $q_0 = Z^2$ and $u = \sqrt{c}$, this gives $\mathbb{E}[N(c)] \propto e^{-c/2}$. So a count of upcrossings at one low reference level c_0 fixes the whole curve [15, (3)]:

$$p_{\text{glob}}(c) \;\approx\; p_{\text{loc}}(c) + \mathbb{E}[N(c_0)]\, e^{-(c-c_0)/2}. \tag{4.85}$$

At a low level upcrossings are frequent, so a handful of background-only scans measures $\mathbb{E}[N(c_0)]$ well. With $c_0 = 0.5$ and only the first 100 toys we count $\mathbb{E}[N(c_0)] = 2.78$ (all 20000 give 2.804), and (4.85) at $c = 10.79$ gives $p_{\text{glob}} \approx 0.0167$, against 0.0159 ± 0.0009 from the full simulation. Figure 4.38 (left) compares the whole curves.

The trials factor grows with the significance. Divide (4.85) by $p_{\text{loc}} = \Phi(-Z)$, with $c = Z^2$, and use the large-Z tail estimate $\Phi(-Z) \approx e^{-Z^2/2}/(\sqrt{2\pi}\,Z)$ from the first part of the chapter. Writing $\mathcal{N}_1 = \mathbb{E}[N(c_0)]e^{c_0/2}$, so that $\mathbb{E}[N(c)] = \mathcal{N}_1 e^{-c/2}$,

$$\frac{p_{\text{glob}}}{p_{\text{loc}}} \overset{(1)}{=} 1 + \frac{\mathcal{N}_1 e^{-Z^2/2}}{\Phi(-Z)} \overset{(2)}{\approx} 1 + \mathcal{N}_1 e^{-Z^2/2}\cdot\sqrt{2\pi}\,Z\,e^{Z^2/2} \overset{(3)}{=} 1 + \sqrt{2\pi}\,\mathcal{N}_1 Z. \tag{4.86}$$

(1) Divide (4.85) by p_{loc} and insert $c = Z^2$.
(2) The Gaussian tail estimate.
(3) The exponentials cancel.

The trials factor is not a fixed "number of independent masses". It grows linearly with the local significance [15, (12)]. (Gross and Vitells write $1 + \sqrt{\pi/2}\,\mathcal{N}Z$ for the two-sided statistic, whose level crossings are twice as many, $\mathcal{N} = 2\mathcal{N}_1$: the same formula.) Here $\mathcal{N}_1 = 3.60$, so a local 3σ bump carries a trials factor of about 28 and our 3.28σ bump about 31.3, matching the toys (Figure 4.38, right). *Why does it grow?* A higher level is crossed only near the top of a fluctuation, and the part of the fluctuation above the level gets narrower as the level rises. A pre-chosen mass must land on that narrow top, so the local p-value falls faster than the chance that the top appears somewhere in the range. For a local 5σ excess in this search, (4.85) gives $p_{\text{glob}} = 1.36\times10^{-5}$, a global significance of 4.20σ, from $p_{\text{loc}} = 2.87\times10^{-7}$: no simulation of 10^7 scans needed.

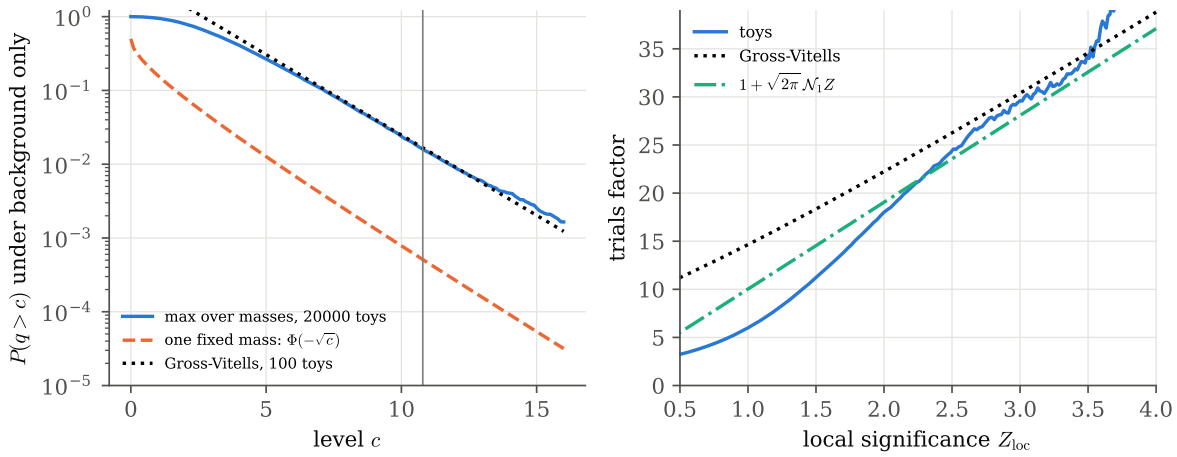

Figure 4.38: Left: the probability, with background only, that the largest excess exceeds a level c anywhere in the scan (blue, 20 000 toys), compared with the local probability at one fixed mass (orange dashed) and the Gross–Vitells formula calibrated on 100 toys (black dotted). The vertical line marks the observed bump. Right: the trials factor, global over local p-value, as a function of the local significance, with the Gross–Vitells prediction and its asymptotic straight line.

What "elsewhere" means. The global p-value refers to the range of the scan, and that range must be fixed before the data are seen. But other decay channels, other signal widths and other analyses in the same experiment are also places one could have looked. There is no unique answer to how far "elsewhere" extends. That is why experiments quote the local significance together with the global one for a stated range.

How this is used in real research: How searches report the look-elsewhere effect

A search at a collider quotes the local p-value of the largest excess, and a global p-value over a stated mass range, obtained from background-only toys where affordable and from the upcrossing formula (4.85) otherwise. The test statistic is the profile likelihood ratio of [27] with the nuisance parameters (background shape, energy scale) fitted in every toy. The same formula applies to any scan over a parameter that exists only under the signal hypothesis: the position of a localised feature in the CMB power spectrum, the frequency of an oscillation in a Galactic-centre spectrum, the sky position and frequency of a gravitational-wave template.

The Bayesian language of Chapter 5 handles the same problem differently. The unknown mass gets a prior spread over the search range. The evidence for a signal is then automatically diluted by the fraction of the range that is compatible with the bump. This dilution, the *Occam factor*, plays the role of the trials factor.

Two things were held simple in this scan: the background shape was known, and the only question was discovery. A real search fits the background together with its systematic uncertainties, and when nothing is found it must say which signal strengths are excluded. Section 4.15 builds the likelihood with nuisance parameters that the scan's $q_0(m)$ then uses, and Section 4.16 turns the same profile likelihood ratio into upper limits, CL_s and the expected band.

4.15 A search as a likelihood: templates and nuisance parameters

In the summer of 2012 two experiments at the LHC showed the same kind of plot: a histogram of the invariant mass of photon pairs, a smooth background falling from left to right, and a small bump near 125 GeV. The question put to that histogram was simple to say. Is there a signal in it, and how big is it? The size is quoted as a **signal strength** μ [the number of signal events seen, divided by the number the Standard Model predicts], so $\mu = 0$ means "background only" and $\mu = 1$ means "the predicted Higgs boson".

But the number of signal events the Standard Model "predicts" in that histogram is not known exactly. It depends on how many collisions were recorded (the luminosity), on how often a real photon pair passes the selection (the efficiency), and on where exactly a 125 GeV peak lands on the measured mass axis (the photon energy scale). Each of these was measured in a separate calibration, each to a few per cent. The background level under the peak is not predicted at all; it has to be read off the data. So the honest statement of the experiment's knowledge is not one number for the prediction but a prediction that depends on several uncertain inputs, each of which has been measured somewhere. Writing all of that as one likelihood is what turns a histogram into a measurement of μ, and the same construction serves any search: a dark-matter recoil spectrum, a line in an X-ray spectrum, an excess of gravitational-wave triggers above the noise.

The question in words.

1. What is the probability of the whole histogram, given a signal strength and everything else the prediction depends on?
2. What is a "systematic uncertainty" in this language, and why does it become a parameter with a measurement of its own?
3. How do we remove those extra parameters to speak about μ alone, and how does this compare with the profile likelihood of Chapter 3 and with the Bayesian marginalisation of Chapter 5?

4.15.1 The probability of a histogram

Start with what is recorded. Each selected event has a measured mass x, and the events are sorted into bins, $n_1, \dots, n_N$ events in bins $1, \dots, N$. What is the probability of this list of counts?

The inputs. Two physical assumptions carry everything, the same ones that gave the Poisson distribution in Chapter 2: the collisions that produce selected events happen independently of each other, one at a time, and at a rate that does not change during the run. Then the total number of selected events N_{tot} is Poisson with some mean ν_{tot}. One more input, also physical: each event lands in bin i with a probability p_i that does not depend on the other events.

The question: the bins split one Poisson stream into N pieces; what is the joint probability of the counts in the pieces? Given the total, the counts are multinomial (each of the N_{tot} events chooses its bin independently). So, with $N_{\text{tot}} = \sum_i n_i$ and $\nu_i = \nu_{\text{tot}} p_i$,

$$\begin{aligned} \mathrm{P}(n_1, \dots, n_N) &\overset{(1)}{=} \mathrm{P}(N_{\text{tot}})\ \mathrm{P}(n_1, \dots, n_N \mid N_{\text{tot}}) \overset{(2)}{=} \frac{\nu_{\text{tot}}^{N_{\text{tot}}} e^{-\nu_{\text{tot}}}}{N_{\text{tot}}!}\ \frac{N_{\text{tot}}!}{n_1! \cdots n_N!}\ p_1^{n_1} \cdots p_N^{n_N} \\ &\overset{(3)}{=} \prod_{i=1}^{N} \frac{(\nu_{\text{tot}} p_i)^{n_i}}{n_i!}\, e^{-\nu_{\text{tot}} p_i} \overset{(4)}{=} \prod_{i=1}^{N} \frac{\nu_i^{n_i}}{n_i!}\, e^{-\nu_i}. \end{aligned} \tag{4.87}$$

(1) The product rule: first the total, then how it is shared among the bins.
(2) Poisson for the total; multinomial for the sharing.
(3) The $N_{\text{tot}}!$ cancel; write $\nu_{\text{tot}}^{N_{\text{tot}}} = \prod_i \nu_{\text{tot}}^{n_i}$ and $e^{-\nu_{\text{tot}}} = \prod_i e^{-\nu_{\text{tot}} p_i}$, using $\sum_i n_i = N_{\text{tot}}$ and $\sum_i p_i = 1$.
(4) Name the mean of bin i, $\nu_i = \nu_{\text{tot}} p_i$.

The joint probability factorises: the bin counts are *independent* Poisson variables, each with its own mean. Nothing about the bins being "far apart" was needed; the independence comes from the Poisson total.

Signal plus background. In each bin the events come from two independent sources, signal and background. The sum of two independent Poisson counts is Poisson with the summed mean (Chapter 2), so the mean of bin i is

$$\nu_i = \mu\, s_i + b_i, \qquad s_i = S\, f_i, \quad b_i = B\, g_i. \tag{4.88}$$

Here S and B are the expected total numbers of signal (for $\mu = 1$) and background events, and f_i, g_i are the fractions of each falling in bin i [27, (2)–(4)].

Working definition 4.8 (template)

A **template** is the predicted histogram of one process: the fractions f_i (signal) or g_i (background) of its events expected in each bin [a shape, normalised to one, usually made by running the detector simulation on many simulated events]. The analysis fits the data as a sum of templates with free or constrained normalisations. *Operationally:* histogram the simulated events of each process with the binning of the data, divide by their number.

Example: the search we will follow. Our pseudo-experiment has sixty 1 GeV bins from 100 to 160 GeV. The background template g_i is a falling exponential of decay length 30 GeV with $B = 3000$ expected events; the signal template f_i is a Gaussian peak at 125 GeV with the mass resolution $\sigma_m = 1.5$ GeV and $S = 60$ expected events. The data were generated with $\mu = 1$ by the library `code/ch04/lib_templates.py`. With every input known, the likelihood would be (4.87) with (4.88) inserted, a function of μ alone, exactly the likelihood that was scanned over masses in Section 4.14.3.

4.15.2 Systematic uncertainties become nuisance parameters

Now let the inputs be uncertain, as they are. Take the three of our example one at a time, and ask of each: *how does it change the predicted counts, and who measured it?*

- *The background normalisation* β. The background is βB instead of B. Nobody predicts β well; the data measure it, from the bins away from the peak (the **sidebands**) or from a separate **control region** chosen to contain no signal.
- *The signal yield* κ, luminosity times efficiency relative to its nominal value. The signal is $\mu\kappa S$ instead of μS. A calibration measured κ: its result was $a_\kappa = 1$ with an error of $\sigma_\kappa = 0.10$.
- *The energy scale* δ. A mis-calibration shifts every measured photon energy, so the peak sits at $125 + \delta$ and the signal template becomes $f_i(125 + \delta)$. The scale was calibrated on the well-known Z boson peak: $a_\delta = 0$ with $\sigma_\delta = 0.5$ GeV.

Each of these is a parameter the predicted counts depend on and that we do not want to report: a **nuisance parameter** (Chapter 3). The first one is different from the other two in kind. It changes the background, which the histogram itself measures. The other two change the signal,

which the histogram cannot separate from μ: a larger κ and a smaller μ give the same peak. Only the calibration can tell them apart.

What should be done with κ? There are three candidates. We could fix it at 1; that pretends the calibration was perfect, and Chapter 3 showed what this costs: intervals too short by the factor $\sqrt{1-\rho^2}$ and coverage below its promise. We could leave it free with no information; then μ and κ are completely degenerate and μ is not measured at all. Or we could use what the calibration actually found. The calibration is a measurement like any other. Its result a_κ is a random number whose distribution depends on the true κ: Gaussian, with mean κ and standard deviation σ_κ. The probability of the calibration result, read as a function of κ, is its likelihood. The calibration and the search are independent measurements, so the probability of both results is the product of their probabilities. This gives the complete likelihood

$$\mathcal{L}(\mu, \boldsymbol{\theta}) = \prod_{i=1}^{N} \frac{\big(\mu\, s_i(\boldsymbol{\theta}) + b_i(\boldsymbol{\theta})\big)^{n_i}}{n_i!}\, e^{-(\mu s_i(\boldsymbol{\theta}) + b_i(\boldsymbol{\theta}))} \;\times\; \prod_k p\big(a_k \mid \theta_k\big), \tag{4.89}$$

with $\boldsymbol{\theta} = (\beta, \kappa, \delta)$ the nuisance parameters and one factor $p(a_k \mid \theta_k)$ for each auxiliary measurement [27, (6)], [29]. For a calibration quoted as $a_k \pm \sigma_k$,

$$p(a_k \mid \theta_k) = \frac{1}{\sqrt{2\pi}\,\sigma_k} \exp\!\left[-\frac{(a_k - \theta_k)^2}{2\sigma_k^2}\right], \tag{4.90}$$

a **constraint term**. If the auxiliary measurement is itself a count, a control region with m events expected to be $\tau\beta B$, the factor is Poisson instead; Section 4.15.4 works that case out.

Watch out: A constraint term is a likelihood, not a prior

The Gaussian factor (4.90) looks like a prior on θ_k, and in a Bayesian analysis it is combined with one. But in (4.89) it is the probability of an observed number, the calibration result a_k, given the parameter. In pseudo-experiments, therefore, a_k must be *generated* afresh together with the histogram (the calibration would have come out differently too), not held at its observed value [27].

A nuisance parameter can change the *shape* of a template, not only its size: the energy scale moves the peak. Real analyses rarely have a formula like $f_i(125+\delta)$. They have the nominal template and two shifted ones, made by re-running the simulation with the calibration moved up and down by one standard deviation, and they interpolate between them bin by bin [29]. With θ measured in units of its calibration error, the simplest choice is

$$f_i(\theta) = f_i^0 + \theta\,\big(f_i^+ - f_i^0\big) \quad (\theta \ge 0), \qquad f_i(\theta) = f_i^0 + \theta\,\big(f_i^0 - f_i^-\big) \quad (\theta < 0), \tag{4.91}$$

so that $\theta = 0, \pm 1$ give back the three simulated templates, and the constraint term is a standard normal in θ.

Figure 4.39 shows how the pieces of (4.89) hang together: every parameter predicts some measurements, every measurement contributes one factor, and the likelihood is their product.

4.15.3 Removing the nuisance parameters: fix, profile or integrate

We have met this problem twice before, and it is worth recalling both times concretely. In Chapter 3, in the section on nuisance parameters and the profile likelihood, a counting experiment saw 20 events in a signal region and 8 in a control region of the same size. The estimated signal was $\hat{s} = 12$. Holding the background fixed at its best value gave the error $^{+4.811}_{-4.145}$, letting it adjust (profiling) gave $^{+5.47}_{-5.192}$, and in simulated repetitions only the profile interval

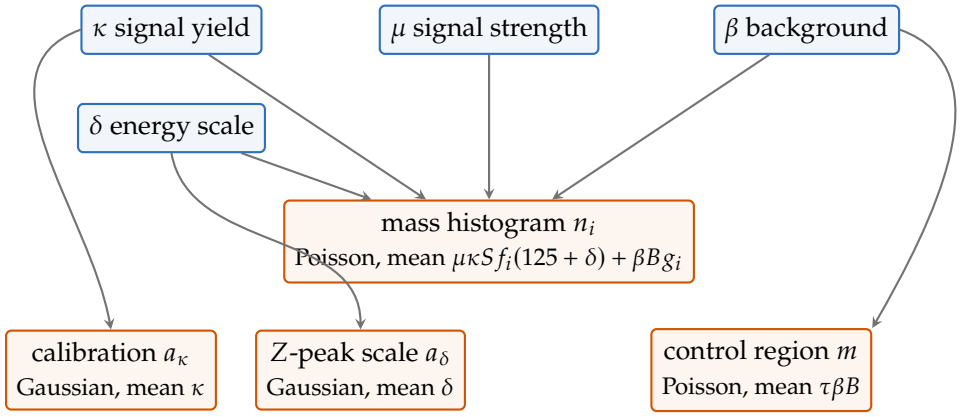

Figure 4.39: The structure of a search likelihood. Parameters (blue) predict the measurements (orange). The signal strength μ is predicted only by the main histogram, where it always appears multiplied by the signal yield κ; the calibrations measure κ and the energy scale δ on their own, and the background normalisation β is measured by the histogram's sidebands and, optionally, by a control region. The likelihood is the product of one factor per measurement.

covered the truth 68% of the time (0.6849 against 0.6088). In Chapter 5, in the section on nuisance parameters, the Bayesian removed a background level by integrating the joint posterior over it, and found that integrating and maximising agree when the likelihood is Gaussian, and differ by a "volume" factor (how many values of the nuisance parameter fit almost as well) when it is not. The search likelihood (4.89) is the same problem with three differences: there are several nuisance parameters, their information comes from separate auxiliary measurements, and the goal is not only an interval but the test statistics of Section 4.16.

The frequentist tool is the same as in Chapter 3: the **profile likelihood ratio**

$$\lambda(\mu) = \frac{\mathcal{L}\big(\mu, \hat{\hat{\boldsymbol{\theta}}}(\mu)\big)}{\mathcal{L}(\hat{\mu}, \hat{\boldsymbol{\theta}})}, \qquad 0 \le \lambda(\mu) \le 1, \tag{4.92}$$

where $\hat{\mu}, \hat{\boldsymbol{\theta}}$ maximise $\mathcal{L}$ over everything, and $\hat{\hat{\boldsymbol{\theta}}}(\mu)$ maximises it over the nuisance parameters with μ held fixed [27, (7)]. The double hat is read "the best nuisance parameters for this μ". The numerator can never exceed the denominator, because the denominator is maximised over more.

Set the three ways of removing $\boldsymbol{\theta}$ side by side.

- *Fix* $\boldsymbol{\theta}$ at $\hat{\boldsymbol{\theta}}$: the conditional likelihood. It keeps only the statistical fluctuation of the histogram. Its width is the "statistical error".
- *Profile*: at each μ, let $\boldsymbol{\theta}$ take its best value. The width of $-2\ln\lambda(\mu)$ is the total error.
- *Integrate*: give $\boldsymbol{\theta}$ a prior (here flat in β, and the calibrations' Gaussians, which are then genuinely priors) and integrate the joint posterior over it, as in Chapter 5.

What is the same? For a Gaussian likelihood all three are Gaussians in μ; profiling and integrating give the same width, the full variance $V_{\mu\mu}$, and fixing gives the smaller $1/F_{\mu\mu}$ (Chapter 3). *What differs?* The meaning: the profile curve is a likelihood ratio whose sampling distribution we will compute, the marginal is a posterior density that needs a prior. And the shape, as soon as the likelihood is not Gaussian, through the volume factor.

How large is the systematic part of the error? Analyses quote it separately, by subtraction. For one nuisance parameter, Chapter 3 found $1/F_{\mu\mu} = V_{\mu\mu}(1-\rho^2)$, with ρ the correlation of $\hat{\mu}$ and

$\hat{\theta}$, so

$$\sigma^2_{\text{syst}} \equiv \sigma^2_{\text{tot}} - \sigma^2_{\text{stat}} \overset{(1)}{=} V_{\mu\mu} - \frac{1}{F_{\mu\mu}} \overset{(2)}{=} V_{\mu\mu} - V_{\mu\mu}(1-\rho^2) = \rho^2\, V_{\mu\mu}. \tag{4.93}$$

(1) The profile width is $\sqrt{V_{\mu\mu}}$, the conditional width $\sqrt{1/F_{\mu\mu}}$.
(2) The identity of Chapter 3.

The "systematic error" is the part of the variance of $\hat{\mu}$ that it shares with the nuisance parameter through their correlation. It adds to the statistical one in quadrature by construction, not by assumption. With several nuisance parameters the same subtraction is used, and ρ^2 becomes the fraction of the variance of $\hat{\mu}$ that all of them together account for.

Example: the template fit. The script `code/ch04/19_hep_templates.py` maximises (4.89) for our pseudo-data. The heart of it is the negative log-likelihood:

Listing 4.14: The search likelihood: Poisson bins times two Gaussian constraint terms (`code/ch04/lib_templates.py`)

```
def expected(mu, theta, m=125.0):
    beta, kappa, delta = theta
    return mu * kappa * S0 * sig_template(m + delta) + beta * B0 * G

def nll(mu, theta, n, m=125.0, aux=(A_KAPPA, A_DELTA)):
    """-ln L(mu, theta) up to a constant: Poisson bins times Gaussian constraint terms."""
    nu = expected(mu, theta, m)
    if np.any(nu <= 0):
        return 1e12
    beta, kappa, delta = theta
    pois = np.sum(nu - n * np.log(nu))
    cons = 0.5 * ((kappa - aux[0]) / SIG_KAPPA) ** 2 + 0.5 * ((delta - aux[1]) / SIG_DELTA)
    ** 2
    return pois + cons
```

`expected` builds the mean counts (4.88) with the three nuisance parameters inserted; `nll` returns $-\ln\mathcal{L}$ without the constants $\ln n_i!$ and $\ln\sqrt{2\pi}\sigma_k$, which cancel in every ratio. A numerical minimiser (`scipy.optimize.minimize`) does the rest, over all four parameters for the denominator of (4.92), over the three nuisance parameters at each fixed μ for the numerator. The global fit gives

$$\hat{\mu} = 1.07, \qquad \hat{\beta} = 0.972, \qquad \hat{\kappa} = 1.00, \qquad \hat{\delta} = -0.14\,\text{GeV}.$$

Why is $\hat{\kappa}$ exactly the calibration value? Because the histogram sees only the product $\mu\kappa$. Whatever the product the histogram prefers, the fit can reach it with any κ by moving μ, so it sets κ where its own measurement, the calibration, wants it. The energy scale, in contrast, is pulled a little by the data: the peak in the histogram sits slightly below 125 GeV, and the fit moves it by a fraction of the calibration error.

Figure 4.40 (right) shows the three curves. Read at $-2\ln(\mathcal{L}/\mathcal{L}_{\max}) = 1$:

$$\text{fixed: } \hat{\mu}^{+0.30}_{-0.32}, \qquad \text{profile: } \hat{\mu}^{+0.34}_{-0.34}, \qquad \text{marginal: } 1.04^{+0.36}_{-0.32}.$$

So $\sigma_{\text{stat}} = 0.31$, $\sigma_{\text{tot}} = 0.34$, and by (4.93) $\sigma_{\text{syst}} = 0.15$. Most of the systematic part is the 10% yield calibration: since the histogram measures $\mu\kappa$, a 10% error on κ is a 10% error on μ, about $0.1\,\hat{\mu} \approx 0.11$, and $\sqrt{0.31^2 + 0.11^2} \approx 0.33$. Profiling and marginalising nearly agree: the marginal peaks slightly lower, at 1.04, with almost the same width, and the largest difference between the two curves inside the plotted interval is 0.27 in $-2\ln$. That is the volume effect of Chapter 5

at work, small here because the likelihood is close to Gaussian. The sizes are the lesson. A 1.5 GeV resolution and 3000 background events make the statistical error dominant; a ten times larger data set would shrink σ_{stat} by $\sqrt{10}$ and leave σ_{syst} untouched, and the calibration would then limit the measurement.

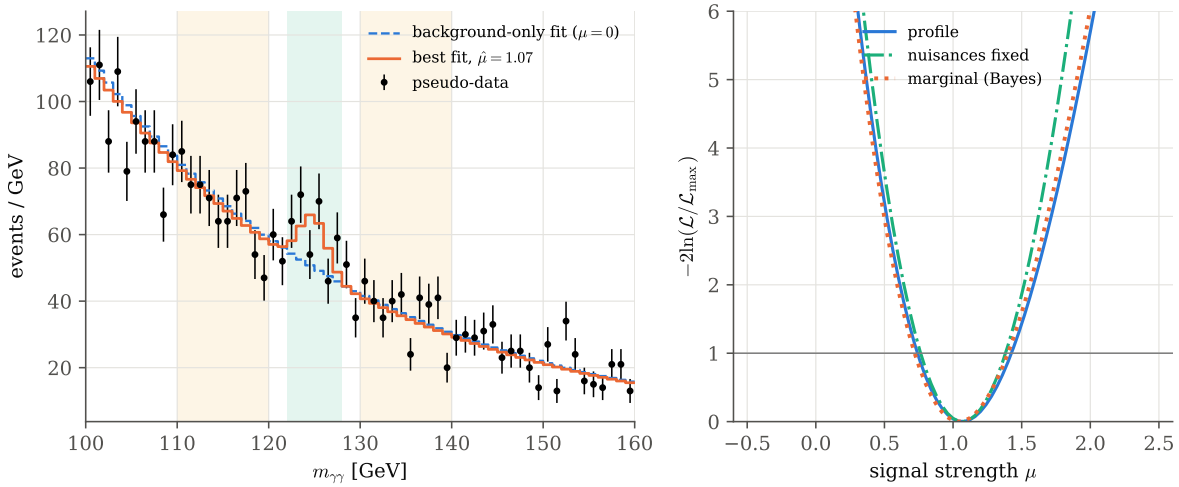

Figure 4.40: Left: the pseudo-data (points), the best background-only fit (blue dashed) and the best signal-plus-background fit (orange). The green band is the signal window and the yellow bands the sidebands used by the counting version of the search. Right: three ways of turning the four-parameter likelihood into a curve for μ. Fixing the nuisance parameters gives the narrowest curve (the statistical error); profiling them gives the total error; integrating them with priors (Bayes) gives nearly the same curve, slightly shifted towards smaller μ. The grey line at one marks the 68% interval.

4.15.4 The smallest search: a signal window and its sidebands

Every piece of the template likelihood can be seen working, and solved by hand, in a stripped-down version of the same search. Keep only two numbers from the histogram: the count n in a signal window around the peak, 122–128 GeV, and the count m in two sidebands, 110–120 and 130–140 GeV (Figure 4.40, left). In the window we expect $\mu s + b$ events, where $s = 57.3$ is the nominal signal falling in the window and b the unknown background. In the sidebands we expect τb, where $\tau = 3.531$ is the ratio of the background template integrated over the sidebands to its integral over the window. The shape is taken as known; only its normalisation b is not. The sidebands are the control region and b is the nuisance parameter. The likelihood is two Poisson factors [27, (90)],

$$\ln \mathcal{L}(\mu, b) = n \ln(\mu s + b) - (\mu s + b) + m \ln(\tau b) - \tau b + \text{const}, \tag{4.94}$$

the on/off likelihood of Chapter 3 with k renamed τ and the signal written as μs.

The global maximum. Setting the two derivatives to zero,

$$\begin{aligned} \frac{\partial \ln \mathcal{L}}{\partial \mu} &\overset{(1)}{=} s\left(\frac{n}{\mu s + b} - 1\right) = 0 \;\Rightarrow\; \hat{\mu} s + \hat{b} = n, \\ \frac{\partial \ln \mathcal{L}}{\partial b} &\overset{(2)}{=} \frac{n}{\mu s + b} - 1 + \frac{m}{b} - \tau = 0 \;\Rightarrow\; \hat{b} = \frac{m}{\tau}, \qquad \hat{\mu} = \frac{n - m/\tau}{s}. \end{aligned} \tag{4.95}$$

(1) Only the first two terms of (4.94) contain μ.

(2) By the first equation the first two terms cancel, leaving $m/b = \tau$; then $\hat{\mu} s = n - \hat{b}$.

In words: the sidebands estimate the background, scaled down to the window by τ, and the signal is what is left over. With $n = 365$ and $m = 1047$, $\hat{b} = 296.5$ and $\hat{\mu} = 1.20$. We allow $\hat{\mu} < 0$ here: it is whatever value maximises the likelihood, as long as the mean count $\mu s + b$ stays positive. Section 4.16 needs this.

The best background for a given μ. Hold μ fixed and solve only the second equation of (4.95):

$$\begin{aligned} 0 &\overset{(1)}{=} n\,b - b(\mu s + b) + m(\mu s + b) - \tau b(\mu s + b) \\ &\overset{(2)}{=} -(1+\tau)\,b^2 + \big[n + m - (1+\tau)\mu s\big]\,b + m\mu s, \\ \hat{\hat{b}}(\mu) &\overset{(3)}{=} \frac{A}{2(1+\tau)} + \sqrt{\frac{A^2 + 4(1+\tau)\,m\,\mu s}{4(1+\tau)^2}}, \qquad A = n + m - (1+\tau)\mu s. \end{aligned} \tag{4.96}$$

(1) Multiply $\partial \ln \mathcal{L}/\partial b = 0$ by $b(\mu s + b) > 0$.
(2) Collect powers of b.
(3) The quadratic formula; for $\mu > 0$ the constant term $m\mu s$ is positive, so the roots have opposite signs and only the + root is a background.

This is [27, (93)], and the same quadratic as in Chapter 3. At $\mu = 0$ the square root equals $A/(2(1+\tau))$ and $\hat{\hat{b}}(0) = (n+m)/(1+\tau)$: with no signal, the window and the sidebands are pooled into one background measurement. Here $\hat{\hat{b}}(0) = 311.7$, more than $\hat{b}$, because the pooled estimate also uses the excess in the window.

The discovery statistic. For $\hat{\mu} > 0$, $q_0 = -2\ln\lambda(0)$. At the global maximum $\hat{\mu}s + \hat{b} = n$ and $\tau\hat{b} = m$; at $\mu = 0$ the window mean is $\hat{\hat{b}}(0)$ and the sideband mean $\tau\hat{\hat{b}}(0)$, and the two linear terms add up to $(1+\tau)\hat{\hat{b}}(0) = n + m$. So

$$\begin{aligned} q_0 &\overset{(1)}{=} 2\Big[\big(n\ln n - n + m\ln m - m\big) - \big(n\ln\hat{\hat{b}}(0) + m\ln\tau\hat{\hat{b}}(0) - (n+m)\big)\Big] \\ &\overset{(2)}{=} 2\left[n\ln\frac{n}{\hat{\hat{b}}(0)} + m\ln\frac{m}{\tau\,\hat{\hat{b}}(0)}\right]. \end{aligned} \tag{4.97}$$

(1) (4.94) at the two maxima, using the values just listed.
(2) The $-(n+m)$ terms cancel; combine the logarithms.

The numbers give $q_0 = 11.28$, a significance $Z = \sqrt{q_0} = 3.36$ (Section 4.16.2 shows why the square root is the significance even with a nuisance parameter). Compare with two neighbours.

- *The background known exactly*, $b = 302.1$: the formula of the first part of the chapter, $q_0 = 2[n\ln(n/b) - (n-b)]$, gives $Z = 3.50$.
- *The full template fit* of Section 4.15.3, with three nuisance parameters: $Z = \sqrt{q_0} = 3.53$.

One pseudo-experiment is a poor judge of which method is better: all three values of Z move with the luck of the same data. The expected significances, computed with the Asimov data set of Section 4.16.3, do not: 2.80 for the window with sidebands, 3.20 with the background known, and 3.32 for the template fit. Measuring the background instead of knowing it costs significance. The template fit wins it back, because it uses every bin, each weighted by its own ratio of signal to background, instead of a window with a hard edge.

The size of the cost is easiest to see in the Gaussian limit. $\hat{\mu} = (n - m/\tau)/s$ is a difference of independent counts, so its variance is about $(n + m/\tau^2)/s^2$, an error of 0.37; with the background known it would be $\sqrt{n}/s = 0.33$. The control region adds the term $m/\tau^2 \approx b/\tau$: a control region τ times larger than the window adds a fraction $1/\tau$ of the background variance.

The lesson in one line: a systematic uncertainty is a parameter with a measurement of its own, and the search likelihood is the product of the main measurement and those auxiliary measurements.

4.16 Discovery and exclusion with nuisance parameters: q_0, $\tilde{q}_\mu$, CL_s and the Brazil band

The discovery statistic q_0 has appeared twice already. In the first part of the chapter, a count N on a *known* background b gave $q_0 = 2[N\ln(N/b) - (N-b)]$ for $N > b$ and zero otherwise; with background only it is half the time zero and otherwise χ^2_1, so its tail is $\Phi(-\sqrt{q_0})$ and the significance is simply $Z = \sqrt{q_0}$. For Cowan's peak of 11 events on an expected 3.2 this gave $Z = 3.40$, against 3.29 from the exact Poisson tail. In Section 4.14.3 the same q_0 was computed at every hypothesised mass, again with the background known, and the largest one needed the look-elsewhere correction. The statistic is the same now; three things are new. The background and the calibrations are nuisance parameters, profiled in q_0, and we need to know whether $Z = \sqrt{q_0}$ survives that. We need a second statistic for *excluding* a signal, and the distribution of both statistics when the signal is present, to say what an experiment can expect. And we need a rule for exclusion that does not reward an experiment for a lucky downward fluctuation.

The question in words.

1. With nuisance parameters, which number measures how badly the data disagree with "no signal", and which with "a signal of strength μ"?
2. What are their distributions, without simulating millions of experiments?
3. Before looking at the data, what discovery significance and what limit should the experiment expect, and how far from it may the observed values reasonably fall?
4. Why do the LHC experiments exclude with CL_s rather than with the plain p-value?

4.16.1 Three statistics built from the profile likelihood ratio

All three statistics are built from the profile likelihood ratio $\lambda(\mu)$ of (4.92): the best likelihood with μ fixed, nuisance parameters at their best, divided by the best likelihood overall. A value near one says that μ fits about as well as anything; a small value says that it does not. The basic statistic is $t_\mu = -2\ln\lambda(\mu)$, large when μ fits badly. The physical question decides which fluctuations should count against μ, and that gives the three variants [27, §2].

Discovery: testing $\mu = 0$. A signal can only add events. If the data show fewer events than the background predicts ($\hat{\mu} < 0$), that may be evidence of a badly modelled background, but it is no evidence for a signal. So

$$q_0 = \begin{cases} -2\ln\lambda(0), & \hat{\mu} \geq 0, \\ 0, & \hat{\mu} < 0, \end{cases} \tag{4.98}$$

[27, (12)], the one-sided statistic of the first part of the chapter, now with nuisance parameters inside λ.

Exclusion: testing a signal $\mu > 0$. To set an upper limit we ask whether the data have too *few* events for μ. Data with $\hat{\mu} > \mu$ (more signal-like than μ itself) are not evidence against μ when the question is an upper limit, so they count as perfect agreement. And since $\mu \geq 0$ is physical,

the reference fit should not use a negative signal: if $\hat{\mu} < 0$, the best *physical* fit is $\mu = 0$. Taking these one at a time gives the statistic

$$\tilde{q}_\mu = \begin{cases} -2\ln \dfrac{\mathcal{L}\big(\mu, \hat{\hat{\boldsymbol{\theta}}}(\mu)\big)}{\mathcal{L}\big(0, \hat{\hat{\boldsymbol{\theta}}}(0)\big)}, & \hat{\mu} < 0, \\ -2\ln \dfrac{\mathcal{L}\big(\mu, \hat{\hat{\boldsymbol{\theta}}}(\mu)\big)}{\mathcal{L}\big(\hat{\mu}, \hat{\boldsymbol{\theta}}\big)}, & 0 \le \hat{\mu} \le \mu, \\ 0, & \hat{\mu} > \mu, \end{cases} \tag{4.99}$$

[27, (16)]. Replacing $\hat{\mu}$ by the best physical value when $\hat{\mu} < 0$ is the move of Feldman and Cousins, whose ordering used $\mu_{\text{best}} = \max(0, x)$ (Section 4.13.3). (The variant q_μ without the tilde keeps $\hat{\mu}$ in the denominator in all cases; in the approximation of the next subsection both give the same limits.)

Figure 4.41 draws the two statistics as functions of $\hat{\mu}$, in the approximation derived next, for a signal μ two standard deviations from zero. Both are monotonic where they are not zero: q_0 grows as $\hat{\mu}$ rises, $\tilde{q}_\mu$ grows as $\hat{\mu}$ falls. That monotonicity is what makes their distributions easy.

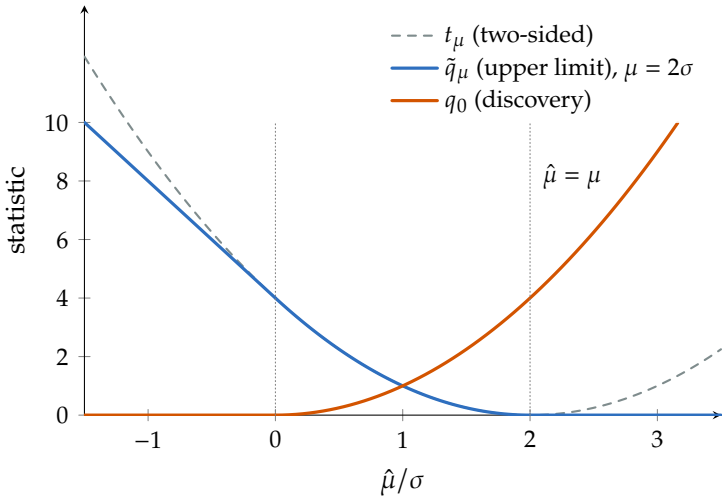

Figure 4.41: The test statistics as functions of the estimated signal strength, in units of its standard deviation, for a tested signal $\mu = 2\sigma$. The discovery statistic q_0 (orange) is zero for a deficit and grows as $(\hat{\mu}/\sigma)^2$ for an excess. The upper-limit statistic $\tilde{q}_\mu$ (blue) is zero for $\hat{\mu} > \mu$, follows the two-sided t_μ (grey dashed) between 0 and μ, and for $\hat{\mu} < 0$ continues as a straight line, because the reference fit stops at the physical boundary.

4.16.2 Wald's approximation and the half-χ^2

The question: if the true signal strength is μ', how is $\tilde{q}_\mu$ (or q_0) distributed? The answer rests on one approximation, due to Wald [27, (17)]: for a large data sample,

$$-2\ln \lambda(\mu) \approx \frac{(\mu - \hat{\mu})^2}{\sigma^2}, \qquad \hat{\mu} \sim \mathcal{N}(\mu', \sigma^2), \tag{4.100}$$

where $\sigma^2 = V_{\mu\mu}$ is the variance of $\hat{\mu}$ *including* the nuisance parameters. Both halves come from Chapter 3. Near its maximum every smooth log-likelihood is quadratic, and maximising the quadratic over the nuisance directions leaves a parabola in μ with curvature $1/V_{\mu\mu}$: that is the profile result of Chapter 3 (the section on nuisance parameters), which gives

$\ln \mathcal{L}_p(\mu) - \ln \mathcal{L}_{\max} = -(\mu-\hat\mu)^2/2V_{\mu\mu}$, and -2 times this is (4.100). And the maximum-likelihood estimator of a large sample is Gaussian about the true value with that variance (Chapter 3). The corrections are of relative order $1/\sqrt{N_{\text{events}}}$. The nuisance parameters enter only through σ, which they make larger. That is the whole reason the formulas of the first part of the chapter survive with nuisance parameters.

The distribution of q_0. With (4.100) at $\mu = 0$, $-2\ln\lambda(0) = \hat\mu^2/\sigma^2$, so $q_0 = \hat\mu^2/\sigma^2$ for $\hat\mu \geq 0$ and 0 otherwise. *The question:* what is $\mathrm{P}(q_0 \leq x)$ for $x > 0$? The event "$q_0 \leq x$" happens in two ways: $\hat\mu < 0$ (then $q_0 = 0$), or $0 \leq \hat\mu \leq \sigma\sqrt{x}$. Together this is just $\hat\mu \leq \sigma\sqrt{x}$:

$$
\begin{aligned}
F(q_0 \,|\, \mu') &\overset{(1)}{=} \mathrm{P}\big(\hat\mu \leq \sigma\sqrt{q_0}\big) \overset{(2)}{=} \Phi\Big(\frac{\sigma\sqrt{q_0} - \mu'}{\sigma}\Big) = \Phi\Big(\sqrt{q_0} - \frac{\mu'}{\sigma}\Big), \\
f(q_0 \,|\, \mu') &\overset{(3)}{=} \Big[1 - \Phi\Big(\frac{\mu'}{\sigma}\Big)\Big]\delta(q_0) + \frac{1}{2\sqrt{2\pi q_0}} \exp\Big[-\frac{1}{2}\Big(\sqrt{q_0} - \frac{\mu'}{\sigma}\Big)^2\Big].
\end{aligned}
\tag{4.101}
$$

(1) The two ways combined.
(2) Standardise: $(\hat\mu - \mu')/\sigma$ is standard normal.
(3) The jump of F at $q_0 = 0$, $\Phi(-\mu'/\sigma)$, is a point mass; for $q_0 > 0$ differentiate with the chain rule, $\mathrm{d}\sqrt{q_0}/\mathrm{d}q_0 = 1/(2\sqrt{q_0})$, and $\Phi' = \varphi$.

For $\mu' = 0$ this is $\frac{1}{2}\delta(q_0)$ plus half a χ^2_1 density [27, (48)–(49)]; its p-value is $p_0 = 1 - F(q_0 \,|\, 0) = 1 - \Phi(\sqrt{q_0})$, and the significance $Z_0 = \Phi^{-1}(1-p_0) = \sqrt{q_0}$ [27, (53)]. The result of the first part of the chapter, now with any number of profiled nuisance parameters.

The distribution of $\tilde q_\mu$. Insert (4.100) into the three cases of (4.99). The middle case is $(\mu-\hat\mu)^2/\sigma^2$ directly. In the first, the reference is the fit at $\mu = 0$ instead of the global one:

$$
\begin{aligned}
-2\ln\frac{\mathcal{L}(\mu, \hat{\hat{\boldsymbol\theta}}(\mu))}{\mathcal{L}(0, \hat{\hat{\boldsymbol\theta}}(0))} &\overset{(1)}{=} -2\ln\frac{\mathcal{L}(\mu, \hat{\hat{\boldsymbol\theta}}(\mu))}{\mathcal{L}(\hat\mu, \hat{\boldsymbol\theta})} + 2\ln\frac{\mathcal{L}(0, \hat{\hat{\boldsymbol\theta}}(0))}{\mathcal{L}(\hat\mu, \hat{\boldsymbol\theta})} \\
&\overset{(2)}{=} \frac{(\mu-\hat\mu)^2}{\sigma^2} - \frac{\hat\mu^2}{\sigma^2} \overset{(3)}{=} \frac{\mu^2 - 2\mu\hat\mu}{\sigma^2}.
\end{aligned}
\tag{4.102}
$$

(1) Multiply and divide by the global maximum: $-2\ln\lambda(\mu) + 2\ln\lambda(0)$.
(2) (4.100) at μ and at 0.
(3) Expand the square; the $\hat\mu^2$ cancel.

This is the straight line of Figure 4.41, matching the parabola at $\hat\mu = 0$ where both equal μ^2/σ^2 [27, (62)].

The question: if the truth is μ', how probable is a value of $\tilde q_\mu$ at least as large as the observed $\tilde q_{\text{obs}}$? Since $\tilde q_\mu$ falls as $\hat\mu$ rises (where it is not zero), "$\tilde q_\mu \geq \tilde q_{\text{obs}}$" is the same event as "$\hat\mu \leq \hat\mu_{\text{obs}}$", where $\hat\mu_{\text{obs}}$ is the estimate that produces $\tilde q_{\text{obs}}$. So

$$
\mathrm{P}\big(\tilde q_\mu \geq \tilde q_{\text{obs}} \,|\, \mu'\big) = \mathrm{P}\big(\hat\mu \leq \hat\mu_{\text{obs}} \,|\, \mu'\big) = \Phi\Big(\frac{\hat\mu_{\text{obs}} - \mu'}{\sigma}\Big). \tag{4.103}
$$

To express this through the statistic itself, invert each branch. For $\tilde q_{\text{obs}} \leq \mu^2/\sigma^2$ (the parabola), $\hat\mu_{\text{obs}} = \mu - \sigma\sqrt{\tilde q_{\text{obs}}}$; for $\tilde q_{\text{obs}} > \mu^2/\sigma^2$ (the line), $\hat\mu_{\text{obs}} = (\mu^2 - \sigma^2\tilde q_{\text{obs}})/(2\mu)$. Inserting each into (4.103),

$$
1 - F(\tilde q_\mu \,|\, \mu') \overset{(1)}{=} \begin{cases} \Phi\big(-\sqrt{\tilde q_\mu} + (\mu - \mu')/\sigma\big), & \tilde q_\mu \leq \mu^2/\sigma^2, \\ \Phi\Big(-\dfrac{\tilde q_\mu - (\mu^2 - 2\mu\mu')/\sigma^2}{2\mu/\sigma}\Big), & \tilde q_\mu > \mu^2/\sigma^2, \end{cases}
\tag{4.104}
$$

(1) First branch: $(\mu - \sigma\sqrt{\tilde{q}} - \mu')/\sigma$. Second branch: $(\mu^2 - \sigma^2\tilde{q} - 2\mu\mu')/(2\mu\sigma)$, then divide top and bottom by σ.

which is [27, (65)]. For $\mu' = \mu$, the p-value of the tested signal is $p_\mu = 1 - \Phi(\sqrt{\tilde{q}_\mu})$ on the parabola: the half-χ^2 again.

The upper limit. The 95% upper limit is the μ whose p-value is $\alpha = 0.05$. By (4.103) with $\mu' = \mu$, $p_\mu = \Phi((\hat{\mu} - \mu)/\sigma)$ on *both* branches, and setting it equal to α gives

$$\mu_{\mathrm{up}} = \hat{\mu} + \sigma\,\Phi^{-1}(1 - \alpha) \tag{4.105}$$

[27, (69)]: the classical one-sided limit (4.74) of Section 4.13.1, with σ now including the systematics. It inherits that limit's flaw. When $\hat{\mu} < -1.645\,\sigma$ the limit is negative, and it excludes every physical signal including none at all.

Toys against the formulas. How large must the sample be? The formulas are tested by the script `code/ch04/20_cls_limits.py` on the smallest case available, the window-and-sideband experiment of Section 4.15.4 with Cowan et al.'s numbers $s = 10$, $b = 10$, $\tau = 1$ [27, §5.1]: ten signal events on ten background events, the background measured in a control region of the same size. The statistics follow from (4.96)–(4.97) with no numerical fitting:

Listing 4.15: Profiled background, q_0 and $\tilde{q}_\mu$ for the counting experiment with a control region, for many toys at once (`code/ch04/20_cls_limits.py`)

```
    def bhh(self, mu, n, m):          # profiled background, Cowan et al. (93)
        s, t = self.s, self.tau
        a = n + m - (1 + t) * mu * s
        return np.maximum(a / (2 * (1 + t)) + np.sqrt(a**2 + 4 * (1 + t) * m * mu * s) / (2
    * (1 + t)), 1e-12)

    def lnL(self, mu, b, n, m):
        nu = np.maximum(mu * self.s + b, 1e-300)
        return n * np.log(nu) - nu + m * np.log(self.tau * b) - self.tau * b

    def mle(self, n, m):
        return (n - m / self.tau) / self.s, m / self.tau

    def lnL_hat(self, n, m):          # at the MLE: mu s + b = n, tau b = m (0 ln 0 = 0)
        with np.errstate(divide="ignore", invalid="ignore"):
            return np.where(n > 0, n * np.log(np.maximum(n, 1e-300)), 0) - n + \
                   np.where(m > 0, m * np.log(np.maximum(m, 1e-300)), 0) - m

    def q0(self, n, m):
        mu_h, _ = self.mle(n, m)
        q = 2 * (self.lnL_hat(n, m) - self.lnL(0.0, self.bhh(0.0, n, m), n, m))
        return np.where(mu_h > 0, np.maximum(q, 0), 0.0)

    def qt(self, mu, n, m):           # q~_mu, Cowan et al. (16)
        mu_h, _ = self.mle(n, m)
        l_mu = self.lnL(mu, self.bhh(mu, n, m), n, m)
        l_ref = np.where(mu_h >= 0, self.lnL_hat(n, m), self.lnL(0.0, self.bhh(0.0, n, m),
    n, m))
        return np.where(mu_h > mu, 0.0, np.maximum(2 * (l_ref - l_mu), 0.0))
```

`bhh` is (4.96); `lnL_hat` is the log-likelihood at the global maximum, where the means equal the counts; `q0` and `qt` are (4.98) and (4.99), case by case, with `np.where` choosing the branch for every toy. With 400 000 toys for each hypothesis (Figure 4.42): with background only, $q_0 = 0$ in a fraction 0.546 of the toys (above one half because the counts are integers), and $\mathrm{P}(q_0 \geq 9) = 0.001572$, against $\Phi(-3) = 1.35 \times 10^{-3}$; with the signal present, the toys follow the

shifted density of (4.101), with σ taken from the Asimov data set of the next subsection. Even with twenty events, the formulas describe the bulk of the distributions; the far tails, and the discreteness, are where toys are still needed.

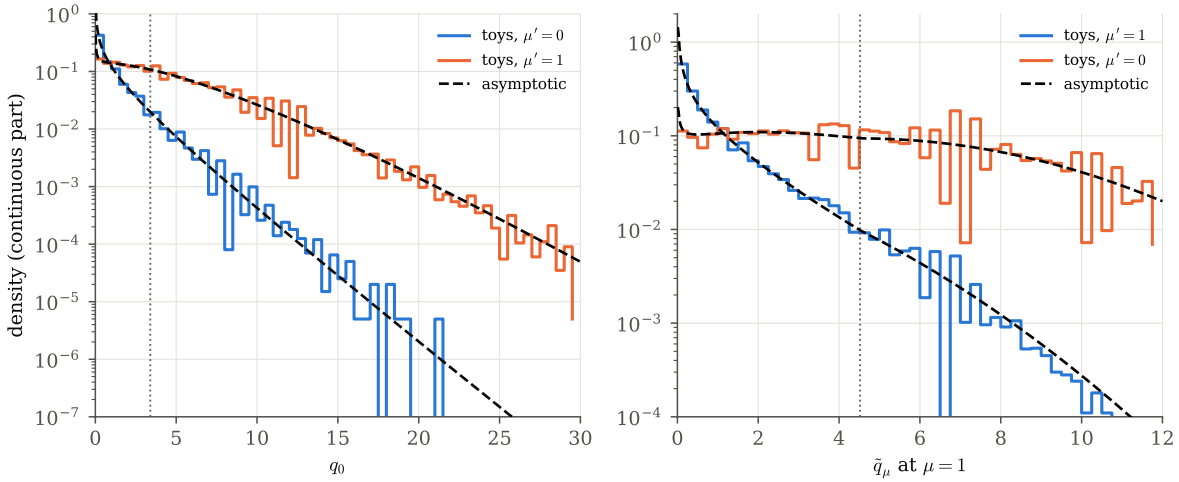

Figure 4.42: Distributions of the test statistics for a counting experiment with $s = 10$, $b = 10$ and a control region of the same size, from toys (steps) and from the asymptotic formulas (dashed). Left: q_0 with background only (blue, the half-χ^2) and with the signal present (orange). Right: $\tilde{q}_\mu$ for $\mu = 1$, when the signal is present (blue, again a half-χ^2) and when it is absent (orange). The dotted lines are the Asimov values, which estimate the medians of the orange distributions. The jagged steps come from the integer counts.

4.16.3 The Asimov data set: what an experiment should expect

Before an experiment runs, its designers want to know its *sensitivity*: if the signal is there, what significance will it typically reach, and if not, what limit will it typically set? "Typically" means the median over repetitions. Simulating thousands of experiments answers this; one artificial data set answers it too.

Working definition 4.9 (Asimov data set)

The **Asimov data set** for a strength μ' is the data set in which every count equals its expectation, $n_i = \mu' s_i + b_i$, and every auxiliary measurement equals the nominal value of its nuisance parameter [no statistical fluctuation anywhere, the counts are allowed to be non-integer] [27, (24)–(25)]. *Operationally:* fill the histogram with the model prediction and fit it like data.

Why do the estimators return the true values on it? The maximum of $\ln \mathcal{L}$ is where every derivative vanishes. For the Poisson part of (4.89), $\ln \mathcal{L} = \sum_i [n_i \ln \nu_i - \nu_i] + \text{const}$, so for any parameter θ_j (including μ)

$$\frac{\partial \ln \mathcal{L}}{\partial \theta_j} \overset{(1)}{=} \sum_i \left(\frac{n_i}{\nu_i} - 1 \right) \frac{\partial \nu_i}{\partial \theta_j} \overset{(2)}{=} 0 \quad \text{when } n_i = \nu_i \text{ for all } i, \tag{4.106}$$

(1) Differentiate $n_i \ln \nu_i - \nu_i$ with the chain rule.

(2) Every bracket vanishes. The Gaussian constraint terms vanish in the same way when $a_k = \theta_k$.

So the true parameters are a maximum [27, (23)]: fitted on the Asimov data set, $\hat{\mu} = \mu'$ and $\hat{\boldsymbol{\theta}} = \boldsymbol{\theta}$.

Why does it give the median? By (4.100), q_0 and $\tilde{q}_\mu$ are monotonic functions of $\hat{\mu}$, and $\hat{\mu}$ is Gaussian with mean and median μ'. The median of a monotonic function is that function of the median. And the value of the statistic at $\hat{\mu} = \mu'$ is exactly what the Asimov data set gives. So

$$\mathrm{med}[Z_0 \,|\, \mu'] = \sqrt{q_{0,\mathrm{A}}}, \qquad \sigma_{\mathrm{A}}^2 = \frac{(\mu - \mu')^2}{q_{\mu,\mathrm{A}}}, \tag{4.107}$$

where the subscript A marks a statistic evaluated on the Asimov data set [27, (29)–(30), (79)]. The second formula reads (4.100) backwards: on the Asimov data set $\hat{\mu} = \mu'$, so $-2\ln\lambda_{\mathrm{A}}(\mu) = (\mu - \mu')^2/\sigma^2$ can be solved for σ. This is how the σ in all the formulas is obtained in practice: one fit to one artificial data set, nuisance parameters included.

The expected significance of a counting experiment. Take a count with known background b and nominal signal s, and evaluate $q_0 = 2[n\ln(n/b) - (n-b)]$ on the Asimov count $n = s + b$:

$$\begin{aligned} Z_{\mathrm{A}}^2 = q_{0,\mathrm{A}} &\overset{(1)}{=} 2\left[(s+b)\ln\frac{s+b}{b} - s\right] \overset{(2)}{=} 2\left[(s+b)\ln\left(1+\frac{s}{b}\right) - s\right], \\ Z_{\mathrm{A}} &= \sqrt{2\left[(s+b)\ln\left(1+\frac{s}{b}\right) - s\right]} \overset{(3)}{\approx} \frac{s}{\sqrt{b}}\left(1 - \frac{s}{6b}\right). \end{aligned} \tag{4.108}$$

(1) The known-background q_0 at $n = s + b$, where $n - b = s$.
(2) $(s+b)/b = 1 + s/b$.
(3) The expansion $q_{0,\mathrm{A}} = (s^2/b)[1 - s/3b + \dots]$ worked out in the first part of the chapter, and $\sqrt{1-u} \approx 1 - u/2$.

This is the same algebra as in the first part of the chapter; what is new is its meaning, the *median* significance, which (4.107) supplies. The familiar $s/\sqrt{b}$ is its small-signal limit and overestimates it. For $s = b = 10$, $Z_{\mathrm{A}} = 2.78$.

With the background measured in a control region, the Asimov counts are $n = s + b$ and $m = \tau b$, and (4.97) with $\hat{\hat{b}}(0) = (s + b + \tau b)/(1 + \tau)$ gives

$$Z_{\mathrm{A}}^2 = 2\left[(s+b)\ln\frac{(1+\tau)(s+b)}{s+(1+\tau)b} + \tau b\ln\frac{(1+\tau)\,b}{s+(1+\tau)b}\right]. \tag{4.109}$$

For $s = b = 10$ and $\tau = 1$ this is $Z_{\mathrm{A}} = 1.84$, against 2.78 with the background known: measuring the background in a region no larger than the signal region costs a third of the expected significance. As $\tau \to \infty$ the control region measures b perfectly: the second logarithm is $\ln[1 - s/(s + (1+\tau)b)] \approx -s/(\tau b)$, so the second term tends to $-s$, the first to $(s+b)\ln(1+s/b)$, and (4.108) returns. The toys agree: their median q_0 under the signal is 3.40, the same as the Asimov value 3.40 to the digits shown. (Here the expected counts are whole numbers, so the Asimov data set is itself a possible outcome of the experiment.)

4.16.4 CL_s: not excluding what we cannot see

The limit (4.105) has the defect met at the start of Section 4.13: a downward fluctuation of the background makes it negative. There is a sharper way to see what is wrong, and it is the reason CL_s exists.

The event. An experiment with almost no sensitivity to some signal (because the signal is tiny compared with the background, $\mu/\sigma \ll 1$) reports that it excludes that signal at 95% confidence. *What made it exclude?* The data cannot tell signal from no signal, so it can only have been a downward fluctuation of the background. *How often does that happen when there is no signal?* The

rule "exclude μ if $p_\mu < \alpha$" with $p_\mu = \Phi((\hat{\mu} - \mu)/\sigma)$ excludes when $\hat{\mu} < \mu - \sigma\Phi^{-1}(1-\alpha)$. With background only, $\hat{\mu} \sim \mathcal{N}(0, \sigma^2)$:

$$\mathrm{P}(\text{exclude } \mu \mid 0) \overset{(1)}{=} \mathrm{P}\Big(\frac{\hat{\mu}}{\sigma} < \frac{\mu}{\sigma} - \Phi^{-1}(1-\alpha)\Big) \overset{(2)}{=} \Phi\Big(\frac{\mu}{\sigma} - \Phi^{-1}(1-\alpha)\Big) \xrightarrow{\mu/\sigma \to 0} \alpha. \tag{4.110}$$

(1) Divide the exclusion condition by σ.
(2) $\hat{\mu}/\sigma$ is standard normal.

An experiment blind to a signal still excludes it in 5% of runs. That is correct coverage (the signal is absent, so excluding it is no error) but it is not a statement any physicist wants to publish: the exclusion says nothing about the signal, only about the luck of the background. The counting experiment of our toys, with a weak signal $s = 1$ on $b = 10$ and $\tau = 1$, has $\sigma = 4.47$ at $\mu = 1$; in background-only toys it excludes $\mu = 1$ in a fraction 0.082 of the runs (the formula: 0.078), not far above the 5% of a completely blind experiment, although one signal event on ten background events measured this way is all but invisible.

Working definition 4.10 (CL_s)

For a tested signal μ and the statistic $\tilde{q}_\mu$, let $\mathrm{CL}_{s+b} = \mathrm{P}(\tilde{q}_\mu \geq \tilde{q}_{\mathrm{obs}} \mid \mu)$ be the p-value of the signal hypothesis and $\mathrm{CL}_b = \mathrm{P}(\tilde{q}_\mu \geq \tilde{q}_{\mathrm{obs}} \mid 0)$ the same tail computed with background only [how background-poor the data look, judged by the same statistic]. Then

$$\mathrm{CL}_s = \frac{\mathrm{CL}_{s+b}}{\mathrm{CL}_b},$$

and μ is excluded at confidence level $1 - \alpha$ if $\mathrm{CL}_s < \alpha$ [30, 31]. In the notation of [27], $p_\mu/(1 - p_b)$.

This is the same ratio as (4.79) of Section 4.13.4, where the statistic was the count itself; the profile likelihood ratio generalises it to any number of bins and nuisance parameters. *Why does dividing help?* Take the two extremes.

- *No sensitivity.* The signal changes nothing, so both tails are computed from nearly the same distribution: $\mathrm{CL}_{s+b} \approx \mathrm{CL}_b$ and $\mathrm{CL}_s \approx 1$. The signal is never excluded. In the weak-signal toys, CL_s excluded $\mu = 1$ in none of the runs (a fraction 0.0000).
- *Good sensitivity.* Data that disfavour the signal are typical for the background, CL_b is near one, and $\mathrm{CL}_s \approx \mathrm{CL}_{s+b}$. Nothing changes.

In between, dividing by $\mathrm{CL}_b \leq 1$ raises the ratio exactly when the data look background-poor, which is when the plain p-value would have been lucky. The price is over-coverage: a CL_s limit is above the classical one and covers the true value in more than 95% of repetitions, as Figure 4.35 showed for counts. CL_s is a ratio of p-values, not a p-value, and not a probability of the signal.

The asymptotic CL_s limit. By (4.103), $\mathrm{CL}_{s+b} = \Phi((\hat{\mu} - \mu)/\sigma)$ and, with $\mu' = 0$, $\mathrm{CL}_b = \Phi(\hat{\mu}/\sigma)$. The limit solves $\mathrm{CL}_s = \alpha$:

$$\Phi\Big(\frac{\hat{\mu} - \mu_{\mathrm{up}}}{\sigma}\Big) = \alpha\,\Phi\Big(\frac{\hat{\mu}}{\sigma}\Big) \implies \mu_{\mathrm{up}} = \hat{\mu} + \sigma\,\Phi^{-1}\Big(1 - \alpha\,\Phi\Big(\frac{\hat{\mu}}{\sigma}\Big)\Big), \tag{4.111}$$

using $\Phi^{-1}(\alpha u) = -\Phi^{-1}(1 - \alpha u)$. Compare (4.75) of Section 4.13.2: it is the same formula. The asymptotic CL_s limit on a Gaussian estimate is the flat-prior Bayesian upper limit, just as for counts the CL_s limit equalled the flat-prior Bayesian limit (4.80). Two different questions, a

ratio of frequentist tails and a posterior probability with the boundary built into the prior, give the same number. That coincidence is part of why CL_s was accepted: it behaves like a Bayesian limit near the boundary and like a classical one far from it.

For the counting experiment with $s = b = 10$, $\tau = 1$ and an observation of $n = 14$ events in the signal region and $m = 9$ in the control region, the 95% CL_s limit computed with toys (tables of $\tilde{q}_\mu$ under μ and under 0 on a grid of μ, 40 000 toys each) is $\mu_{\mathrm{up}} = 1.37$; the asymptotic formulas, with $\sigma = \sigma_{\mathrm{A}}(\mu)$ from (4.107), give 1.37.

4.16.5 The expected limit and the Brazil band

A limit means little without knowing what the experiment should have achieved. If there is no signal, $\hat{\mu} \sim \mathcal{N}(0, \sigma^2)$, and the CL_s limit (4.111) is an increasing function of $\hat{\mu}$. *The question:* what limit does an experiment with no signal typically report, and in what range? Since the limit is monotonic in $\hat{\mu}$, its quantiles are the limits at the quantiles of $\hat{\mu}$. The median is at $\hat{\mu} = 0$; the $\pm N$ standard-deviation quantiles at $\hat{\mu} = N\sigma$. Putting $\hat{\mu} = N\sigma$ into (4.111),

$$\mu_{\mathrm{up}}(N) \overset{(1)}{=} N\sigma + \sigma\,\Phi^{-1}\big(1 - \alpha\,\Phi(N)\big), \qquad \mu_{\mathrm{up}}(0) \overset{(2)}{=} \sigma\,\Phi^{-1}(1 - \alpha/2) = 1.96\,\sigma, \tag{4.112}$$

(1) (4.111) with $\hat{\mu}/\sigma = N$.
(2) $\Phi(0) = \frac{1}{2}$, and $\Phi^{-1}(0.975) = 1.96$ for $\alpha = 0.05$.

For $N = -2, -1, 0, 1, 2$ the bracket is 1.05, 1.41, 1.96, 2.73 and 3.66 times σ. The band is lopsided: a downward fluctuation of the background cannot push the CL_s limit much below σ, while an upward one raises it freely. (The plain limit (4.105) would have given $1.645\sigma + N\sigma$, down to $-0.36\,\sigma$ at $N = -2$.) Since $\sigma = \sigma_{\mathrm{A}}(\mu)$ depends on the μ being tested, each line of (4.112) is solved for μ_{up} numerically [27, (88)–(89)].

Toys against Asimov. For the counting experiment with $s = b = 10$, $\tau = 1$, the script computes the CL_s limit of 4000 background-only experiments with toys and takes the quantiles:

	-2σ	-1σ	median	$+1\sigma$	$+2\sigma$
toys	0.44	0.62	0.90	1.28	1.71
Asimov, (4.112)	0.48	0.65	0.92	1.32	1.86

For an experiment of twenty events the asymptotic band is within a few per cent in the middle and within ten per cent at the edges, a little conservative throughout. In the tails the integer counts matter, and the toys are the reference.

The Higgs-style plots. For the template search of Section 4.15, the script repeats the whole procedure at every hypothesised mass from 110 to 150 GeV: the observed CL_s limit on μ from the pseudo-data, the expected median and bands from the Asimov background-only data set at that mass, and the local p_0 with its Asimov expectation for $\mu = 1$ (Figure 4.43). The green and yellow bands that give the plot its nickname, the **Brazil band**, are (4.112). The expected limit falls from 0.79 to 0.39 across the range, because the background falls with mass while the signal does not. Away from 125 GeV the observed limit wanders inside the bands, as a background-only experiment should, and $\mu = 1$ is excluded at 34 of the 41 masses. Near 125 GeV the observed limit rises far above the band (1.68 against an expected 0.60): the data there refuse to exclude a signal, and the right panel says why. The local significance at 125 GeV is 3.53σ, close to the 3.32σ expected for $\mu = 1$. It is local: a search over this range must correct it for the look-elsewhere effect of Section 4.14.3.

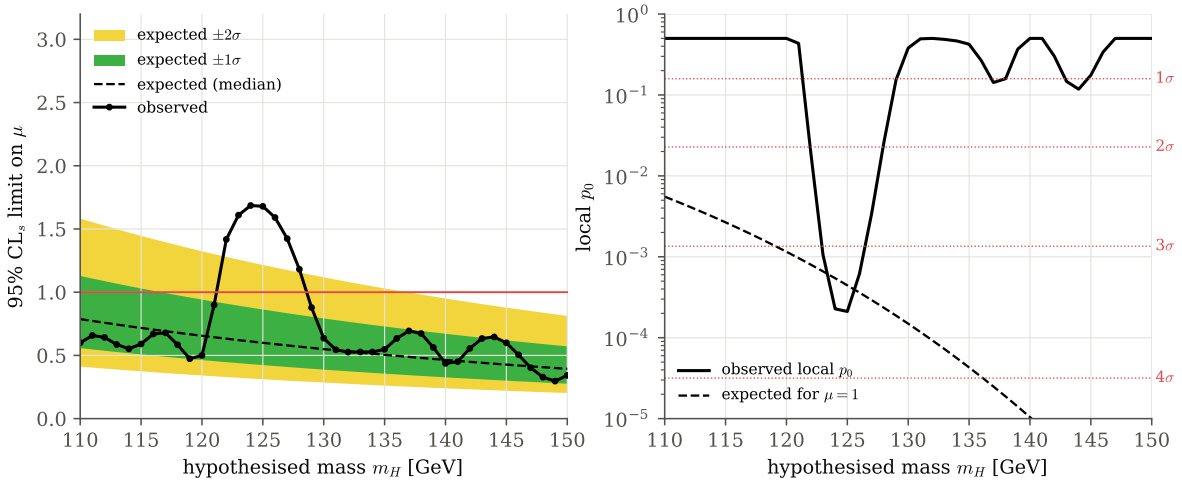

Figure 4.43: The template search as the LHC experiments show it. Left: the 95% CL_s upper limit on the signal strength at each hypothesised mass (solid), with the median expected for background only (dashed) and the $\pm1\sigma$ (green) and $\pm2\sigma$ (yellow) bands. Masses where the solid line is below the thin horizontal line at $\mu = 1$ are excluded for the nominal signal. Right: the local p-value of the background-only hypothesis (solid) and its median expectation if the nominal signal is present (dashed); the dotted lines mark 1 to 4σ.

Key idea: The LHC recipe in four lines

Write the search as a likelihood with nuisance parameters constrained by their auxiliary measurements. Test "no signal" with q_0 and report $Z = \sqrt{q_0}$, local and global. Exclude a signal when $CL_s = CL_{s+b}/CL_b < 0.05$, using $\tilde{q}_\mu$. Show the observed limit against the expected one and its Brazil band, both from the Asimov data set, and check with toys where counts are small.

How this is used in real research: How the experiments compute it

The likelihoods of real searches have hundreds of bins and hundreds of nuisance parameters, with templates interpolated as in (4.91). They are written in standard formats (HistFactory, with the RooStats, `pyhf` and CMS `Combine` tools) and minimised numerically; the asymptotic formulas of [27] give q_0, the CL_s limit and the Brazil band from the observed and Asimov fits alone, and toys are run where counts are small or near the boundary [29]. Our two scripts verify the formulas against toys on a case where both are cheap. In research the same machinery is the instrument: the toys are the reference whenever the formulas are in doubt, and published likelihoods let others combine results, as Section 4.13.1 urged.

The lesson in one line: with nuisance parameters profiled, the significance is still $\sqrt{q_0}$ and the limit still comes from a half-χ^2, and CL_s divides by the background's own p-value so that a signal is never excluded by luck.

4.17 Confidence intervals and credible intervals

Ten one-minute runs of a low-background detector record a total of six events. Two analysts report a 90% interval for the rate λ per run. The first, using Garwood's construction, reports $[0.261,\ 1.184]$. The second, using Bayes' theorem with a mild prior, reports $[0.299,\ 1.077]$ [CasellaBerger Exs. 9.2.15–9.2.16]. The numbers are close. The statements are not. The first is a confidence interval: it comes from a recipe that covers the true rate in at least 90% of repeated

experiments. The second is a **credible interval**: given these data and the prior, it contains the rate with probability 90%. The first is a prediction-direction statement, about which data each rate would produce. The second is an inference-direction statement, about which rates could have produced the data we saw. Bayes' theorem is the bridge between them. Comparing the two on the same data shows what each one claims and what it needs; Chapter 5 develops the Bayesian side in full.

The question in words.

1. What does each interval say, in words, and what is random in each?
2. Does a credible interval cover like a confidence interval, and does a confidence interval hold the posterior probability it claims?
3. When do the two coincide?

4.17.1 A credible set

In the Bayesian framework θ has a probability distribution, first the prior $\pi(\theta)$ and, after the data, the posterior $\pi(\theta \mid \boldsymbol{x}) \propto p(\boldsymbol{x} \mid \theta)\pi(\theta)$. Any set A of parameter values has a **credible probability** $\mathrm{P}(\theta \in A \mid \boldsymbol{x}) = \int_A \pi(\theta \mid \boldsymbol{x})\,\mathrm{d}\theta$ [CasellaBerger (9.2.18)], and a set with credible probability $1-\alpha$ is a $1-\alpha$ credible set. The different name keeps the two kinds of probability apart. As with confidence intervals, many sets have the required probability, so we must choose one. Two common choices are the *equal-tailed* interval, with posterior probability $\alpha/2$ beyond each end, and the **highest density interval** (HDI) [every point inside has higher posterior density than every point outside], which makes $\pi(a \mid \boldsymbol{x}) = \pi(b \mid \boldsymbol{x})$ and is the shortest interval with the required probability [Cowan (9.42)], [Kruschke §11.3.2].

Example: the Poisson rate. Take n observations from Poisson(λ) with sum $y = \sum x_i$, and a gamma prior with shape a and scale b, density $\propto \lambda^{a-1}e^{-\lambda/b}$. Then

$$\pi(\lambda \mid \boldsymbol{x}) \overset{(1)}{=\!\propto} \Big(\prod_i \lambda^{x_i}e^{-\lambda}\Big)\lambda^{a-1}e^{-\lambda/b} \overset{(2)}{=} \lambda^{a+y-1}e^{-\lambda(n+1/b)} \overset{(3)}{=} \mathrm{Gamma}\Big(a+y,\ \frac{b}{nb+1}\Big), \tag{4.113}$$

(1) Bayes' theorem: likelihood of independent Poisson counts times prior; factors not involving λ are dropped.
(2) Collect powers of λ and the exponentials.
(3) This is the gamma density with shape $a+y$ and rate $n+1/b$, that is scale $1/(n+1/b) = b/(nb+1)$ [CasellaBerger (9.2.19)].

A gamma variable of shape k and scale s, multiplied by $2/s$, is χ^2 with $2k$ degrees of freedom, so $2(nb+1)\lambda/b \sim \chi^2_{2(a+y)}$ under the posterior, and the equal-tailed interval has χ^2 quantiles for ends [CasellaBerger (9.2.20)]. With $a = b = 1$, $n = 10$, $y = 6$: $22\lambda \sim \chi^2_{14}$, and the 5% and 95% quantiles 6.571 and 23.685 give $[0.299, 1.077]$. The credible interval is shorter than the confidence interval and pulled towards zero. Both effects come from the prior. It adds information, which narrows the interval. And it favours small rates (its density $e^{-\lambda}$ falls with λ), which pulls the interval down.

4.17.2 Judging each interval by the other's standard

Each interval keeps its own promise exactly. *The question:* how does each do when judged by the other's promise [CasellaBerger Ex. 9.2.17]?

Coverage of the credible interval. Fix a true λ. Simulate the total of the ten runs, $y \sim \text{Poisson}(10\lambda)$, many times (or sum exactly over y), build the credible interval each time and count hits. Figure 4.44 (left) shows the result. For small λ near the prior's bulk the credible interval covers about 90%, sometimes more, sometimes less (minimum 0.727 on $0 < \lambda < 3$). For large λ the prior's pull towards small values becomes a bias, and the coverage collapses: 0.844 at $\lambda = 5$, 0.620 at $\lambda = 20$, 0.302 at $\lambda = 50$, tending to zero [CasellaBerger (9.2.22)]. A credible interval is not a confidence interval.

Credible probability of the confidence interval. Fix the data, compute the posterior, and ask how much posterior probability lies inside the Garwood interval. At $y = 6$ it is 0.947; it decreases steadily with y, reaching 0.868 at $y = 50$, and tends to zero for $y \to \infty$ unless the prior scale is $b = 1/n$ (Figure 4.44, right). A confidence interval is not a credible interval either.

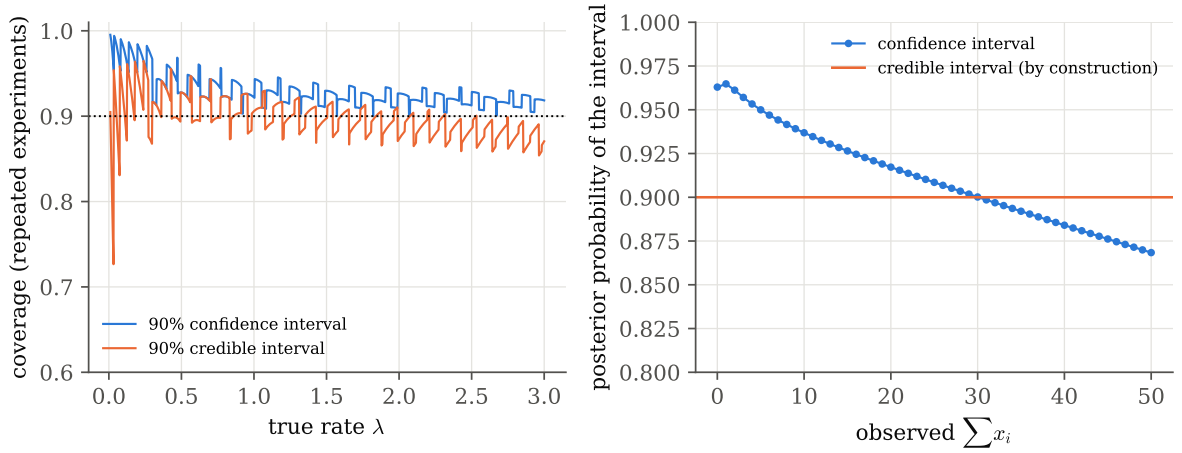

Figure 4.44: Two 90% intervals for a Poisson rate from ten observations, judged by each other's criterion. Left: the frequentist coverage as a function of the true rate. The confidence interval (blue) never drops below 90%; the credible interval with a gamma(1, 1) prior (orange) scatters around 90% at small rates and falls away as the rate grows past the prior's range. Right: the posterior probability contained in each interval, as a function of the observed total. The credible interval holds 90% by construction; the confidence interval holds more for small totals and less for large ones.

Example: a Gaussian mean with a Gaussian prior. Here the calculation can be done in closed form [CasellaBerger Ex. 9.2.18]. Let $X_1, \dots, X_n$ be $\mathcal{N}(\theta, \sigma^2)$ and the prior $\mathcal{N}(\mu, \tau^2)$, and write $\gamma = \sigma^2/(n\tau^2)$ for the ratio of the data variance of the mean to the prior variance. The posterior is Gaussian with mean $\delta = (\gamma\mu + \bar{x})/(1+\gamma)$ and variance $V = \sigma^2/(n(1+\gamma))$, and the $1-\alpha$ credible interval is $\delta \pm z_{\alpha/2}\sqrt{V}$. Its coverage at a fixed true θ, with $Z = \sqrt{n}(\bar{X} - \theta)/\sigma \sim \mathcal{N}(0,1)$ and $\Delta = \sqrt{n}(\theta - \mu)/\sigma$, is

$$
\begin{aligned}
\mathrm{P}_\theta\big(|\theta - \delta| \le z_{\alpha/2}\sqrt{V}\big) &\overset{(1)}{=} \mathrm{P}_\theta\left(\left|\frac{\gamma(\theta-\mu) - (\bar{X}-\theta)}{1+\gamma}\right| \le z_{\alpha/2}\frac{\sigma}{\sqrt{n(1+\gamma)}}\right) \\
&\overset{(2)}{=} \mathrm{P}\big(|\gamma\Delta - Z| \le \sqrt{1+\gamma}\, z_{\alpha/2}\big) \\
&\overset{(3)}{=} \Phi\big(\gamma\Delta + \sqrt{1+\gamma}\, z_{\alpha/2}\big) - \Phi\big(\gamma\Delta - \sqrt{1+\gamma}\, z_{\alpha/2}\big).
\end{aligned} \tag{4.114}
$$

(1) $\theta - \delta = [(1+\gamma)\theta - \gamma\mu - \bar{X}]/(1+\gamma) = [\gamma(\theta-\mu) - (\bar{X}-\theta)]/(1+\gamma)$.
(2) Multiply both sides by $(1+\gamma)\sqrt{n}/\sigma$ and use the definitions of Z and Δ.
(3) Z is standard normal: the probability that it lies within $\sqrt{1+\gamma}\, z_{\alpha/2}$ of $\gamma\Delta$.

So the coverage depends on how far the truth is from the prior mean, measured by Δ in units of the standard error $\sigma/\sqrt{n}$. If the truth sits at the prior mean, $\Delta = 0$, the interval overcovers (for $\gamma = 1$ and 95%, the coverage is 0.994), because the prior's information is correct. If the truth is two or four standard errors away from the prior mean, the coverage is 0.780 or 0.110 (Figure 4.45, right). As $\tau \to \infty$, $\gamma \to 0$ and (4.114) becomes $\Phi(z_{\alpha/2}) - \Phi(-z_{\alpha/2}) = 1 - \alpha$ for every θ: with a flat prior the credible interval is the confidence interval $\bar{x} \pm z_{\alpha/2}\sigma/\sqrt{n}$, number for number. This coincidence, like the counting-experiment coincidence of Cowan's (9.55), is special to location parameters and flat priors; it is why the two schools rarely argue about a well-measured Gaussian quantity.

4.17.3 The coin again: the HDI does not depend on the stopping rule

Kruschke returns to $z = 7$ heads in $N = 24$ flips with a prior beta(11, 11), a coin that looks fair [Kruschke §11.3.2]. The posterior is beta(11 + 7, 11 + 17) and its 95% HDI is $[0.254, 0.531]$; with a uniform prior it would be $[0.141, 0.483]$. Figure 4.45 (left) shows both posteriors with the four confidence intervals of Section 4.10.4 underneath. The four confidence intervals differ; the HDI is the same for all four. *Why?* The Bayesian interval sees the data only through the likelihood $\theta^7(1-\theta)^{17}$, and that is the same whether the experimenter meant to stop at $N = 24$, at $z = 7$, or when time ran out. The confidence interval also depends on which cloud of imaginary outcomes the plan would have produced. Kruschke lists three advantages of the HDI [Kruschke pp. 324–325]: it is a direct statement about the credibility of values of θ; it does not depend on sampling and testing intentions; and it responds, openly, to prior knowledge. The price is the prior itself, which must be stated and defended.

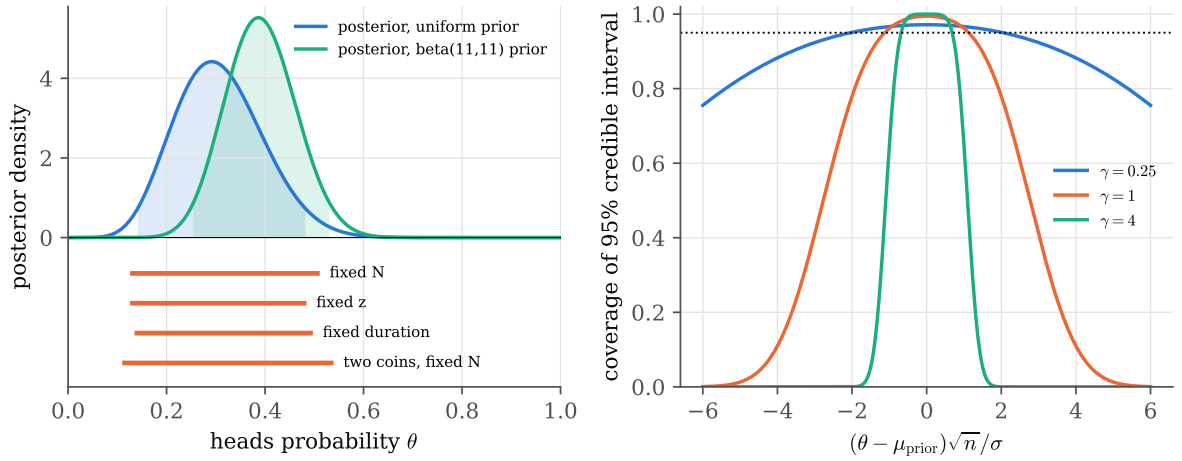

Figure 4.45: Left: posteriors for 7 heads in 24 flips with a uniform (blue) and a beta(11, 11) (green) prior; the shaded parts are the 95% highest density intervals. Below the axis, the four 95% confidence intervals that four stopping intentions produce from the same data. Right: frequentist coverage of a 95% credible interval for a Gaussian mean with a Gaussian prior, as a function of the distance between the true value and the prior mean (in units of the standard error), for three ratios γ of data variance to prior variance. A strong prior (large γ) covers only near its own centre.

Deciding with an interval: the ROPE. A test asks whether θ equals a null value exactly, a question whose answer is almost always "no" with enough data. Kruschke replaces it by a **region of practical equivalence** (ROPE) [a small range of values that are, for the purpose at hand, as good as the null value], and a rule [Kruschke §12.1.1]: reject the null value if the 95% HDI lies entirely outside the ROPE; accept it for practical purposes if the HDI lies entirely inside; otherwise, withhold judgement. For a coin with ROPE $[0.45, 0.55]$ and a uniform prior,

325 heads in 500 flips give the HDI $[0.608, 0.691]$, outside the ROPE: not fair. 490 heads in 1000 give $[0.459, 0.521]$, inside: fair for practical purposes (the posterior probability of the ROPE is 0.994). Unlike a p-value, this rule can *accept* a null value, and only when the measurement is precise enough to deserve it. The physicist's analogue is familiar: a calibration is declared good when its uncertainty band lies within the tolerance, not when a test fails to reject perfection.

4.17.4 What each interval says

The two kinds of interval differ in what they claim, what they treat as random, what they need as input, what they guarantee, and how they typically go wrong.

Taxonomy: Confidence interval or credible interval

	confidence interval	credible interval
in words	"a recipe that, applied to data from any θ, contains that θ 95% of the time"	"given these data and this prior, θ is in here with probability 95%"
random	the interval (through the data)	θ (through the posterior)
fixed	the true θ	the observed data
needs	$p(\boldsymbol{x} \mid \theta)$ for all data that could have occurred, including the stopping and search plan	the likelihood of the observed data and a prior
guarantee	coverage for every θ	correct posterior probability, if the prior is right
typical failure	empty or unphysical intervals, flip-flopping, dependence on intentions	poor coverage where the prior is wrong
coincide when	location parameters with flat priors: Gaussian mean, Poisson with no background	

In the pipeline of the book, both are ways of turning the sampling distribution $P(S \mid \theta)$ of a summary into a statement about the physics. The confidence interval stays in the prediction direction and asks which θ would make the observed summary typical. The credible interval crosses into the inference direction and asks how probable each θ is. Cosmologists quote credible intervals from MCMC posteriors (Chapter 9); particle physicists quote confidence intervals and limits; the Fisher forecasts of Chapter 10 are, for linear-Gaussian models, both at once. Chapter 5 builds the Bayesian side properly: priors, the evidence, and the reallocation of credibility that a posterior is.

Recap

- A $1 - \alpha$ confidence interval is a recipe with coverage at least $1 - \alpha$ for every parameter value. The interval is random, the parameter fixed.
- Inverting a family of level-α tests gives a $1 - \alpha$ confidence set: keep the null values that are not rejected. The p-value function displays all the tests at once.
- The Neyman construction draws the acceptance regions of all tests as a belt in the (data, parameter) plane; the interval is its vertical cut. Gaussian estimates give $\hat{\theta} \pm \sigma$, Poisson counts give Garwood's χ^2 intervals, and $\Delta \ln \mathcal{L} = \frac{1}{2}$ (or $\Delta\chi^2 = 1$) is the large-sample shortcut. With m parameters the 68.3% region is $\Delta\chi^2 = 2.30$ for $m = 2$.

- Coverage is checked by simulation. Normal quantiles with an estimated σ undercover at small n; $n \pm \sqrt{n}$ fails at small counts; discrete data force over-coverage with a saw-tooth.
- Near a physical boundary the classical limit can be negative or the interval empty. Choosing between limit and interval after seeing the data undercovers (85% for a nominal 90%). Feldman–Cousins ordering by a likelihood ratio fixes both; CL_s (equal to the flat-prior Bayesian limit for counting) protects against excluding what the experiment cannot see.
- Many tests: Bonferroni controls the chance of any false rejection, BH the fraction of false discoveries. In a scan, the global p-value exceeds the local one by a trials factor that grows linearly with the significance; the Gross–Vitells formula gets it from a few toys.
- A credible interval is a probability statement about θ given the data and a prior. It does not guarantee coverage; a confidence interval does not hold its nominal posterior probability; they agree for flat priors on location parameters.

Reading the literature

- **Main line.** [Wasserman Ch. 10] for hypothesis testing: the null and the alternative, power and size, the Wald test, p-values and their uniformity, the χ^2 and permutation tests, likelihood-ratio tests, multiple testing (Bonferroni and Benjamini–Hochberg) and goodness of fit; [Wasserman §6.3.2] for confidence sets, their interpretation and the Berger–Wolpert example.
- **The physicist's version.** [Cowan Ch. 4] for test statistics, particle selection, the Neyman–Pearson lemma, goodness of fit and the significance of a signal; [Cowan Ch. 9] for confidence belts, Gaussian and Poisson intervals, Fisher's z, likelihood intervals, confidence regions and limits near a boundary, with and without background.
- **Careful derivations.** [CasellaBerger §8.3] for the Neyman–Pearson lemma and valid p-values; [CasellaBerger §10.3] for the asymptotic distribution of the likelihood ratio; [CasellaBerger §§9.1–9.2] for interval estimators, coverage and confidence coefficients, test inversion, pivots, Garwood's Poisson intervals and the coverage of credible sets.
- **The Bayesian critique.** [Kruschke Ch. 11] for how p-values and confidence intervals depend on stopping and testing intentions, and for multiple comparisons; [Kruschke Ch. 12] for the HDI and the region of practical equivalence. [Lambert §2.8] for the frequentist's imaginary samples.
- **Original papers.** Feldman and Cousins' unified approach to small signals [28]; Gross and Vitells on trials factors for the look-elsewhere effect [15]; Cowan, Cranmer, Gross and Vitells on asymptotic formulae for likelihood-based tests of new physics, including the profile likelihood ratio, the Asimov data set and the CL_s remark [27]; Wilks on the asymptotic χ^2 distribution of likelihood ratios [22].

Chapter summary

Before a measurement is published it must answer three questions. Could this be chance? Which parameter values are compatible with what we saw? How often do our recipes mislead us? All three start from the sampling distribution of a summary. Tests answer the first: they are built around the one hypothesis whose predictions we know, the null, and measure surprise with p-values. Intervals and limits answer the second: they are families of tests, inverted. Coverage checks and corrections for the many places we looked answer the third. In the pipeline of the book,

$$\text{model} \to \text{data} \to \text{summary } S \to P(S \mid \theta) \to \boxed{\text{infer physics}},$$

tests and intervals are the frequentist form of the last arrow, and Chapter 5 gives the Bayesian one.

Testing the null (first half)

concept	operational meaning	used later in
null hypothesis	the hypothesis whose sampling distribution we know and can simulate: "it happened by chance"	every search, Chapters 8 and 12
test statistic, rejection region	one number, large under the alternative; reject when it exceeds a critical value fixed in advance	Chapters 8 and 12
p-value	probability under H_0 of a statistic at least as extreme, in the alternative's direction; simulate if no formula	Chapters 6, 8 and 12
one- and two-sided, stopping rule	the direction and the experimental plan are part of the question; they change the p-value	Chapter 5
size, power	false-alarm rate α; rejection probability under the truth; plan the experiment by the power	Chapter 10
uniformity of p	under a continuous null $p \sim \mathrm{U}(0,1)$; for discrete data $\mathrm{P}(p \le \alpha) \le \alpha$; a histogram of null p-values checks a pipeline	Chapters 6 and 8
$p \neq \mathrm{P}(H_0 \mid \text{data})$	the posterior of the null needs a prior and the power (Bayes)	Chapter 5
Wald, t, permutation tests	estimate over standard error; Student t for small Gaussian samples; relabel the data for a distribution-free null	Chapters 6 and 12
Neyman–Pearson, likelihood ratio	for simple hypotheses the likelihood ratio is the most powerful statistic	Chapters 8 and 10
Wilks, q_0, $Z = \sqrt{q_0}$	$-2\ln\lambda \sim \chi^2$ with as many degrees of freedom as the null fixes; half-χ^2 on a boundary	Chapters 9 and 10
Pearson χ^2, KS	goodness of fit of a whole model; fitted parameters reduce the degrees of freedom; simulate sparse cases	Chapters 7 and 8
$p \to Z\sigma$, 5σ	$Z = \Phi^{-1}(1-p)$; 3σ evidence, 5σ observation, because of many searches, backgrounds and rarity	Chapter 12

Intervals, coverage and many tests (second half)

concept	operational meaning	used later in
confidence interval	a recipe with coverage $\geq 1-\alpha$ for every θ; the interval is random, θ fixed	Chapters 8 and 10
test inversion, p-value function	keep the null values a level-α test does not reject	Chapter 8
Neyman belt	acceptance intervals at every θ, cut vertically at the observation; build on a grid from simulations when there is no formula	Chapters 6 and 8
Gaussian and Poisson intervals	$\hat{\theta} \pm \sigma$ is the 68.3% central interval; Garwood's χ^2 quantiles for counts; $-\ln 0.05 = 3$ for zero events	Chapters 7 and 8
likelihood interval, $\Delta\chi^2$ regions	$\Delta \ln \mathcal{L} = \frac{1}{2}$, $\Delta\chi^2 = 1$ in one dimension; 2.30 (68.3%) and 5.99 (95%) in two	Chapters 9 and 10
coverage check	simulate at fixed θ, count hits; exact sums for counts; t not z for estimated σ	Chapters 6, 8 and 9
limits near a boundary	report $\hat{\theta} \pm \sigma$ always; classical, shifted, Bayesian, Feldman–Cousins, CL_s; fix the recipe in advance	Chapter 10
Bonferroni, BH	$P_i < \alpha/m$ controls any false rejection; the BH line $i\alpha/m$ controls the false discovery rate	Chapter 12
look-elsewhere effect	global p-value from toys scanned like the data; $p_{\mathrm{glob}} \approx p_{\mathrm{loc}} + \mathbb{E}\, N(c_0) e^{-(c-c_0)/2}$; trials factor $\propto Z$	Chapters 8 and 12
search likelihood, nuisance parameters	Poisson bins of signal and background templates times one constraint term per calibration; profile to get $\lambda(\mu)$; $\sigma^2_{\mathrm{syst}} = \sigma^2_{\mathrm{tot}} - \sigma^2_{\mathrm{stat}}$	Chapters 8 and 10
q_0, $\tilde{q}_\mu$, CL_s, Brazil band	$Z = \sqrt{q_0}$ with profiled nuisances (Wald); exclude when $\mathrm{CL}_{s+b}/\mathrm{CL}_b < 0.05$; expected limit and $\pm 1, 2\sigma$ bands from the Asimov data set; toys for small counts	Chapters 10 and 12
credible interval, HDI, ROPE	posterior probability of a set given data and prior; shortest set; accept or reject a value for practical purposes	Chapters 5 and 9

Chapter 5

Bayes' Theorem and Bayesian Inference

Where this chapter is going

Nature produced one set of data. Several situations could have produced it: a disease or no disease, signal or background, a fair coin or a biased one, a universe with one value of Ω_m or another. Physics usually tells us how each situation *generates* data. What we want is the reverse: given the data we actually have, how should probability be spread over the situations that could have produced them? Bayes' theorem is the rule that turns the first kind of knowledge into the second, and one picture carries it throughout. Before the evidence, the whole sample space is in play. The evidence tells us that we are somewhere in the region where it is true, so the sample space shrinks to that region, and every hypothesis is re-measured by the share of the surviving region it occupies.

With a handful of discrete hypotheses the picture can be drawn and computed by hand. Credibility is reallocated: hypotheses that predicted the observation well gain, the others lose, and the total stays one. The ratio of two hypotheses changes by a single factor, the likelihood ratio, so evidence multiplies odds and adds in logarithms. Observations arriving one by one are absorbed one by one, the posterior of each step becoming the prior of the next, and the order does not matter. The denominator of the theorem is the sum over every path that could have led to the observation. When the hypotheses become the values of a continuous parameter, the list becomes a density, the likelihood comes from a model of the noise, and we need ways to summarise a posterior and to integrate out parameters we do not care about. Finally the hypotheses can be whole models with their own parameters. Then the denominator, the evidence, is what compares them, and computing it in many dimensions is so hard that it motivates the sampling methods of Chapter 9.

Bayes' theorem is the last arrow of the pipeline of Section 0.3: it takes the sampling distribution $P(S \mid \theta)$ of a summary S and turns it into a statement about the physics. Chapters 2 to 4 built the forward object $P(S \mid \theta)$; here it is read backwards.

5.1 One joint table, read in two directions

A collider experiment writes an event to disk because its first-level trigger fired. Three independent trigger paths can fire it: the muon system, the calorimeter, and a fast track trigger. From the trigger rates we know what share of the recorded events each path is responsible for: 25% muon, 60% calorimeter, 15% track. The event record of one particular event has lost the flag that says which path fired. Offline, the reconstruction finds an isolated muon with large transverse momentum in it. Which path most probably fired the trigger?

The physics of each trigger tells us something in the *forward* direction. If the muon path

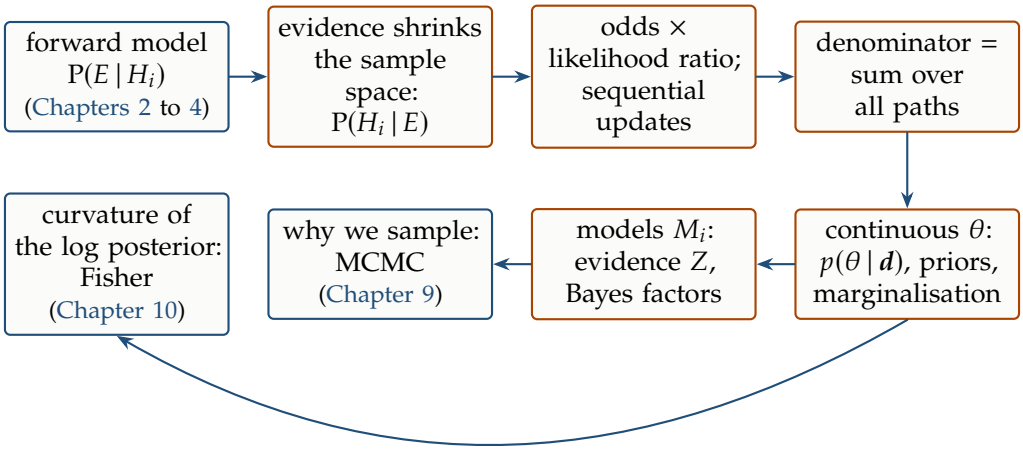

Figure 5.1: How the ideas of Bayesian inference connect. The top row works with a list of discrete hypotheses: a forward model gives the probability of the observation under each, the observation shrinks the sample space, odds change by the likelihood ratio, and the denominator collects every path to the observation. The bottom row replaces the list by a continuous parameter and then by competing models; the cost of the denominator in many dimensions leads to Markov chain Monte Carlo, and the curvature of the log posterior near its peak leads to the Fisher matrix. The boxes with blue borders belong to other chapters.

fired, the event contains an isolated high-p_T muon 70% of the time (the rest are fakes and muons outside the offline acceptance). If the calorimeter path fired, only 5% of such events contain one. If the track path fired, 20% do. These numbers answer "given the path, what do we see?". We want the reverse: "given what we see, which path?".

The two questions use probability in two opposite directions. In the first, we fix one possible situation (here, the path that fired) and ask what it can lead to: which outcomes, and how probable each one is. The outcome is still uncertain, and probability forecasts it. This is **prediction**. In the second, the outcome has already happened: the muon is on disk. Several situations could have led to it, and we want to know which one did. So we start from the outcome and work back to its possible sources. We ask which hypotheses could have produced what we saw, and how probable each one is now that we have seen it. This is **inference**. We met the two directions in Chapter 0 and read a first tree backwards in Chapter 1. All of Bayesian inference rests on this one step: turning the forward question into the backward one.

The question in words. Every backward question can be put into four short questions before a single symbol is written:

1. What did we actually see?
2. Which hypotheses could have given rise to it?
3. Under each of those hypotheses, how probable was what we saw?
4. In the light of that evidence, how must the probabilities we gave the hypotheses beforehand be revised?

For the trigger: (1) we observed an isolated high-p_T muon, call it E; (2) the three paths H_μ, H_{cal}, H_{trk} could have produced it, and exactly one of them fired this event (we ignore the rare events fired by two paths at once); (3) the observation had probability 0.70, 0.05 and 0.20 under them; (4) the original probabilities 0.25, 0.60, 0.15 must be updated in the light of E. Steps 1 to 3 are prediction, done once for each hypothesis. Only step 4 is new.

5.1.1 Deduction runs forward, inference runs backward

The same two directions appear in the difference between deduction and inference [Sivia §1.1, Fig. 1.1]. In *deductive* reasoning the cause is given and we work out its consequences. If a coin is fair, the probability of seven heads in ten tosses follows by counting. Pure mathematics, and every game of chance, runs this way. Most of science runs the other way. We see the effects and ask for the cause: ten tosses gave seven heads; is the coin fair? Several causes could have produced the same effect, so no amount of logic makes the answer certain. Sivia calls this *plausible reasoning*. The question is whether plausible reasoning has rules we can compute with.

It does, and they are the rules of probability we already know. Cox asked a plain question: if we give numbers to degrees of belief, what rules must those numbers obey for the reasoning to be consistent? Consistent means, among other things, that two different ways of using the same information must give the same answer. His answer was that any such numbers can be relabelled so that they obey exactly two rules [Sivia §1.2, (1.1)–(1.2)]:

$$\mathrm{P}(X \mid I) + \mathrm{P}(\bar{X} \mid I) = 1 \qquad \text{(sum rule)}, \tag{5.1}$$

$$\mathrm{P}(X, Y \mid I) = \mathrm{P}(X \mid Y, I)\ \mathrm{P}(Y \mid I) \qquad \text{(product rule)}. \tag{5.2}$$

Here $\bar{X}$ ["X is false"] is the complement, the comma means "and", and I is the **background information** [everything we take as given, such as the trigger rates and the detector model]. Every probability in inference is conditional on some I, even when we stop writing it. Many heated arguments about data analysis are really arguments about an I that nobody wrote down [Sivia §1.2].

The product rule already contains Bayes' theorem. The joint statement "X and Y" is the same statement as "Y and X", so the product rule can be applied in either order and must give the same number:

$$\mathrm{P}(X \mid Y, I)\ \mathrm{P}(Y \mid I) \overset{(1)}{=} \mathrm{P}(X, Y \mid I) \overset{(2)}{=} \mathrm{P}(Y, X \mid I) \overset{(3)}{=} \mathrm{P}(Y \mid X, I)\ \mathrm{P}(X \mid I).$$

Dividing by $\mathrm{P}(Y \mid I) > 0$,

$$\mathrm{P}(X \mid Y, I) \overset{(4)}{=} \frac{\mathrm{P}(Y \mid X, I)\ \mathrm{P}(X \mid I)}{\mathrm{P}(Y \mid I)}. \tag{5.3}$$

(1) Product rule (5.2).
(2) "X and Y" is logically the same proposition as "Y and X".
(3) Product rule again, with the roles of X and Y exchanged.
(4) Divide both sides of the first line by $\mathrm{P}(Y \mid I)$.

Put $X = H$, a hypothesis, and $Y = E$, the observed evidence. The theorem turns the quantity physics hands us, $\mathrm{P}(E \mid H, I)$, into the quantity we want, $\mathrm{P}(H \mid E, I)$ [Sivia §1.3], [Kruschke §5.1.1], [Lambert §3.6].

Bayes' theorem is the first consequence of the two rules. The second is **marginalisation** [Sivia (1.5)–(1.7)]: it answers "how probable is E when we do not know which hypothesis is true?". If $H_1, \ldots, H_k$ are **mutually exclusive and exhaustive** [exactly one of them is true], then

$$\mathrm{P}(E \mid I) \overset{(1)}{=} \sum_{i=1}^{k} \mathrm{P}(E, H_i \mid I) \overset{(2)}{=} \sum_{i=1}^{k} \mathrm{P}(E \mid H_i, I)\ \mathrm{P}(H_i \mid I). \tag{5.4}$$

(1) E happens together with exactly one of the H_i, so its probability is the sum of the probabilities of the k disjoint pieces $E \cap H_i$. This is the law of total probability of Chapter 1; Sivia derives it from the sum and product rules alone.

(2) Product rule on each term.

It is the denominator of Bayes' theorem, and it will get a section of its own (Section 5.6).

Put $X = H_i$ in (5.3) and replace the denominator by the marginalisation (5.4). For mutually exclusive and exhaustive hypotheses $H_1, \dots, H_k$ and an observation E with $\mathrm{P}(E) > 0$ this gives the working form of Bayes' theorem:

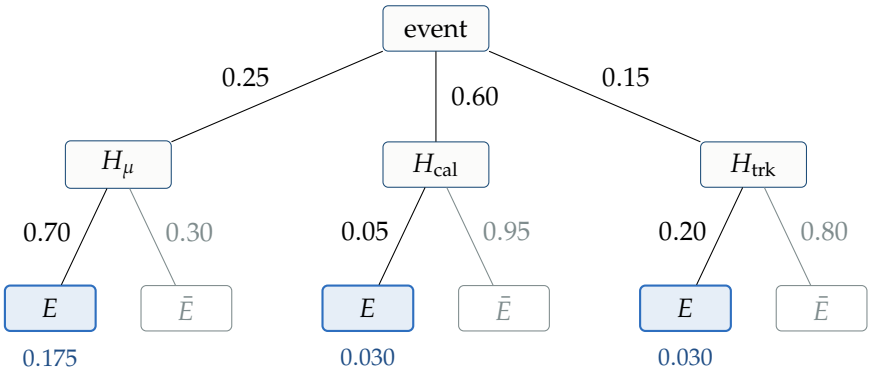
$$\underbrace{\mathrm{P}(H_i \mid E)}_{\text{posterior}} = \frac{\overbrace{\mathrm{P}(E \mid H_i)}^{\text{likelihood}}\ \overbrace{\mathrm{P}(H_i)}^{\text{prior}}}{\underbrace{\sum_j \mathrm{P}(E \mid H_j)\ \mathrm{P}(H_j)}_{\text{evidence } \mathrm{P}(E)}}. \tag{5.5}$$

Key idea: Bayes' theorem in words

Posterior = likelihood × prior / evidence. It is the product rule applied in both orders. The numerator is one path through the tree; the denominator is the sum over every path that ends in E.

5.1.2 The tree and the trigger

Draw the trigger problem as a tree (Figure 5.2). The first split is nature's choice of path, with the priors on the branches. The second split is what the offline reconstruction sees, with the forward probabilities on the branches. Multiplying along a path gives the probability of the leaf, the joint probability $\mathrm{P}(H_i \cap E)$.



leaf probabilities of the observed branch E (products along each path)

Figure 5.2: The trigger problem as a tree. Nature first chooses the path that fires, with the priors on the upper branches; the lower branches give the probability that each path's events contain an isolated high-p_T muon (E) or not ($\bar{E}$). The observed branch is outlined in blue, and the number under each blue leaf is the product along its path. Inference keeps only the blue leaves and asks what share of their total each one carries.

Prediction reads the tree top-down: pick a path, follow it, get the probability of each outcome. Inference starts at the bottom. We saw the muon, so we know we are on a blue leaf, but not on which one. So we collect the three blue leaves and ask what share of their total each one holds:

$$\mathrm{P}(E) \overset{(1)}{=} 0.25 \times 0.70 + 0.60 \times 0.05 + 0.15 \times 0.20 = 0.175 + 0.030 + 0.030 = 0.235,$$

$$\mathrm{P}(H_\mu \mid E) \overset{(2)}{=} \frac{0.175}{0.235} \approx 0.745, \qquad \mathrm{P}(H_{\text{cal}} \mid E) = \mathrm{P}(H_{\text{trk}} \mid E) = \frac{0.030}{0.235} \approx 0.128.$$

(1) Marginalisation (5.4): the sum of the three blue leaves.
(2) Bayes' theorem (5.5): one blue leaf over all of them.

The muon path most probably fired the trigger. The calorimeter path was the most probable before we looked (0.60), and it is now one of the two least probable. It lost because it rarely produces what we saw. The track path was the least probable before, and it ends level with the calorimeter path. Only the product of prior and likelihood enters, so a small prior times a larger likelihood (0.15×0.20) can match a large prior times a small likelihood (0.60×0.05). The prior still matters: the posteriors are *not* the likelihoods rescaled to sum to one. Those would be 0.70, 0.05, 0.20 divided by their sum 0.95, that is 0.74, 0.05, 0.21.

5.1.3 The joint table: a column for prediction, a row for inference

A tree is one way to store a joint distribution. A table is another, and it makes the two directions of reading especially plain [Kruschke §5.1.2, Tables 5.1 and 5.5]. Let the columns be the hypotheses and the rows be the possible observations. Each cell holds the joint probability $\mathrm{P}(E_r, H_c) = \mathrm{P}(E_r \mid H_c)\,\mathrm{P}(H_c)$. Summing a column gives the prior $\mathrm{P}(H_c)$ in the bottom margin; summing a row gives $\mathrm{P}(E_r)$ in the right margin. Figure 5.3 shows it for the trigger.

	H_μ	H_{cal}	H_{trk}	row sum
E	0.175	0.030	0.030	0.235
$\bar{E}$	0.075	0.570	0.120	0.765
column sum	0.25	0.60	0.15	1

prediction: one column, divided by its sum
inference: the observed row, divided by its sum

Figure 5.3: The joint probabilities of trigger path (columns) and offline observation (rows). A prediction fixes a hypothesis and looks down its column: $0.175/0.25 = 0.70$ is the probability of seeing the muon if the muon path fired. An inference fixes the observation and looks along its row: $0.175/0.235 = 0.745$ is the probability that the muon path fired given that we see the muon. Both divide the same cell, by different sums.

Now the two directions are two ways of dividing the same cell. Prediction fixes a column and divides by the column sum: $\mathrm{P}(E \mid H_\mu) = 0.175/0.25$. Inference fixes the row we observed and divides by the row sum: $\mathrm{P}(H_\mu \mid E) = 0.175/0.235$. Observing E means *restricting attention to one row of the table* [Kruschke §5.2]. The other row, $\bar{E}$, is still a perfectly good row. It is simply not what happened, and it drops out of every calculation. That is the shrinking of the sample space in its most compact form. Section 5.2 draws it to scale.

The table also shows why the forward numbers are called a **likelihood** rather than a probability once we read them the inference way [Lambert §4.4]. Along a column, the forward probabilities of all possible observations sum to one: $0.70 + 0.30 = 1$. Along the observed row, the forward probabilities $\mathrm{P}(E \mid H_c)$ of that *one* observation under the different hypotheses are 0.70, 0.05, 0.20. They sum to 0.95, and nothing forces them to sum to one. Read along a row they are a function of the hypothesis, not a distribution over it.

Example: a coin table. Lambert makes the same point with a coin allowed only six values of its probability of heads, $\theta \in \{0, 0.2, 0.4, 0.6, 0.8, 1\}$, tossed twice [Lambert §4.4, Table 4.1]. The number of heads X is binomial, so the table entries are $\mathrm{P}(X \mid \theta) = \binom{2}{X}\theta^X(1-\theta)^{2-X}$:

θ	$X=0$	$X=1$	$X=2$	sum over X
0.0	1.00	0.00	0.00	1
0.2	0.64	0.32	0.04	1
0.4	0.36	0.48	0.16	1
0.6	0.16	0.48	0.36	1
0.8	0.04	0.32	0.64	1
1.0	0.00	0.00	1.00	1
sum over θ	2.20	1.60	2.20	

Each row (fixed θ) is a probability distribution for the data: it sums to one. Each column (fixed data) is a likelihood: for $X=1$ it sums to 1.60. The same happens for a continuous $\theta \in [0,1]$. With one head in two tosses,

$$\int_0^1 \mathrm{P}(X=1 \mid \theta)\,\mathrm{d}\theta \overset{(1)}{=} \int_0^1 2\theta(1-\theta)\,\mathrm{d}\theta \overset{(2)}{=} 2\Big(\frac{1}{2}-\frac{1}{3}\Big) = \frac{1}{3} \neq 1.$$

(1) The binomial probability of one head in two tosses.

(2) $\int_0^1 \theta\,\mathrm{d}\theta = \frac{1}{2}$ and $\int_0^1 \theta^2\,\mathrm{d}\theta = \frac{1}{3}$.

A likelihood has no reason to integrate to one over the parameter. That is why Bayes' theorem needs both a prior, to turn it into a joint probability, and a denominator, to normalise the row.

Watch out: A likelihood is not a probability of the hypothesis

$\mathrm{P}(E \mid H)$ read as a function of H is a likelihood. It can be large for two hypotheses at once, and its sum over hypotheses means nothing. "The muon path explains the data with probability 0.70" is a misreading: 0.70 is the probability of the data if the muon path fired. The probability of the path is 0.745 here, and only because of the particular priors.

5.1.4 Logical, not causal, connections

Inference runs backwards in logic, not in time. A later event cannot cause an earlier one, but it can still tell us about it. Jaynes' example shows this [Sivia §1.4].

Example: the second ball tells us about the first. A bag holds five red and seven green balls. We draw two, one after the other, without putting the first back.

The event. We are not told the colour of the first ball. We are told that the second is green. Call this G_2.

The question. Is the probability that the first ball was red still 5/12, as it was before we heard about the second? The first draw happened before the second, so the second cannot have caused it. But the second can be evidence about it.

The candidates. There are two: the first ball was red (R_1) or green (G_1). Under each, the second draw is a draw from a different bag. After a red first ball the bag holds 4 red and 7 green, so a green second ball has probability 7/11. After a green first ball it holds 5 red and 6 green, so a green second ball has probability 6/11. A green second ball is a little more likely if the first was red, because the first draw then left all seven greens in the bag.

Only then the numbers. The priors are $\mathrm{P}(R_1) = 5/12$ and $\mathrm{P}(G_1) = 7/12$:

$$\mathrm{P}(G_2) \overset{(1)}{=} \mathrm{P}(G_2 \mid R_1)\,\mathrm{P}(R_1) + \mathrm{P}(G_2 \mid G_1)\,\mathrm{P}(G_1) = \frac{7}{11}\cdot\frac{5}{12} + \frac{6}{11}\cdot\frac{7}{12} = \frac{35+42}{132} = \frac{7}{12},$$

$$\mathrm{P}(R_1 \mid G_2) \overset{(2)}{=} \frac{\mathrm{P}(G_2 \mid R_1)\,\mathrm{P}(R_1)}{\mathrm{P}(G_2)} = \frac{35/132}{77/132} = \frac{5}{11}.$$

(1) Marginalisation over the first draw, with $P(G_2 \mid R_1) = 7/11$ and $P(G_2 \mid G_1) = 6/11$ found above.
(2) Bayes' theorem.

The answer moved from $5/12 \approx 0.417$ to $5/11 \approx 0.455$. The extreme case makes it obvious: with one red and one green ball in the bag, a green second ball means the first was red with certainty. A conditional probability records what one statement *tells us* about another, not what causes what. Inference from the leaves of a tree back to its first split works the same way: the observation comes later in the physics, but it tells us about what happened first.

5.1.5 What the probabilities mean

There are two readings of what a probability is, and Wasserman sets them side by side [Wasserman pp. 175–176]. The frequentist reading rests on three postulates. Probability is a long-run relative frequency. Parameters are fixed constants, so no probability statements are made about them. A procedure is judged by how often it gives the right answer over many repetitions. The Bayesian reading rests on three others. Probability describes a degree of belief. We may therefore make probability statements about parameters. Inference about a parameter means producing a probability distribution for it. The second reading is the one that lets us give a probability to a one-off event. The weather forecast's "90% chance of rain tomorrow" is such a probability [SeeingTheory p. 49]. So is Laplace's posterior for the mass of Saturn. He summarised it as a bet of 11 000 to 1 that his estimate was not wrong by more than 1%. A further 150 years of data changed the estimate by only 0.63% [Sivia §1.4].

For the trigger path both readings work. Which path fires is the outcome of a process that repeats with every event, and 0.745 is the fraction of recorded events with an isolated muon that were fired by the muon path. A physical constant is different: nature chose its value once, so only the degree-of-belief reading is available. The arithmetic of (5.5) is the same either way. A degree of belief is not arbitrary: two people with the same background information I must assign the same probabilities [Sivia §1.4]. When they disagree, they disagree about I, and Bayes' theorem forces each of them to write I down.

5.2 Information shrinks the sample space

A disease affects one person in a hundred. A test for it comes out positive for 95% of the people who have the disease and, falsely, for 10% of the people who do not. A person picked at random tests positive. How worried should they be? Most people's first answer is "about 95%". The right answer is about 9%. We computed it by formula in Chapter 1. Here we want to *see* it, in one picture that works for every inference problem.

The picture rests on one idea. Before the evidence, every possibility in the sample space is still in play, and the probability of a hypothesis is the fraction of the whole space it occupies. The evidence tells us that we are somewhere in the region where the evidence is true. Everything outside that region is ruled out. The sample space has shrunk, and each hypothesis is now measured by the fraction of the *surviving* region that it occupies. Bayes' theorem is nothing more than this re-measurement. What makes it a useful calculating tool is that the surviving region can be built out of numbers we know: priors and forward probabilities.

5.2.1 The unit square

Take a square of side one. Its area, one, is the total probability. Cut it by a vertical line into a strip of width $P(H)$ on the left, the hypothesis, and a strip of width $P(\neg H) = 1 - P(H)$ on the

right, its negation. Inside the left strip, shade from the bottom a bar of height $\mathrm{P}(E \mid H)$: the fraction of the H-world in which the evidence E occurs. Inside the right strip, shade a bar of height $\mathrm{P}(E \mid \neg H)$. That is the whole construction (Figure 5.4, top left).

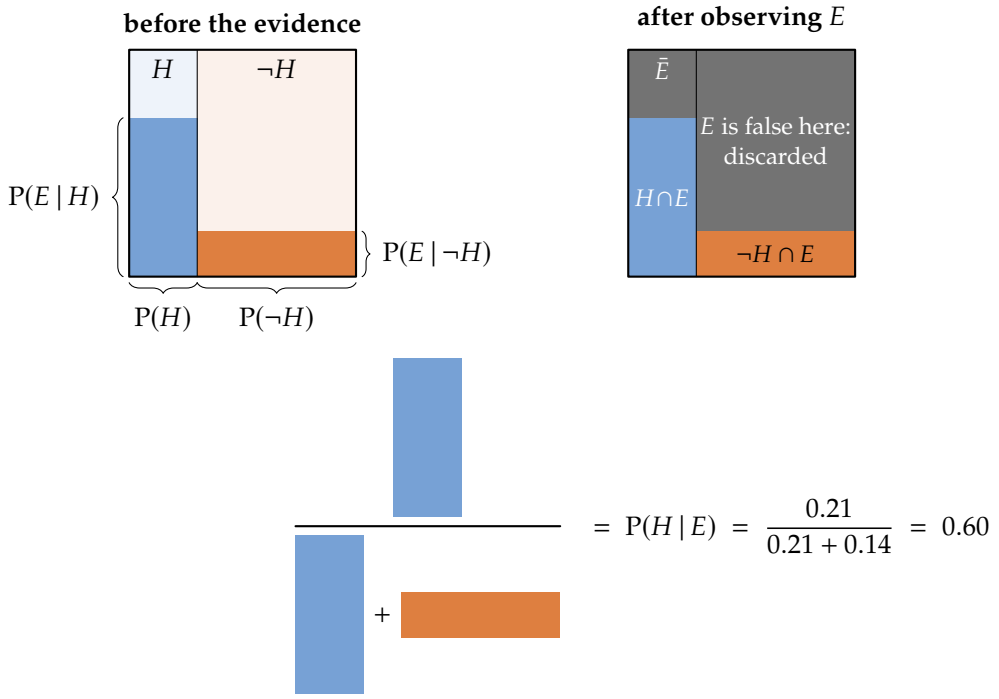


Figure 5.4: Bayes' theorem as information shrinking the sample space, for $\mathrm{P}(H) = 0.3$, $\mathrm{P}(E \mid H) = 0.7$, $\mathrm{P}(E \mid \neg H) = 0.2$. Top left: the square is split at the prior, and each strip carries a bar whose height is the probability that its hypothesis produces the evidence. Top right: once E is observed, everything above the bars is greyed out; only the two bars survive. Bottom: the posterior is the blue rectangle divided by the sum of the two surviving rectangles, drawn at the same scale as the square.

Every number in the problem now has a shape. A prior is a *width*. A forward probability, the likelihood of the evidence under one hypothesis, is a *height* measured inside that hypothesis's strip. The joint probability of "H and E" is the *area* of the blue bar, because the product rule says

$$\text{area of the blue bar} \overset{(1)}{=} \mathrm{P}(H) \times \mathrm{P}(E \mid H) \overset{(2)}{=} \mathrm{P}(H \cap E). \tag{5.6}$$

(1) A rectangle's area is its width times its height.
(2) Product rule (5.2).

The orange bar, likewise, has area $\mathrm{P}(\neg H \cap E)$. The two bars are disjoint and together they are all of E, so their total area is $\mathrm{P}(E)$.

Now observe E. Every point of the square above the bars is a possibility in which E did *not* happen, and we grey it out (Figure 5.4, top right). What survives is the two bars. The probability of H is now the fraction of the surviving area that lies in the H strip:

$$\begin{aligned} \mathrm{P}(H \mid E) &\overset{(1)}{=} \frac{\text{area}(H \cap E)}{\text{area}(E)} \overset{(2)}{=} \frac{\text{area}(H \cap E)}{\text{area}(H \cap E) + \text{area}(\neg H \cap E)} \\ &\overset{(3)}{=} \frac{\mathrm{P}(E \mid H)\ \mathrm{P}(H)}{\mathrm{P}(E \mid H)\ \mathrm{P}(H) + \mathrm{P}(E \mid \neg H)\ \mathrm{P}(\neg H)}. \end{aligned} \tag{5.7}$$

(1) Definition of conditional probability: E is the new, shrunk sample space, and $\mathrm{P}(\cdot \mid E)$ measures areas relative to it.
(2) The surviving region E is the union of the two disjoint bars.

(3) Each bar's area is width times height, (5.6).

The last line is Bayes' theorem (5.5) for the two hypotheses H and $\neg H$. The picture has derived it with no algebra beyond "area is width times height".

The same overlap also gives the forward probability. Measured against the H strip instead of against E,

$$\mathrm{P}(E \mid H) = \frac{\text{area}(H \cap E)}{\text{area}(H)}.$$

The numerator is the same blue bar in both conditional probabilities. What changes is the region we divide by: the whole H strip for prediction, the surviving region E for inference.

Once the square is drawn, Bayes' theorem is hard to avoid. There is a single overlap, the blue bar $H \cap E$, and two places to stand when we measure it. Standing in H, we ask how much of the H strip the evidence also covers, and the answer is $\mathrm{P}(E \mid H)$. Standing in E, we ask how much of the surviving region belongs to H, and the answer is $\mathrm{P}(H \mid E)$. Bayes' theorem is the algebra that turns the first measurement of this one overlap into the second.

Working definition 5.1 (prior, likelihood, posterior, evidence)

For hypotheses H_i that partition the sample space and an observation E:

- the **prior** $\mathrm{P}(H_i)$ [how plausible H_i was before E] is the width of strip i;
- the **likelihood** $\mathrm{P}(E \mid H_i)$ [how probable the observed E would be if H_i were true, read as a function of i] is the height of the bar in strip i (in the box picture of Figure 1.11, the share of strip i that E covers);
- the **evidence** $\mathrm{P}(E) = \sum_j \mathrm{P}(E \mid H_j)\,\mathrm{P}(H_j)$ [the total probability of the observation] is the total surviving area;
- the **posterior** $\mathrm{P}(H_i \mid E)$ [how plausible H_i is after E] is the area of E inside strip i divided by the total surviving area.

Operationally: multiply each prior by its likelihood, add the products, divide each product by the sum.

5.2.2 The medical test, to scale

Now draw the medical test with its true proportions. The disease strip has width $\mathrm{P}(D) = 0.01$; on a rectangle 5 cm wide that is half a millimetre. On the square of Figure 5.4 its bar would be a needle of that width, too thin to see. So we use the box picture of Figure 1.11 instead. It shows the same areas, but draws the evidence as one region, the box (Figure 5.5). A positive test covers 0.95 of the thin disease strip, because the test catches the disease 95% of the time, and 0.10 of the healthy strip, which is 0.99 wide. The two pieces sit side by side and make one box, the event +. The reason for the surprising answer is visible at once: the box is almost all healthy piece. That piece covers only a tenth of its strip, but its strip is ninety-nine times wider.

The event. What we observed is a positive test, written +.

What could have produced it? The one thing we do not know about the person is whether they are ill, so there are two candidate explanations: D, they have the disease, and D^c, they do not. Each is a route by which a positive result can arise.

How probable was the event along each route? If the person is ill, the test catches the disease 95% of the time, so $\mathrm{P}(+ \mid D) = 0.95$. If they are healthy, a positive result is a false alarm, which the test gives 10% of the time, so $\mathrm{P}(+ \mid D^c) = 0.10$. These are the shares of the two strips that the box covers.

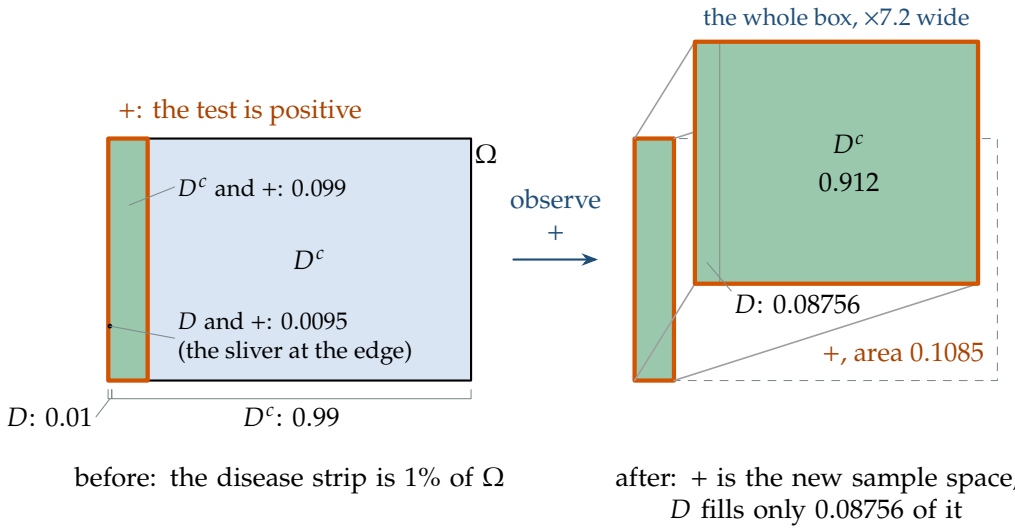

Figure 5.5: The medical test drawn to scale, in the picture of Figure 1.11. Left: Ω has area 1, cut into the disease strip D, of width 0.01, and the healthy strip D^c, of width 0.99. The event + (orange outline) covers 0.95 of the D strip, because the test catches the disease 95% of the time, and 0.10 of the D^c strip, because it gives a false alarm to one healthy person in ten. Its two pieces have areas $0.01 \times 0.95 = 0.0095$ and $0.99 \times 0.10 = 0.099$; at this scale the D piece hides under the orange outline. Right: a positive result discards everything outside the box. The raised inset magnifies the whole box about seven times horizontally, with the height unchanged (the grey lines join each corner of the box to the matching corner of the inset): the D piece is the narrow piece at the start of the box, and it fills only 0.08756 of the box's area.

Only then the priors, and the normalisation. Before the test, the person was ill with probability $\mathrm{P}(D) = 0.01$ and healthy with $\mathrm{P}(D^c) = 0.99$: the widths of the strips. The numbers are the areas:

$$\begin{aligned} \mathrm{P}(+) &\overset{(1)}{=} \mathrm{P}(+ \mid D)\,\mathrm{P}(D) + \mathrm{P}(+ \mid D^c)\,\mathrm{P}(D^c) = 0.95 \times 0.01 + 0.10 \times 0.99 \\ &= 0.0095 + 0.099 = 0.1085, \\ \mathrm{P}(D \mid +) &\overset{(2)}{=} \frac{0.0095}{0.1085} = 0.08756. \end{aligned}$$

(1) The area of the box: the sum of its two pieces.
(2) The D piece's share of it, (5.7).

The arithmetic is not the lesson. A positive result can come by two routes: through the disease, or through a false alarm on a healthy person. The disease route begins with little weight, 0.01, and the test favours it over the healthy route by a factor of only about 9.5 (0.95 against 0.10). A factor of 9.5 applied to so small a start cannot lift the posterior anywhere near 95%. In the box, the positive result covers 9.5 times more of the disease strip than of the healthy strip, but the healthy strip is 99 times wider.

Other versions of the same problem teach the same lesson: prevalence 0.001 with sensitivity 0.99 and false-alarm rate 0.05 gives 0.019 [Kruschke §5.1.2, Table 5.4]; prevalence 0.001 with 95% accuracy either way also gives 0.019, a twentyfold increase on the prior that is still far from certainty [SeeingTheory pp. 50–51]; breast-cancer screening with prevalence 1%, sensitivity 80% and false-positive rate 10% gives 0.075 [Lambert §3.6.2]. In every case the healthy piece covers a small share of a very wide strip.

Watch out: A share of the strip is not a share of the box

The 95% that people quote is the share of the disease strip that a positive result covers, $P(+ \mid D)$. The answer is the disease piece's share of the box, $P(D \mid +)$. The first tells us how the test behaves on diseased people; only the widths of both strips turn it into a statement about this person.

5.2.3 More than two hypotheses: Monty Hall

Nothing in the construction needs two strips. With k hypotheses the sample space is cut into k strips of widths $P(H_i)$, the evidence covers the share $P(E \mid H_i)$ of strip i, and the posterior of H_i is the share of the evidence that lies in strip i.

Example: Monty Hall, to scale. Three doors hide one car and two goats. We choose door A. Monty, who knows where the car is, always opens one of the two other doors to show a goat, choosing at random when he has a choice. Then he opens door C.

The event. What we observed is "Monty opened door C". Call it M_C.

What made him open that door? Before any number, we ask which situations could have produced this event. The only thing we do not know is where the car is, so the possible explanations are the three possible locations of the car. We call them H_A, H_B and H_C, with the car behind A, B or C respectively. The question is which of these locations could have led to the event we saw, Monty opening C.

How probable was the event under each hypothesis? We go through the three locations one by one and ask how likely Monty was to open C if that location were the truth. Monty knows where the car is, he never opens the door we chose, and he never reveals the car.

- Under H_A the car is behind our door. Both B and C hide goats, so he may open either, and he picks at random: $P(M_C \mid H_A) = \frac{1}{2}$.
- Under H_B the car is behind B. He cannot open A (ours) or B (the car), so he is forced to open C: $P(M_C \mid H_B) = 1$.
- Under H_C the car is behind C. He never reveals the car, so he would not open C: $P(M_C \mid H_C) = 0$.

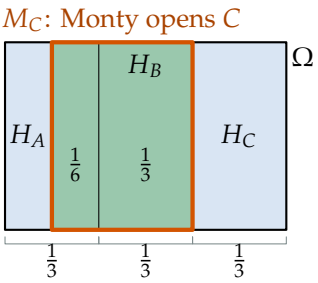
These three numbers are the shares of the three strips covered by the box in Figure 5.6 (the picture of Figure 1.22, here with doors A, B, C). They are also the three branches ending in "Monty opens C" of the tree in Chapter 1.

Only then the priors, and the normalisation. Before Monty acted, each location was equally probable, $P(H_A) = P(H_B) = P(H_C) = \frac{1}{3}$: these are the widths of the three strips. Multiplying each width by the share the box covers gives the area of each piece of the box: half of the A strip, all of the B strip and none of the C strip. Dividing each piece by the whole box,

$$P(H_B \mid M_C) \overset{(1)}{=} \frac{P(M_C \mid H_B)\,P(H_B)}{P(M_C \mid H_A)\,P(H_A) + P(M_C \mid H_B)\,P(H_B) + P(M_C \mid H_C)\,P(H_C)}$$
$$\overset{(2)}{=} \frac{1 \cdot \frac{1}{3}}{\frac{1}{2} \cdot \frac{1}{3} + 1 \cdot \frac{1}{3} + 0 \cdot \frac{1}{3}} = \frac{1/3}{1/2} = \frac{2}{3}, \qquad P(H_A \mid M_C) = \frac{1/6}{1/2} = \frac{1}{3}, \qquad P(H_C \mid M_C) = 0.$$

(1) Bayes' theorem (5.5): the B piece over the whole box, the denominator being the sum over the three paths that can end in "Monty opens C".
(2) The shares found above and the widths $\frac{1}{3}$. The area of the box is 0.5.

Figure 5.6 draws the last line. Bayes' theorem is a division of areas: the piece of the box that lies in the B strip, divided by the whole box, which is the A piece and the B piece side by side.



priors are the strip widths; the box covers half of A, all of B, none of C

$$P(H_B \mid M_C) = \frac{B}{A + B} = \frac{1/3}{1/6 + 1/3} = \frac{2}{3}$$

Bayes: the B piece over the whole box

Figure 5.6: Monty Hall drawn to scale, and Bayes' theorem as a division of areas. Left: the sample space Ω has area 1. The three places the car can be fill it in strips of width $\frac{1}{3}$, the priors. The box M_C, "Monty opens door C", covers half of the A strip (with the car behind our door he picks B or C at random), all of the B strip (he is forced to open C) and none of the C strip (he never reveals the car); each green piece has area prior × likelihood. Right: the posterior of H_B is the B piece divided by the whole box, the A piece and the B piece together. All three pieces are shrunk by the same factor, so the ratio of areas you see is the posterior, $\frac{2}{3}$. The posterior of H_A is the A piece over the same box, $\frac{1}{3}$.

Why not fifty–fifty? The tempting argument says that Monty has taken one door away, so the two that remain must be equally likely. It ignores what Monty's choice tells us. Opening C was not equally probable under the two hypotheses still standing: if the car is behind B he had to open C, while if it is behind A he opened C only half the time. The evidence is twice as probable under H_B as under H_A, and with equal priors that factor of two passes straight into the posteriors. In the box the factor of two is visible directly: the B piece is twice as wide as the A piece, cut from strips of the same width.

The two-strip picture still works if we lump hypotheses together. Take $H = H_B$ and $\neg H =$ "H_A or H_C" (the car is behind A or behind C). Then $P(H) = \frac{1}{3}$, $P(M_C \mid H) = 1$, and the share of the $\neg H$ strip that the evidence covers is the average of the shares it replaces, weighted by their widths:

$$P(M_C \mid \neg H) \overset{(1)}{=} \frac{P(M_C \cap H_A) + P(M_C \cap H_C)}{P(H_A) + P(H_C)} = \frac{\frac{1}{3}\cdot\frac{1}{2} + \frac{1}{3}\cdot 0}{\frac{2}{3}} = \frac{1}{4},$$

(1) Definition of conditional probability, with the event $\neg H = H_A \cup H_C$ split into its disjoint parts.

and (5.7) gives $\frac{1/3}{1/3+(2/3)(1/4)} = \frac{2}{3}$ again. Merging strips merges their pieces into one piece of the same total area.

Example: two urns. The urn problem is the simplest picture of all. Urn A holds 8 red and 2 blue balls, urn B holds 2 red and 8 blue, and one urn is picked with probability $\frac{1}{2}$ each. A red ball is drawn.

The event is the red ball, R. What could have produced it? Either urn: the two candidate sources are A and B. How probable was a red ball from each? Urn A is eight-tenths red, so $P(R \mid A) = 0.8$; urn B is two-tenths red, so $P(R \mid B) = 0.2$. These are the shares of the two strips that the evidence covers. Only then the priors: each urn was picked with probability $\frac{1}{2}$, so the

strips are equal, and normalising the surviving areas gives $\mathrm{P}(A \mid R) = 0.4/(0.4 + 0.1) = 0.8$ and $\mathrm{P}(B \mid R) = 0.2$.

Drawing the red ball did nothing to the urns: each still holds what it held. What changed is our belief about which urn the ball came from, and that belief is fixed by two things together, the probability with which each urn was picked and the probability that each urn gives a red ball.

5.2.4 A physics example: signal or background after the trigger

Before the trigger, 5% of the collisions entering an analysis preselection are signal (S) and 95% are background (B). The trigger keeps 90% of signal events and 2% of background events.

The event. An event has been triggered.

The question. Is it signal? There are two candidate explanations, S and B. Under S the trigger fires with probability 0.90; under B with probability 0.02.

The numbers. Drawn to scale (Figure 5.7), the S strip has width 0.05 and the trigger keeps 0.90 of it; the B strip has width 0.95 and the trigger keeps only 0.02 of it. The two pieces of the triggered box have areas 0.045 for signal and 0.019 for background, so the triggered sample has signal fraction

$$\mathrm{P}(S \mid \mathrm{trig}) \overset{(1)}{=} \frac{0.05 \times 0.90}{0.05 \times 0.90 + 0.95 \times 0.02} = \frac{0.045}{0.064} = 0.7031.$$

(1) Bayes' theorem (5.7); 0.064 is the fraction of all preselected events that the trigger keeps.

The trigger has raised the signal fraction from 5% to 70%. In detector language, $\mathrm{P}(\mathrm{trig} \mid S)$ is the *efficiency* and $\mathrm{P}(S \mid \mathrm{trig})$ is the *purity* of the triggered sample. The picture shows the difference. The efficiency is a share of the S strip, so it does not depend on the strip widths. The purity is a share of the box, so it does.

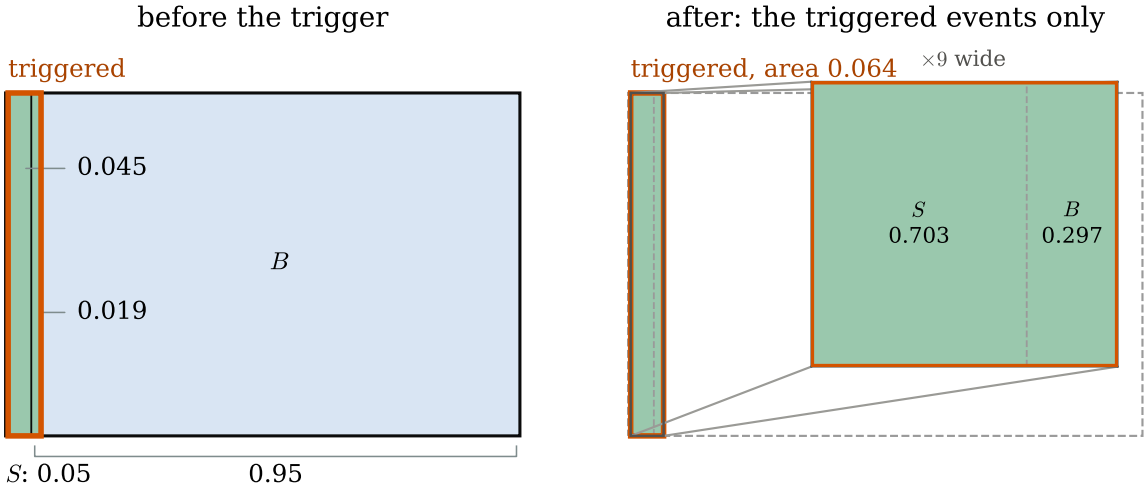


Figure 5.7: The trigger drawn to scale, in the picture of Figure 1.11. Left: the signal strip S has width 0.05 and the background strip B width 0.95; the triggered events (orange outline) cover 0.90 of the signal strip but only 0.02 of the background strip, so the two pieces have areas 0.045 and 0.019. The background piece covers a small share of its strip, but its strip is nineteen times wider. Right: once we keep only triggered events, the box is the new sample space; the inset magnifies it horizontally. Signal fills 0.7031 of it.

5.2.5 Drawing the boxes in Python

The trigger figure was drawn by one short function, `box_diagram`, which takes any list of priors and likelihoods and draws the box picture to scale. Its geometry is the loop over strips:

Listing 5.1: The strips and the pieces of the evidence (`code/ch05/lib_area.py`)

```
143     priors, likes = np.asarray(priors, float), np.asarray(likes, float)
144     k = len(priors)
145     edges = W_OMEGA * np.concatenate([[0.0], np.cumsum(priors)])
146     pieces = []
147     for i in range(k):
148         x0, x1 = edges[i], edges[i + 1]
149         w = (x1 - x0) * likes[i]
150         left_has = i > 0 and likes[i - 1] > 0
151         right_has = i < k - 1 and likes[i + 1] > 0
152         if right_has and not left_has:     # lean right, towards the next piece
153             pieces.append((x1 - w, x1))
154         else:                              # lean left (or fill the strip if likes[i] = 1)
155             pieces.append((x0, x0 + w))
156     return edges, pieces
```

Line 145 turns the priors into the positions of the strip edges, so strip i runs from the sum of the earlier priors to that sum plus its own prior. Line 149 is the whole of the likelihood's role: the piece of E in strip i is as wide as the strip times $\mathrm{P}(E \mid H_i)$, and it runs the full height, so its area is prior times likelihood. Lines 150–155 only decide where the piece sits inside its strip: it is pushed against a neighbouring strip that also has a piece, so that the pieces join into one box, as in Figure 1.22. The companion function `posterior` in the same file computes the numbers: the joint areas are `priors * likes`, their sum is $\mathrm{P}(E)$, and the posterior is their ratio. The same file keeps `area_diagram`, which draws the square of Figure 5.4 with bars. The script `code/ch05/01_area_diagrams.py` computes the medical test, Monty Hall and the trigger, draws the trigger, and writes the posteriors quoted above.

5.3 Reallocating credibility across possibilities

We step outside in the morning and the pavement is wet. Rain? A garden sprinkler? A burst pipe? A passer-by who spilled a drink? Each possibility has some credibility before we look further, rain more than a spilled drink. Then we look around. If the trees and the parked cars are wet as far as we can see, credibility flows to rain. If the wet patch is small and there is an empty cup beside it, credibility flows to the spilled drink, although it started low. Kruschke puts the whole of Bayesian inference into one sentence: it is the **reallocation of credibility across possibilities** [Kruschke §2.1].

The phrase says two things, and the square of Section 5.2 makes both exact. First, the total credibility is fixed. It is always one, shared among possibilities that exclude each other and together cover everything we consider. Second, credibility moves towards the possibilities that account well for what was seen. Which ones gain? The posterior of a possibility is its prior times its likelihood, divided by $\mathrm{P}(E)$. And $\mathrm{P}(E)$ is the average of all the likelihoods, each weighted by its prior. So a possibility gains exactly when its likelihood, the height of its bar in the square, is above that average. This means any inference problem needs only three things: a list of possibilities, a prior over the list, and, for each item, the probability of what we saw.

Key idea: Posterior is proportional to likelihood times prior

$$\mathrm{P}(H_i \mid E) \;\propto\; \mathrm{P}(E \mid H_i)\,\mathrm{P}(H_i),$$

with the constant fixed by $\sum_i \mathrm{P}(H_i \mid E) = 1$ [Wasserman p. 177, (11.2)]. Equivalently, the posterior of H_i is its prior multiplied by the factor $\mathrm{P}(E \mid H_i)/\mathrm{P}(E)$, which exceeds one exactly when H_i predicted E better than the prior-weighted average of all hypotheses.

5.3.1 The Bayes box

The bookkeeping fits in a table with one row per possibility, which Lambert calls a **Bayes box** [Lambert §5.5.1]. Columns: the possibility, its prior, its likelihood, their product, and the product divided by the column sum.

Example: the fish game. A covered bowl holds five fish, each red or white. We want the number α of red fish. We pull out one fish at random and it is red: that is the event. The candidates are the six possible bowls, $\alpha \in \{0, 1, \ldots, 5\}$. We have no idea beforehand, so each gets prior $\frac{1}{6}$. How probable is a red fish under each candidate? A bowl with α red fish out of five gives a red fish with probability $\alpha/5$.

α	prior	likelihood $\alpha/5$	prior × likelihood	posterior
0	1/6	0	0	0
1	1/6	1/5	1/30	1/15
2	1/6	2/5	2/30	2/15
3	1/6	3/5	3/30	3/15
4	1/6	4/5	4/30	4/15
5	1/6	1	5/30	5/15
sum	1	3	15/30 = P(red)	1

The posterior column is the product column divided by its sum, $\frac{1}{2}$. The table shows three things. First, the likelihood column sums to 3, not to 1: as in Section 5.1, a likelihood is not a distribution over the possibilities. Second, $\alpha = 0$ is eliminated, because a bowl with no red fish cannot produce a red fish. Third, with a flat prior the posterior has the same shape as the likelihood, here a straight line rising to $\alpha = 5$. Suppose instead we believed that the game-maker likes mixed bowls. A prior peaked at $\alpha = 2, 3$ would then pull the posterior back towards the middle. The posterior is a compromise between prior and likelihood [Lambert §5.5.1], [Kruschke §5.3].

5.3.2 Elimination and exoneration

Sherlock Holmes said: "when you have eliminated the impossible, whatever remains, however improbable, must be the truth". In the Bayes box this is a likelihood of zero. If the observation is impossible under H_j, then $\mathrm{P}(E \mid H_j) = 0$, and that row's posterior is zero. If the other possibilities all have the same likelihood, their posteriors are just their priors rescaled to sum to one. Kruschke draws four suspects at 0.25 each: rule out A, and B, C, D get $\frac{1}{3}$ each; rule out B as well, and C, D get $\frac{1}{2}$; rule out C, and D gets 1 [Kruschke §2.1, Fig. 2.1]. The reverse, *exoneration*, is an observation that only one possibility can produce: then that possibility gets credibility one and all the others are cleared [Kruschke Fig. 2.2].

Example: the trigger path, continued. Recall the event of Section 5.1 that had lost its trigger flag. One of three paths fired it: muon (H_μ), calorimeter (H_{cal}) or track (H_{trk}). The isolated

muon E moved their credibility from $(0.25, 0.60, 0.15)$ to $(0.745, 0.128, 0.128)$. Now we read the run log and find that during this run the muon trigger was masked: it could not fire. How probable is that log entry under each path? If the muon path fired the event, a mask is impossible, so the probability is 0. If either other path fired it, the mask is certain to be in the log, so the probability is 1. The new likelihoods multiply the old posteriors:

$$\mathrm{P}(H_\mu \mid E, \text{mask}) \overset{(1)}{=} \frac{0 \times 0.745}{0 \times 0.745 + 1 \times 0.128 + 1 \times 0.128} = 0,$$

$$\mathrm{P}(H_{\text{cal}} \mid E, \text{mask}) = \mathrm{P}(H_{\text{trk}} \mid E, \text{mask}) \overset{(2)}{=} \frac{1}{2}.$$

(1) Bayes' theorem with the previous posterior as the new prior (justified in Section 5.5); the mask entry has likelihoods $(0, 1, 1)$.

(2) The two survivors have equal likelihood, so they keep the ratio of their previous credibilities, which was $1 : 1$.

The muon path, the favourite a moment ago, is gone. Its 0.745 has been shared between the two survivors in proportion to what they had. Figure 5.8 shows the whole sequence as bars.

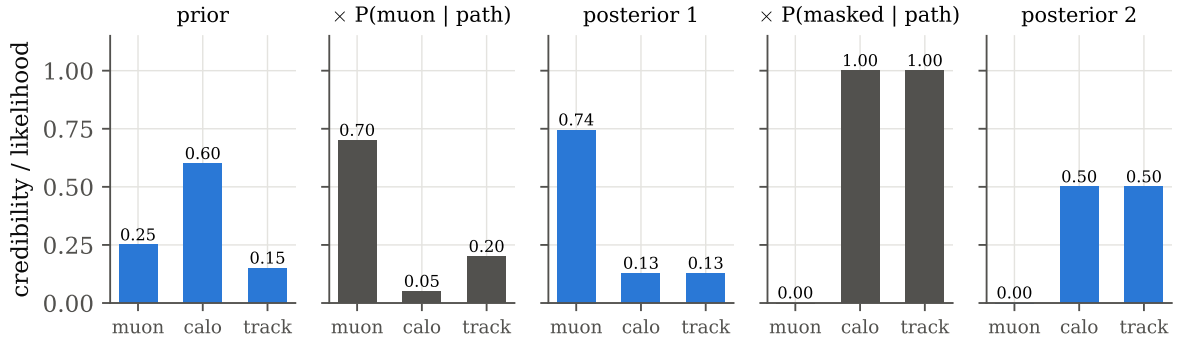

Figure 5.8: Credibility of the three trigger paths. From left: the prior (share of recorded events); the likelihood of an isolated high-p_T muon under each path; the posterior; the likelihood of the run-log entry "muon trigger masked"; the final posterior. Blue bars always sum to one; grey bars need not. Each blue panel is the previous blue panel times the grey panel, renormalised.

Watch out: A zero prior can never be revived

If a possibility has prior zero, its posterior is zero whatever is observed, because $0 \times \mathrm{P}(E \mid H) = 0$. Lambert's example is someone so certain that the Earth is flat that the round Earth gets prior zero; no amount of astronomical data can then move it [Lambert §5.7.1]. Truncating a prior ("the prevalence is surely below 25%") does the same to every value beyond the cut. Give every possibility you cannot rule out on physical grounds a nonzero prior.

5.3.3 Noisy data only nudge

Holmes' clues were decisive: each one set some likelihoods exactly to zero. Real measurements are noisy. A noisy measurement is only somewhat more probable under one possibility than under another, so credibility moves gradually and nothing is ruled out.

Example: which ball size? A factory makes balls in four sizes, with nominal diameters $1, 2, 3, 4$ (in some unit). Inflation varies, so a ball of size s has a diameter spread around s; take it Gaussian with standard deviation $\sigma = 1.17$.[1] We ordered three balls of size 2.

[1] This value reproduces Kruschke's percentages; he does not state the spread he used.

The event. We measure the three diameters $d = (1.77, 2.23, 2.70)$.

The question. Did we get what we ordered [Kruschke §2.1.1, Fig. 2.3]? Which size could have produced these three diameters?

The candidates. The four sizes $s = 1, 2, 3, 4$. The factory may have lost our order, so we do not trust the label and give each size prior $\frac{1}{4}$.

How probable are the data under each size? The three diameters are independent once the size is fixed, so the likelihood is a product of three Gaussian densities:

$$p(\boldsymbol{d} \mid s) \overset{(1)}{=} \prod_{i=1}^{3} \frac{1}{\sqrt{2\pi}\,\sigma} \exp\!\left[-\frac{(d_i - s)^2}{2\sigma^2}\right] \overset{(2)}{=} \frac{1}{(2\pi\sigma^2)^{3/2}} \exp\!\left[-\frac{1}{2\sigma^2}\sum_{i=1}^{3}(d_i - s)^2\right]. \tag{5.8}$$

(1) Independence given s: the joint density is the product of the three single-ball densities $\mathcal{N}(d_i; s, \sigma^2)$.

(2) Collect the three exponentials into one.

The prefactor is the same for every s, so it cancels in the posterior. Only the sum of squared distances from the data to s matters, and the smaller it is, the larger the likelihood. The sums are 5.00, 0.60, 2.20 and 9.80 for $s = 1, 2, 3, 4$: size 2 is closest to the three measurements.

Only then the numbers. With equal priors, the posterior (Figure 5.9) is 0.1118, 0.5578, 0.311, 0.01937 for sizes 1 to 4. Size 2 is the most credible, but far from certain. Its likelihood is only 1.794 times that of size 3, because the spread of a single ball, $\sigma = 1.17$, is larger than the distance between sizes. No size is ruled out, since a Gaussian is never exactly zero. Size 4 is merely very unlikely.

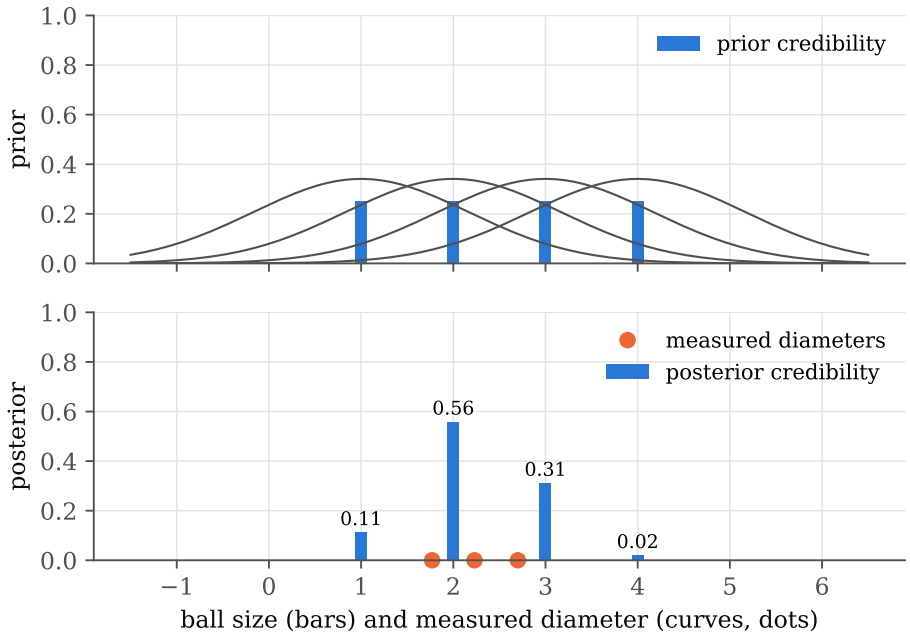

Figure 5.9: Top: four candidate ball sizes with equal prior credibility (bars), and the spread of diameters each size produces (curves). Bottom: the three measured diameters (dots on the axis) and the posterior credibility of each size. The data sit between sizes 2 and 3, closer to 2, and the credibility moves accordingly, without ruling anything out.

Data analysis is exactly this, with the balls replaced by physical parameters. We list the possible sources of the data, write down how each would produce data, and let the data reallocate the credibility [Kruschke §2.1.1]. The recipe has the same steps in every textbook.

Identify the data. Write a model that gives the probability of the data for each possibility. Put a prior on the possibilities. Apply Bayes' theorem. Check that the most credible possibilities actually reproduce the data [Kruschke §2.3], [Wasserman p. 176]. Repeat as new data arrive [SeeingTheory p. 51]. The possibilities are usually the values of the parameters of a model [Kruschke §2.2]. When a parameter is continuous, the row of bars becomes a density over it. Each value of the parameter, here the ball size s, is then one candidate explanation of the measured data, and its likelihood says how easily that value could have produced them; this is parameter estimation, taken up for continuous parameters in Section 5.7.

5.3.4 Which source produced this photon?

A gamma-ray burst goes off, and in the 100 s after it a gamma-ray telescope records photons from a $10^\circ \times 10^\circ$ patch of sky around it. Each photon comes with a reconstructed direction $\boldsymbol{r}$ and energy E. Three sources can produce a photon in this patch: the burst itself (G), a steady blazar 1.3° away (Bz), and the diffuse gamma-ray background spread over the whole patch (D). For each photon we ask: which source produced it? This is the trigger-path problem again. The candidates are the three sources, and the evidence is the photon's direction and energy, which are continuous.

Priors from rates. Before we look at a photon's direction or energy, the probability that it came from source k is that source's share of the expected photon count in the window. We take 30 expected burst photons, 8 from the blazar and 40 from the diffuse background, so the priors are 0.3846, 0.1026 and 0.5128. The diffuse background is the most probable source of a random photon.

Likelihoods from the instrument. The telescope does not report a direction exactly. A photon from a point source at $\boldsymbol{r}_k$ is reconstructed at $\boldsymbol{r}$ with a probability density given by the **point-spread function** [the density of reconstructed directions for a point source, here a 2-D Gaussian of width $\sigma(E)$], which is wide at low energy and narrow at high energy; we take $\sigma(E) = 0.8^\circ\,(E/1\,\mathrm{GeV})^{-0.8}$. The energy of a photon from source k is distributed according to that source's spectrum, a power law $p(E \mid k) \propto E^{-\gamma_k}$ with $\gamma = 2.0$ for the burst, 2.4 for the blazar and 2.6 for the diffuse emission. Direction and energy are independent given the source, apart from the energy dependence of the PSF width, so

$$p(\boldsymbol{r}, E \mid k) \overset{(1)}{=} p(E \mid k)\, p(\boldsymbol{r} \mid E, k) \overset{(2)}{=} \begin{cases} p(E \mid k)\, \dfrac{1}{2\pi\sigma(E)^2} \exp\!\left[-\dfrac{|\boldsymbol{r} - \boldsymbol{r}_k|^2}{2\sigma(E)^2}\right], & k = \mathrm{G}, \mathrm{Bz}, \\ p(E \mid \mathrm{D})\, \dfrac{1}{A}, & k = \mathrm{D}. \end{cases} \tag{5.9}$$

(1) Product rule for densities.
(2) For a point source the direction density is the PSF centred on the source. For the diffuse background every direction in the patch of area $A = 100\,\mathrm{deg}^2$ is equally likely.

Densities as likelihoods. The observation "the photon arrived exactly at $\boldsymbol{r}$ with exactly energy E" has probability zero under every source. What the telescope really reports is "in a small cell $\mathrm{d}^2\boldsymbol{r}\,\mathrm{d}E$ around $(\boldsymbol{r}, E)$", and that has probability $p(\boldsymbol{r}, E \mid k)\,\mathrm{d}^2\boldsymbol{r}\,\mathrm{d}E$. The cell size is the same factor for every source and cancels between the numerator and the denominator of Bayes' theorem. So densities can stand in for probabilities as likelihoods, as long as all of them are densities in the same variables.

Example: one photon. A photon arrives at $\boldsymbol{r} = (0.7°, 0.3°)$ with $E = 2\,\text{GeV}$, between the burst and the blazar and a little closer to the blazar. At this energy the PSF width is 0.4595°. The three likelihoods (5.9) are 0.004776, 0.004006 and 6.629×10^{-5} per deg^2 per GeV. Then

$$\mathrm{P}(\mathrm{G} \mid \boldsymbol{r}, E) \overset{(1)}{=} \frac{0.3846 \times 0.004776}{0.3846 \times 0.004776 + 0.1026 \times 0.004006 + 0.5128 \times 6.629 \times 10^{-5}} \overset{(2)}{=} 0.8051,$$

(1) Bayes' theorem with the three sources as the partition.
(2) Numerically, $1.84 \times 10^{-3} / 2.28 \times 10^{-3}$.

and likewise $\mathrm{P}(\mathrm{Bz} \mid \boldsymbol{r}, E) = 0.18$, $\mathrm{P}(\mathrm{D} \mid \boldsymbol{r}, E) = 0.0149$. The burst wins, and each source's result has a plain reason. The photon is closer to the blazar, so the direction alone slightly favours the blazar. But the burst is nearly four times brighter in this window, which gives it the larger prior, and its harder spectrum makes a 2 GeV photon more probable. The product of prior and likelihood is therefore largest for the burst. The diffuse background was the most probable source before we looked at the photon. It loses because its likelihood is spread evenly over the whole patch: it predicts *this* direction no better than any other.

Figure 5.10 does this for every photon of one simulated window. Photons near the burst are dark (almost surely burst photons), photons far from both point sources are pale (mostly background), and photons between the two point sources are shared. A soft photon far out, at $(-3°, 2°)$ with $E = 0.3\,\text{GeV}$, still has $\mathrm{P}(\mathrm{G} \mid \boldsymbol{r}, E) = 0.4088$: at 0.3 GeV the PSF is about 2° wide, so the burst can put a photon there.

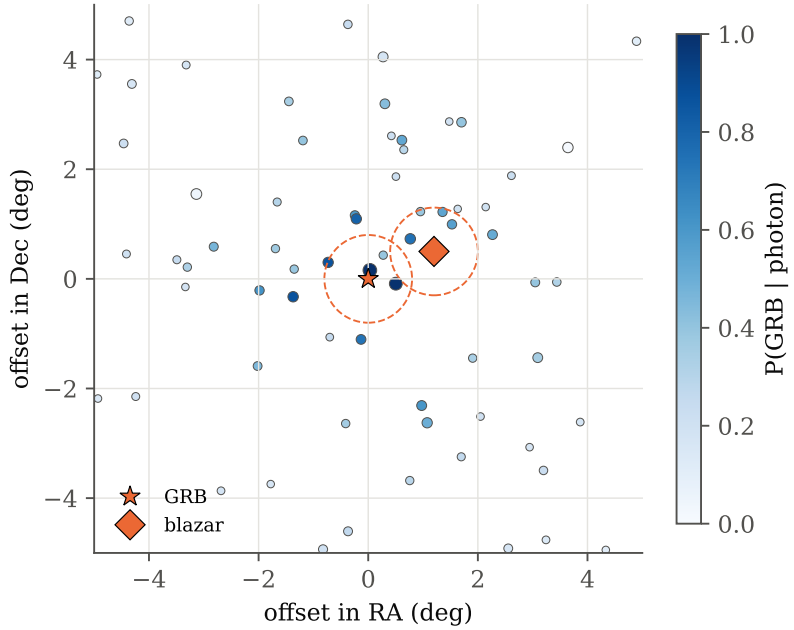

Figure 5.10: One simulated 100 s window of photons around a gamma-ray burst (star), with a blazar nearby (diamond) and a diffuse background. Each dot is a photon, larger for higher energy, shaded by its posterior probability of having come from the burst. The dashed circles have the radius of the point-spread function at 1 GeV. Dark dots cluster on the burst; photons far from both point sources are pale.

Listing 5.2: Posterior source probabilities for a photon (`code/ch05/03_grb_source.py`)

```
def likelihoods(r, E):
    """p(r, E | k) for each source k (columns in SRC order)."""
    return np.stack([p_energy(E, GAMMA["GRB"]) * psf(r, POS["GRB"], E),
                     p_energy(E, GAMMA["blazar"]) * psf(r, POS["blazar"], E),
                     p_energy(E, GAMMA["diffuse"]) / AREA], axis=-1)
```

```
61
62
63 def membership(r, E, use=(0, 1, 2)):
64     prior = np.array([MU[s] for s in SRC])[list(use)]
65     L = likelihoods(r, E)[..., list(use)]
66     w = prior * L
67     return w / w.sum(axis=-1, keepdims=True)
```

Lines 58–60 are the three cases of (5.9), one column per source. Line 66 multiplies each column by its prior (the expected counts; their common normalisation cancels), and line 67 divides by the sum over sources. It works on a whole array of photons at once. Adding the burst column over all photons of the window gives 23.65, an estimate of the number of burst photons; the simulation actually contained 25 of the 68. Such per-photon source probabilities are used in gamma-ray astronomy to weight photons when searching for pulsations or transients, so that background photons dilute the signal less.

5.4 Odds and the likelihood ratio: evidence as a multiplier

A search for a rare process uses a boosted decision tree, a classifier that gives every event a score x between 0 and 1. Signal events tend to score high, background events low, and both distributions are known from simulation. Before we look at its score, an event is signal with probability π, the signal fraction of the sample. Then one event scores $x = 0.9$. How probable is it that this event is signal? And how would the answer change in another analysis with the same classifier but a hundred times less signal?

The answer splits into two factors. One depends only on the classifier and the score. The other depends only on the sample. The second question then needs no new work: we keep the first factor and change the second. This split is the odds form of Bayes' theorem, and it gives the simplest working rule for the question "which hypothesis produced this?".

5.4.1 Odds

The **odds** on a hypothesis are its probability divided by the probability of its negation, $O(H) = \mathrm{P}(H)/\mathrm{P}(\neg H)$. Odds and probability carry the same information:

$$O = \frac{p}{1-p} \qquad \Longleftrightarrow \qquad p = \frac{O}{1+O}. \tag{5.10}$$

A probability of $\frac{1}{2}$ is odds 1 ("evens"), 0.9 is odds 9, 0.01 is odds 1/99. More generally, for any two hypotheses H_1, H_2 in a partition, the ratio $\mathrm{P}(H_1)/\mathrm{P}(H_2)$ is the odds of H_1 against H_2.

How do the odds of H_1 against H_2 change when we observe E? Write Bayes' theorem (5.5) for H_1 and for H_2 and divide:

$$\frac{\mathrm{P}(H_1 \mid E)}{\mathrm{P}(H_2 \mid E)} \overset{(1)}{=} \frac{\mathrm{P}(E \mid H_1)\,\mathrm{P}(H_1)/\mathrm{P}(E)}{\mathrm{P}(E \mid H_2)\,\mathrm{P}(H_2)/\mathrm{P}(E)} \overset{(2)}{=} \underbrace{\frac{\mathrm{P}(E \mid H_1)}{\mathrm{P}(E \mid H_2)}}_{\text{likelihood ratio}} \times \underbrace{\frac{\mathrm{P}(H_1)}{\mathrm{P}(H_2)}}_{\text{prior odds}}. \tag{5.11}$$

(1) Bayes' theorem in numerator and denominator.
(2) The evidence $\mathrm{P}(E)$ is common to both and cancels.

We write Λ for the likelihood ratio.

Key idea: Evidence multiplies odds

$$\text{posterior odds} = \Lambda \times \text{prior odds}, \qquad \Lambda = \frac{\mathrm{P}(E \mid H_1)}{\mathrm{P}(E \mid H_2)}.$$

The **likelihood ratio** Λ is everything the observation has to say about H_1 versus H_2. It does not involve the priors, it does not involve any other hypothesis, and it does not need $\mathrm{P}(E)$.

In the square of Section 5.2 every factor of (5.11) is a ratio of shapes. The prior odds are the ratio of the two strip *widths*. The likelihood ratio is the ratio of the two bar *heights*. Their product, width ratio times height ratio, is the ratio of the two surviving *areas*, which is the posterior odds. Take the medical test of Figure 5.5. The strip widths are $\mathrm{P}(D) = 0.01$ and $\mathrm{P}(D^c) = 0.99$, a ratio of $1 : 99$. The positive result covers 0.95 of the disease strip and 0.10 of the healthy one, a likelihood ratio of $9.5 : 1$. So the surviving areas are in the ratio $9.5 : 99 \approx 1 : 10.4$, and the posterior probability is $1/11.4 \approx 0.088$ by (5.10). The test is good evidence, a factor of 9.5, but it is applied to odds that started at one to ninety-nine.

5.4.2 Evidence adds in logarithms

Take logarithms of (5.11). Products become sums:

$$\log O(H_1{:}H_2 \mid E) = \log \Lambda + \log O(H_1{:}H_2). \tag{5.12}$$

So each piece of evidence *adds* its log likelihood ratio to the log odds. We call $\log \Lambda$ the *weight of evidence*. A convenient unit is the **decibel**: $10 \log_{10}$ of the odds, the same unit physicists use for the gains along an amplifier chain. Odds of $1 : 99$ are -20 dB, evens are 0 dB, odds of $99 : 1$ are $+20$ dB. A positive medical test adds $10 \log_{10} 9.5 = +9.8$ dB. One positive test takes the patient from -20.0 dB to -10.2 dB, which is odds 0.096 and probability 0.088. Suppose a second positive test is taken, independent of the first *given* the disease status (a condition examined in Section 5.5). It adds another 9.8 dB, to -0.4 dB, probability 0.48. A third takes it to $+9.4$ dB, probability 0.90 (Figure 5.11).

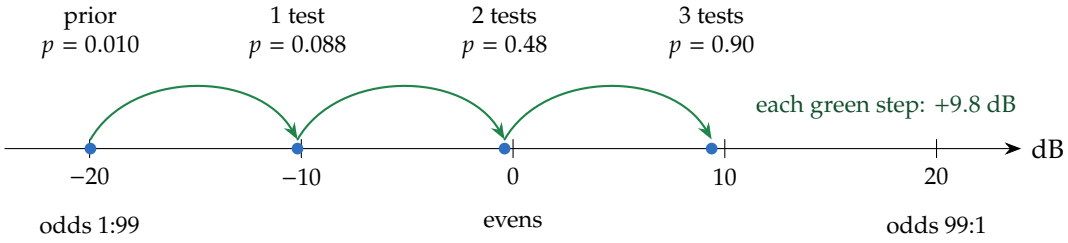

Figure 5.11: The medical test as a walk on a scale of log odds. The prior, one person in a hundred, sits at -20 dB. Each positive result from an independent test adds the same weight of evidence, $10 \log_{10} 9.5 \approx 9.8$ dB. The probability above each dot follows from the odds by $p = O/(1 + O)$: three positive tests are needed before the disease becomes the likely explanation.

The additive form explains two habits of practising physicists. First, analyses add log likelihoods rather than multiply likelihoods, because independent pieces of evidence add in logarithms. Second, "how strong is this evidence?" has an answer that does not depend on the prior: $\log \Lambda$. Whether it is strong *enough* depends on where the prior odds started. A $+10$ dB piece of evidence decides a question that started at evens, and barely dents one that started at -40 dB.

5.4.3 Signal or background, given a classifier score

Back to the boosted decision tree of the opening, which gives each event a score x between 0 and 1, and to the question: given one event's score, is it signal (S) or background (B)? Suppose the simulation shows that signal scores follow the density $f_S(x) = 30\,x^4(1-x)$ and background scores the density $f_B(x) = 30\,x(1-x)^4$ on $[0,1]$ (Figure 5.12, left). Both are Beta densities, Beta(5, 2) and Beta(2, 5); all we need is that each integrates to one, which the factor 30 ensures. The evidence is the score of one event, a continuous quantity, so the likelihoods are densities, and the cell $\mathrm{d}x$ cancels in the ratio exactly as the cell $\mathrm{d}^2\boldsymbol{r}\,\mathrm{d}E$ did for the photon in Section 5.3. The likelihood ratio is

$$\Lambda(x) \overset{(1)}{=} \frac{f_S(x)}{f_B(x)} \overset{(2)}{=} \frac{30\,x^4(1-x)}{30\,x(1-x)^4} \overset{(3)}{=} \left(\frac{x}{1-x}\right)^3. \tag{5.13}$$

(1) Likelihood ratio of signal to background for the observed score.
(2) The two densities.
(3) Cancel 30, one power of x and one power of $(1-x)$.

With prior odds $\pi/(1-\pi)$, the posterior odds are $\Lambda(x)\,\pi/(1-\pi)$. In logarithms, with the **logit** $\operatorname{logit} p = \ln[p/(1-p)]$ [the natural log of the odds],

$$\operatorname{logit} \mathrm{P}(S \mid x) = \operatorname{logit} \pi + 3 \operatorname{logit} x. \tag{5.14}$$

This is the split promised at the start. The score contributes a term, $3 \operatorname{logit} x$, that depends only on the classifier. The sample contributes a term, $\operatorname{logit} \pi$, that depends only on the signal fraction π.

Example: the same score in two analyses. For $x = 0.9$ the likelihood ratio is $9^3 = 729$. With $\pi = 0.01$ the prior odds are $1/99$, the posterior odds $729/99 = 7.36$, and

$$\mathrm{P}(S \mid x = 0.9) \overset{(1)}{=} \frac{7.36}{1 + 7.36} = 0.8804.$$

(1) Posterior odds converted to a probability by (5.10).

In the analysis with a hundred times less signal, $\pi = 10^{-4}$, the likelihood ratio is unchanged and only the prior odds change. The same score gives posterior odds $729/9999 = 0.073$, so $\mathrm{P}(S \mid x = 0.9) = 0.06795$. Same event, same classifier, and now it is probably background. A score of 0.8 is weaker evidence, $\Lambda = 4^3 = 64$, and gives only 0.3926 at $\pi = 0.01$. The score at which an event becomes more likely signal than not, $\mathrm{P}(S \mid x) = \frac{1}{2}$, is where $3 \operatorname{logit} x = -\operatorname{logit} \pi$: $x_{1/2} = 0.8223$ for $\pi = 0.01$ and 0.9556 for $\pi = 10^{-4}$ (Figure 5.12, right).

Checking it by selection. We can check the formula without algebra, because conditioning on an observation is the same as selecting the events that show it (Chapter 1). The script `code/ch05/04_bdt_posterior.py` generates 10^7 events with $\pi = 0.01$, draws each event's score from f_S or f_B, keeps the 2238 events with $|x - 0.9| < 0.005$, and counts the signal among them: the fraction is 0.882 ± 0.006818, against 0.8804 from (5.14). Bayes' theorem is the statement of what this selection returns.

5.4.4 Be exact about what you observed

A score and a cut are different observations, and they give different answers. The dotted curve in Figure 5.12 shows the cut. Suppose we do not look at each event's score but select all events

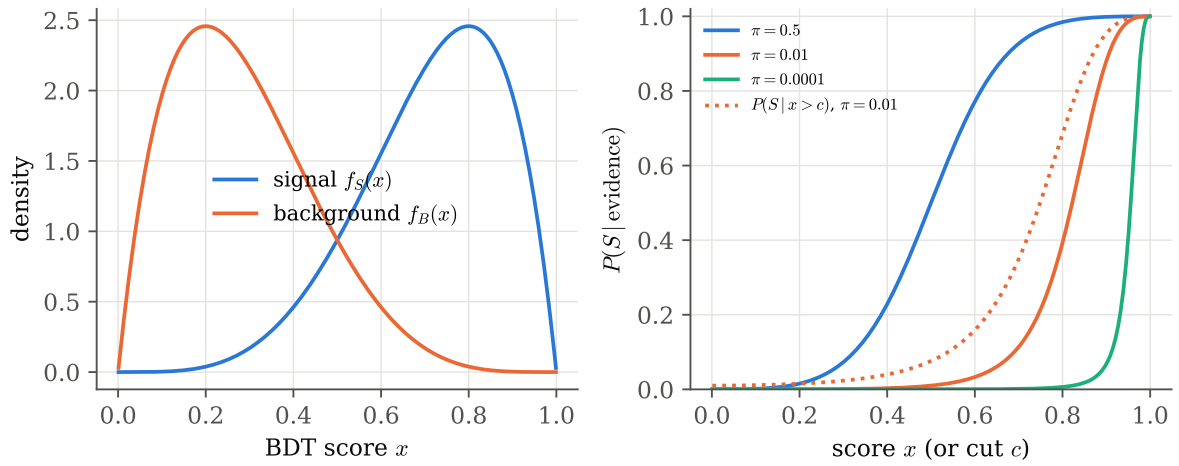

Figure 5.12: Left: the score densities of signal and background. Right: the probability that an event is signal given its score x, for three signal fractions π (solid). The curves are the same likelihood ratio combined with different prior odds, so they are shifted copies of one another on the logit scale. The dotted curve is a different question: the signal fraction of the whole sample with $x > c$, plotted against the cut c, for $\pi = 0.01$.

with $x > c$ and ask for the signal fraction of the selected sample, its **purity**. The observed event is now "$x > c$", whose probability under each hypothesis is an efficiency, $\varepsilon_S(c) = \int_c^1 f_S \, \mathrm{d}x$ and $\varepsilon_B(c) = \int_c^1 f_B \, \mathrm{d}x$. For $c = 0.8$ these are 0.3446 and 0.0016, so

$$\Lambda(x > 0.8) \overset{(1)}{=} \frac{\varepsilon_S}{\varepsilon_B} = 215.4, \qquad \mathrm{P}(S \mid x > 0.8) \overset{(2)}{=} 0.6851.$$

(1) The likelihood ratio of the event "$x > 0.8$" is the ratio of the probabilities of that event, the two efficiencies.

(2) Posterior odds 215.4/99, converted with (5.10).

This is much larger than $\mathrm{P}(S \mid x = 0.8) = 0.3926$. Why? The selected sample contains all the events with x between 0.8 and 1. Most of them score well above 0.8, and their scores are much stronger evidence. An event that sits exactly at the cut is among the *least* signal-like in the sample. Bayes' theorem conditions on exactly the statement we say we know, nothing more. "The score is 0.8" and "the score is above 0.8" are different observations with different likelihood ratios, and mixing them is a common error in quoting per-event probabilities.

Why the likelihood ratio is the right score. For two hypotheses, (5.11) says that the posterior depends on the data only through Λ. Any two events with the same Λ are equally signal-like, whatever else differs between them. This is the Bayesian face of the Neyman–Pearson lemma of Chapter 4: the most powerful selection at any background rejection is a cut on Λ. A classifier whose score is a monotonic function of Λ is already optimal, and our score is one, since $(x/(1-x))^3$ increases with x.

How this is used in real research: The likelihood-ratio trick

A classifier trained with balanced samples of simulated signal and background, and a loss such as the cross-entropy, learns in the limit of enough data and flexibility to output $s(x) = \mathrm{P}(S \mid x)$ at $\pi = \frac{1}{2}$, that is $s = \Lambda/(1+\Lambda)$. Then $\Lambda(x) = s/(1-s)$ is recovered from the output, and (5.11) converts it to the posterior for the actual signal fraction of any sample. The same trick turns classifiers into estimators of likelihood ratios between two parameter

points, which is how simulation-based inference compares hypotheses whose likelihoods cannot be written down.

5.5 Sequential updating: yesterday's posterior is today's prior

We find a coin on the pavement and want to know how biased it is. We toss it once and it lands heads. It is tempting to say that one toss tells us nothing. It tells us something: the coin is not two-tailed, a possibility that was open a moment ago, and coins that favour heads are now a little more credible than before [SeeingTheory p. 53]. We toss again, and again. Each toss should move our belief a little more, starting from wherever the previous tosses left it. Is that legitimate? Do we get the same answer as if we had waited for all the tosses and analysed them at once? And does it matter in which order the tosses came?

5.5.1 The update rule

Let D_1 be the first piece of data and D_2 the second. Everything we know after both is $\mathrm{P}(H \mid D_1, D_2)$. The question is whether we can reach it in two steps: first update on D_1, then update the result on D_2. To see, apply Bayes' theorem to D_2 alone, with D_1 added to the background information of every probability:

$$\mathrm{P}(H \mid D_1, D_2) \overset{(1)}{=} \frac{\mathrm{P}(D_2 \mid H, D_1)\ \mathrm{P}(H \mid D_1)}{\mathrm{P}(D_2 \mid D_1)} \tag{5.15}$$

$$\overset{(2)}{=} \frac{\mathrm{P}(D_2 \mid H)\ \mathrm{P}(H \mid D_1)}{\sum_j \mathrm{P}(D_2 \mid H_j)\ \mathrm{P}(H_j \mid D_1)}. \tag{5.16}$$

(1) Bayes' theorem (5.3) with $X = H$, $Y = D_2$ and background information I replaced by "I and D_1". Every rule of probability holds with extra information in the conditioning, since $\mathrm{P}(\cdot \mid D_1)$ is itself a probability [Sivia §1.2].

(2) *If* D_2 is independent of D_1 given each hypothesis, $\mathrm{P}(D_2 \mid H_j, D_1) = \mathrm{P}(D_2 \mid H_j)$. The denominator is then the marginalisation (5.4) over the H_j, done inside $\mathrm{P}(\cdot \mid D_1)$.

Line (5.16) is Bayes' theorem for D_2 alone, with the posterior after D_1 in the place of the prior. So the answer is yes: the posterior of one step is the prior of the next. This needs one condition, that the data are **conditionally independent** [independent once the hypothesis is fixed, although not independent when the hypothesis is unknown]. Line (5.15) needs no assumption at all.

The order does not matter. Doing D_2 first and D_1 second must give the same answer. Both routes compute the probability of H given the *single* statement "D_1 and D_2", and "D_1 and D_2" is the same statement as "D_2 and D_1". The formula shows the same thing. Under conditional independence, doing the two updates in one go gives [Kruschke §5.2.1]

$$\mathrm{P}(H \mid D_1, D_2) \overset{(1)}{=} \frac{\mathrm{P}(D_1, D_2 \mid H)\ \mathrm{P}(H)}{\sum_j \mathrm{P}(D_1, D_2 \mid H_j)\ \mathrm{P}(H_j)} \overset{(2)}{=} \frac{\mathrm{P}(D_1 \mid H)\ \mathrm{P}(D_2 \mid H)\ \mathrm{P}(H)}{\sum_j \mathrm{P}(D_1 \mid H_j)\ \mathrm{P}(D_2 \mid H_j)\ \mathrm{P}(H_j)}$$

$$\overset{(3)}{=} \frac{\mathrm{P}(D_2 \mid H)\ \mathrm{P}(D_1 \mid H)\ \mathrm{P}(H)}{\sum_j \mathrm{P}(D_2 \mid H_j)\ \mathrm{P}(D_1 \mid H_j)\ \mathrm{P}(H_j)} \overset{(4)}{=} \mathrm{P}(H \mid D_2, D_1).$$

(1) Bayes' theorem for the combined data.

(2) Conditional independence: the joint likelihood is the product.

(3) Multiplication of numbers commutes.

(4) Bayes' theorem read backwards, with the data in the other order.

Updating one datum at a time computes the same product in stages. Each stage multiplies by one likelihood and renormalises. Renormalising early instead of at the end changes nothing, because a constant factor cancels in the ratio.

Key idea: Sequential updating

For data that are independent given the hypothesis, updating one datum at a time, each posterior serving as the next prior, gives exactly the posterior of updating with all the data at once, in any order. In log-odds form each datum simply adds its log likelihood ratio. Without conditional independence the general rule (5.15) still holds, and the order still does not matter, but each datum's likelihood must then be conditioned on the data before it.

5.5.2 The sample space, toss by toss

A coin is either fair, P(heads) = 0.5, or biased, P(heads) = 0.8, and we give each prior $\frac{1}{2}$. We toss it four times and see H, H, T, H. Figure 5.13 shows two ways of watching the sample space shrink.

The top row keeps the original sample space, drawn as in Figure 1.11: two strips of width $\frac{1}{2}$, the biased coin on the left. After each toss, the evidence "the tosses so far" is a box, and the part of each strip that it covers is the part that survives. The share of the strip it covers is the probability of the whole sequence so far under that coin: 0.8, 0.64, 0.128, 0.1024 for the biased coin and 0.5, 0.25, 0.125, 0.0625 for the fair one. The box only ever shrinks. After all four tosses its area is

$$\mathrm{P}(\mathrm{HHTH}) \overset{(1)}{=} \tfrac{1}{2} \times 0.8^3 \times 0.2 + \tfrac{1}{2} \times 0.5^4 = 0.0512 + 0.03125 = 0.08245,$$

(1) Marginalisation over the two coins, with the product of the four toss probabilities (conditionally independent given the coin) as each likelihood.

the probability, before any toss, of seeing exactly this sequence.

The bottom row blows the surviving box back up to area one after each toss. The dividing line is then the current posterior, which is the prior for the next toss: 0.5, then 0.6154 after H, 0.7191 after HH, 0.5059 after HHT, and 0.621 after HHTH. The box in each rescaled panel is the next toss, covering a share of each strip equal to its likelihood. A head is $0.8/0.5 = 1.6$ times more likely from the biased coin and moves the line right; the tail is $0.2/0.5 = 0.4$ times as likely and moves it back left. Both rows give the same final posterior, $0.0512/0.08245 = 0.621$: renormalising at every step or only at the end is the same calculation.

5.5.3 A grid of biases

Real coins are not limited to two types. The real question is: what is the coin's probability of heads θ, which could be anywhere in $[0, 1]$? Kruschke's answer is to allow a grid of candidate values, say $\theta_j \in \{0, 0.01, \ldots, 1\}$, as if a factory made coins of 101 types, and to treat each θ_j as one hypothesis [Kruschke §5.3]. A single toss y ($y = 1$ for heads, 0 for tails) has the Bernoulli likelihood [Kruschke (5.10)]

$$\mathrm{P}(y \mid \theta_j) = \theta_j^{\,y}(1 - \theta_j)^{1-y}, \tag{5.17}$$

which is θ_j for a head and $1 - \theta_j$ for a tail. Updating is then one line of code:

Listing 5.3: One toss: multiply by the likelihood on the grid and renormalise (`code/ch05/05_coin_grid.py`)

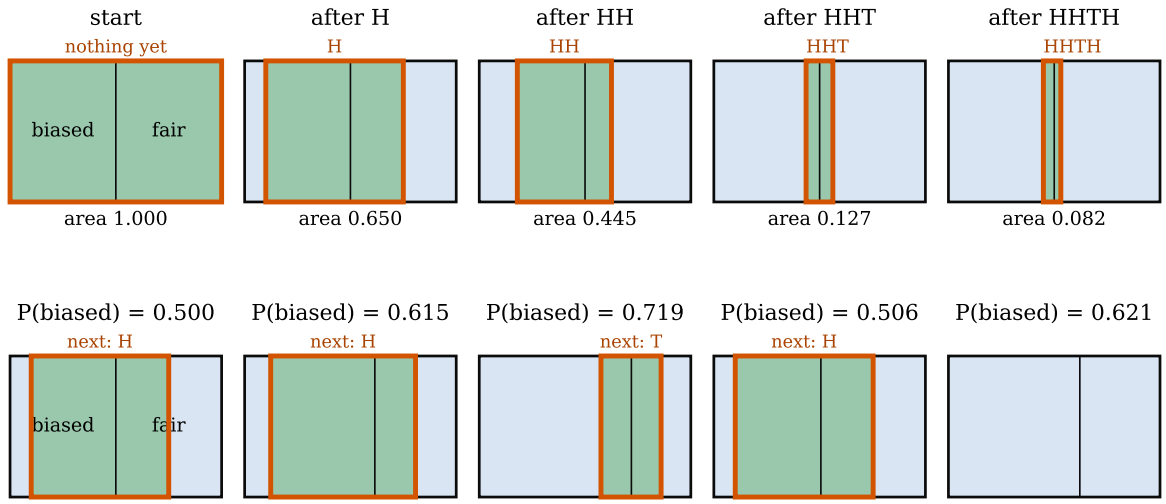

Figure 5.13: The sample space shrinking toss by toss, for a biased coin (left strip) against a fair one (right strip), drawn to scale as in Figure 1.11. Top row: the original sample space, with the tosses so far as a box (orange outline) that covers 0.8 or 0.5 of each strip per head and 0.2 or 0.5 per tail; the number under each panel is the area of the box, the probability of the sequence so far. Bottom row: the surviving box rescaled to area one, so that the dividing line is the current posterior of the biased coin; the box drawn in it is the next toss (the last panel has no next toss).

```
34 def update(prior, y):
35     """One toss y (1 = heads, 0 = tails): multiply by the Bernoulli likelihood,
       renormalise."""
36     post = prior * (theta if y == 1 else 1 - theta)
37     return post / post.sum()
```

Line 36 multiplies the whole array of credibilities by the array of likelihoods, one value per grid point, and line 37 divides by the sum, the discrete evidence. This is the Bayes box of Section 5.3 with 101 rows, recomputed after each toss.

The main lesson of Figure 5.14 is that with few data the prior matters, and with many data it hardly does. The figure follows 50 tosses of a coin with true $\theta = 0.3$, which produced 16 heads. It starts from two priors. One is flat. The other is triangular, with its peak at $\frac{1}{2}$ and zero at 0 and 1; it encodes the belief that most coins are roughly fair.

Each toss acts in a way we can predict. After one tail, the flat-prior posterior is the straight line $1 - \theta$, because the likelihood of a tail is $1 - \theta$. The coin that always lands heads, $\theta = 1$, is ruled out. After the first head, $\theta = 0$ is ruled out too. As tosses accumulate, the posterior narrows around the observed fraction of heads. The two posteriors move towards each other, and after 50 tosses they nearly coincide; the flat-prior posterior has mean 0.3269. So with few data the posterior is a compromise between prior and likelihood, and with many the likelihood dominates [Kruschke §5.3.1–5.3.2]. Kruschke's numbers show the same thing on a grid of 1001 values with the triangular prior [Kruschke Fig. 5.2]. One head in 4 tosses gives a posterior mode of 0.4, pulled far from the observed fraction 0.25 towards the prior's peak. Ten heads in 40 tosses give 0.268, close to 0.25.

The script also checks the order claim numerically. It updates the flat prior with the same 50 tosses in 1000 random orders and compares each result with the batch posterior $\propto \theta^z(1-\theta)^{N-z}$ computed in one step (z heads in N tosses, [Kruschke (5.11)]). The largest difference at any grid point is 1.041×10^{-16}, the size of floating-point rounding.

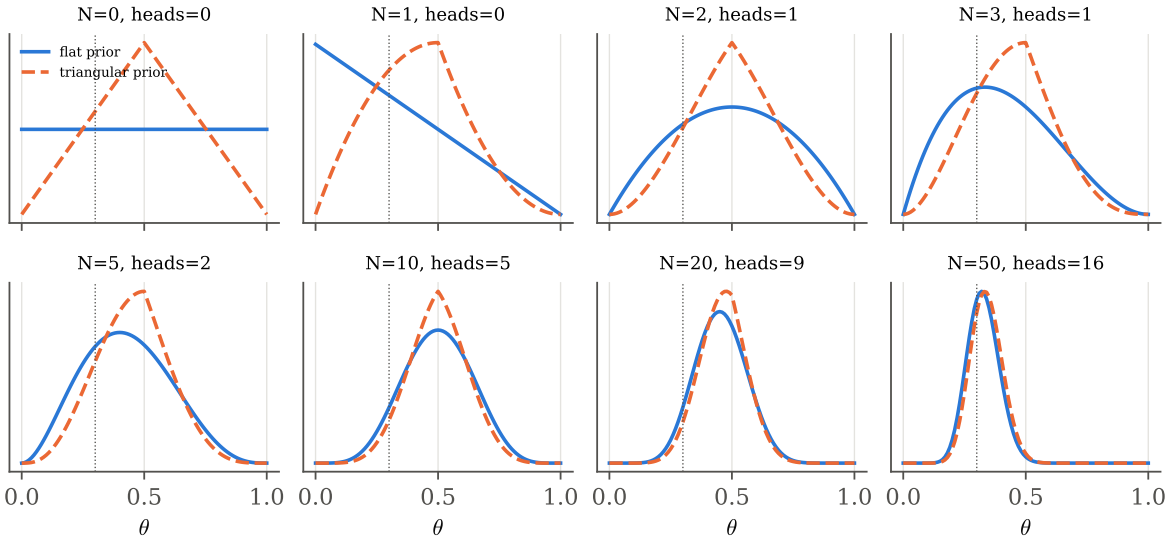

Figure 5.14: Credibility of 101 candidate biases θ after N tosses of a coin whose true bias is 0.3 (dotted line), starting from a flat prior (solid) and from a triangular prior peaked at $\frac{1}{2}$ (dashed). Early on the two posteriors differ, because the data are few; by $N = 50$ both are narrow and nearly identical, centred near the observed fraction of heads.

5.5.4 Evidence accumulates as a random walk

Return to two hypotheses, now a fair coin ($\theta_0 = 0.5$) against a biased one ($\theta_1 = 0.7$), with prior odds 1. By (5.12) the $\log_{10}$ odds of biased against fair add $\log_{10}(0.7/0.5) = 0.1461$ for each head and $\log_{10}(0.3/0.5) = -0.2218$ for each tail. The log odds perform a random walk (Figure 5.15). If the coin really is biased, the average step per toss is

$$\mathbb{E}[\text{step} \mid \theta_1] \overset{(1)}{=} \theta_1 \log \frac{\theta_1}{\theta_0} + (1-\theta_1) \log \frac{1-\theta_1}{1-\theta_0} \equiv D_{\mathrm{KL}}(\theta_1 \| \theta_0), \tag{5.18}$$

(1) A head, with probability θ_1, contributes $\log(\theta_1/\theta_0)$; a tail, with probability $1-\theta_1$, contributes $\log[(1-\theta_1)/(1-\theta_0)]$.

This average step is the **Kullback–Leibler divergence** between the two coins [the average log likelihood ratio in favour of the true distribution; in statistical mechanics it is the relative entropy]. It is never negative, and it is zero only if the two coins are the same. So the walk drifts towards the truth, whichever coin is true. The rate is 0.03574 in $\log_{10}$ per toss when the biased coin is true, and 0.03786 when the fair coin is true. Reaching odds of 100 : 1, which is 2 in $\log_{10}$, therefore takes about $2/0.03574 \approx 56$ tosses on average, with large scatter from one sequence to the next. The more alike the two hypotheses, the smaller the divergence and the longer the wait: telling apart two nearly identical coins, like two nearly identical cosmologies, needs a lot of data.

5.5.5 When the data are not independent given the hypothesis

Conditional independence is an assumption about how the data are produced, and it can fail. When it fails, repeated evidence is worth less than the product of its parts. Take the medical test again (prevalence 0.01, $\mathrm{P}(+ \mid D) = 0.95$, $\mathrm{P}(+ \mid D^c) = 0.10$), and suppose its false positives have two causes. Half of them come from a harmless antibody that 5% of healthy people carry, and it makes the test positive every time. The other half are random, and happen to the other healthy people with probability $r = 0.05/0.95$ per test. The single-test false positive rate is still

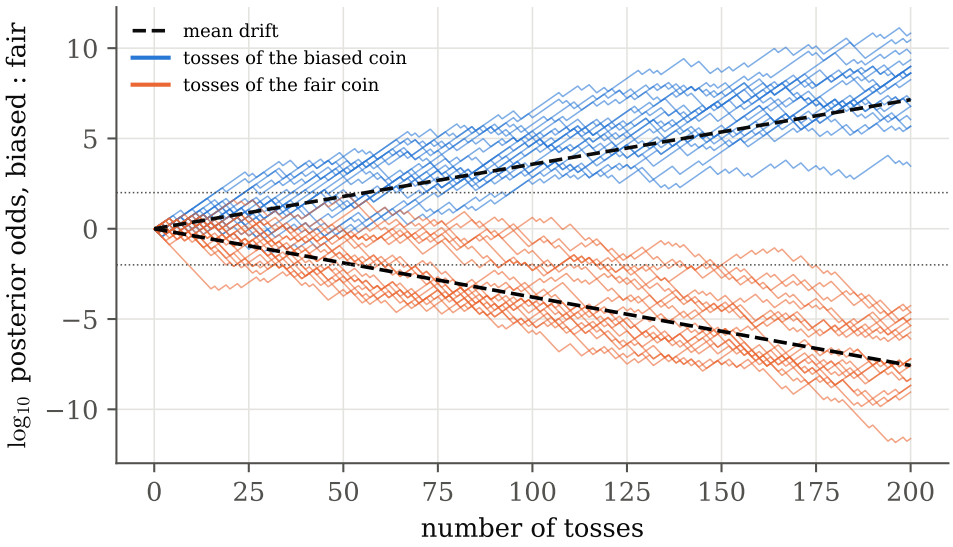

Figure 5.15: Log posterior odds of "biased ($\theta = 0.7$)" against "fair" along 20 simulated sequences of 200 tosses from each coin, starting at odds 1. Every head steps up, every tail steps down. Sequences from the biased coin (blue) drift upward and those from the fair coin (orange) downward, each at the rate given by a Kullback–Leibler divergence (dashed lines). The dotted lines mark odds of 100 : 1 each way.

$0.05 + 0.95\,r = 0.10$. But for a healthy person two positive tests in a row are now much more likely than 0.10^2:

$$\mathrm{P}(++ \mid D^c) \overset{(1)}{=} 0.05 \times 1 + 0.95 \times r^2 = 0.05 + 0.95 \times 0.00277 = 0.0526.$$

(1) Split the healthy population into antibody carriers (both tests positive for sure) and the others (two independent random false positives).

For the diseased we keep independent tests, $\mathrm{P}(++ \mid D) = 0.95^2 = 0.9025$. The likelihood ratio of two positives is $0.9025/0.0526 = 17.1$, not $9.5^2 = 90$. Starting from odds $1/99$, the posterior odds are 0.173 and $\mathrm{P}(D \mid ++) = 0.15$, where the naive product would have given 0.48. The second test is weaker evidence because a large part of what made the first test positive in a healthy person repeats itself.

Watch out: Correlated data are not independent evidence

Multiplying likelihoods, or adding log likelihood ratios, assumes that the data are independent *given* each hypothesis. Repeated measurements that share a calibration offset, a common background mismodelling, overlapping sky patches or the same patient-specific cause are correlated even given the hypothesis. Treating them as independent double-counts the shared part and makes the evidence look far stronger than it is. The remedy is to write the joint likelihood with its correlations, as a multivariate Gaussian with a full covariance matrix $\mathbf{C}$ does for Gaussian data.

5.5.6 Screening for breast cancer, test by test

A woman of fifty with no symptoms goes for a routine screening mammogram. The result is positive. She is recalled for an ultrasound, and if that is positive too, for a biopsy. After each result she, and her doctor, want to know one thing: how probable is it now that she has cancer? We use round numbers of the right size for this age group, illustrative rather than

taken from a particular study: a **prevalence** [the fraction of women screened at this age who have breast cancer at the time of screening] of 1%; for the mammogram a sensitivity of 0.87 and a specificity of 0.90; for the ultrasound 0.80 and 0.90; for the biopsy 0.95 and 0.99. Sensitivity is $\mathrm{P}(+ \mid C)$, the chance that the test is positive if she has cancer (C); specificity is $\mathrm{P}(- \mid C^c)$, the chance that it is negative if she has none (C^c).

There are two hypotheses throughout, C and C^c, and each test redistributes the whole unit of probability between them. The posterior after one test is the prior for the next, by (5.16), as long as the tests are conditionally independent given her true state; we come back to that assumption at the end.

Test 1: the mammogram. *The event.* What we observed is "the mammogram is positive". Call it M_+.

What could have produced it? The only thing we do not know is whether she has cancer. So there are two explanations: she has cancer and the mammogram detected it, or she has none and the mammogram raised a false alarm.

How probable was the event under each hypothesis?

- Under C the mammogram is positive when it detects the tumour, which is the sensitivity: $\mathrm{P}(M_+ \mid C) = 0.87$.
- Under C^c it is positive only by a false alarm, from dense tissue, a benign lump or a shadow: $\mathrm{P}(M_+ \mid C^c) = 1 - 0.90 = 0.10$.

Only then the priors, and the update. Before the test her probability of cancer was the prevalence, 0.01, so her prior odds were 1/99. With the odds form (5.11),

$$O(C \mid M_+) \overset{(1)}{=} \frac{\mathrm{P}(M_+ \mid C)}{\mathrm{P}(M_+ \mid C^c)} \cdot \frac{\mathrm{P}(C)}{\mathrm{P}(C^c)} \overset{(2)}{=} \frac{0.87}{0.10} \cdot \frac{0.01}{0.99} = \frac{8.7}{99} = 0.0879, \qquad \mathrm{P}(C \mid M_+) \overset{(3)}{=} \frac{0.0879}{1.0879} = 0.0808.$$

(1) Posterior odds are the likelihood ratio times the prior odds.
(2) The two likelihoods just found, and the prevalence.
(3) Odds back to probability, (5.10).

A positive mammogram leaves her with about an 8% chance of cancer. The positive result is 8.7 times more probable if she has cancer, but cancer was 99 to 1 against, and 8.7 times 1/99 is still about 1 to 11. The low base rate is the whole reason: among a hundred women screened, about one has cancer and is very likely to test positive, while about ten of the ninety-nine healthy women test positive too. This is the picture of Figure 5.5, drawn for the mammogram's numbers in the first panel of Figure 5.17.

A positive and a negative result do not carry the same information. For any test, write the odds update for each result:

$$O(C \mid +) \overset{(1)}{=} \frac{\mathrm{P}(+ \mid C)}{\mathrm{P}(+ \mid C^c)}\, O(C) = \underbrace{\frac{\text{sens}}{1 - \text{spec}}}_{\mathrm{LR}_+}\, O(C), \qquad O(C \mid -) \overset{(2)}{=} \frac{\mathrm{P}(- \mid C)}{\mathrm{P}(- \mid C^c)}\, O(C) = \underbrace{\frac{1 - \text{sens}}{\text{spec}}}_{\mathrm{LR}_-}\, O(C).$$

(1) (5.11) with $E = +$; $\mathrm{P}(+ \mid C^c) = 1 - \mathrm{P}(- \mid C^c)$.
(2) (5.11) with $E = -$; $\mathrm{P}(- \mid C) = 1 - \mathrm{P}(+ \mid C)$.

These two numbers are the **positive and negative likelihood ratios** of the test. For the mammogram $\mathrm{LR}_+ = 8.70$ and $\mathrm{LR}_- = 0.144$: a positive multiplies the odds by 8.7, a negative

divides them by 6.9. They are not reciprocals, and they are controlled by different numbers. LR_+ is large when the false-alarm rate $1 - \text{spec}$ is small, so a highly specific test is good at confirming (the biopsy has $\mathrm{LR}_+ = 95.0$). LR_- is small when the miss rate $1 - \text{sens}$ is small, so a highly sensitive test is good at excluding. On the probability scale the low prior sharpens the asymmetry: a negative mammogram would have moved her from 1% to 0.00146, less than one percentage point, while the positive moved her to 8%.

Test 2: the ultrasound. *The event.* The ultrasound is positive, U_+.

What could have produced it? The same two explanations, but their weights are no longer 0.01 and 0.99. They are the posteriors after the mammogram, 0.0808 and $1 - 0.0808$: the first result is now part of the prior.

How probable was the event under each? Under C, $\mathrm{P}(U_+ \mid C) = 0.80$. Under C^c, $\mathrm{P}(U_+ \mid C^c) = 0.10$, provided the ultrasound's false alarms have nothing to do with the mammogram's once her state is fixed. So $\mathrm{LR}_+ = 8.00$, and

$$O(C \mid M_+, U_+) \overset{(1)}{=} 8.0 \times 0.0879 = 0.703, \qquad \mathrm{P}(C \mid M_+, U_+) = \frac{0.703}{1.703} = 0.413.$$

(1) The update (5.16) in odds form: the posterior odds after the mammogram are the prior odds for the ultrasound.

A second positive multiplies the odds again, and she is now at about 41%. Had the ultrasound been negative, its $\mathrm{LR}_- = 0.222$ would have pulled the odds down by a factor 4.5, to 0.0195 and $\mathrm{P}(C) = 0.0192$. One positive and one negative do not cancel: $8.7 \times 0.222 = 1.93$, so she would still be about twice as likely to have cancer as before screening.

Test 3: the biopsy. *The event.* The biopsy is positive, B_+.

What could have produced it? The same two explanations, now weighted by the posterior after two positive images, odds 0.703.

How probable was the event under each? A pathologist looking at the tissue finds the cancer with probability 0.95 if it is there, and reports cancer in healthy tissue with probability 0.01. So $\mathrm{LR}_+ = 0.95/0.01 = 95$.

The update. The odds become $95 \times 0.703 = 66.8$, and $\mathrm{P}(C \mid M_+, U_+, B_+) = 0.9852$. A negative biopsy instead would give odds $0.703 \times 0.0505 = 0.0355$ and $\mathrm{P}(C) = 0.0343$. That is still above the prevalence, which is why a negative biopsy after two positive images is often repeated.

Figure 5.16 shows all eight sequences of results at once, and Figure 5.17 the sample space re-drawn before each test along the path +, +, +, with the current posterior as the width of the cancer strip. The calculation is one function, called once per test:

Listing 5.4: One test is one Bayes update; three tests are three updates in a row (`code/ch05/30_screening.py`)

```
32 def update(p, sens, spec, result):
33     """One test: multiply by the likelihood of the result under {cancer, no cancer},
       renormalise."""
34     likes = [sens, 1 - spec] if result == "+" else [1 - sens, spec]
35     return posterior([p, 1 - p], likes)[2][0]
36
37
38 def lr(sens, spec):
39     return sens / (1 - spec), (1 - sens) / spec
40
41
42 # ---------- every sequence of results ----------
```

```
paths = {}
for res in itertools.product("+-", repeat=3):
    p, traj = prev, [prev]
    for (name, se, sp), r in zip(tests, res):
        p = update(p, se, sp, r)
        traj.append(p)
    paths["".join(res)] = traj
```

Line 34 picks the likelihoods of the observed result under C and C^c, line 35 is Bayes' theorem through `posterior` of `lib_area.py` (Section 5.2.5), and lines 44–49 feed each posterior into the next test for every one of the 2^3 sequences. The script also simulates 4×10^6 women, gives each a true state and three test results, and keeps those with the observed results, conditioning by filtering as in Chapter 1. The fraction with cancer among them is 0.0805 after M_+, 0.413 after M_+U_+ and 0.9847 after all three, agreeing with the exact values within the Monte Carlo error.

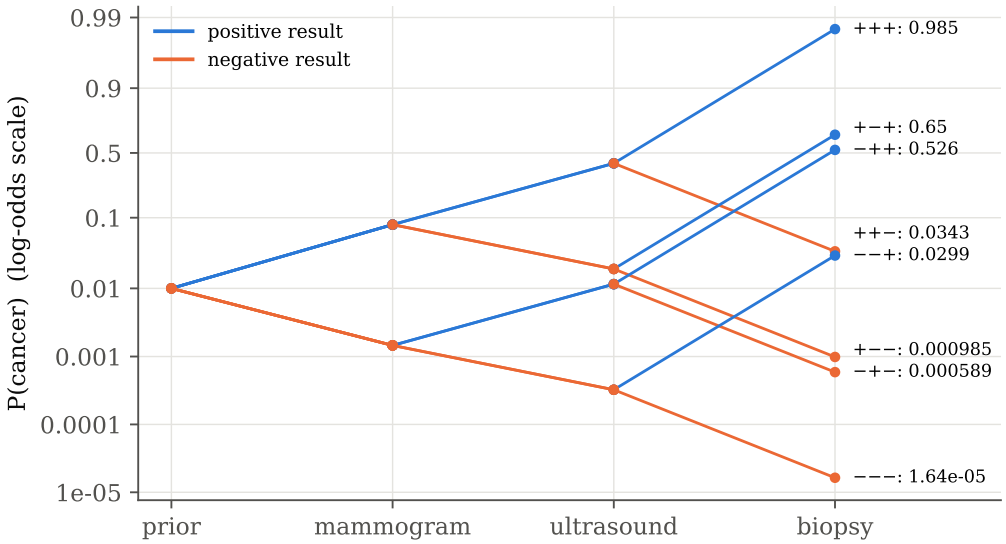

Figure 5.16: The probability of cancer after each test, for every sequence of results, on a log-odds axis, where each test moves the curve by the same step whatever came before. A positive (blue) steps up by $\log_{10} \mathrm{LR}_+$, a negative (orange) down by $\log_{10} \mathrm{LR}_-$; the end labels give the final probability for each sequence. The biopsy's steps are much longer than the imaging tests', because its likelihood ratios are much further from one.

The assumption behind the multiplication. Multiplying the odds by each test's likelihood ratio assumes that the tests are independent given her true state. For a healthy woman this says that a false alarm on the mammogram makes a false alarm on the ultrasound neither more nor less likely. That can fail: two imaging tests can be fooled by the same thing, since a benign lump or very dense tissue may look suspicious to both. Model it as for the antibody in the previous subsection. Say 5% of healthy women carry such a feature and test positive on both. The rest have independent false alarms at the rate $r = 0.05/0.95$, chosen so that each test alone still has false-positive rate 0.10. Then three numbers change: $\mathrm{P}(M_+U_+ \mid C^c) = 0.05 + 0.95\,r^2 = 0.0526$ instead of 0.01; the pair of positives has likelihood ratio $0.87 \times 0.80/0.0526 = 13.2$ instead of $8.7 \times 8.0 = 70$; and her probability after two positive images is 0.118 (simulation 0.119), not 0.413. The second positive is worth less, because much of what made the first one positive in a healthy woman repeats itself. The biopsy examines the tissue itself, a different failure mode altogether, which is why it is the test that settles the question.

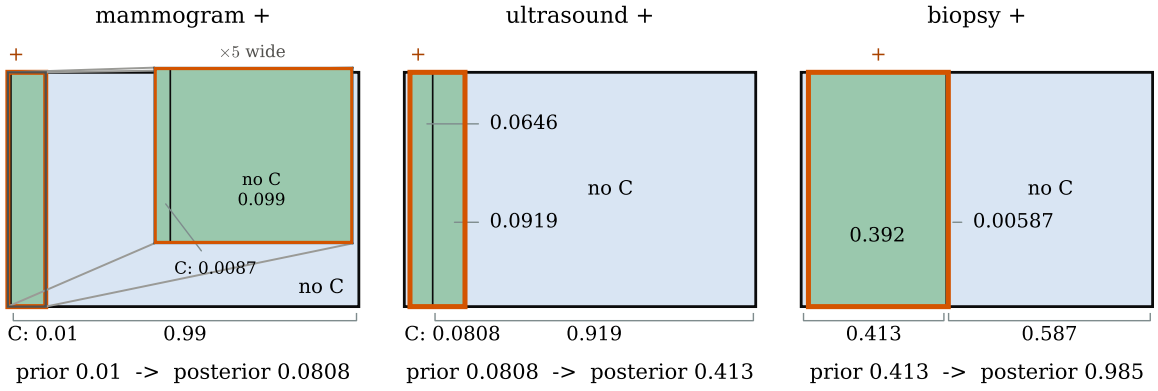

Figure 5.17: The sample space re-drawn before each test along the path +, +, +, in the box picture of Figure 1.11, with the function of Section 5.2.5. In each panel the width of the cancer strip (C) is the current prior, and the positive result is the box (orange outline): it covers the sensitivity's share of the C strip and the false-alarm rate's share of the other, and the numbers are the areas of its two pieces. Before the mammogram the cancer strip is 1% of the width (magnified in the inset); after it, the posterior 0.081 becomes the width of the strip for the ultrasound, and after the ultrasound, 0.41 becomes the width for the biopsy.

Problem. In a younger screening population the prevalence is 0.5%. Test A has sensitivity 0.90 and specificity 0.92; test B has sensitivity 0.85 and specificity 0.95. (a) Assuming the tests are conditionally independent, find $\mathrm{P}(C \mid A_+, B_+)$ and $\mathrm{P}(C \mid A_+, B_-)$. (b) How many independent positive results of test A are needed for the probability of cancer to exceed 95%? (c) Now suppose that 3% of healthy women carry a benign feature that makes both A and B positive, while the other healthy women have independent false positives at rates chosen so that each test alone keeps its specificity. Redo (a), and say why the answers moved.

Solution. (a) The prior odds are $O_0 = 0.005/0.995 = 0.005025$. The likelihood ratios are $\mathrm{LR}^A_+ = 0.90/0.08 = 11.25$, $\mathrm{LR}^B_+ = 0.85/0.05 = 17.0$ and $\mathrm{LR}^B_- = 0.15/0.95 = 0.1579$. Then

$$O(C \mid A_+, B_+) \overset{(1)}{=} \mathrm{LR}^B_+ \, \mathrm{LR}^A_+ \, O_0 = 17.0 \times 11.25 \times 0.005025 = 0.9611, \quad \mathrm{P}(C \mid A_+, B_+) \overset{(2)}{=} 0.490,$$

$$O(C \mid A_+, B_-) \overset{(3)}{=} \mathrm{LR}^B_- \, \mathrm{LR}^A_+ \, O_0 = 0.008926, \qquad \mathrm{P}(C \mid A_+, B_-) = 0.00885.$$

(1) Two sequential updates in odds form; conditional independence lets each test enter through its own likelihood ratio.
(2) $p = O/(1+O)$.
(3) The same with the negative ratio of B.

After a positive A alone the probability is 0.0535; a positive B brings it to about one half, while a negative B brings it back to under 1%, still above the prevalence of 0.5%.

(b) After n independent positives of A the odds are $(\mathrm{LR}^A_+)^n O_0$, and 95% means odds of 19:

$$(\mathrm{LR}^A_+)^n \, O_0 \geq 19 \overset{(1)}{\iff} n \geq \frac{\ln(19/O_0)}{\ln \mathrm{LR}^A_+} = \frac{\ln 3781}{\ln 11.25} = 3.40.$$

(1) Take logarithms; $\ln \mathrm{LR}^A_+ > 0$, so the inequality keeps its direction.

So $n = 4$: three positives give 0.877, four give 0.9877. This assumes that repeating test A on the same woman gives independent errors, which for a repeated image of the same breast is exactly the assumption that part (c) questions.

(c) With a fraction $g = 0.03$ of healthy women carrying the feature, the other healthy women must have false-positive rates $q_A = (0.08 - g)/(1 - g) = 0.05155$ and $q_B = (0.05 - g)/(1 - g) = 0.02062$, so that each test alone is unchanged. For a healthy woman,

$$\mathrm{P}(A_+B_+ \mid C^c) \overset{(1)}{=} g + (1-g)\, q_A q_B = 0.03103, \qquad \mathrm{P}(A_+B_- \mid C^c) \overset{(2)}{=} (1-g)\, q_A (1-q_B) = 0.04897,$$

(1) Carriers are positive on both; the others are positive on both by two independent false alarms.
(2) A carrier is never negative on B, so only non-carriers contribute.

while for a woman with cancer nothing changes, $\mathrm{P}(A_+B_+ \mid C) = 0.90 \times 0.85$ and $\mathrm{P}(A_+B_- \mid C) = 0.90 \times 0.15$. The joint likelihood ratios replace the products of (a):

$$\mathrm{P}(C \mid A_+, B_+) \overset{(1)}{=} \frac{O_0 \cdot 0.765/0.03103}{1 + O_0 \cdot 0.765/0.03103} = 0.110, \qquad \mathrm{P}(C \mid A_+, B_-) \overset{(2)}{=} 0.0137.$$

(1) Odds form with the likelihood ratio of the *pair* of results, $0.765/0.03103 = 24.7$, instead of $11.25 \times 17 = 191$.
(2) The same with $0.135/0.04897$.

Both answers moved towards the prior. Two positives are now worth a factor 24.7 rather than 191, because a healthy woman who is positive on A is quite likely to be a carrier (0.03/0.08 of them), and a carrier is positive on B for certain. The negative B is less reassuring for the same reason: among healthy women positive on A, a negative B is now rarer, so it says less about health. The script checks all four numbers by simulation, 0.489, 0.00898, 0.110 and 0.0139.

5.6 The denominator: the sum over all paths

The denominator $\mathrm{P}(E)$ of Bayes' theorem is the model's prediction for the data. So far it has looked like bookkeeping: the number we divide by so that the posteriors add up to one. In the odds form it cancelled altogether. But it is a probability in its own right, and a meaningful one. Recall the trigger problem of Section 5.1, where E was an isolated high-p_T muon and three trigger paths could have fired the event. There $\mathrm{P}(E) = 0.235$. This says that, *before* we looked at the event, the model of the three paths predicted that 23.5% of recorded events would contain such a muon. Suppose a large sample of events showed 60%. No reallocation of credibility among the three paths could explain that. The trouble would lie in the list of paths or in the forward probabilities, not in the priors. The denominator is also the one place in Bayes' theorem that needs every hypothesis at once.

5.6.1 Every path, and only paths

The denominator is the marginalisation (5.4): the sum, over every hypothesis, of the probability of reaching the observation along that hypothesis's path (Figure 5.18),

$$\mathrm{P}(E) = \sum_i \mathrm{P}(E \mid H_i)\ \mathrm{P}(H_i) \quad \text{(discrete)}, \qquad p(\boldsymbol{d}) = \int p(\boldsymbol{d} \mid \theta)\, p(\theta)\, \mathrm{d}\theta \quad \text{(continuous)}. \tag{5.19}$$

In the square of Section 5.2 it is the total surviving area. It does not depend on which hypothesis we are asking about. It depends only on the observation and on the whole list of hypotheses with their priors. Two names are in use: the **evidence**, and the **marginal likelihood**, because it is the likelihood averaged over the hypotheses with the prior as the weight [Kruschke §5.2, (5.8)–(5.9)]. Wasserman calls its continuous version $c_n = \int \mathcal{L}_n(\theta) f(\theta)\, \mathrm{d}\theta$ the **normalizing constant** and notes that it can be dropped and recovered later [Wasserman p. 177, (11.3)].

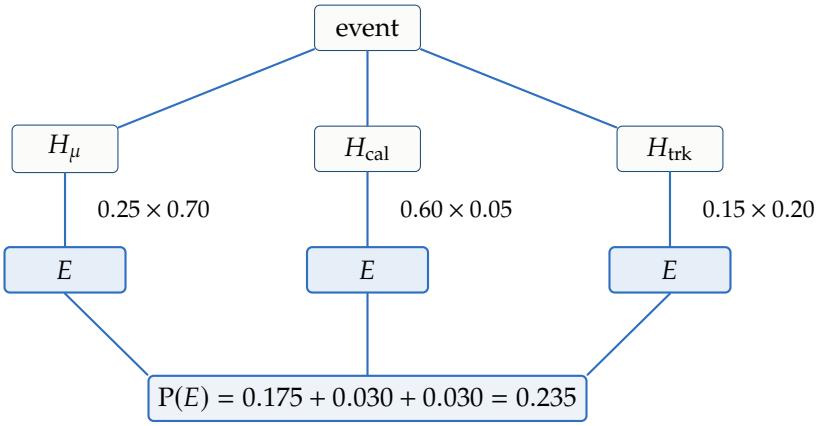

Figure 5.18: The denominator of Bayes' theorem as the sum over paths. Each hypothesis contributes one path from the root to the observed leaf E, with probability equal to the product of its two branch probabilities (written beside the path). The evidence collects all of them. A hypothesis missing from the tree is a path missing from the sum.

5.6.2 The denominator is a prediction

Now read (5.19) as a function of the data rather than as one number. Before the data are taken, ask: how probable is each possible observation E? The answer, $\mathrm{P}(E)$ for every E, is the model's forecast of what we are going to see, averaged over our uncertainty about which hypothesis is true. It is called the **prior predictive distribution** [Lambert §6.3.4]. Unlike the likelihood, it is a genuine probability distribution over the data: summed over all possible observations it gives one, because $\sum_E \mathrm{P}(E \mid H_i) = 1$ for each i and the priors sum to one.

Example: what did we expect from ten tosses? Take the grid of 101 coin biases of Section 5.5 with a flat prior, and ask for the probability of z heads in $N = 10$ tosses before any toss is made. In the continuum limit of the grid, the flat prior density is $p(\theta) = 1$ on $[0, 1]$, and

$$\mathrm{P}(z) \overset{(1)}{=} \int_0^1 \binom{N}{z} \theta^z (1-\theta)^{N-z} \, \mathrm{d}\theta \overset{(2)}{=} \binom{N}{z} \frac{z!\,(N-z)!}{(N+1)!} \overset{(3)}{=} \frac{N!}{z!\,(N-z)!} \cdot \frac{z!\,(N-z)!}{(N+1)!} = \frac{1}{N+1}. \quad (5.20)$$

(1) The evidence (5.19) with the binomial likelihood and the flat prior.

(2) The Beta integral $\int_0^1 \theta^a (1-\theta)^b \, \mathrm{d}\theta = a!\,b!/(a+b+1)!$ for integers $a, b \geq 0$; it follows by integrating by parts b times.

(3) Write out the binomial coefficient; the factorials cancel.

Every number of heads from 0 to 10 was equally expected, with probability $\frac{1}{11} = 0.091$. The 101-point grid gives 0.08993 for $z = 9$, the small difference being the grid's approximation of the integral. A prior concentrated on fair coins predicts something quite different (Figure 5.19). If we are certain that the coin is fair, $\mathrm{P}(z = 9) = \binom{10}{9} 2^{-10} = 0.009766$. The triangular prior sits in between, 0.0604. Each prior predictive sums to one over $z = 0, \ldots, 10$, as the script confirms.

The whole computation is one matrix product:

Listing 5.5: The prior predictive as a sum over paths (`code/ch05/07_evidence.py`)

```
z = np.arange(N + 1)
like = stats.binom.pmf(z[:, None], N, theta[None, :])      # P(z | theta_j), rows z, columns j
pred = {k: like @ p for k, p in priors.items()}            # sum over paths theta_j
```

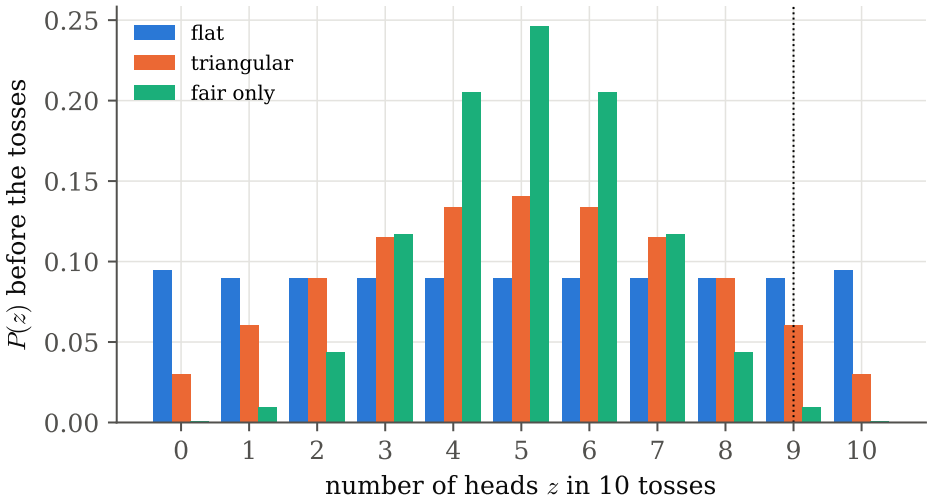

Figure 5.19: The denominator of Bayes' theorem as a forecast. For each of three beliefs about the coin, the bars give the probability of each number of heads in ten tosses, computed before any toss as a sum over all candidate biases. The flat prior spreads its forecast evenly; "the coin is fair" concentrates it near five heads. The dotted line marks the observed nine heads.

Line 34 builds the table of Section 5.1: one row per possible observation z, one column per hypothesis θ_j, entries $\mathrm{P}(z \mid \theta_j)$. Line 35 multiplies it by the vector of priors, which for each row is the sum over the paths θ_j of likelihood times prior.

Now nine heads have been observed. Which model predicted that better? The flat-prior model had given this outcome probability 0.08993, the fair-coin model only 0.009766. So the flat model predicted the observation 9.208 times better. A ratio of two evidences is a likelihood ratio in which each "hypothesis" is a whole model together with its prior. By (5.11) it multiplies the prior odds of one model against the other. This ratio, the *Bayes factor*, is the tool for comparing models, and comparing models is the one job for which the denominator cannot be skipped.

5.6.3 A missing path distorts every posterior

Because the denominator sums over the hypotheses we listed, it silently assumes that the list is complete. If the truth is not on the list, Bayes' theorem still returns posteriors that sum to one, now shared among the wrong candidates. Kruschke's example is the wet pavement caused by something nobody listed [Kruschke §2.2].

Example: forgetting the background. In the gamma-ray example of Section 5.3, the soft photon at $(-3°, 2°)$ had source probabilities 0.4088 (burst), 0.04486 (blazar) and 0.5463 (diffuse background). Suppose we forget the diffuse background and keep only the two point sources. The denominator loses the largest of its three paths, and the same photon now gets 0.9011 for the burst and 0.09887 for the blazar. Nothing in the output warns us: the posteriors still sum to one. The warning is in the denominator itself. Without the background, the model predicts that almost no photons arrive far from the two point sources, so the evidence of a map full of such photons is tiny compared with that of the model with the background. Comparing evidences, or checking whether the most credible hypotheses actually reproduce the data [Kruschke §2.2], is how a missing path is found.

Watch out: A small evidence is not by itself a refutation

Every particular data set has a small probability: any one sequence of ten tosses has probability $2^{-10} \approx 0.001$ under a fair coin. The value of $\mathrm{P}(E)$ alone says little. It becomes informative when compared, either with the evidence of another model for the same data, or with the spread of $\mathrm{P}(E)$ over the data sets the model itself would typically produce.

5.6.4 Why the denominator is the hard part

The denominator is hard because it needs every hypothesis at once, and in many dimensions there are far too many. For a handful of hypotheses the sum (5.19) is trivial. For a continuous parameter it is an integral, which a grid approximates by a sum, as in the 101-point coin grid. For D parameters a grid with n points per axis has n^D points. With $n = 1000$ and $D = 6$, the number of parameters of the standard cosmological model, that is 10^{18} evaluations of the likelihood [Kruschke §5.4], [Lambert §6.4].

There are two ways out. The first is to choose priors that match the form of the likelihood, so that the integral can be done by hand; these *conjugate* priors give posteriors of a known shape. The second is to notice that estimating parameters never needs the denominator at all. It cancels in every ratio of posteriors, exactly as it cancelled in the odds (5.11). A method that only ever compares the posterior at two points, $p(\theta' \mid \boldsymbol{d})/p(\theta \mid \boldsymbol{d}) = p(\boldsymbol{d} \mid \theta')p(\theta')/p(\boldsymbol{d} \mid \theta)p(\theta)$, can explore the posterior without knowing its normalisation. That is the idea behind Markov chain Monte Carlo (Chapter 9) [Lambert §6.5]. Only when models themselves are compared must the evidence be computed, and that needs its own methods.

The trigger paths, the medical test, Monty's door, the urns and the ball sizes were all solved in the same way, and the way is worth making a habit: put the question into words before touching a symbol. First ask: which hypotheses could have produced what we observed? With that list settled, ask: how probable would the observation have been if each of them were true? These two answers sort the whole problem. The first answer says what the posterior is a distribution over, and so fixes the list of paths that the denominator sums over. The second answer is the likelihood: it fixes the height of each bar in the square.

Recap

- Prediction reads $\mathrm{P}(E \mid H)$, inference wants $\mathrm{P}(H \mid E)$. Both come from one joint distribution: a column of the joint table for prediction, the observed row for inference.
- Bayes' theorem is the product rule applied in both orders. Observing E shrinks the sample space to E; each hypothesis is re-measured by its share of the surviving region.
- In the unit square: priors are widths, likelihoods are heights, joint probabilities are areas, the evidence is the surviving area, and the posterior is one surviving rectangle over all of them.
- Base rates matter: evidence covering most of a thin strip (medical test, trigger purity, rare signal) can lose to evidence covering a small share of a wide strip.
- Inference is reallocation of credibility: a zero likelihood eliminates, a zero prior can never be revived, noisy data only nudge.
- Posterior odds = likelihood ratio × prior odds. The likelihood ratio is all the evidence says about two hypotheses; in logarithms, independent evidence adds (decibels, log-odds random walk with drift equal to a Kullback–Leibler divergence).

- Condition on exactly what was observed: "score = 0.8" and "score > 0.8" are different evidence.
- Sequential updating: the posterior becomes the prior; the order of the data does not matter; multiplying likelihoods requires independence given the hypothesis.
- The denominator is the sum over all paths: the normaliser, the prior predictive forecast of the data, and the quantity that compares models. It needs the complete list of hypotheses and is hard to compute in many dimensions, which is why parameter estimation works with ratios of posteriors.

5.7 From a list of hypotheses to a continuous parameter

A theorist hands us a formula. If a parameter λ of nature has a certain value, an instrument should read $\mu(\lambda)$. The parameter could be the mass of a particle, a coupling, a lifetime or the matter density of the universe. The instrument is not perfect, so what it actually reads is the prediction plus some noise. We take one reading, d. Which values of λ could have produced it, and how much credibility should each value get?

We answer it in the same order as the Monty Hall problem (Figure 5.6). *The event.* What we observed is "the instrument showed d". *The question.* What made it show that value? The possible explanations are the possible values of λ, each one a possible state of nature. *Each candidate in turn.* For each value of λ we ask how probable the reading d was if that value were the truth. The prediction would then have been $\mu(\lambda)$, so the question is how likely the noise was to push $\mu(\lambda)$ to exactly the d we saw. *Only then the priors, and the normalisation.* We multiply by the prior weight of each value and divide by the total.

This is the question "which urn did the ball come from?" or "is this event signal or background?" with one change. There the candidate explanations formed a short list, $H_1, H_2, \ldots$. Here every real number in some range is a candidate. Bayes' theorem still holds, but three things need care. A probability spread over a continuum is a density. The sum over paths in the denominator becomes an integral. And a computer can evaluate the density only at finitely many points.

5.7.1 The tree, continuous in spirit

Write the reading as prediction plus noise,

$$d = \mu(\lambda) + \epsilon, \qquad \epsilon \sim \mathcal{N}(0, \sigma^2), \tag{5.21}$$

where σ is the known size of the noise. The forward question, prediction, asks: if nature chose λ, what readings would we see, and how often? Its answer is a Gaussian centred on the prediction,

$$p(d \mid \lambda) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{\big(d - \mu(\lambda)\big)^2}{2\sigma^2}\right]. \tag{5.22}$$

Held at the reading we have and read as a function of λ, it is the **likelihood** $\mathcal{L}(\lambda)$, which scores each candidate by the probability of the noise, $d - \mu(\lambda)$, it would have needed (Section 3.8).

The inference question runs the other way, and its picture is a probability tree with one branch per candidate value (Figure 5.20). The first split chooses λ with prior weight $p(\lambda)$. The second step produces the reading, with probability $p(d \mid \lambda)$ along each branch. Every branch can reach the same leaf d, because Gaussian noise can turn any prediction into any reading,

only with very different probabilities. With infinitely many branches the tree cannot be drawn literally, but it can be drawn in spirit: pick three candidates $\lambda_1, \lambda_2, \lambda_3$ and remember that there is one branch for every value in between.

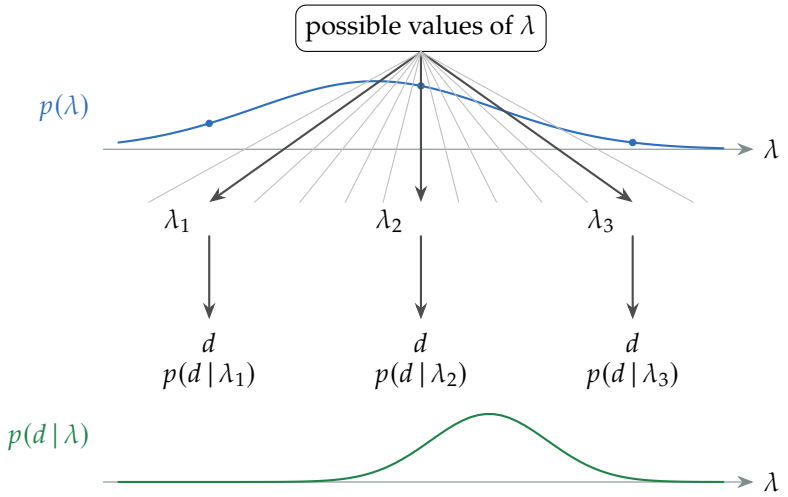

Figure 5.20: The probability tree for a continuous parameter, drawn in spirit. The top curve is the prior density, the weight with which each branch is chosen. Three branches are drawn in full and the faint fan stands for the continuum of branches between them. Every branch can end at the same observed reading d, each with its own probability. The bottom curve collects those probabilities as a function of λ: the likelihood.

Key idea: Parameter estimation is inference with a continuum of explanations

Every candidate value of the parameter λ is one possible explanation of the data. The reading d is the event that actually happened. The likelihood $\mathcal{L}(\lambda) = p(d \mid \lambda)$ measures, value by value, how easily that λ could have produced the event.

5.7.2 From a sum over branches to a density

What does Bayes' theorem become when the hypotheses form a continuum? We reduce the question to the case we already know, a finite list. Chop the λ axis into cells of small width $\Delta\lambda$, centred on the points λ_j, and call "λ lies in cell j" hypothesis H_j. Exactly one cell contains the true value, so these hypotheses are a partition and the discrete theorem applies to them. The prior probability of cell j is $\mathrm{P}(H_j) \approx p(\lambda_j)\,\Delta\lambda$, because a density times a small width is a probability. Then

$$\begin{aligned} \frac{\mathrm{P}(H_j \mid d)}{\Delta\lambda} &\overset{(1)}{=} \frac{1}{\Delta\lambda}\,\frac{p(d \mid \lambda_j)\,p(\lambda_j)\,\Delta\lambda}{\sum_k p(d \mid \lambda_k)\,p(\lambda_k)\,\Delta\lambda} \\ &\overset{(2)}{=} \frac{p(d \mid \lambda_j)\,p(\lambda_j)}{\sum_k p(d \mid \lambda_k)\,p(\lambda_k)\,\Delta\lambda} \\ &\xrightarrow{\Delta\lambda \to 0} \frac{p(d \mid \lambda_j)\,p(\lambda_j)}{\int p(d \mid \lambda)\,p(\lambda)\,\mathrm{d}\lambda}. \end{aligned} \tag{5.23}$$

(1) Discrete Bayes' theorem for the cells, with the prior probability of each cell written as density times width.

(2) The $\Delta\lambda$ in the numerator cancels the $1/\Delta\lambda$ in front. The one in the denominator stays inside the sum.

Now let the cells shrink. In the denominator each term is multiplied by its width, so the sum is a Riemann sum and becomes an integral. On the left, the probability of a cell divided by its width becomes a probability per unit λ: the **posterior density** $p(\lambda \mid d)$. So the continuous theorem is [Wasserman p. 177, (11.1)]

$$p(\lambda \mid d) = \frac{p(d \mid \lambda)\, p(\lambda)}{p(d)}, \qquad p(d) = \int p(d \mid \lambda)\, p(\lambda)\, \mathrm{d}\lambda. \tag{5.24}$$

The denominator $p(d)$ is the old sum over every path to the observation, now an integral over every branch of the tree in Figure 5.20. It does not depend on λ, so the shape of the posterior is set by the numerator alone [Wasserman p. 177, (11.2)–(11.3)]:

$$p(\lambda \mid d) \;\propto\; \mathcal{L}(\lambda)\, p(\lambda), \tag{5.25}$$

"posterior is proportional to likelihood times prior". The constant is recovered at the end by demanding that $\int p(\lambda \mid d)\, \mathrm{d}\lambda = 1$.

Working definition 5.2 (posterior density)

The **posterior density** of a continuous parameter λ given data d is $p(\lambda \mid d) = \mathcal{L}(\lambda)\, p(\lambda)/p(d)$, where $\mathcal{L}(\lambda) = p(d \mid \lambda)$ is the likelihood [the probability density of the data actually observed, read as a function of λ], $p(\lambda)$ is the prior density [credibility per unit λ before the data], and $p(d)$ is the evidence [the same product integrated over all λ. It makes the posterior integrate to one]. *Operationally:* evaluate $\mathcal{L}(\lambda)p(\lambda)$ at every λ you care about, and divide by its integral. The probability that λ lies between a and b is $\int_a^b p(\lambda \mid d)\, \mathrm{d}\lambda$.

A density is not itself a probability. Its value at a point, say $p(\lambda \mid d) = 3$, means "probability $3\,\Delta\lambda$ for a small cell of width $\Delta\lambda$ around this point", and it carries units of one over the units of λ. Only areas under the curve are probabilities. This matters as soon as we change variables (Section 5.12): the height of a density changes when we stretch the axis, while the probabilities of corresponding intervals do not.

Example: a linear prediction and a flat prior. Let $\mu(\lambda) = \lambda$, so the instrument reads the parameter itself plus noise, and take a prior that is constant, $p(\lambda) = 1/(\lambda_{\max} - \lambda_{\min})$, over a range much wider than σ and containing d. Then

$$p(\lambda \mid d) \overset{(1)}{=} \frac{\mathcal{L}(\lambda)\, p(\lambda)}{\int \mathcal{L}(\lambda')\, p(\lambda')\, \mathrm{d}\lambda'} \overset{(2)}{=} \frac{e^{-(d-\lambda)^2/2\sigma^2}}{\int_{\lambda_{\min}}^{\lambda_{\max}} e^{-(d-\lambda')^2/2\sigma^2}\, \mathrm{d}\lambda'} \overset{(3)}{=} \frac{1}{\sqrt{2\pi\sigma^2}}\, e^{-(\lambda-d)^2/2\sigma^2}.$$

(1) Bayes' theorem (5.24).

(2) The flat prior is the same constant in numerator and denominator and cancels, and so does the factor $1/\sqrt{2\pi\sigma^2}$ of the likelihood.

(3) The range is many σ wide around d, so the integral is, to excellent accuracy, the full Gaussian integral $\int_{-\infty}^{\infty} e^{-u^2/2\sigma^2}\mathrm{d}u = \sqrt{2\pi\sigma^2}$.

The posterior is a Gaussian in λ, centred on the reading d, with width equal to the noise size σ. Values of λ whose prediction lies close to the reading get the most credibility. The formula looks like the likelihood with d and λ swapped, and here it is exactly that. But this is a coincidence of the linear prediction $\mu(\lambda) = \lambda$, as the next example shows.

Example: a rate that depends on the square of a coupling. Many rates in particle physics are proportional to the square of a coupling g: a decay width, a cross-section, an oscillation

probability. Take $\mu(g) = g^2$ in suitable units, with noise $\sigma = 0.1$, and suppose the true coupling is $g = 0.8$. *The event.* One simulated reading came out as $d = 0.6041$. *The question.* Which couplings could have produced it? A coupling g predicts the rate g^2, so the candidates that explain the reading well are those with g^2 close to d. *The candidates.* There are two groups of them, not one: g near $+\sqrt{d}$ and g near $-\sqrt{d}$. The reason is that g and $-g$ predict the same rate, so no reading can tell them apart. *Only then the numbers.* With a flat prior on $g \in [-1.5, 1.5]$,

$$p(g \mid d) \propto \exp\left[-\frac{(d - g^2)^2}{2\sigma^2}\right].$$

This is largest where $g^2 = d$, that is at the *two* points $g = \pm\sqrt{d} = \pm 0.7772$ (Figure 5.21). The function is even in g, so exactly half the posterior probability lies on each side: the computed mass at $g > 0$ is 0.5. *What it means.* The data say "$|g|$ is about 0.7772" and nothing about the sign. The posterior reports this honestly with two peaks; a single "best value with an error bar" could not. If theory tells us that $g > 0$, that is prior information. Put it in the prior, $p(g) = 0$ for $g < 0$, and the posterior becomes the right-hand peak alone, renormalised.
