How fast the symmetric walker comes home. For $p = \frac{1}{2}$ there is an exact statement: the probability of no return by step $2n$ equals the probability $p_{00}(2n)$ of being at the origin at step $2n$. A quick check at $n = 1$: the walker fails to return at step 2 with probability $\frac{1}{2}$, and $p_{00}(2) = \binom{2}{1}\frac{1}{4} = \frac{1}{2}$. The general proof uses the series above once more. Write $u_n = p_{00}(2n)$ and f_n for the probability that the *first* return happens at step $2n$. Being at 0 at step $2n \ge 2$ means a first return at some step $2k \le 2n$ followed, by the Markov property, by being back at 0 after $2n - 2k$ more steps, so $u_n = \sum_{k=1}^{n} f_k u_{n-k}$. Multiply by s^n and sum over n; with $U(s) = \sum_{n\ge0} u_n s^n$ and $F(s) = \sum_{n\ge1} f_n s^n$ this reads $U = 1 + FU$, and the binomial series with $x = s/4$ gives $U(s) = (1-s)^{-1/2}$. Then

$$\sum_{n\ge0} \mathrm{P}(T_{00} > 2n)\, s^n \overset{(1)}{=} \sum_{n\ge0}\Big(1 - \sum_{k=1}^{n} f_k\Big)s^n \overset{(2)}{=} \frac{1-F(s)}{1-s} \overset{(3)}{=} \frac{1}{(1-s)\,U(s)} \overset{(4)}{=} (1-s)^{-1/2} = U(s).$$

(1) No return by step $2n$ means the first return comes later than step $2n$.
(2) $\sum_n s^n = 1/(1-s)$, and $\sum_n s^n \sum_{k\le n} f_k = F(s)/(1-s)$ (each f_k appears in every term with $n \ge k$).
(3) $U = 1 + FU$ gives $1 - F = 1/U$.
(4) $U(s) = (1-s)^{-1/2}$.

Two power series that are equal have equal coefficients, so $\mathrm{P}(T_{00} > 2n) = p_{00}(2n) \simeq 1/\sqrt{\pi n}$ by (9.20), which predicts the returned fraction 0.992 seen in the simulation.

How long until it comes back? Recurrence says that the return happens; it does not say how soon. The **recurrence time** $T_{ii} = \min\{n > 0 : X_n = i\}$ (for $X_0 = i$) has distribution

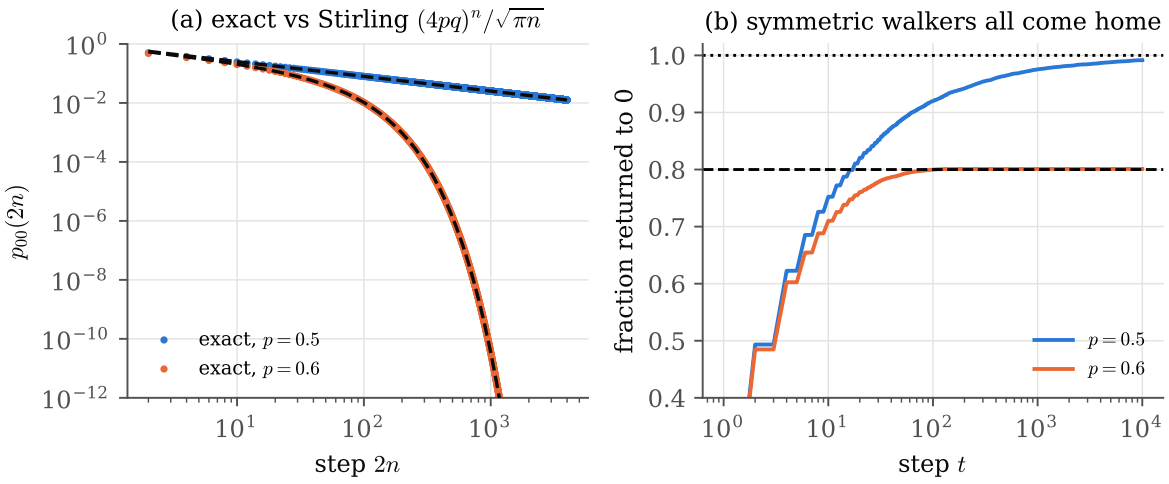

Figure 9.9: (a) The probability of being back at the origin after $2n$ steps: exact (dots) and Stirling's approximation (dashed). The symmetric walk decays only as $1/\sqrt{n}$; a bias of 0.6 makes it decay geometrically. (b) The fraction of 10^4 walkers that have returned to the origin at least once: all of them eventually for the symmetric walk, 80% for the biased one (dashed line).

$f_{ii}(n) = \mathrm{P}(X_1 \neq i, \ldots, X_{n-1} \neq i, X_n = i \mid X_0 = i)$ and the **mean recurrence time** is $m_i = \mathbb{E}(T_{ii}) = \sum_n n f_{ii}(n)$ [Wasserman p. 390]. A recurrent state with $m_i = \infty$ is **null recurrent**; otherwise it is **positive recurrent**.

A mean from the tail. For a waiting time T taking values $1, 2, 3, \ldots$ there is a convenient way to compute the mean. Write T as a count of the steps $k = 0, 1, \ldots, T-1$ before it, $T = \sum_{k\geq 0} I(T > k)$, with I the indicator (1 if true, 0 if not)„ and take expectations term by term (all terms are non-negative):

$$\mathbb{E}(T) = \sum_{k\geq 0} \mathrm{P}(T > k).$$

The mean is finite exactly when the tail probabilities $\mathrm{P}(T > k)$ have a finite sum.

The symmetric walk is null. The symmetric walk on the integers is the standard null-recurrent chain: every walker comes home, but the probability of not yet being home after $2n$ steps is $p_{00}(2n) \simeq 1/\sqrt{\pi n}$, as just shown. Each value $\mathrm{P}(T_{00} > 2n)$ appears twice in the tail sum (for $k = 2n$ and $k = 2n+1$, since returns happen only at even steps), so $\mathbb{E}(T_{00}) \approx \sum_n 2/\sqrt{\pi n}$, which diverges like $\sqrt{n}$. At a null-recurrent state the walker is certain to return, yet the chance of finding it at home at any given late time goes to zero, $p_{ii}(n) \to 0$, because it spends longer and longer excursions away [Wasserman p. 390, Lemma 23.19]; the symmetric walk shows it directly, with $p_{00}(2n) \simeq 1/\sqrt{\pi n}$. We will meet the null walker again as the free diffusion of Section 9.7.

A finite chain has no null states. Take a state i in a closed irreducible class of a finite chain. From every state j of the class some path leads to i, and we may take it of length at most M, the number of states (a shortest path never visits a state twice). Its probability is positive, and since there are only finitely many j, the smallest of these probabilities is some $\varepsilon > 0$. So wherever the walker stands, the chance of reaching i within the next M steps is at least ε, and by the Markov property this holds afresh for each block of M steps. Missing i in k blocks in a row therefore has probability at most $(1-\varepsilon)^k$:

$$\mathrm{P}(T_{ii} > kM) \leq (1-\varepsilon)^k, \qquad m_i = \sum_{n\geq 0} \mathrm{P}(T_{ii} > n) \leq M \sum_{k\geq 0} (1-\varepsilon)^k = \frac{M}{\varepsilon} < \infty,$$

using the tail formula and the fact that $\mathrm{P}(T_{ii} > n)$ can only decrease with n, so each block of M terms is at most M times its first term. A geometric tail leaves no room for the ever-

longer excursions of a null state: in a finite chain every recurrent state is positive recurrent [Wasserman p. 390, Lemma 23.20].

9.3.3 Rhythm: periodicity

The deterministic cycle $1 \to 2 \to 3 \to 1$ (Figure 9.8b),

$$P = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix},$$

started in state 1 is in state 1 at times $0, 3, 6, 9, \ldots$ and never in between [Wasserman p. 390]. The **period** of state i is $d(i) = \gcd\{n \geq 1 : p_{ii}(n) > 0\}$, the greatest common divisor of the possible return times; i is **periodic** if $d(i) > 1$ and **aperiodic** if $d(i) = 1$. Period is a class property: communicating states have the same period (Lemma 23.21). Two quick tests cover most chains met in practice. A single self-loop ($p_{ii} > 0$) makes the period 1, since then 1 is a possible return time. A walk that alternates between two sets, such as ± 1 steps on a ring of even length, has period 2: it returns only after an even number of steps. The politician's chain is aperiodic because every island has $p_{\theta\theta} = 1/(2\theta) > 0$; refused proposals act as self-loops. A "tilted" die that always moves to a neighbouring face round the ring of six faces [Lambert §12.10] has period 2, and we will see in Section 9.6 what that does and does not spoil.

Example: four lakes on a ring. Lambert's marooned fisherman camps each evening beside one of four lakes A, B, C, D joined in a ring [Lambert §13.3]. He wants to fish each lake in proportion to its fish stock, so he uses the politician's rule: flip a coin to propose the clockwise or the anticlockwise neighbour, go there if it holds more fish, and otherwise go with probability equal to the ratio of the stocks. If the four stocks were equal, every proposal would be accepted and he would alternate between $\{A, C\}$ and $\{B, D\}$: period 2. Take stocks in the ratio $1 : 2 : 4 : 3$ (our numbers). Then

$$P = \begin{pmatrix} 0 & \frac{1}{2} & 0 & \frac{1}{2} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{2} & 0 \\ 0 & \frac{1}{4} & \frac{3}{8} & \frac{3}{8} \\ \frac{1}{6} & 0 & \frac{1}{2} & \frac{1}{3} \end{pmatrix}$$

(rows and columns A, B, C, D; for example $p_{CD} = \frac{1}{2} \cdot \frac{3}{4}$ and $p_{CC} = 1 - \frac{1}{4} - \frac{3}{8}$). Lake A has no self-loop, since both neighbours are bigger and every proposal is accepted, but B, C and D have refused proposals, hence $p_{ii} > 0$ and period 1. Communicating states share their period, so the whole chain is aperiodic: unequal stocks break the rhythm that equal stocks would impose. The chain is also irreducible, so it is ergodic, and $\pi = (0.1, 0.2, 0.4, 0.3)$ balances every pair of neighbours (for instance $\pi_A p_{AB} = 0.05 = \pi_B p_{BA}$).

Working definition 9.4 (ergodic state and chain)

A state is **ergodic** if it is recurrent, non-null [finite mean return time] and aperiodic [return times have greatest common divisor 1]. A chain is ergodic if all its states are [Wasserman p. 390, Def. 23.22]. *Operational test for a finite chain:* it is ergodic if and only if it is irreducible and aperiodic, and then some power P^m has every entry strictly positive.

Why some power of P is strictly positive. The operational test in the box rests on a small fact about numbers. Fix a state i and let $R_i = \{n \geq 1 : p_{ii}(n) > 0\}$ be its possible return times.

Return times can be added. If m and n are in R_i, so is $m+n$: by Chapman–Kolmogorov (9.15), $p_{ii}(m+n) = \sum_k p_{ik}(m)p_{ki}(n) \geq p_{ii}(m)\,p_{ii}(n) > 0$, keeping only the term $k = i$ (go round one loop, then the other).

Coprime loops fill in every large number. Aperiodic means $\gcd(R_i) = 1$. Take the simplest case, return times 3 and 5. Adding them in all combinations gives $3a + 5b$ for whole numbers $a, b \geq 0$, and these include $8 = 3+5$, $9 = 3\cdot 3$, $10 = 5\cdot 2$, and then every larger number, because adding 3 to $8, 9, 10$ gives $11, 12, 13$, and so on. Only $1, 2, 4, 7$ are missed. The same holds for any set of positive integers with greatest common divisor 1 that is closed under addition (a classical fact of elementary number theory, of which the $3, 5$ case is the pattern): it contains every integer beyond some N_i. So the walker can return to i in *exactly* n steps for every $n \geq N_i$.

Then go anywhere. For any pair i, j, irreducibility gives a path from i to j of some length ℓ_{ij} with $p_{ij}(\ell_{ij}) > 0$. Waste $N_i + k$ steps looping at i, then take the path:

$$p_{ij}(N_i + k + \ell_{ij}) \geq p_{ii}(N_i + k)\,p_{ij}(\ell_{ij}) > 0 \qquad \text{for every } k \geq 0.$$

One power for all pairs. There are finitely many pairs, so take m larger than every $N_i + \ell_{ij}$. Then $p_{ij}(m) > 0$ for all i, j, which is $P^m > 0$ entrywise. Finally, a finite irreducible chain is automatically positive recurrent (Section 9.3.2, the geometric-tail argument), so irreducible and aperiodic is all the test needs.

Example: six states. Wasserman's Ex. 23.28 has

$$P = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} & 0 & 0 & 0 & 0 \\ \frac{1}{4} & \frac{3}{4} & 0 & 0 & 0 & 0 \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & 0 & 0 \\ \frac{1}{4} & 0 & \frac{1}{4} & \frac{1}{4} & 0 & \frac{1}{4} \\ 0 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2} \\ 0 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2} \end{pmatrix}$$

[Wasserman p. 392]. Rows 1–2 and 5–6 send probability only within $\{1, 2\}$ and $\{5, 6\}$, so these are closed irreducible classes. States 3 and 4 communicate with each other, but the path $3 \to 4 \to 6$ leads into $\{5, 6\}$, from which there is no way back, so 3 and 4 are transient. Every state has a self-loop, so all are aperiodic: 1, 2, 5 and 6 are ergodic, 3 and 4 are transient (Figure 9.8c). The chain as a whole is not irreducible, and its long-run behaviour depends on which closed class swallows the walker.

Irreducible is not the same as ergodic. Some texts say "irreducible (or ergodic)" [Lambert §13.6.2], but these are different conditions. The deterministic 3-cycle is irreducible but periodic, so its distribution at time t never settles; the symmetric random walk on the integers is irreducible and recurrent but null, so it has no equilibrium at all. Irreducibility says the chain can get everywhere; ergodicity adds that it comes back often enough and without a fixed rhythm. The vocabulary of classification, collected:

property	meaning	example
transient	left for good with positive probability	state 3 of Figure 9.8a
null recurrent	returns surely, mean return time infinite	symmetric walk on $\mathbb{Z}$
positive recurrent	returns, finite mean return time	any state of a finite irreducible chain
periodic ($d > 1$)	returns only at multiples of d	deterministic 3-cycle
ergodic	positive recurrent and aperiodic	every island of the politician

9.4 Equilibrium: stationary distributions and detailed balance

Go back to the crowd of independent politicians of Section 9.2.3, all following the island-hopping rule. Suppose that tonight the crowd happens to be spread over the islands in proportion to their populations, a fraction $\theta/28$ on island θ. Tomorrow some of them move east, some west, some stay. Kruschke's "climactic implication" is that the crowd is still spread as $\theta/28$ [Kruschke §7.2.5]: individuals move, the histogram does not. This is what equilibrium means for a random walk, and it is the property that makes the target distribution something a chain can settle into.

The question. Is there a distribution of the walkers that one step of the chain leaves unchanged? If so, is there only one, and how do we find it without solving for it?

Working definition 9.5 (stationary distribution)

A probability vector $\pi = (\pi_1, \dots, \pi_K)$ [non-negative entries that sum to one] is a **stationary** (or invariant) distribution of the chain if

$$\pi = \pi P, \qquad \text{that is} \qquad \pi_j = \sum_i \pi_i \, p_{ij} \quad \text{for every } j. \tag{9.21}$$

It is a left eigenvector of P with eigenvalue 1 [Wasserman p. 390, Def. 23.23]. *Operational recipe:* solve the linear system $\pi(P - \mathbb{1}) = 0$ together with $\sum_i \pi_i = 1$, or compute the left eigenvector of P for eigenvalue 1 and normalise it (`stationary` in `lib_markov.py`).

If the chain starts in a stationary distribution it stays there forever. With $X_0 \sim \pi$, (9.16) gives $p_1 = \pi P = \pi$, $p_2 = \pi P^2 = (\pi P)P = \pi P = \pi$, and by induction $p_n = \pi P^n = \pi$ for all n [Wasserman p. 391]. Each individual walker keeps moving; only the distribution of the crowd is frozen.

A stationary vector always exists for a finite chain, because the eigenvalue 1 always occurs: the rows of P sum to one, which says $P\mathbf{1} = \mathbf{1}$ for the column vector $\mathbf{1}$ of ones, so 1 is an eigenvalue of P, and a matrix and its transpose have the same eigenvalues, so there is also a left eigenvector. That this left eigenvector can be chosen with non-negative entries, and that it is unique when the chain is irreducible, are the content of the Perron–Frobenius theorem; Section 9.5 proves both by a direct argument.

Balance of flows. Think of probability as a conserved fluid on the states, with $\pi_i p_{ij}$ the amount that flows from i to j in one step. Write the stationarity condition (9.21) for state j in two ways, separating in each the part that stays put at j:

$$\pi_j \overset{(1)}{=} \sum_i \pi_i \, p_{ij} = \pi_j \, p_{jj} + \sum_{i \neq j} \pi_i \, p_{ij},$$
$$\pi_j \overset{(2)}{=} \pi_j \sum_k p_{jk} = \pi_j \, p_{jj} + \sum_{k \neq j} \pi_j \, p_{jk}.$$

(1) Stationarity: what is at j tomorrow is what arrives from everywhere, including from j itself; take the $i = j$ term out of the sum.

(2) Row j of P sums to one, so multiplying π_j by that sum changes nothing; take the $k = j$ term out.

The left sides are equal, so the right sides are. Cancel the common term $\pi_j p_{jj}$, the probability that sits at j and stays:

$$\underbrace{\sum_{i\neq j}\pi_i\,p_{ij}}_{\text{flow into } j} \;=\; \underbrace{\sum_{k\neq j}\pi_j\,p_{jk}}_{\text{flow out of } j} \qquad \text{for every } j. \tag{9.22}$$

Stationarity is **global balance**: at every state the inflow equals the outflow, like Kirchhoff's current law at every node of a circuit. It does not say that the flow along each wire vanishes. That stronger statement is detailed balance, below.

Example: Wasserman's weather. For (9.11) the first component of $\pi = \pi P$ reads $\pi_S = 0.4\pi_S + 0.8\pi_C$, so $0.6\pi_S = 0.8\pi_C$, and with $\pi_S + \pi_C = 1$, $\pi = (\frac{4}{7}, \frac{3}{7})$. In the long run four days in seven are sunny. For a general two-state chain with $a = p_{12}$ and $b = p_{21}$ the same two lines give

$$\pi = \Big(\frac{b}{a+b},\ \frac{a}{a+b}\Big), \tag{9.23}$$

the flow balance $\pi_1 a = \pi_2 b$ in disguise: the state that is harder to leave gets more weight.

Example: a three-state weather chain. Our running example of a chain has states sunny (S), cloudy (C) and rainy (R) and

$$P = \begin{pmatrix} 0.6 & 0.2 & 0.2 \\ 0.3 & 0.7 & 0 \\ 0.6 & 0 & 0.4 \end{pmatrix}. \tag{9.24}$$

Cloud tends to persist; rain clears straight to sun, and there is no direct cloud–rain transition in either direction. The three equations of $\pi = \pi P$ are

$$\pi_S = 0.6\pi_S + 0.3\pi_C + 0.6\pi_R, \qquad \pi_C = 0.2\pi_S + 0.7\pi_C, \qquad \pi_R = 0.2\pi_S + 0.4\pi_R.$$

The second gives $\pi_C = \frac{2}{3}\pi_S$, the third $\pi_R = \frac{1}{3}\pi_S$ (the first is then automatic, since the three equations add up to an identity), and normalisation gives

$$\pi = \big(\tfrac{1}{2},\ \tfrac{1}{3},\ \tfrac{1}{6}\big). \tag{9.25}$$

Example: the Hardy–Weinberg law. A gene comes in two types A and a, and each person carries two copies, so people are of genotype AA, Aa or aa [Wasserman p. 392, Ex. 23.29]. Each parent passes on one of its two copies at random, and mates are chosen at random.

The gene pool. Let a population have genotype fractions r (AA), s (Aa) and $1 - r - s$ (aa). Pool all the genes: an AA person contributes two A's, an Aa person one A out of two, so the fraction of A genes in the pool is $g = r + s/2$, and the fraction of a genes is $h = 1 - g$. A child gets one gene from each parent, each an independent draw from the pool, so it is AA with probability g^2, Aa with $2gh$ (an A from either parent) and aa with h^2. Its own genes then carry the fraction $g^2 + \frac{1}{2}(2gh) = g(g + h) = g$ of A: the gene frequency does not change, and from the second generation on the genotype fractions are $(g^2, 2gh, h^2)$, the Hardy–Weinberg law.

One family line. Now follow a single person and their descendants, one child per generation, each child's other parent drawn at random from the population. The genotype of the nth descendant depends only on the genotype of the $(n-1)$th (and on the fixed pool), so it is a Markov chain on $\{AA, Aa, aa\}$. Its rows come from asking what each parent passes on.

- An AA parent always passes A; the mate passes A with probability g. The child is AA with probability g and Aa with h.

- An Aa parent passes A or a with probability $\frac{1}{2}$ each. The child is AA if both pass A, probability $\frac{1}{2}g$; aa if both pass a, probability $\frac{1}{2}h$; and Aa otherwise, probability $\frac{1}{2}h+\frac{1}{2}g=\frac{1}{2}$ (using $g+h=1$).
- An aa parent always passes a. The child is Aa with probability g and aa with h.

So

$$P=\begin{pmatrix} g & h & 0 \\ \frac{g}{2} & \frac{1}{2} & \frac{h}{2} \\ 0 & g & h \end{pmatrix}.$$

Hardy–Weinberg is stationary. Take $\pi=(g^2,2gh,h^2)$ and check $\pi P=\pi$ component by component, using $g+h=1$,

$$\begin{aligned}(\pi P)_{AA} &= g^2\cdot g+2gh\cdot\tfrac{g}{2}=g^2(g+h)=g^2,\\ (\pi P)_{Aa} &= g^2\cdot h+2gh\cdot\tfrac{1}{2}+h^2\cdot g=gh(g+h)+gh=2gh,\\ (\pi P)_{aa} &= 2gh\cdot\tfrac{h}{2}+h^2\cdot h=h^2(g+h)=h^2.\end{aligned}$$

From the crowd to one line. The chain is irreducible when $0<g<1$ (every genotype can reach every other within two generations) and aperiodic (the diagonal entries are positive), so by the ergodic theorem (Section 9.6) the fraction of its generations that one family line spends as AA tends to $\pi_{AA}=g^2$: the same as the fraction of AA people in any one generation.

9.4.1 Stationary does not mean convergent

A stationary distribution is an equilibrium. Whether the chain ever reaches it is a different question [Wasserman p. 392, Ex. 23.27]. The deterministic 3-cycle of Section 9.3.3 has the uniform distribution $\pi=(\frac{1}{3},\frac{1}{3},\frac{1}{3})$ as a stationary distribution (πP just permutes the three equal entries). Started in π it stays in π. Started in state 1 it is in state 1, then 2, then 3, then 1 again: p_t is a spike that rotates forever, and its distance from π never shrinks (Figure 9.11, blue). What does converge is the *time average* of p_t over a period, which is uniform; we will see in Section 9.6 that time averages need less than distributions do.

The chain has a **limiting distribution** π if the rows of P^n all converge to the same vector π,

$$\lim_{n\to\infty} p_{ij}(n)=\pi_j \quad \text{for every } i, \qquad \text{i.e.} \qquad P^n\to\begin{pmatrix}\pi\\ \pi\\ \vdots\\ \pi\end{pmatrix} \tag{9.26}$$

[Wasserman p. 391, Def. 23.24]. Then $p_n=p_0P^n\to\sum_i p_0(i)\pi=\pi$ for every initial distribution: the chain forgets where it started. The 3-cycle has a stationary distribution but no limiting one.

9.4.2 Detailed balance

Kruschke's argument for why the island rule works starts not from $\pi=\pi P$ but from pairs of neighbouring islands [Kruschke §7.2.5, Eq. (7.2)]. The ratio of the probability of hopping east from θ to that of hopping back west from $\theta+1$ is, by (9.12),

$$\frac{p_{\theta,\theta+1}}{p_{\theta+1,\theta}}=\frac{\frac{1}{2}}{\frac{1}{2}\,\theta/(\theta+1)}=\frac{\theta+1}{\theta}=\frac{P(\theta+1)}{P(\theta)}.$$

Rearranged, $P(\theta)\,p_{\theta,\theta+1}=P(\theta+1)\,p_{\theta+1,\theta}$: with the crowd spread in proportion to the populations, as many politicians cross from θ to $\theta+1$ each night as cross back. Every bridge carries equal traffic both ways.

Working definition 9.6 (detailed balance)

A distribution π satisfies **detailed balance** with respect to P if

$$\pi_i \, p_{ij} = \pi_j \, p_{ji} \qquad \text{for every pair } i, j \tag{9.27}$$

[the probability flow from i to j equals the flow from j to i, for each pair separately] [Wasserman p. 391, (23.15)]. A chain with such a π is called **reversible**. *Operational test:* for each pair with $p_{ij} > 0$, check that $p_{ji} > 0$ and that $p_{ij}/p_{ji} = \pi_j/\pi_i$. Only ratios of π enter.

Detailed balance is stronger than stationarity, and it implies it. Sum (9.27) over i:

$$(\pi P)_j = \sum_i \pi_i \, p_{ij} \overset{(1)}{=} \sum_i \pi_j \, p_{ji} \overset{(2)}{=} \pi_j \sum_i p_{ji} \overset{(3)}{=} \pi_j . \tag{9.28}$$

(1) Detailed balance, term by term.
(2) π_j does not depend on the summation index.
(3) Row j of P sums to one.

That is the whole proof [Wasserman p. 391, Thm 23.26]. Compare it with Kruschke's verification of stationarity for the islands, which needs the four cases of whether each neighbour is larger or smaller [Kruschke §7.2.5, Eq. (7.4)]: detailed balance does all four at once.

Key idea: Detailed balance $\Rightarrow$ stationary

If $\pi_i p_{ij} = \pi_j p_{ji}$ for all pairs, then $\pi P = \pi$. To build a chain with a prescribed stationary distribution it is enough to make every pair of moves balance, and that needs only the ratios π_j/π_i, never the normalisation of π.

Example: the politician's equilibrium. For the islands, (9.27) holds with $\pi_\theta \propto \theta$ for each pair of neighbours (just shown), and trivially for non-neighbours, where both sides are zero. So $\pi_\theta = \theta/28$ is stationary. The politician never needed the total population 28: his rule uses only the ratio of two neighbouring populations, and the ratio is all detailed balance asks for. That is the whole secret of the Metropolis algorithm, and why it can sample a posterior whose evidence Z is unknown [36, 143].

Example: the three-state weather chain is reversible. For (9.24) with $\pi = (\frac{1}{2}, \frac{1}{3}, \frac{1}{6})$: $\pi_S p_{SC} = \frac{1}{2} \cdot 0.2 = 0.1 = \frac{1}{3} \cdot 0.3 = \pi_C p_{CS}$; $\pi_S p_{SR} = \frac{1}{2} \cdot 0.2 = 0.1 = \frac{1}{6} \cdot 0.6 = \pi_R p_{RS}$; and $\pi_C p_{CR} = 0 = \pi_R p_{RC}$. Each of the three "bridges" carries 0.1 of the probability each way per day (Figure 9.10a).

The physical picture: equilibrium without currents. In statistical mechanics, detailed balance is the statement that in thermal equilibrium every elementary process is balanced by its reverse: as many molecules react $A \to B$ per second as react $B \to A$, as many photons are absorbed in a transition as are emitted in the reverse one. This principle of microscopic reversibility is what made Einstein's A and B coefficients consistent with the Planck spectrum. There are no net probability currents anywhere. A stationary state can exist with currents, however, as a steady current flows round a circuit driven by a battery: global balance (9.22) holds at every node, but the flow on each wire does not vanish. Such states are *non-equilibrium steady states*.

Example: a biased cycle has a stationary distribution but no detailed balance. On a ring of three states let the walker step clockwise with probability 0.6, anticlockwise with 0.2, and stay

with 0.2:

$$P = \begin{pmatrix} 0.2 & 0.6 & 0.2 \\ 0.2 & 0.2 & 0.6 \\ 0.6 & 0.2 & 0.2 \end{pmatrix}.$$

Its columns sum to one as well as its rows (a **doubly stochastic** matrix), so the uniform $\pi = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ is stationary: $(\pi P)_j = \frac{1}{3}\sum_i p_{ij} = \frac{1}{3}$. But $\pi_1 p_{12} = 0.2 \neq \pi_2 p_{21} = 0.0\overline{6}$. Each edge carries a net clockwise current $J = \frac{1}{3}(0.6 - 0.2) = 0.1333$ per step, the same on all three edges, so the inflow and outflow balance at every node while probability circulates for ever (Figure 9.10b). A reversible chain could not do this. Going round any closed loop of states, detailed balance forces the product of the transition probabilities one way to equal the product the other way, because the π's cancel ($p_{12}p_{23}p_{31} = \frac{\pi_2}{\pi_1}p_{21} \cdot \frac{\pi_3}{\pi_2}p_{32} \cdot \frac{\pi_1}{\pi_3}p_{13}$), and here $0.6^3 \neq 0.2^3$. (The converse also holds, and this loop test is Kolmogorov's criterion for reversibility.)

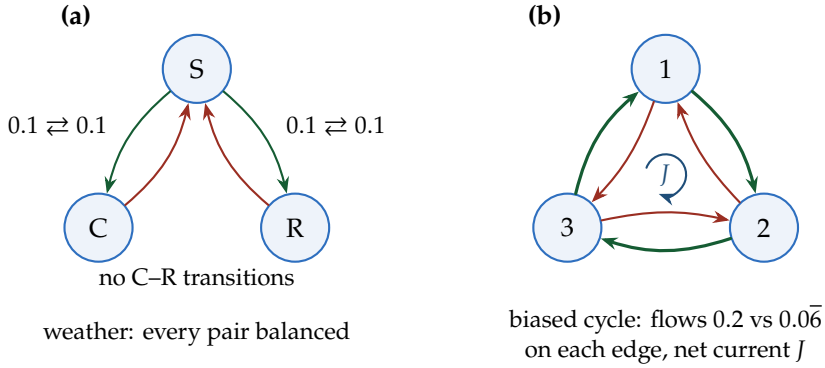

Figure 9.10: Probability flows $\pi_i p_{ij}$ in two stationary chains. (a) The three-state weather chain: each pair of states exchanges 0.1 of the probability per day in each direction, so no net current flows anywhere (equilibrium). (b) The biased three-state cycle: the clockwise flow (thick green) exceeds the anticlockwise one (red) on every edge, and a net current circulates round the ring, although inflow equals outflow at each state (a steady state that is not an equilibrium).

The biased cycle nevertheless converges to its uniform π (Figure 9.11, orange): it is irreducible and aperiodic (it has self-loops), and that is all convergence needs. Detailed balance is sufficient for stationarity, not necessary. Its signature in the dynamics is visible in the figure: the approach to π oscillates.

The eigenvalues of the biased cycle. P is **circulant**: each row is the row above shifted one place to the right, because the ring looks the same from every state. For such a matrix the eigenvectors can be written down at once. Let $w = e^{2\pi i/3}$, a cube root of one, and try $v_k = (1, w^k, w^{2k})$ for $k = 0, 1, 2$. Row 1 of Pv_k is $0.2 + 0.6w^k + 0.2w^{2k}$; row 2 is $0.2 + 0.2w^k + 0.6w^{2k} = w^k(0.2w^{-k} + 0.2 + 0.6w^k)$, which is w^k times the same number because $w^{-k} = w^{2k}$, and row 3 works the same way. So v_k is a right eigenvector with eigenvalue

$$\lambda_k = 0.2 + 0.6\,w^k + 0.2\,w^{-k}$$

(the same step as for the ring in (9.56)). For $k = 0$, $\lambda_0 = 1$, the uniform mode. For $k = 1$, with $w = -\frac{1}{2} + i\frac{\sqrt{3}}{2}$ and $w^{-1} = -\frac{1}{2} - i\frac{\sqrt{3}}{2}$,

$$\lambda_1 \overset{(1)}{=} 0.2 + 0.6\left(-\tfrac{1}{2} + i\tfrac{\sqrt{3}}{2}\right) + 0.2\left(-\tfrac{1}{2} - i\tfrac{\sqrt{3}}{2}\right) \overset{(2)}{=} -0.2 + 0.4 \cdot \tfrac{\sqrt{3}}{2}\,i = -0.2 + 0.346\,i,$$
$$|\lambda_1| \overset{(3)}{=} \sqrt{0.2^2 + 0.346^2} = \sqrt{0.04 + 0.12} = 0.4.$$

(1) Substitute w and w^{-1}.

(2) Real part $0.2 - 0.3 - 0.1 = -0.2$; imaginary part $(0.6 - 0.2)\frac{\sqrt{3}}{2}$.

(3) Modulus of a complex number; $0.346^2 = 0.4^2 \cdot \frac{3}{4} = 0.12$.

λ_2 is the complex conjugate. Clockwise and anticlockwise steps enter with different weights, 0.6 and 0.2, so the imaginary parts do not cancel; with equal weights λ_1 would be real.

A complex eigenvalue is a rotation. Write $\lambda_1 = 0.4\, e^{i\alpha}$ with $\alpha = 120°$. Then $\lambda_1^t = 0.4^t e^{i\alpha t}$: each step multiplies the size by 0.4 and advances the phase by 120°, one third of a turn, as the walker drifts one state clockwise. The deviation $p_t - \pi$ is a combination of this mode and its conjugate, so each of its components is 0.4^t times a cosine of αt plus a phase that differs from state to state: the excess probability is carried round the ring while it shrinks, a spiral into π, with distance decaying as 0.4^t (Figure 9.11b). A reversible chain cannot rotate: with $D = \mathrm{diag}(\sqrt{\pi_i})$, detailed balance says that DPD^{-1} is a symmetric matrix ($\sqrt{\pi_i}p_{ij}/\sqrt{\pi_j} = \sqrt{\pi_j}p_{ji}/\sqrt{\pi_i}$), so all eigenvalues of P are real.

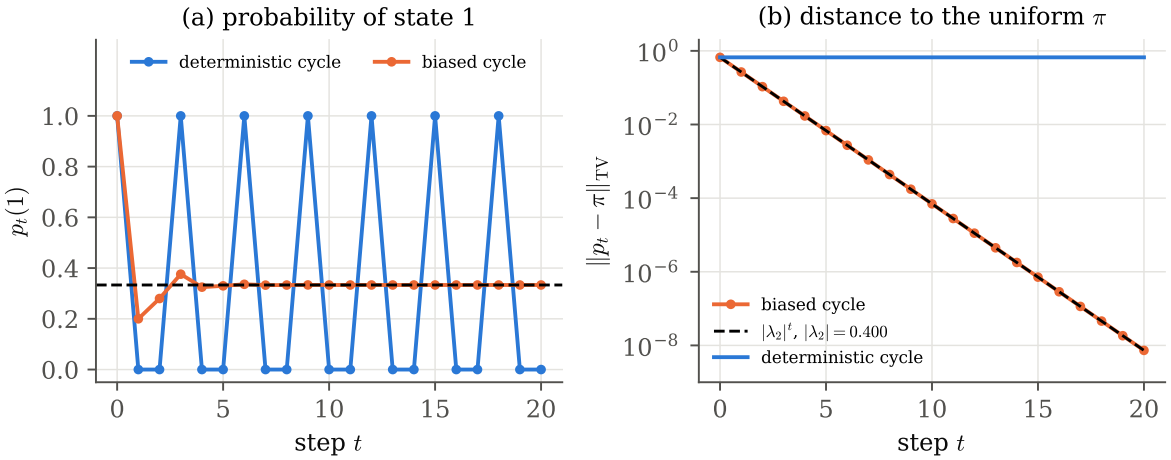

Figure 9.11: Two chains on a ring of three states, both with the uniform distribution as equilibrium, started in state 1. (a) The deterministic cycle (blue) carries its spike round forever; the biased cycle (orange) spirals in towards $\frac{1}{3}$. (b) The distance to the uniform distribution: constant for the deterministic cycle, and decaying as 0.4^t for the biased one.

Reversibility as a movie run backwards. The name "reversible" has a literal meaning. In equilibrium, $X_t \sim \pi$, the probability of seeing the step $i \to j$ is $\mathrm{P}(X_t = i, X_{t+1} = j) = \pi_i p_{ij}$, and of seeing $j \to i$ it is $\pi_j p_{ji}$. Detailed balance says these are equal, so a film of the stationary chain has the same statistics played forwards or backwards [Lambert §13.6.3]. For the biased cycle the film run backwards shows a walker that prefers anticlockwise steps; you can tell the direction of time.

9.4.3 Continuous states

Nothing changes for a continuous state space except that sums become integrals. The transition matrix becomes a **transition kernel** $p(x, y)$, the density of the next state y given the current state x, with $\int p(x, y)\,\mathrm{d}y = 1$ [Wasserman p. 413]. A density f_t of walkers moves to

$$f_{t+1}(y) = \int f_t(x)\, p(x, y)\,\mathrm{d}x \tag{9.29}$$

(the transition operator applied to f_t, [Lambert §13.6.1]), a density f is stationary if $f(y) = \int f(x)p(x, y)\,\mathrm{d}x$, and detailed balance reads $f(x)\,p(x, y) = f(y)\,p(y, x)$. The proof that it implies stationarity is (9.28) with integrals [Wasserman p. 414, (24.7)]: $\int f(x)p(x, y)\,\mathrm{d}x = \int f(y)p(y, x)\,\mathrm{d}x = f(y)\int p(y, x)\,\mathrm{d}x = f(y)$.

Example: a Gaussian walker with a pull. Let the next state be $Y = \rho x + \sqrt{1-\rho^2}\,Z$ with $Z \sim \mathcal{N}(0,1)$ and $|\rho| < 1$, so that $p(x,y)$ is the $\mathcal{N}(\rho x, 1-\rho^2)$ density in y: a fraction ρ of the current position is kept and fresh noise is added. This is the **AR(1)** chain (autoregressive of order 1), the discrete-time version of a Brownian particle in a harmonic well (the Ornstein–Uhlenbeck process). Is $f = \mathcal{N}(0,1)$ stationary? Check detailed balance: the exponent of $f(x)p(x,y)$ is

$$-\frac{x^2}{2} - \frac{(y-\rho x)^2}{2(1-\rho^2)} \overset{(1)}{=} -\frac{x^2(1-\rho^2) + y^2 - 2\rho xy + \rho^2 x^2}{2(1-\rho^2)} \overset{(2)}{=} -\frac{x^2 - 2\rho xy + y^2}{2(1-\rho^2)},$$

(1) Common denominator, and $(y-\rho x)^2 = y^2 - 2\rho xy + \rho^2 x^2$.
(2) The $\rho^2 x^2$ terms cancel.

which is symmetric under $x \leftrightarrow y$, and the prefactor $1/(2\pi\sqrt{1-\rho^2})$ is symmetric too. So $f(x)p(x,y) = f(y)p(y,x)$: the AR(1) chain is reversible with stationary law $\mathcal{N}(0,1)$. The joint law of two consecutive states in equilibrium is the bivariate Gaussian with correlation ρ, the same whichever way round you read it. We will watch this chain forget its starting point in Section 9.7.

9.5 Forgetting where you started

Five weather forecasters use the same three-state weather chain (9.24) (sunny, cloudy, rainy, with $p_{SS} = 0.6$, $p_{CC} = 0.7$, $p_{RR} = 0.4$, rain clearing straight to sun and no direct cloud–rain changes), but they disagree violently about today. One is certain it is sunny, one certain it is cloudy, one certain it is raining; one has no idea and says $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$; one is 90% sure of rain. Each forecasts day t by $p_t = p_0 P^t$. Figure 9.12a shows their forecasts of rain: wildly different on day 0, nearly indistinguishable by day 5, all on the line $\pi_R = \frac{1}{6}$ of the stationary distribution (9.25) soon after. The chain has forgotten where it started.

This is the property an MCMC run relies on. We cannot start a sampler from the target distribution (if we could draw from it we would not need the sampler), so we start it anywhere, and we need a guarantee that the start is forgotten, together with a rate.

The questions.

1. Does $p_t = p_0 P^t$ converge to the same π for every p_0?
2. How fast does the memory of p_0 fade?
3. What property of P guarantees it?

To answer "how fast" we need a distance between distributions.

Working definition 9.7 (total-variation distance)

For two distributions p, q on the same states,

$$\|p - q\|_{\mathrm{TV}} = \tfrac{1}{2}\sum_i |p_i - q_i| = \max_A |p(A) - q(A)|\,, \tag{9.30}$$

where A runs over all events [all subsets of states]. It is the largest disagreement between p and q about the probability of any event, so it lies between 0 (identical) and 1 (no overlap at all). *Operational recipe:* half the sum of absolute differences (`tv` in `lib_markov.py`).

The two expressions in (9.30) agree. Let $A^* = \{i : p_i > q_i\}$. For any event A, $p(A) - q(A) = \sum_{i\in A}(p_i - q_i)$ is largest when A contains exactly the states where the difference is positive, so the

maximum is $p(A^*) - q(A^*)$ (and the most negative value is $-(p(A^*) - q(A^*))$, at the complement). Because $\sum_i (p_i - q_i) = 1 - 1 = 0$, the positive and the negative differences have equal total size, and each is half of $\sum_i |p_i - q_i|$.

9.5.1 Two states: the whole story in one line

Take a two-state chain with $a = p_{12}$, $b = p_{21}$ and stationary distribution $\pi = (\frac{b}{a+b}, \frac{a}{a+b})$ (9.23). Let $d_t = p_t(1) - \pi_1$ be the forecaster's excess belief in state 1. Then

$$d_{t+1} = p_{t+1}(1) - \pi_1 \overset{(1)}{=} \big[p_t(1)(1-a) + (1-p_t(1))\,b\big] - \big[\pi_1(1-a) + (1-\pi_1)\,b\big]$$
$$\overset{(2)}{=} (1-a-b)\big(p_t(1) - \pi_1\big) = \lambda\, d_t, \qquad \lambda \equiv 1 - a - b. \tag{9.31}$$

(1) One step of (9.14) for the first component, for p_t and for the stationary π (for which one step changes nothing).
(2) Collect the terms in $p_t(1)$ and π_1: the constant b cancels.

So $d_t = \lambda^t d_0$, and since $p_t(2) - \pi_2 = -d_t$,

$$p_t = \pi + \lambda^t\,(p_0 - \pi), \qquad \|p_t - \pi\|_{\mathrm{TV}} = |\lambda|^t\ \|p_0 - \pi\|_{\mathrm{TV}}\,. \tag{9.32}$$

The memory of the start decays geometrically with ratio $|\lambda| = |1 - a - b|$, and λ is the second eigenvalue of P (the trace of P is $2 - a - b = 1 + \lambda$). The two ways for $|\lambda|$ to equal 1 are exactly the failures of Section 9.3: $a = b = 0$, two absorbing states and a reducible chain, which remembers its start forever; and $a = b = 1$, a deterministic flip with period 2, for which $\lambda = -1$ and the excess d_t changes sign every day without shrinking. Every other two-state chain forgets.

Example: Wasserman's weather. For (9.11), $a = 0.6$, $b = 0.8$, so $\lambda = -0.4$ and $\pi = (\frac{4}{7}, \frac{3}{7})$. Starting on a sunny day, $d_0 = 1 - \frac{4}{7} = \frac{3}{7}$, and $p_t(\text{sunny}) = \frac{4}{7} + \frac{3}{7}(-0.4)^t$: 1, 0.4, 0.64, 0.544, ..., the sequence found by brute force in Section 9.2.3. The negative λ explains the overshoot: a sunny day makes cloud likely tomorrow, which makes sun likely the day after, and the alternation damps by a factor 0.4 a day.

9.5.2 Many states: the eigenvalues of P

For a K-state chain the role of λ is played by the eigenvalues of P. Let us assume that P has K independent eigenvectors (this is always true for a reversible chain, whose eigenvalues were shown to be real in Section 9.4.2; for the rest see the end of this subsection). There are right eigenvectors, $Pv_k = \lambda_k v_k$ (columns), and left eigenvectors, $\ell_k P = \lambda_k \ell_k$ (rows), with the same eigenvalues. A left and a right eigenvector with different eigenvalues are orthogonal: $\ell_k P v_m$ equals both $\lambda_k \ell_k v_m$ and $\lambda_m \ell_k v_m$, so $\ell_k v_m = 0$ when $\lambda_k \neq \lambda_m$. Label $\lambda_1 = 1$, with right eigenvector $v_1 = \mathbf{1}$ (rows sum to one) and left eigenvector $\ell_1 = \pi$, and order the rest by modulus, $|\lambda_2| \geq |\lambda_3| \geq \cdots$. Expand the starting distribution in left eigenvectors, $p_0 = \sum_k c_k \ell_k$; multiplying by v_k and using the orthogonality picks out one coefficient, $c_k = p_0 v_k / (\ell_k v_k)$. Then

$$p_t = p_0 P^t \overset{(1)}{=} \sum_k c_k\, \ell_k P^t \overset{(2)}{=} \sum_k c_k\, \lambda_k^t\, \ell_k \overset{(3)}{=} \pi + \sum_{k \geq 2} c_k\, \lambda_k^t\, \ell_k. \tag{9.33}$$

(1) Expand p_0; the product is linear.
(2) Each ℓ_k is a left eigenvector, so $\ell_k P^t = \lambda_k^t \ell_k$.
(3) $\lambda_1 = 1$, $\ell_1 = \pi$ and $c_1 = p_0 \mathbf{1} / (\pi \mathbf{1}) = 1/1 = 1$: every probability vector contains exactly one unit of the stationary distribution.

Every other component is multiplied by λ_k^t each step. If $|\lambda_k| < 1$ for all $k \geq 2$, all of them die and $p_t \to \pi$ from any start. At late times the slowest one dominates,

$$\|p_t - \pi\|_{\mathrm{TV}} \simeq C\ |\lambda_2|^t\,, \qquad \ln \|p_t - \pi\|_{\mathrm{TV}} \simeq \ln C + t \ln |\lambda_2|\,, \tag{9.34}$$

a straight line of slope $\ln|\lambda_2|$ on a log plot. The number of steps for the memory to fall by a factor e is the **relaxation time** $t_{\mathrm{rel}} = -1/\ln|\lambda_2|$, and $1 - |\lambda_2|$ is called the **spectral gap**. This is exactly the physics of normal modes in a damped system: the initial condition is a superposition of modes, each decays at its own rate, and after a while only the slowest one is visible.

Why $|\lambda| \leq 1$, and why only one eigenvalue equals 1. This is the Perron–Frobenius theorem for stochastic matrices, and for our purposes it has a two-line proof. Take a right eigenvector, $Pv = \lambda v$, and look at its largest entry in modulus, at state i^*. Row i^* of Pv is an *average* of the entries of v with weights $p_{i^*j} \geq 0$ that sum to one, and an average cannot exceed the largest thing being averaged:

$$|\lambda|\ |v_{i^*}| = |(Pv)_{i^*}| \overset{(1)}{=} \Big|\sum_j p_{i^*j} v_j\Big| \overset{(2)}{\leq} \sum_j p_{i^*j}\,|v_j| \overset{(3)}{\leq} \sum_j p_{i^*j}\,|v_{i^*}| \overset{(4)}{=} |v_{i^*}|\,. \tag{9.35}$$

(1) Definition of the matrix–vector product.
(2) Triangle inequality.
(3) $|v_j| \leq |v_{i^*}|$ by the choice of i^*.
(4) Row i^* sums to one.

So $|\lambda| \leq 1$. Now suppose the chain is ergodic, so that some power P^m has all entries positive (Section 9.3.3), and apply the same argument to P^m, whose eigenvalue for v is λ^m. If $|\lambda| = 1$, both inequalities in (9.35) must be equalities. With every weight $p_{i^*j}(m)$ positive, equality in (3) forces $|v_j| = |v_{i^*}|$ for *all* j, and equality in the triangle inequality (2) forces all the v_j to have the same phase. So v is constant, $v \propto \mathbf{1}$, and then $Pv = v$ says $\lambda = 1$. Hence for an ergodic chain the eigenvalue 1 belongs only to the constant vector and every other eigenvalue has $|\lambda_k| < 1$. The failures are again the ones of Section 9.3: the deterministic 3-cycle has the eigenvalues $1, e^{\pm 2\pi i/3}$, all of modulus 1, which rotate the spike forever; a chain with two closed classes has the eigenvalue 1 twice, one stationary distribution living on each class.

When there are not enough eigenvectors. The expansion (9.33) assumed K independent eigenvectors. A matrix can fall short of that, and the simplest example shows what changes. Take the 2×2 block

$$B = \begin{pmatrix} \lambda & 1 \\ 0 & \lambda \end{pmatrix}, \qquad B^t = \begin{pmatrix} \lambda^t & t\lambda^{t-1} \\ 0 & \lambda^t \end{pmatrix},$$

which has the single eigenvector $(1,0)^{\mathsf{T}}$. The formula for B^t holds at $t = 1$, and multiplying it by B once more gives the off-diagonal entry $\lambda^t + t\lambda^{t-1}\lambda = (t+1)\lambda^t$, so it holds for all t. The power still decays like $|\lambda|^t$, only with an extra factor t, which a geometric decay overwhelms. Every square matrix can be brought to blocks of this kind (its Jordan form), and a block of size $r+1$ gives factors up to t^r; the decay is again geometric with ratio $|\lambda_2|$, so the conclusion is unchanged. The general block is not worked out here, and nothing below depends on it: the Doeblin argument of Section 9.5.3 proves geometric forgetting without any eigenvectors.

Example: the three-state weather chain, exactly. Take the three-state weather chain (9.24) (sunny, cloudy, rainy), with $\pi = (\frac{1}{2}, \frac{1}{3}, \frac{1}{6})$ from (9.25), and find all of its eigenvalues and eigenvectors by hand.

The eigenvalues. The sum of the eigenvalues is the trace, $0.6+0.7+0.4 = 1.7$, and their product is the determinant. Expanding along the first row, each entry times the 2×2 determinant left when its row and column are struck out,

$$\det P = 0.6\begin{vmatrix}0.7 & 0\\ 0 & 0.4\end{vmatrix} - 0.2\begin{vmatrix}0.3 & 0\\ 0.6 & 0.4\end{vmatrix} + 0.2\begin{vmatrix}0.3 & 0.7\\ 0.6 & 0\end{vmatrix} = 0.6(0.28) - 0.2(0.12) + 0.2(-0.42) = 0.06.$$

With $\lambda_1 = 1$ the other two satisfy $\lambda_2 + \lambda_3 = 0.7$ and $\lambda_2\lambda_3 = 0.06$, the roots of $\lambda^2 - 0.7\lambda + 0.06 = 0$: $\lambda_2 = 0.6$ and $\lambda_3 = 0.1$.

The right eigenvectors. For $\lambda = 0.6$ the equation $(P - 0.6\,\mathbb{1})v = 0$ is three row equations,

$$0.2v_2 + 0.2v_3 = 0, \qquad 0.3v_1 + 0.1v_2 = 0, \qquad 0.6v_1 - 0.2v_3 = 0.$$

The third gives $v_3 = 3v_1$, the second $v_2 = -3v_1$, and the first is then satisfied ($-0.6v_1 + 0.6v_1 = 0$), as it must be for an eigenvalue. Choosing $v_1 = 1$ gives $v_2 = (1, -3, 3)^{\mathsf{T}}$. For $\lambda = 0.1$ the rows read $0.5v_1 + 0.2v_2 + 0.2v_3 = 0$, $0.3v_1 + 0.6v_2 = 0$ and $0.6v_1 + 0.3v_3 = 0$, so $v_2 = -\frac{1}{2}v_1$ and $v_3 = -2v_1$; with $v_1 = 2$, $v_3 = (2, -1, -4)^{\mathsf{T}}$ (the first row checks: $1 - 0.2 - 0.8 = 0$).

The left eigenvectors from reversibility. The chain satisfies detailed balance (Section 9.4.2), and that turns each right eigenvector into a left one. Define $\ell(i) = \pi_i v(i)$, each entry of v weighted by the stationary probability. Then

$$(\ell P)_j \overset{(1)}{=} \sum_i \pi_i v_i\, p_{ij} \overset{(2)}{=} \sum_i \pi_j p_{ji}\, v_i \overset{(3)}{=} \pi_j\,(Pv)_j \overset{(4)}{=} \lambda\,\pi_j v_j = \lambda\,\ell_j.$$

(1) Row vector times matrix, with $\ell_i = \pi_i v_i$.
(2) Detailed balance, $\pi_i p_{ij} = \pi_j p_{ji}$.
(3) π_j does not depend on i; what is left is row j of Pv.
(4) v is a right eigenvector.

So

$$v_2 = (1,-3,3)^{\mathsf{T}}, \qquad \ell_2 = \left(\tfrac{1}{2}, -1, \tfrac{1}{2}\right), \qquad \ell_2 v_2 = 5,$$
$$v_3 = (2,-1,-4)^{\mathsf{T}}, \qquad \ell_3 = \left(1, -\tfrac{1}{3}, -\tfrac{2}{3}\right), \qquad \ell_3 v_3 = 5.$$

(Check one: the first entry of $\ell_2 P$ is $\frac{1}{2}(0.6) - 1(0.3) + \frac{1}{2}(0.6) = 0.3 = 0.6\cdot\frac{1}{2}$.) For the forecaster certain of rain, $p_0 = (0,0,1)$, so $c_2 = p_0 v_2/5 = \frac{3}{5}$ and $c_3 = p_0 v_3/5 = -\frac{4}{5}$, and (9.33) becomes

$$p_t = \left(\tfrac{1}{2}, \tfrac{1}{3}, \tfrac{1}{6}\right) + \tfrac{3}{5}\,(0.6)^t\left(\tfrac{1}{2}, -1, \tfrac{1}{2}\right) - \tfrac{4}{5}\,(0.1)^t\left(1, -\tfrac{1}{3}, -\tfrac{2}{3}\right). \tag{9.36}$$

At $t = 0$ this is $(0,0,1)$, as it must be. The 0.1^t mode is gone within two or three days; after that $\|p_t - \pi\|_{\mathrm{TV}} \simeq \frac{3}{5}(0.6)^t \cdot \frac{1}{2}(\frac{1}{2} + 1 + \frac{1}{2}) = \frac{3}{5}(0.6)^t$. On day 10 this predicts 0.0036, and the exact distance is 0.0036; by day 20 it is 2.19×10^{-5}. Fitting a straight line to $\ln\|p_t - \pi\|$ over days 10–30 gives slope -0.5108, against $\ln 0.6 = -0.5108$ (Figure 9.12b). All five forecasters have the same slope; they differ only in the constant C, which is the size of their initial error along ℓ_2. The uniform forecaster starts closest and stays closest. Simulating 200 000 independent weather histories from a rainy day reproduces the exact curve until it hits the Monte Carlo floor $\approx 1.2\times 10^{-3}$, the typical distance between π and a histogram of that many draws from π.

Key idea: A finite ergodic chain forgets its start

If a finite chain is irreducible and aperiodic, it has exactly one stationary distribution π, and for every initial distribution p_0, $\left\|p_0 P^t - \pi\right\|_{\mathrm{TV}} \to 0$ geometrically. The rate is set by the second-largest eigenvalue modulus: $\|p_t - \pi\|_{\mathrm{TV}} \simeq C\,|\lambda_2|^t$.

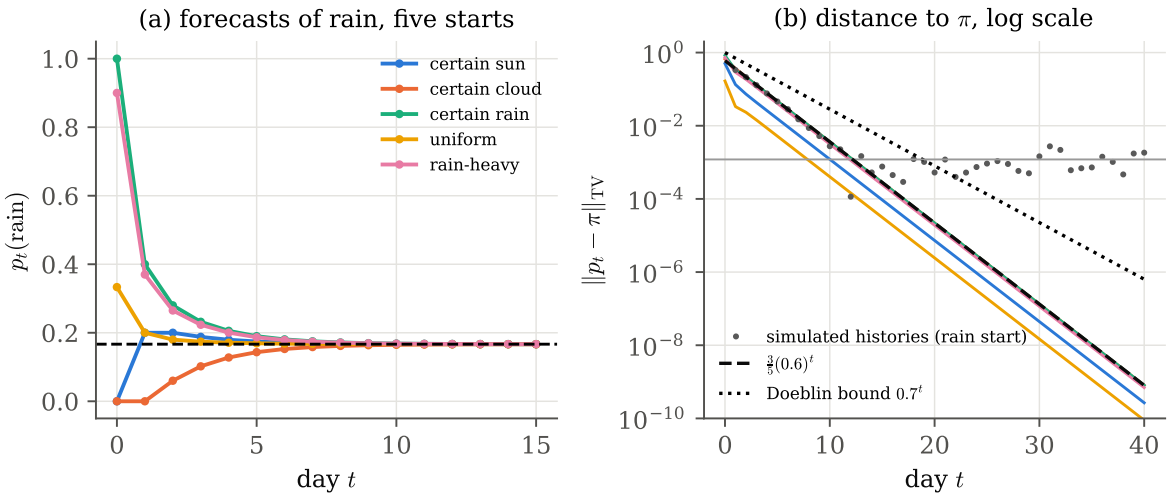

Figure 9.12: Five forecasters with very different beliefs about day 0, one weather chain. (a) Their forecasts of rain converge to $\pi_R = \frac{1}{6}$ (dashed) within a few days. (b) The total-variation distance to π on a log scale: after a short transient from the fast 0.1^t mode, every curve is a straight line of slope $\ln 0.6$, parallel to $\frac{3}{5}(0.6)^t$ (dashed). Grey dots are 2×10^5 simulated histories started on a rainy day; they follow the exact curve down to the sampling-noise floor (horizontal line). The dotted line is the Doeblin bound 0.7^t of Section 9.5.3, which lies above every curve.

9.5.3 The easy-to-see proof: a contraction

The eigenvalue argument gives the exact rate, but it needs the eigenvectors. There is a cruder argument that needs nothing, works directly with probability, and proves convergence, existence and uniqueness of π at once. It goes back to Doeblin.

The idea. Look at the rows of the weather matrix (9.24) as three forecasts for tomorrow, one for each kind of today (Figure 9.13). Whatever today is, tomorrow is sunny with probability at least 0.3 (the smallest entry of the first column). That 0.3 is common to all three forecasts: it does not depend on today at all. So we may think of tomorrow's weather as drawn in two stages. With probability $\delta = 0.3$, ignore today completely and draw tomorrow from a fixed distribution ν (here, sun for certain). With probability $1 - \delta = 0.7$, draw it from what is left of today's row. Whenever the first branch is taken, the memory of today is wiped out. After t days the memory survives only if the second branch was taken every time, which has probability 0.7^t.

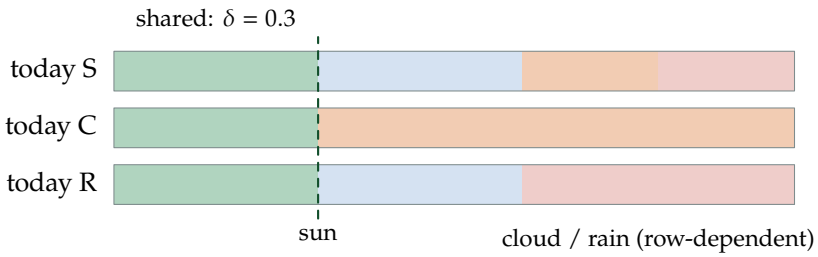

Figure 9.13: The rows of the weather matrix as stacked bars: tomorrow's sun (green and blue), cloud (orange) and rain (red), for each kind of today. The green part, a probability 0.3 of sun, is the same in every row; the rest depends on today. Each day, the shared part erases the dependence on the past with probability $\delta = 0.3$.

The calculation. Define the **Doeblin coefficient** $\delta = \sum_j \min_i p_{ij}$, the total mass that all rows have in common, and suppose $\delta > 0$. Then $v_j = \min_i p_{ij}/\delta$ is a probability vector, and $R = (P - \delta\,\mathbf{1}v)/(1-\delta)$ is a stochastic matrix (its entries are non-negative because $p_{ij} \geq \min_k p_{kj}$, and its rows sum to $(1-\delta)/(1-\delta) = 1$). So

$$P = \delta\,\mathbf{1}v + (1-\delta)\,R, \tag{9.37}$$

where $\mathbf{1}v$ is the matrix with every row equal to v. Take any two distributions p and q:

$$\begin{aligned} \|pP - qP\|_{\mathrm{TV}} &\overset{(1)}{=} \tfrac{1}{2}\big\|\delta\,(p-q)\mathbf{1}\,v + (1-\delta)(p-q)R\big\|_1 \overset{(2)}{=} (1-\delta)\,\tfrac{1}{2}\,\|(p-q)R\|_1 \\ &\overset{(3)}{\leq} (1-\delta)\,\tfrac{1}{2}\,\|p-q\|_1 = (1-\delta)\;\|p-q\|_{\mathrm{TV}}\,. \end{aligned} \tag{9.38}$$

(1) Insert (9.37); $\|x\|_1 = \sum_j |x_j|$.
(2) $(p-q)\mathbf{1} = \sum_i p_i - \sum_i q_i = 0$: the shared part sends both distributions to the same place, so it cancels in the difference.
(3) A stochastic matrix cannot increase the ℓ_1 norm: $\sum_j \left|\sum_i x_i R_{ij}\right| \leq \sum_j \sum_i |x_i|\,R_{ij} = \sum_i |x_i|$, using the triangle inequality and then the row sums of R.

One step of the chain shrinks the distance between any two distributions by at least the factor $1-\delta$. Three consequences follow at once.

- *Uniqueness.* If π and π' were both stationary, $\|\pi - \pi'\| = \|\pi P - \pi' P\| \leq (1-\delta)\,\|\pi - \pi'\|$, which forces $\|\pi - \pi'\| = 0$.
- *Existence.* The sequence $p_0, p_0P, p_0P^2, \ldots$ has steps that shrink geometrically, so it is a Cauchy sequence and converges; its limit is unchanged by one more step, so it is stationary. (This is the contraction-mapping theorem.)
- *Forgetting, with a guaranteed rate.* Taking $q = \pi$ and iterating,

$$\big\|p_0P^t - \pi\big\|_{\mathrm{TV}} \leq (1-\delta)^t\;\|p_0 - \pi\|_{\mathrm{TV}} \leq (1-\delta)^t. \tag{9.39}$$

Example: two states, where the bound is exact. For the two-state chain, $\delta = \min(1-a, b) + \min(a, 1-b)$. If $a+b \leq 1$ then $1-a \geq b$ and $1-b \geq a$, so $\delta = a+b$ and $1-\delta = 1-a-b$. If $a+b > 1$ the minima are $1-a$ and $1-b$, so $1-\delta = a+b-1$. Either way $1-\delta = |1-a-b| = |\lambda|$: for two states the contraction factor is exactly the eigenvalue modulus, and (9.39) is the exact solution (9.32). For Wasserman's weather, $\delta = \min(0.4, 0.8) + \min(0.6, 0.2) = 0.6$ and $1-\delta = 0.4 = |-0.4|$.

Example: three states, where it is only a bound. For the three-state weather chain the column minima are 0.3, 0 and 0, so $\delta = 0.3$ and the guaranteed factor is 0.7 per day, against the true 0.6 (Figure 9.12b, dotted line). The bound is honest but pessimistic: it only uses the part of the rows that is literally identical, while the eigenvalue sees all the averaging.

When no column is shared. For the politician, no island can be reached from every island in one night, so every column of (9.13) has a zero and $\delta = 0$. The argument then applies to P^m instead of P: for an ergodic chain some power P^m is strictly positive (Section 9.3.3), so its Doeblin coefficient δ_m is positive, and the distance shrinks by $1-\delta_m$ every m steps.

The seven islands. After three nights, can every island have sent the politician to island 4? From island 1 the only way is east, east, east, with probability $\frac{1}{2}\cdot\frac{1}{2}\cdot\frac{1}{2} = \frac{1}{8}$; from island 7 it is west, west, west, with probability $\frac{3}{7}\cdot\frac{5}{12}\cdot\frac{2}{5} = \frac{1}{14}$. The islands nearer to 4 get there in fewer moves and must spend the remaining nights somewhere, which they can because every island has a

refused proposal, $p_{\theta\theta} = 1/(2\theta) > 0$, by (9.12). Adding the probabilities of all such three-night paths gives column 4 of P^3, from islands $1, \dots, 7$:

$$\big(0.125,\ 0.135,\ 0.309,\ 0.150,\ 0.254,\ 0.051,\ 0.071\big).$$

Every entry is positive, and the smallest, 0.051 from island 6 (two moves plus one wasted night on an island that rarely refuses), is the mass that all rows of P^3 share in column 4. No other column of P^3 is positive in every row (island 1 cannot reach island 5 or beyond in three nights, island 7 cannot reach 3 or below), so $\delta_3 \approx 0.05$. Longer blocks share more:

block length m	1	2	3	4	5	6
δ_m	0	0	0.051	0.152	0.229	0.316

At $m = 6$ every column has a positive minimum, so P^6 is strictly positive. Geometric forgetting holds; only the guaranteed rate is per block of m steps, for example a factor $1 - 0.316$ every six days.

The actual rate. It is again $|\lambda_2|$, which is 0.887 for the politician. The memory falls as $|\lambda_2|^t$, so it halves after the number of days t with $|\lambda_2|^t = \frac{1}{2}$, that is $t = \ln 2/(-\ln|\lambda_2|) = \ln 2/(-\ln 0.887) \approx 6$ days, slower than the weather, because he can move only one island at a time.

9.5.4 Coupling: two walkers who meet

The two-stage picture of the Doeblin step has a vivid probabilistic version, which turns the inequality into a story about two walkers. Walker A starts from our arbitrary p_0. Walker B starts from the stationary π, so B's distribution is π on every day. Let them move together in a correlated way, each one still obeying the chain P on its own, and arrange that once they stand on the same state they move together forever. Let T be the day they first meet. After T the two walkers are identical, so for any event A,

$$\big|\mathrm{P}(X_t^A \in A) - \mathrm{P}(X_t^B \in A)\big| \overset{(1)}{=} \big|\mathrm{P}(X_t^A \in A,\ T > t) - \mathrm{P}(X_t^B \in A,\ T > t)\big| \overset{(2)}{\le} \mathrm{P}(T > t), \tag{9.40}$$

(1) Split each probability according to whether $T \le t$ or $T > t$. On $T \le t$ the two walkers are at the same place, so those parts are equal and cancel.

(2) Both remaining terms lie between 0 and $\mathrm{P}(T > t)$, so their difference does too.

and, since $X_t^B \sim \pi$, maximising over A gives the **coupling inequality** $\|p_t - \pi\|_{\mathrm{TV}} \le \mathrm{P}(T > t)$. Forgetting the start is the same as meeting a walker who never had one to forget.

The Doeblin split (9.37) tells us how to make them meet.

The construction. Each day, flip one coin, shared by both walkers, that comes up heads with probability δ. On heads, draw one state from ν and move *both* walkers there. On tails, each walker draws its next state from its own row of R, independently of the other. Once they stand on the same state, let them use the same random numbers from then on, so they never separate.

Each walker on its own is still the chain P. Look at walker A alone, standing at i. It goes to j either by heads and then ν choosing j, or by tails and then row i of R choosing j:

$$\mathrm{P}(\text{A moves } i \to j) = \delta\, \nu_j + (1 - \delta)\, R_{ij} = p_{ij},$$

which is exactly row i of (9.37). The same holds for B, and also after the meeting, since then both follow one walker's moves. So the coupling changes how the two walkers are correlated but not how either moves, and $X_t^B \sim \pi$ on every day, as the coupling inequality needs.

The meeting time. Every heads day ends with the walkers together, so they can still be apart on day t only if all t coins came up tails: $\mathrm{P}(T > t) \le (1-\delta)^t$, which is (9.39) again, now as a statement about meeting times. The bound can be sharpened a little at the start. A and B may already stand on the same state on day 0; with their starting draws arranged to agree as often as possible, this happens with probability $\sum_i \min(p_0(i), \pi_i)$. For A starting on a rainy day this is π_R, so the two are apart on day 0 with probability $1-\pi_R$, and $\mathrm{P}(T > t) \le (1-\delta)^t(1-\pi_R)$.

The script `05_coupling.py` runs 200 000 pairs from a rainy day (A) and from π (B), once with this Doeblin coupling and once with the naive coupling in which the two walkers move independently until they happen to meet (Figure 9.14). On day 10 the exact distance is 0.0036; the probability of not having met is 0.0046 for the Doeblin coupling and 0.018 for independent moves; and the guaranteed bound $(0.7)^{10}(1-\pi_R)$ is 0.0235. Each coupling gives a valid upper bound on the distance; a cleverer coupling gives a tighter one.

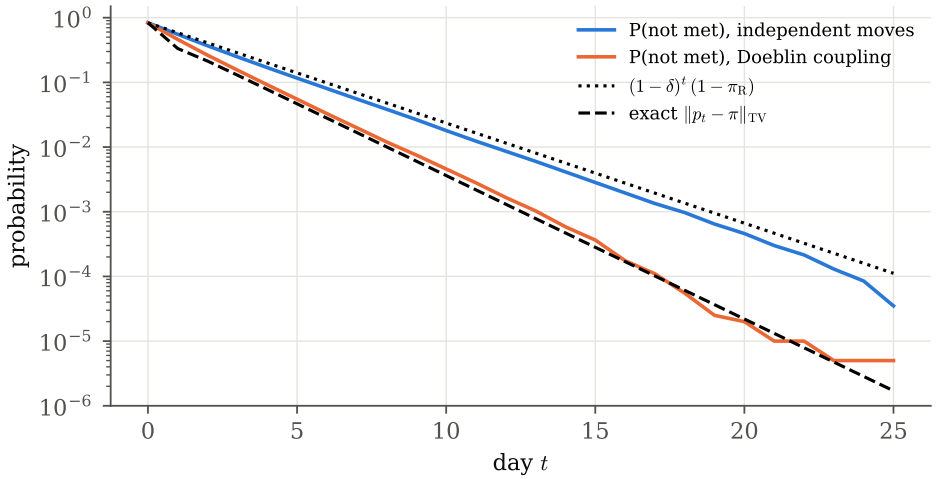

Figure 9.14: Coupling a walker started on a rainy day with one started from the stationary distribution. The probability that they have not yet met, for walkers moving independently (blue) and for the Doeblin coupling that sometimes forces them onto the same state (orange), always lies above the true distance $\|p_t-\pi\|_{\mathrm{TV}}$ (dashed), and the Doeblin coupling lies below its guaranteed bound $(1-\delta)^t(1-\pi_R)$ (dotted).

Watch out: A bound is not a rate

$(1-\delta)^t$ and $\mathrm{P}(T > t)$ guarantee forgetting; they do not measure it. The actual decay of $\|p_t-\pi\|$ is $|\lambda_2|^t$, which can be much faster. In the other direction, a chain can look converged long before it is: a walker trapped in one of two well-separated regions has $|\lambda_2|$ just below 1, a tiny Doeblin coefficient, and a histogram that looks perfectly stable for a long time while it misses half of the target.

9.6 One long walk is a sample: the ergodic theorem

Section 9.5 was about a crowd: the histogram of many independent walkers on day t approaches π. An MCMC run is not a crowd. It is one walker (or a handful), followed for a long time, and what we use is its diary: the fraction of steps it spent in each region, or the average of some quantity g over all the steps. One politician, followed for 100 000 days, spent his days in proportions within 0.0025 of $\theta/28$ (Figure 9.6b). Why should a single walker's diary reproduce the crowd's equilibrium? The successive entries in the diary are not independent, so the ordinary law of large numbers of Chapter 3 does not apply.

The questions.

1. Does the fraction of time one walker spends in state j converge to π_j, and the average of $g(X_t)$ along the walk to $\mathbb{E}_\pi\, g = \sum_j g(j)\pi_j$?
2. How accurate is the average after N steps, given that the steps are correlated?

The first question is the oscillator's question of Section 9.1, time average versus ensemble average, now for a random dynamics.

Key idea: Ergodic theorem for Markov chains

For an irreducible, ergodic Markov chain with stationary distribution π, started anywhere, and for any bounded function g of the state,

$$\frac{1}{N}\sum_{n=1}^{N} g(X_n) \xrightarrow[N\to\infty]{} \mathbb{E}_\pi(g) = \sum_j g(j)\,\pi_j \qquad \text{with probability one} \tag{9.41}$$

[Wasserman p. 391, Thm 23.25]. The time average along one walk equals the average over the stationary ensemble.

It is a law of large numbers for dependent variables, and the iid law is the special case of a chain that ignores its present state [CasellaBerger §5.8.5]. Markov introduced his chains for this very purpose: the law of large numbers does not need independence, only forgetting (in 1913 he marked the two-hundredth anniversary of the law with a celebration of his own [Lambert §12.9]). It is the reason MCMC works at all: estimate any posterior expectation by averaging along the chain [Wasserman p. 411]. Two arguments make it believable at our level: one counts returns, the other computes the variance.

9.6.1 Why: counting returns

Take g to be the indicator of one state j, so that the time average is the fraction of time spent in j. Every time the walker arrives at j, the Markov property says the future is a fresh copy of the chain started at j, independent of how it got there. So the waiting times between successive visits, $T^{(1)}, T^{(2)}, \dots$, are independent copies of the return time T_{jj}, with mean m_j (Section 9.3.2). After the kth visit the elapsed time is $T^{(1)} + \cdots + T^{(k)}$ (plus the time to the first visit, which is finite and does not grow with k), so

$$\frac{\text{visits to } j \text{ in } n \text{ steps}}{n} \overset{(1)}{=} \frac{k}{T^{(1)}+\cdots+T^{(k)}} \overset{(2)}{=} \left(\frac{T^{(1)}+\cdots+T^{(k)}}{k}\right)^{-1} \xrightarrow[k\to\infty]{} \frac{1}{m_j}. \tag{9.42}$$

(1) Choose n at the kth visit; between visits the count does not change, and this changes the fraction by at most $1/k$.

(2) The ordinary law of large numbers for the iid return times: their average tends to m_j.

The long-run fraction of time in j exists and equals $1/m_j$, whatever the start, since an irreducible finite chain reaches j from anywhere.

Which number is $1/m_j$*?* Now run the same walker from a different start: draw X_0 from a stationary distribution π (one exists for every finite chain, Section 9.4). Then $p_t = \pi$ on every day, and the *expected* fraction of time in j over n steps is exactly

$$\mathbb{E}\left(\frac{\text{visits to } j \text{ in } n \text{ steps}}{n}\right) = \frac{1}{n}\sum_{t=1}^{n} \mathrm{P}(X_t = j) = \frac{1}{n}\sum_{t=1}^{n} \pi_j = \pi_j$$

for every n (the expectation of a count of visits is the sum of the probabilities of a visit, as in (9.19)). The fraction itself tends to $1/m_j$ with probability one, and it always lies between 0 and 1. A sequence of random variables that stays between fixed bounds and converges with probability one also has converging expectations (the bounded convergence theorem: no rare, huge values can hold the mean away from the limit). So the constant expectation π_j equals the limit $1/m_j$, which gives **Kac's formula**

$$\pi_j = \frac{1}{m_j} : \tag{9.43}$$

the equilibrium probability of a state is one over its mean recurrence time. A rare state is one that is revisited only after long excursions. Two by-products come free. The argument never asked whether p_t converges from other starts, so it holds for periodic chains too. And since m_j is fixed by the chain, any stationary distribution must equal $(1/m_1, \dots, 1/m_K)$: an irreducible finite chain has only one.

From one state to any function. On a finite state space any function g is a sum of indicators, $g(x) = \sum_j g(j)\, I(x = j)$, so its time average is a weighted sum of time fractions,

$$\frac{1}{N}\sum_{n=1}^{N} g(X_n) = \sum_j g(j) \times \Big(\text{fraction of the } N \text{ steps spent in } j\Big) \xrightarrow[N\to\infty]{} \sum_j g(j)\,\pi_j = \mathbb{E}_\pi(g),$$

each fraction tending to $\pi_j = 1/m_j$ and the finite sum following term by term. That is (9.41).

Example: how long until it rains again? For the three-state weather chain $\pi_R = \frac{1}{6}$, so the mean time from one rainy day to the next is 6 days. In a simulated history of 10^6 days the average gap between rainy days is 6.007. For the politician, $\pi_1 = \frac{1}{28}$: having left island 1, he is back there on average 28 nights later.

Example: the cycle. The deterministic 3-cycle of Section 9.4.1 returns to each state after exactly 3 steps, so $m_j = 3$ and the time fractions are exactly $\frac{1}{3} = \pi_j$. Yet p_t never converges. The return argument used irreducibility and positive recurrence, but not aperiodicity. That is a general fact: periodicity spoils the convergence of the distribution at a fixed time, not the convergence of time averages. The tilted die that always moves to a neighbouring face (Section 9.3.3) has period 2, and its average face value still tends to 3.5.

9.6.2 How accurate: the variance of a time average

Suppose the chain has already reached equilibrium, $X_1 \sim \pi$, so that every X_t has the same distribution and the covariance $C_k = \mathrm{Cov}\big(g(X_t), g(X_{t+k})\big)$ depends only on the lag k. Write $\bar g_N = \frac{1}{N}\sum_{t=1}^{N} g(X_t)$, $\sigma^2 = C_0$, and $\rho_k = C_k/C_0$ for the autocorrelation at lag k. Then

$$\begin{aligned}\mathrm{Var}(\bar g_N) &\overset{(1)}{=} \frac{1}{N^2}\sum_{s=1}^{N}\sum_{t=1}^{N} C_{|s-t|} \overset{(2)}{=} \frac{1}{N^2}\Big[N C_0 + 2\sum_{k=1}^{N-1}(N-k)\,C_k\Big] \\ &\overset{(3)}{=} \frac{\sigma^2}{N}\Big[1 + 2\sum_{k=1}^{N-1}\Big(1-\frac{k}{N}\Big)\rho_k\Big] \;\simeq\; \frac{\sigma^2}{N}\,\tau, \qquad \tau \equiv 1 + 2\sum_{k=1}^{\infty}\rho_k. \end{aligned} \tag{9.44}$$

(1) Variance of a sum is the sum of all covariances (Chapter 1), with stationarity.
(2) There are N pairs with $s = t$ and $2(N-k)$ ordered pairs with $|s-t| = k$.

(3) Factor out N; for N much larger than the correlation length, $k/N \to 0$ in the terms that matter, and the sum extends to infinity.

Is τ finite? The covariances can be computed from P. Centre g on its equilibrium mean, $g_c = g - \mathbb{E}_\pi\, g$. Given $X_t = i$, the expected value of g_c after k more steps is $\sum_j p_{ij}(k) g_c(j) = (P^k g_c)(i)$, so averaging over $X_t \sim \pi$,

$$C_k = \mathbb{E}\big[g_c(X_t)\, g_c(X_{t+k})\big] = \sum_i \pi_i\, g_c(i)\, (P^k g_c)(i).$$

Expand g_c in the right eigenvectors of P, $g_c = \sum_m b_m v_m$, the same expansion as (9.33) with columns in place of rows (assuming, as there, a full set of eigenvectors). There is no $m = 1$ term, since $v_1 = \mathbf{1}$ and the coefficient along it is $\pi g_c = 0$. Each P^k multiplies v_m by λ_m^k, so

$$C_k = \sum_{m \geq 2} a_m\, \lambda_m^k, \qquad a_m = b_m \sum_i \pi_i\, g_c(i)\, v_m(i),$$

a sum of geometric sequences, one per mode. For a finite ergodic chain every $|\lambda_m| < 1$ ($m \geq 2$), so each sums, and

$$\tau = 1 + 2 \sum_{k \geq 1} \frac{C_k}{C_0} = 1 + 2 \sum_{m \geq 2} \frac{a_m}{C_0}\, \frac{\lambda_m}{1 - \lambda_m},$$

using $\sum_{k \geq 1} \lambda^k = \lambda/(1-\lambda)$. Slow modes ($\lambda_m$ near 1) inflate τ in proportion to how much of g lies along them; negative λ_m reduce it. With τ finite, the variance of the time average falls as $1/N$, and $\bar{g}_N \to \mathbb{E}_\pi\, g$ in mean square. That is a second, quantitative route to (9.41). The price of dependence is the factor τ, the **integrated autocorrelation time**: the chain average is as accurate as an average of N/τ independent draws, which is why N/τ is called the effective number of samples. Estimating τ from the chain itself, when no formula is available, is one of the MCMC diagnostics of this chapter; here we compute it exactly where we can.

Example: two states, exactly. For the two-state chain with $a = p_{12}$, $b = p_{21}$ and $\lambda = 1 - a - b$, let g be the indicator of state 1. From (9.32) with $p_0 = (1, 0)$, $d_0 = 1 - \pi_1 = \pi_2$, so $\mathrm{P}(X_k = 1 \mid X_0 = 1) = \pi_1 + \pi_2 \lambda^k$, and

$$\begin{aligned} C_k &\overset{(1)}{=} \mathrm{P}(X_0 = 1, X_k = 1) - \pi_1^2 \overset{(2)}{=} \pi_1(\pi_1 + \pi_2 \lambda^k) - \pi_1^2 = \pi_1 \pi_2\, \lambda^k, \\ \tau &\overset{(3)}{=} 1 + 2 \sum_{k \geq 1} \lambda^k = 1 + \frac{2\lambda}{1 - \lambda} = \frac{1 + \lambda}{1 - \lambda}. \end{aligned} \tag{9.45}$$

(1) $\mathrm{Cov}(I, I') = \mathbb{E}(II') - \mathbb{E}\, I\ \mathbb{E}\, I'$ for indicators, in equilibrium.
(2) $\mathrm{P}(X_0 = 1) = \pi_1$ times the k-step return probability just found.
(3) $\rho_k = \lambda^k$ since $C_0 = \pi_1 \pi_2$; geometric series, $|\lambda| < 1$.

So the fraction of time in state 1 over N steps has variance $\pi_1 \pi_2 \tau / N$. Two cases make the point (Figure 9.15a). Wasserman's weather has $\lambda = -0.4$ and $\tau = 0.429$: consecutive days are *anti*correlated, sun tends to follow cloud, and the chain average is *more* accurate than an average of independent days. A sticky chain with $a = 0.1$, $b = 0.2$ has $\lambda = 0.7$ and $\tau = 5.667$: it lingers, and needs almost six times as many steps for the same accuracy. Over 4000 independent chains of 1000 steps, the measured N Var of the time fraction is 0.1044 against the predicted 0.105 for the weather, and 1.282 against 1.259 for the sticky chain.

Example: the tilted die. Lambert's tilted die makes the dependence tangible [Lambert §12.10]. A fair six-sided die is "thrown" by tilting it: with a probability ε, the *tilt probability*, it rolls

to one of the two neighbouring faces round the ring $1, 2, \dots, 6, 1$ (each with chance $\frac{1}{2}$), and otherwise it is thrown afresh. Call W the matrix of the roll to a neighbour, with $W_{j,j\pm1} = \frac{1}{2}$ (faces counted round the ring) and zeros elsewhere; a fresh throw is the matrix $\frac{1}{6}\mathbf{1}\mathbf{1}^{\mathsf{T}}$ with every entry $\frac{1}{6}$. The transition matrix is the mixture

$$P = (1-\varepsilon)\,\tfrac{1}{6}\mathbf{1}\mathbf{1}^{\mathsf{T}} + \varepsilon\, W.$$

The uniform distribution is stationary. Each column of $\frac{1}{6}\mathbf{1}\mathbf{1}^{\mathsf{T}}$ holds six entries $\frac{1}{6}$ and sums to 1; each column of W holds two entries $\frac{1}{2}$ and also sums to 1. So every column of P sums to $(1-\varepsilon)+\varepsilon = 1$, and then $(\pi P)_j = \frac{1}{6}\sum_i p_{ij} = \frac{1}{6}$ for π uniform. The time average of the face value therefore converges to 3.5 for every ε.

The slowest mode alternates. Try the vector $v_j = (-1)^j$, $+1$ on even faces and -1 on odd ones. Both neighbours of face j have the opposite sign, so $(Wv)_j = \frac{1}{2}(-v_j) + \frac{1}{2}(-v_j) = -v_j$; and v sums to zero, so the fresh-throw part gives 0. Hence $Pv = (1-\varepsilon)\cdot 0 + \varepsilon(-v) = -\varepsilon v$: an eigenvalue $-\varepsilon$. The other non-trivial modes are the smooth waves round the ring of (9.56), with eigenvalues $\varepsilon\cos(2\pi k/6) = \pm\varepsilon/2$. With $\varepsilon = 0.9$ the largest non-trivial modulus is therefore 0.9, from the alternating mode.

Why τ is small anyway. The face value $g(j) = j$ rises steadily round most of the ring, so it lies mostly along the smoothest waves: about 69% of its variance is in the two modes with $\lambda = +0.45$, 23% in those with $\lambda = -0.45$, and only 9% in the alternating mode with $\lambda = -0.9$. Inserted in the formula for τ above, the positive modes add about 1.1, the negative ones subtract about 0.2, and $\tau = 1.9$, as computed by the function below. A negative eigenvalue anticorrelates successive throws, which helps rather than hurts. After 1000 throws the rms error of the average is 0.0744, against 0.055 for a fair die: a ratio close to $\sqrt{\tau}$ (Figure 9.15b). The lesson is that τ depends on the function being averaged, through how it projects on the slow and fast modes, and not on $|\lambda_2|$ alone.

Listing 9.3: The integrated autocorrelation time of $g(X)$ for a stationary finite chain (`code/ch09/06_ergodic_average.py`)

```
56 def tau_of(P, g, kmax=4000):
57     """Integrated autocorrelation time 1 + 2 sum_k rho_k of g(X) for the stationary
       chain."""
58     pi = stationary(P)
59     gc = g - pi @ g
60     var = pi @ gc**2
61     v, s = gc.copy(), 0.0
62     for _ in range(kmax):
63         v = P @ v                                   # v = E[g(X_k) - mean | X_0]
64         s += (pi * gc) @ v
65     return 1 + 2 * s / var
```

Line 59 centres g on its equilibrium mean. Line 63 is the whole trick: $v = P^k g_c$ is the conditional expectation $\mathbb{E}\big(g_c(X_k) \mid X_0 = i\big)$ for every starting state i, so averaging it against $\pi_i g_c(i)$ in line 64 gives the lag-k covariance C_k. The loop sums C_k over lags, and line 65 assembles τ from (9.44).

One long history. Figure 9.16 follows the fraction of rainy days along a single weather history of 10^6 days that starts on a rainy day. The early fraction is dominated by the start and by chance; after a few hundred days it lives inside the band $\pi_R \pm 2\sqrt{\pi_R(1-\pi_R)\tau/N}$, with $\tau = 2.222$ for the rain indicator, and at the end it is 0.1665, against $\frac{1}{6} = 0.1667$, with a predicted standard error of 5.6×10^{-4}. The starting point has been forgotten twice over: its influence on the distribution decays as 0.6^t, and its weight in the running average is diluted as $1/N$.

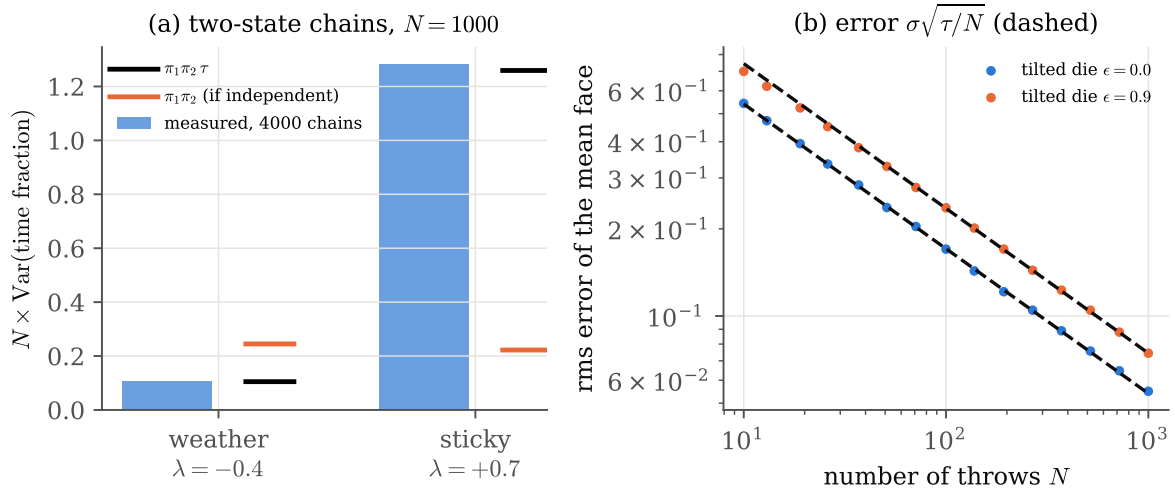

Figure 9.15: The cost (or benefit) of correlated steps. (a) N times the variance of the fraction of time spent in state 1, measured over 4000 chains of 1000 steps (bars), against $\pi_1\pi_2\tau$ (black ticks) and the value for independent draws (orange ticks). The anticorrelated weather chain beats independent sampling; the sticky chain is almost six times worse. (b) The rms error of the average face of the tilted die after N throws, for a fair die ($\varepsilon = 0$) and a strongly tilted one ($\varepsilon = 0.9$); both follow $\sigma\sqrt{\tau/N}$ (dashed).

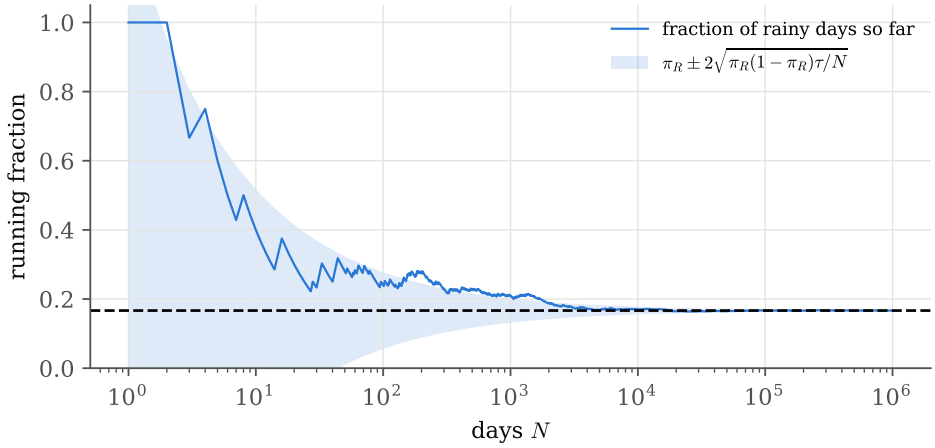

Figure 9.16: The fraction of rainy days so far along one simulated weather history, started on a rainy day, on a logarithmic time axis. It settles on $\pi_R = \frac{1}{6}$ (dashed) and stays within the two-standard-error band predicted by (9.44).

How much the start biases a finite run. Started out of equilibrium, from a distribution p_0, the chain's expected value of g at step t is $p_t g = \sum_j p_t(j) g(j)$. By the spectral expansion (9.33), $p_t = \pi + \sum_{k\geq 2} c_k \lambda_k^t \ell_k$, with c_k the weights of the starting distribution along the left eigenvectors ℓ_k, so

$$\mathbb{E}\, g(X_t) - \mathbb{E}_\pi\, g = \sum_{k\geq 2} c_k\, \lambda_k^t\, (\ell_k g) \simeq c\, \lambda_2^t, \qquad c \equiv c_2\, (\ell_2 g),$$

where at late times the slowest mode dominates. The amplitude c is the product of how far the start sits along the slowest mode (c_2) and how strongly g responds to that mode ($\ell_2 g$). (For a

reversible chain λ_2 is real, Section 9.4.2.) Averaging over the N steps of the run,

$$\mathbb{E}(\bar{g}_N) - \mathbb{E}_\pi\, g \overset{(1)}{=} \frac{1}{N}\sum_{t=1}^{N}\big(\mathbb{E}\, g(X_t) - \mathbb{E}_\pi\, g\big) \overset{(2)}{=} \frac{c}{N}\sum_{t=1}^{N}\lambda_2^t \overset{(3)}{=} \frac{c}{N}\sum_{t=1}^{\infty}\lambda_2^t \overset{(4)}{=} \frac{c\,\lambda_2}{N(1-\lambda_2)}. \tag{9.46}$$

(1) The mean of an average is the average of the means.
(2) The transient of each step, keeping the slowest mode.
(3) The terms beyond $t = N$ add $\lambda_2^{N+1}/(1-\lambda_2)$, negligible once N is many relaxation times.
(4) Geometric series, $\sum_{t\geq 1}\lambda^t = \lambda/(1-\lambda)$ for $|\lambda| < 1$.

The start causes a bias of order $1/N$, while the statistical error $\sigma\sqrt{\tau/N}$ of (9.44) is of order $1/\sqrt{N}$. For a long chain the start is harmless: the bias shrinks faster than the noise. For a short chain started far from the bulk of π, where c is large and λ_2 close to 1, it is not, and practitioners discard the first part of the chain, the **burn-in**.

The conventions of a CMB analysis. Dunkley et al. asked a practical question [144]: how long must a chain for cosmological parameters be, and how much of its start must be thrown away, before the table of means and errors it produces stops changing when the chain is run longer? Their answers are two rules of thumb, and both follow from the formulas above.

Stop when the chain mean is good to a tenth of an error bar. They ask for the variance of the chain mean to be below one percent of the posterior variance. Their convergence ratio r, the variance of the chain mean divided by the variance of the parameter, is in our symbols $\mathrm{Var}(\bar{g}_N)/\sigma^2 = \tau/N$ by (9.44), with g the parameter. So

$$\frac{\sigma^2\tau}{N} \leq 0.01\,\sigma^2 \quad\Longleftrightarrow\quad \frac{N}{\tau} \geq 100:$$

at least about 100 effective samples per parameter, and then the Monte Carlo error of a posterior mean is a tenth of its posterior error bar. Their chain length is our N, and their correlation length plays the role of our τ.

Discard until the density is within a factor 10 of its peak. Their burn-in rule removes the start of the chain until the target density has risen to a tenth of its maximum. For a Gaussian posterior in one parameter the density relative to the peak is $e^{-z^2/2}$ at z standard deviations, so

$$e^{-z^2/2} = 0.1 \quad\Longleftrightarrow\quad z = \sqrt{2\ln 10} \approx 2.15.$$

A walker that has reached that level is within about two standard deviations of the peak, in the bulk of the posterior, where c in (9.46) is no longer large. In d parameters the same rule means $\Delta\chi^2 = 2\ln 10 \approx 4.6$ from the best fit, and since typical posterior points sit at $\Delta\chi^2 \approx d$, for a handful of parameters this is already among typical points.

The toy chains of this section check the ingredients of both rules, τ and the λ_2^t transient, against exact values; a CMB chain has to estimate them from its own output.

How this is used in real research: Chain averages as posterior summaries

Every number in a cosmological parameter table produced by MCMC (CosmoMC, Cobaya, MontePython, `emcee`) is a time average (9.41) along a few long chains: a posterior mean is the chain mean of θ, a credible interval is a pair of chain quantiles, a marginal is the histogram of one column. Its Monte Carlo error is $\sigma\sqrt{\tau/N}$, and the stopping rule $N/\tau \gtrsim 100$ effective samples per parameter derived above keeps it at a tenth of the posterior error. In the toy chains above, the Monte Carlo *verifies* formulas we derived (τ, Kac, $|\lambda_2|^t$); in a

real analysis τ and λ_2 are unknown and must be estimated from the chain itself. Scale is the other difference. Our chains have 10^3–10^6 steps of a model that costs nanoseconds, and run in seconds on a laptop; a Planck analysis runs 4–8 chains of 10^5–10^6 steps with a Boltzmann code costing about a second per step, which takes days on a cluster. A laptop-scale CMB analysis keeps the run short by replacing the Boltzmann code with an emulated or Taylor-expanded spectrum, at the price of a restricted parameter range and some loss of accuracy.

9.7 The walker that never settles: free diffusion

Take Kruschke's politician of Section 9.2 and remove two things: the ends of the archipelago and his habit of comparing populations. He now lives on an endless chain of islands, flips a coin every morning, and moves to the left or right neighbour as the coin says, whatever the islands look like. Make the islands into a continuous coastline and the coin into a Gaussian, and this is the simplest continuous Markov chain there is: the **unbiased random walk**

$$X_{t+1} = X_t + s\,Z_{t+1}, \qquad Z_1, Z_2, \ldots \text{ iid } \mathcal{N}(0,1), \tag{9.47}$$

where s is the step size and each Z_t is a fresh standard Gaussian draw. Its transition kernel (Section 9.4.3, the density of the next position y given the current position x) is $p(x,y) = \varphi_s(y-x)$, with φ_s the $\mathcal{N}(0, s^2)$ density. It is what a Markov chain sampler does if we keep its proposals and throw away every rule that refers to the target. It is also a Brownian particle observed once per time step.

Every result of the previous sections needed some pull towards a target distribution π: the politician's acceptance rule, the weather's fixed transition probabilities on a finite set of states. Here there is none, and the walker is free to wander over the whole real line.

The questions.

1. Where is the walker after t steps, and does the histogram of many walkers settle down?
2. Is there a stationary density, one that the walk would leave unchanged?
3. Does the walk at least forget its starting point?

9.7.1 Where the walker is after t steps

Unrolling (9.47) from a fixed start $X_0 = x_0$ gives the position as the start plus a sum of independent kicks:

$$\begin{aligned} X_t &\overset{(1)}{=} x_0 + s\,(Z_1 + Z_2 + \cdots + Z_t), \\ \mathbb{E}\,X_t &\overset{(2)}{=} x_0, \qquad \operatorname{Var} X_t \overset{(3)}{=} s^2\big(\operatorname{Var} Z_1 + \cdots + \operatorname{Var} Z_t\big) = s^2 t, \\ X_t &\sim \mathcal{N}\big(x_0,\, s^2 t\big). \end{aligned} \tag{9.48}$$

(1) Apply (9.47) t times: $X_t = X_{t-1} + sZ_t = X_{t-2} + sZ_{t-1} + sZ_t = \ldots$
(2) Each Z_k has mean zero.
(3) The kicks are independent, so their variances add (Chapter 1); each Z_k has variance 1.

The last line holds because a sum of independent Gaussians is Gaussian (Chapter 2). The centre never moves, because the walk is unbiased; the width grows as $s\sqrt{t}$, without limit. This is the

random-walk law of Brownian motion, $\langle (X_t - x_0)^2 \rangle \propto t$, which Einstein used to connect the jiggling of pollen grains to the size of molecules.

The same result can be read as an equation for the density of walkers. One step convolves the density with the kernel, $f_{t+1}(y) = \int f_t(x)\, \varphi_s(y - x)\, \mathrm{d}x$ (Eq. (9.29)). Substitute $x = y - u$ and expand f_t around y for small steps:

$$\begin{aligned} f_{t+1}(y) &\overset{(1)}{=} \int f_t(y - u)\, \varphi_s(u)\, \mathrm{d}u \\ &\overset{(2)}{=} \int \left[f_t(y) - u\, f_t'(y) + \tfrac{1}{2} u^2 f_t''(y) - \dots \right] \varphi_s(u)\, \mathrm{d}u \\ &\overset{(3)}{=} f_t(y) + \tfrac{1}{2} s^2 f_t''(y) + O\left(s^4 f_t''''\right). \end{aligned} \tag{9.49}$$

(1) Change of variable $u = y - x$; φ_s is even, so $\varphi_s(y - x) = \varphi_s(u)$.
(2) Taylor expansion of f_t about y, valid when f_t varies little over one step s.
(3) The kernel integrates to 1, has mean $\int u\, \varphi_s\, \mathrm{d}u = 0$ and variance $\int u^2 \varphi_s\, \mathrm{d}u = s^2$; the next surviving term is the fourth moment, $3s^4$.

From steps to a clock. Suppose the walker takes one step every Δt seconds. Call the step number n (it was t in (9.49)), so that after n steps the physical time is $t = n\, \Delta t$, and write $f(x, t)$ for the density of walkers at that time. For small steps taken often, the density changes little from one step to the next, and

$$\Delta t\, \frac{\partial f}{\partial t} \overset{(1)}{=} f(x, t + \Delta t) - f(x, t) \overset{(2)}{=} f_{n+1}(x) - f_n(x) \overset{(3)}{=} \tfrac{1}{2} s^2\, \frac{\partial^2 f}{\partial x^2}.$$

(1) The first-order Taylor expansion in time, valid when f changes little during one step.
(2) One step of the clock is one step of the walk.
(3) (9.49), dropping the higher-order term.

Dividing by Δt gives the **diffusion equation**

$$\frac{\partial f}{\partial t} = D\, \frac{\partial^2 f}{\partial x^2}, \qquad D = \frac{s^2}{2\, \Delta t}, \tag{9.50}$$

the heat equation, with the **diffusion coefficient** D collecting the step size and the step rate. Its solution from a point is the spreading Gaussian of (9.48), and the two descriptions agree on the width: after $n = t/\Delta t$ steps the variance is $s^2 n = s^2 t/\Delta t = 2Dt$. A density of walkers behaves exactly like a drop of ink in still water.

Example: twenty thousand walkers. Figure 9.17 follows 20 000 independent walkers with $s = 1$, all started at the origin. The histograms at $t = 10$, 100, 1000 lie on the Gaussians $\mathcal{N}(0, t)$, and the sample variance is 100.7 at $t = 100$ and 1014 at $t = 1000$, against $s^2 t = 100$ and 1000. The core of the simulation is eight lines:

Listing 9.4: The unbiased random walk for many walkers at once (`code/ch09/07_random_walk_diffusion.py`)

```
x = np.zeros(W)
var_t, keep = [], {}
for t in range(1, T + 1):
    x += s * rng.standard_normal(W)
    var_t.append(x.var())
    if t in snaps:
        keep[t] = x.copy()
var_t = np.array(var_t)
```

Line 20 puts every walker at the origin. Line 23 is (9.47) applied to all of them in one vectorised step: each walker gets its own fresh Gaussian kick. Line 24 records the spread of the crowd, and lines 25–26 keep three snapshots for the histograms. Nothing in the loop refers to any target; the walkers obey the kernel and nothing else.

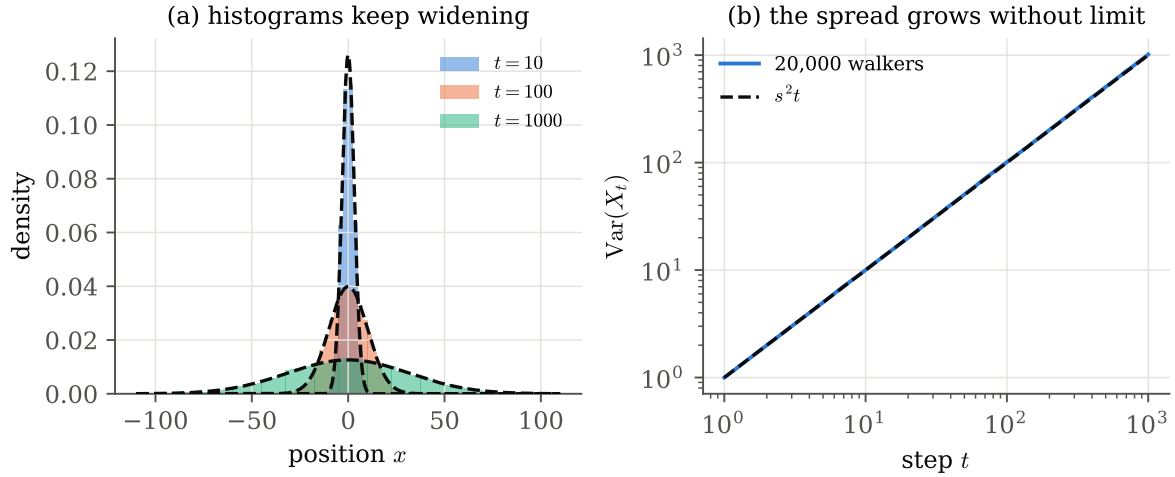

Figure 9.17: The unbiased walker never settles. (a) Histograms of 20 000 walkers started at the origin, after 10, 100 and 1000 steps of size $s = 1$, with the Gaussians $\mathcal{N}(0, s^2 t)$ (dashed): the crowd keeps flattening. (b) The variance of the crowd grows in proportion to the number of steps, on a log–log scale, with no sign of levelling off.

9.7.2 No stationary density

The histograms flatten for ever, which suggests that there is nothing for them to converge to. Let us prove it. A stationary density f would satisfy $f = f * \varphi_s$, a convolution. The convolution theorem turns this into a product for the characteristic functions $\chi_f(k) = \mathbb{E}\, e^{ikX} = \int f(x) e^{ikx}\, \mathrm{d}x$, the Fourier transforms of the densities, and the characteristic function of the Gaussian kick is $e^{-s^2k^2/2}$ (Chapter 2). So

$$\chi_f(k) \overset{(1)}{=} \chi_f(k)\, e^{-s^2k^2/2} \quad \Longrightarrow \quad \chi_f(k)\big(1 - e^{-s^2k^2/2}\big) \overset{(2)}{=} 0 \quad \Longrightarrow \quad \chi_f(k) \overset{(3)}{=} 0 \ \text{ for every } k \neq 0. \tag{9.51}$$

(1) $X_{t+1} = X_t + sZ$ with $X_t \sim f$ independent of Z, so $\mathbb{E}\, e^{ikX_{t+1}} = \mathbb{E}\, e^{ikX_t}\ \mathbb{E}\, e^{iksZ}$, and stationarity demands $X_{t+1} \sim f$.
(2) Move everything to one side.
(3) The bracket is nonzero for $k \neq 0$.

But every probability density has $\chi_f(0) = \int f = 1$ and a characteristic function that is continuous in k. One that is zero for every $k \neq 0$ cannot jump to 1 at $k = 0$. So no probability density is stationary for the free walk.

Detailed balance points to the same answer from another side. The kernel is symmetric, $p(x, y) = \varphi_s(y - x) = p(y, x)$, so the detailed-balance condition $f(x)p(x, y) = f(y)p(y, x)$ of Section 9.4.3 reduces to $f(x) = f(y)$: the only balanced "distribution" is a constant, the flat measure over the whole line. It cannot be normalised. The unbiased walker is, in this precise sense, trying to sample a uniform distribution on $\mathbb{R}$, and there is no such distribution. In the language of Section 9.3.2, the one-dimensional walk is null recurrent: it returns to every neighbourhood, but only after excursions so long that the mean return time m is infinite, and Kac's formula (9.43), $\pi = 1/m$, assigns every region probability zero.

9.7.3 Forgetting without settling

The third question is subtler. Start one crowd at $x_0 = 0$ and another at $x_0 = a$. After t steps they are $\mathcal{N}(0, \sigma_t^2)$ and $\mathcal{N}(a, \sigma_t^2)$ with $\sigma_t = s\sqrt{t}$. How different are they? For two Gaussians of equal width the densities cross at the midpoint $a/2$, so the event on which the first exceeds the second is $\{x < a/2\}$, and the total-variation distance (9.30) (written for densities, $\frac{1}{2}\int |p - q| \, \mathrm{d}x$) is

$$\begin{aligned} \big\| \mathcal{N}(0, \sigma_t^2) - \mathcal{N}(a, \sigma_t^2) \big\|_{\mathrm{TV}} &\overset{(1)}{=} \mathrm{P}_0\Big(X < \frac{a}{2}\Big) - \mathrm{P}_a\Big(X < \frac{a}{2}\Big) \overset{(2)}{=} \Phi\Big(\frac{a}{2\sigma_t}\Big) - \Phi\Big(-\frac{a}{2\sigma_t}\Big) \\ &\overset{(3)}{=} 2\,\Phi\Big(\frac{a}{2\sigma_t}\Big) - 1 \;\simeq\; \frac{a}{\sigma_t\sqrt{2\pi}} = \frac{a}{s\sqrt{2\pi t}}. \end{aligned} \tag{9.52}$$

(1) The maximum of $|p(A) - q(A)|$ is reached on the set where $p > q$ (Section 9.5), here $\{x < a/2\}$.
(2) Standardise: under $\mathcal{N}(\mu, \sigma^2)$, $\mathrm{P}(X < c) = \Phi\big((c - \mu)/\sigma\big)$, with Φ the standard normal CDF.
(3) $\Phi(-z) = 1 - \Phi(z)$; then for small z, $\Phi(z) \simeq \frac{1}{2} + z/\sqrt{2\pi}$, since the standard normal density at 0 is $1/\sqrt{2\pi}$.

The distance goes to zero: the walk does forget where it started. Two crowds launched from different islands become indistinguishable, because both spread so widely that the initial offset is a negligible fraction of their width. But the forgetting is slow, like $1/\sqrt{t}$ rather than geometrically, and, more importantly, the two crowds do not converge to anything. They just become equally flat.

Watch out: Forgetting the start is not converging

A chain can lose all memory of its initial distribution and still have no equilibrium to offer. The free walk does exactly that. For a sampler both properties are needed: a normalisable stationary distribution π (for a countable chain, positive recurrence) and convergence to it. Time averages along a free walk do not estimate anything: the fraction of time spent in any bounded interval goes to zero.

9.7.4 The walker with a pull

Add a restoring pull to the free walk and everything comes back. The AR(1) chain of Section 9.4.3 keeps only a fraction ρ of the current position before the kick,

$$X_{t+1} = \rho\, X_t + \sqrt{1 - \rho^2}\; Z_{t+1}, \qquad |\rho| < 1, \tag{9.53}$$

which is a Brownian particle in a harmonic well, observed at discrete times; we showed there that it satisfies detailed balance with respect to $\mathcal{N}(0, 1)$. Unrolling it from $X_0 = x_0$, the same way as (9.48),

$$\begin{aligned} X_t &\overset{(1)}{=} \rho^t x_0 + \sqrt{1 - \rho^2} \sum_{k=0}^{t-1} \rho^k Z_{t-k}, \\ \mathbb{E}\, X_t &\overset{(2)}{=} \rho^t x_0, \qquad \operatorname{Var} X_t \overset{(3)}{=} (1 - \rho^2) \sum_{k=0}^{t-1} \rho^{2k} \overset{(4)}{=} 1 - \rho^{2t}. \end{aligned} \tag{9.54}$$

(1) Substitute (9.53) into itself t times: the start is multiplied by ρ at every step, and the kick received k steps ago by ρ^k.
(2) The kicks have mean zero.

(3) Independent kicks, each of variance 1, multiplied by $\sqrt{1-\rho^2}\,\rho^k$.
(4) Geometric sum, $\sum_{k=0}^{t-1}\rho^{2k} = (1-\rho^{2t})/(1-\rho^2)$.

So $X_t \sim \mathcal{N}(\rho^t x_0,\, 1-\rho^{2t}) \to \mathcal{N}(0,1)$ for every start. Compare with the free walk: the width now saturates at 1, and the offset of the start shrinks as ρ^t. Two crowds started at x_0 and x_0' have the same width $\sqrt{1-\rho^{2t}}$ and centres $\rho^t x_0$ and $\rho^t x_0'$, so (9.52) with offset $a = \rho^t\left|x_0 - x_0'\right|$ gives a distance $\simeq \rho^t\left|x_0 - x_0'\right|/\sqrt{2\pi}$ once $\rho^{2t} \ll 1$: geometric forgetting at rate ρ.

The rate ρ plays the part of λ_2 of Section 9.5.2. For a finite chain λ_2 belonged to a right eigenvector v, with $(Pv)_i = \mathbb{E}\big(v(X_1)\,|\,X_0 = i\big) = \lambda_2 v_i$. The continuous analogue is a function g whose conditional expectation one step later is a multiple of itself:

$$\begin{aligned}
\mathbb{E}\big(X_1 \,|\, X_0 = x\big) &\overset{(1)}{=} \rho\, x,\\
\mathbb{E}\big(X_1^2 - 1 \,|\, X_0 = x\big) &\overset{(2)}{=} \rho^2 x^2 + (1-\rho^2) - 1 = \rho^2\,(x^2-1),\\
\mathbb{E}\big(X_1^3 - 3X_1 \,|\, X_0 = x\big) &\overset{(3)}{=} \rho^3 x^3 + 3\rho x(1-\rho^2) - 3\rho x = \rho^3\,(x^3 - 3x).
\end{aligned} \tag{9.55}$$

(1) The kick has mean zero.
(2) $\mathbb{E}\big((\rho x + \sqrt{1-\rho^2}Z)^2\big) = \rho^2x^2 + 2\rho x\sqrt{1-\rho^2}\,\mathbb{E}\,Z + (1-\rho^2)\,\mathbb{E}\,Z^2$, with $\mathbb{E}\,Z = 0$ and $\mathbb{E}\,Z^2 = 1$.
(3) Write $\sigma = \sqrt{1-\rho^2}$ and expand the cube: $(\rho x + \sigma Z)^3 = \rho^3x^3 + 3\rho^2x^2\sigma Z + 3\rho x\sigma^2Z^2 + \sigma^3Z^3$, with $\mathbb{E}\,Z = \mathbb{E}\,Z^3 = 0$ (the Gaussian is symmetric) and $\mathbb{E}\,Z^2 = 1$; the $-3X_1$ term has expectation $-3\rho x$. The terms in x then combine to $3\rho x(1-\rho^2-1) = -3\rho^3 x$.

So $g_1(x) = x$ is an eigenfunction with eigenvalue ρ, $g_2(x) = x^2 - 1$ one with eigenvalue ρ^2, and $g_3(x) = x^3 - 3x$ one with eigenvalue ρ^3. Each is the power x^n minus lower powers chosen to cancel the extra terms the kick produces. These are the Hermite polynomials, and the pattern continues: the nth Hermite polynomial has eigenvalue ρ^n (Mehler's formula, not proved here). The slowest non-trivial mode decays as ρ^t, exactly the rate found for the mean in (9.54). The variance lives in the $x^2 - 1$ mode: by (9.54) its distance from the target value 1 is $1 - \operatorname{Var} X_t = \rho^{2t} = (\rho^2)^t$, the eigenvalue ρ^2 of that mode raised to the power t, so it relaxes twice as fast in the exponent.

Example: three starts, one law. With $\rho = 0.9$, Figure 9.18 starts three crowds of 20 000 walkers at $x_0 = -20$, 0 and $+20$, twenty standard deviations of the target apart. The means follow $\rho^t x_0$: from $x_0 = 20$ the crowd's mean after 40 steps is 0.29, against $20 \times 0.9^{40} = 0.296$. After 80 steps the three histograms lie on top of $\mathcal{N}(0,1)$; the crowd started at $+20$ has mean -0.005 and variance 1.016, against 0 and $1 - 0.9^{160} \simeq 1$. Everything a sampler needs is present: a normalisable stationary law, and geometric forgetting of the start.

Example: the free walk on a ring. Is it the randomness or the endless line that stops the free walker from settling? Wrap the line into a ring of K islands, and let the walker stay put with probability $\frac{1}{2}$ and step to each neighbour with probability $\frac{1}{4}$ (staying put removes the period 2 of Section 9.3.3). There is still no bias anywhere. The rows of the transition matrix sum to one and so do its columns (each island receives $\frac{1}{2}$ from itself and $\frac{1}{4}$ from each neighbour), so the uniform distribution $\pi_j = 1/K$ is stationary: $\sum_i \pi_i p_{ij} = \frac{1}{K}\sum_i p_{ij} = \frac{1}{K}\cdot 1$. The eigenvectors are the Fourier modes $v_j = e^{2\pi i\, jk/K}$, $k = 0, \dots, K-1$, the normal modes of a ring of coupled oscillators:

$$\begin{aligned}
(Pv)_j &\overset{(1)}{=} \tfrac{1}{2}v_j + \tfrac{1}{4}v_{j+1} + \tfrac{1}{4}v_{j-1} \overset{(2)}{=} v_j\Big[\tfrac{1}{2} + \tfrac{1}{4}\big(e^{2\pi ik/K} + e^{-2\pi ik/K}\big)\Big]\\
&\overset{(3)}{=} v_j\,\frac{1+\cos(2\pi k/K)}{2} \overset{(4)}{=} v_j\cos^2\frac{\pi k}{K}.
\end{aligned} \tag{9.56}$$

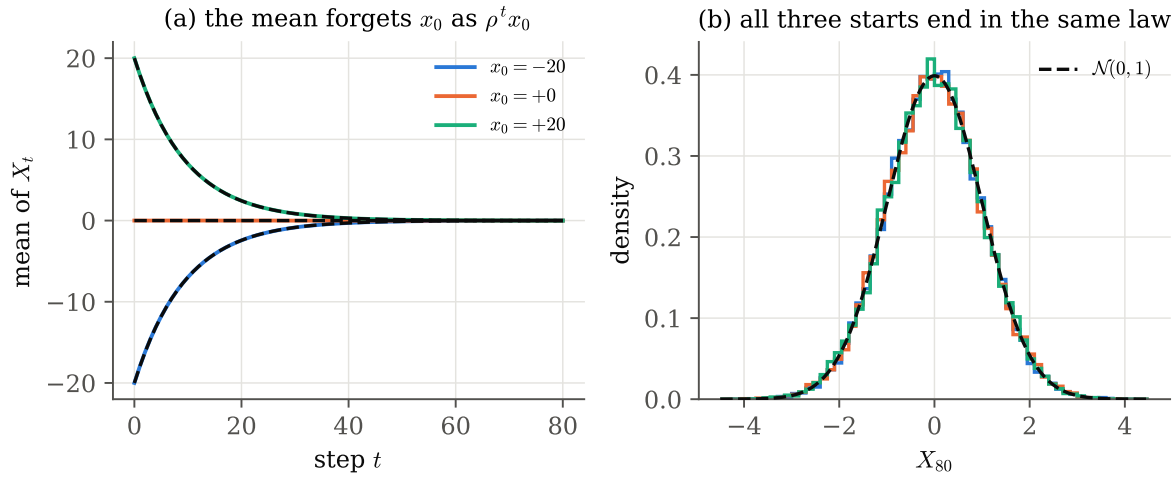

Figure 9.18: The walker with a pull, $X_{t+1} = 0.9X_t + \sqrt{1-0.81}\,Z$, forgets where it started. (a) The mean position of three crowds started at −20, 0 and +20 (solid) follows $\rho^t x_0$ (dashed) back to zero. (b) After 80 steps the three crowds have the same histogram, the standard Gaussian (dashed).

(1) One step: stay with probability $\frac{1}{2}$, move to either neighbour with $\frac{1}{4}$ (indices modulo K, which is the ring).
(2) $v_{j\pm1} = v_j\, e^{\pm 2\pi i k/K}$.
(3) $e^{i\phi} + e^{-i\phi} = 2\cos\phi$.
(4) $1 + \cos 2\alpha = 2\cos^2\alpha$.

Which mode is slowest? The eigenvalue $\cos^2(\pi k/K)$ lies between 0 and 1, and it is largest when the angle $\pi k/K$ is closest to 0 or to π. The mode $k = 0$ gives exactly 1: it is the constant vector, the uniform distribution itself. Among the others, the angle is closest to 0 or π for $k = 1$ and $k = K - 1$, the longest waves round the ring, so $\lambda_2 = \cos^2(\pi/K)$ (shared by the two). The distance from uniform decays as $\cos^{2t}(\pi/K)$, and the relaxation time is

$$\frac{1}{1-\lambda_2} = \frac{1}{\sin^2(\pi/K)} \simeq \frac{K^2}{\pi^2} \text{ steps},$$

using $1 - \cos^2 = \sin^2$ and, for large K, $\sin x \simeq x$ for the small angle $x = \pi/K$. For $K = 10$ islands, $\sin 18^\circ = 0.309$, $\sin^2 18^\circ = 0.0955$, and $1/0.0955 \simeq 10.5$ steps; for $K = 100$, $1/\sin^2 1.8^\circ \simeq 1013$, against $K^2/\pi^2 = 1013$. On a finite ring the free walker does settle, and its target is the flat distribution it was "trying" to sample all along. But the time it takes grows as the *square* of the size of the space, the signature of diffusion: to cross K sites with steps of size one takes about K^2 steps.

What diffusion costs a sampler. The ring makes a point that every random-walk sampler pays for. A chain that explores by unbiased local steps of size s needs about $(L/s)^2$ steps to cross a region of size L. Large steps would cross faster, but on a peaked target most of them land where the probability is tiny. The politician's acceptance rule of Section 9.2 and the Metropolis–Hastings rule built from detailed balance keep the unbiased proposal of (9.47) and add exactly the bias that is missing here, turning the unbiased walker into the biased one of Section 9.1: a step towards higher probability is always taken, a step away from it only sometimes, so that the walker lingers where the target is large [Kruschke §7.2.1], [Wasserman p. 411]. The diffusive cost then sets the length of every MCMC run. In the laptop examples of this chapter it means 10^4–10^5 steps of a fast model; a full cosmological analysis, with a dozen

correlated parameters and an expensive likelihood, needs the same order of steps per chain but at a second per step, which is why it runs on a cluster.

Recap

- A sample is the distribution for every practical purpose. An oscillator of fixed energy samples its own orbit when looked at at random instants, because its motion covers the orbit at the right rate; time average equals ensemble average. Many coupled degrees of freedom, a canonical ensemble or a posterior offer no such motion, so we build one.
- A Markov chain remembers one step: the next state depends only on the current one, through a transition matrix P (rows are pmfs) or kernel $p(x, y)$. A distribution of walkers evolves as $p_{t+1} = p_t P$, and P^n gives the n-step probabilities (Chapman–Kolmogorov). The MLE of p_{ij} from one history is n_{ij}/n_i.
- States split into communicating classes. A good sampler is irreducible (every state reachable from every other), positive recurrent (finite mean return time) and aperiodic. The symmetric walk on the integers is recurrent but null; biased, it is transient.
- π is stationary if $\pi P = \pi$: probability flowing in balances probability flowing out. Detailed balance, $\pi_i p_{ij} = \pi_j p_{ji}$, is a sufficient condition with no net current between any pair, the analogue of thermodynamic equilibrium; a circulating current can be stationary without it.
- A finite irreducible aperiodic chain forgets its starting distribution geometrically: $\|p_t - \pi\|_{\mathrm{TV}} \simeq C\,|\lambda_2|^t$, and the Doeblin contraction bounds it by $(1-\delta)^t$; coupling gives the same result by letting two walkers meet.
- The ergodic theorem: time averages along one walk converge to averages over π, also for periodic chains. Their variance is $\sigma^2\tau/N$ with $\tau = 1 + 2\sum_k \rho_k$, so N steps are worth N/τ independent draws; and $\pi_j = 1/m_j$ (Kac).
- The unbiased random walk on the line spreads as $s\sqrt{t}$, obeys the diffusion equation, and has no normalisable stationary density: it forgets its start, like $1/\sqrt{t}$, but has nothing to converge to. A restoring pull (AR(1)) gives a stationary $\mathcal{N}(0,1)$ and forgetting at rate ρ^t. The missing bias is what Metropolis–Hastings supplies.

9.8 From the drunkard to the biased walker

The free walk of Section 9.7 has a walker on the real line who, at every tick of a clock, takes a step $x_{t+1} = x_t + s\,z_t$ with z_t a fresh standard Gaussian number and s a fixed step length. That walker never settles. His spread grows like $s\sqrt{t}$, his distribution flattens out forever, and there is no normalisable density for him to converge to. He forgets where he started, but he has nothing to remember instead. We will call him the **drunkard**, or the unbiased random walker: every direction is as good as every other, because nothing in his rule knows about any particular distribution.

Now give the walker a job. Suppose the data of an experiment have left us with a posterior density for a parameter x, and that this posterior has two bumps:

$$f(x) = 0.3\,\mathcal{N}\big(x; -2, 0.6^2\big) + 0.7\,\mathcal{N}\big(x; 2, 0.8^2\big), \tag{9.57}$$

where $\mathcal{N}(x; \mu, \sigma^2)$ is the Gaussian density with mean μ and variance σ^2. A sign ambiguity does

this in practice: the data fix $|x|$ well and the sign of x only weakly. In a real problem we would not know that f is a sum of two Gaussians. All we would have is a routine that returns $f(x)$, or rather $\ln f(x)$ up to an additive constant, for any x we ask about. We cannot draw from f directly, but we would like a long list of numbers whose histogram is f: then every average, interval and marginal we want is a count over the list, as in Chapter 6.

The question. Keep the drunkard's way of suggesting a move: from the present position x, propose $y = x + s\,z$. Add one decision, "go to y or stay at x". Which decision rule makes the walker spend, in the long run, a fraction of his time near each x that is proportional to $f(x)$?

Before trying candidates, it helps to list what we are able to do at each step [Kruschke §7.2.4]: we can generate the proposal y; we can evaluate f at x and at y, so in particular the ratio $f(y)/f(x)$; and we can draw a uniform random number U in $[0, 1]$. Any rule must be built from these three things.

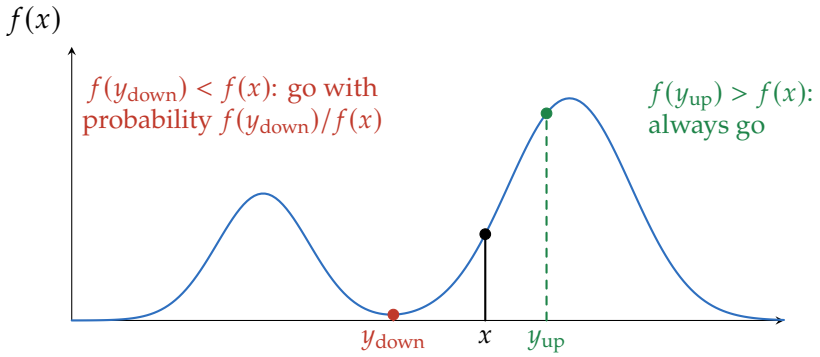

Figure 9.19: The Metropolis decision on the two-bump density. From the present point x the walker proposes a symmetric random step. A proposal to a higher density (green) is always taken. A proposal to a lower density (red) is taken with probability equal to the ratio of the two heights, so that small drops are usually taken and deep drops almost never.

Three candidate rules. We take the natural candidates one at a time and ask, for each, what its walker would do. Figure 9.20 shows the three walkers started at $x_0 = 0$ with step $s = 1.5$, for 50 000 steps.

Always go. This rule ignores f completely, so it cannot know where f is large. It is the drunkard again. Its walker drifts off and never comes back: after 50 000 steps it is at -38.75, a typical distance for a walk whose spread is $s\sqrt{t} \simeq 335.4$ (Figure 9.20a). Its histogram has nothing to do with f and keeps changing as the walk goes on.

Go only uphill. This rule uses f as much as possible: a proposal is taken only if $f(y) \geq f(x)$. Its walker climbs the nearest hill and stays at the top, because once it is at a maximum every proposal is downhill. Of all proposals only a fraction 2.200×10^{-4} were taken, and the walker ended at $x = 2.000$, the top of the right bump (Figure 9.20c). This is an optimiser, not a sampler: it finds the most probable value (here only the local one) and reports nothing about the spread around it.

Go uphill always, downhill sometimes. Between ignoring f and obeying it slavishly there is a middle way. Take every uphill proposal, and take a downhill one with a probability that shrinks the further down it goes: probability $f(y)/f(x)$, the ratio of the two heights (Figure 9.19). A step to a point half as probable is taken half the time; a step to a point a thousand times less probable is almost never taken. The walker now wanders, but it lingers where f is high. After discarding the first 1000 steps, its histogram lies on f (Figure 9.20b): it spent a fraction 0.7083 of its time at

$x > 0$, where (9.57) puts 0.7, its mean is 0.8518 against the exact $0.3 \times (-2) + 0.7 \times 2 = 0.8$, and its variance is 3.84 against 3.916. It accepted a fraction 0.5426 of its proposals.

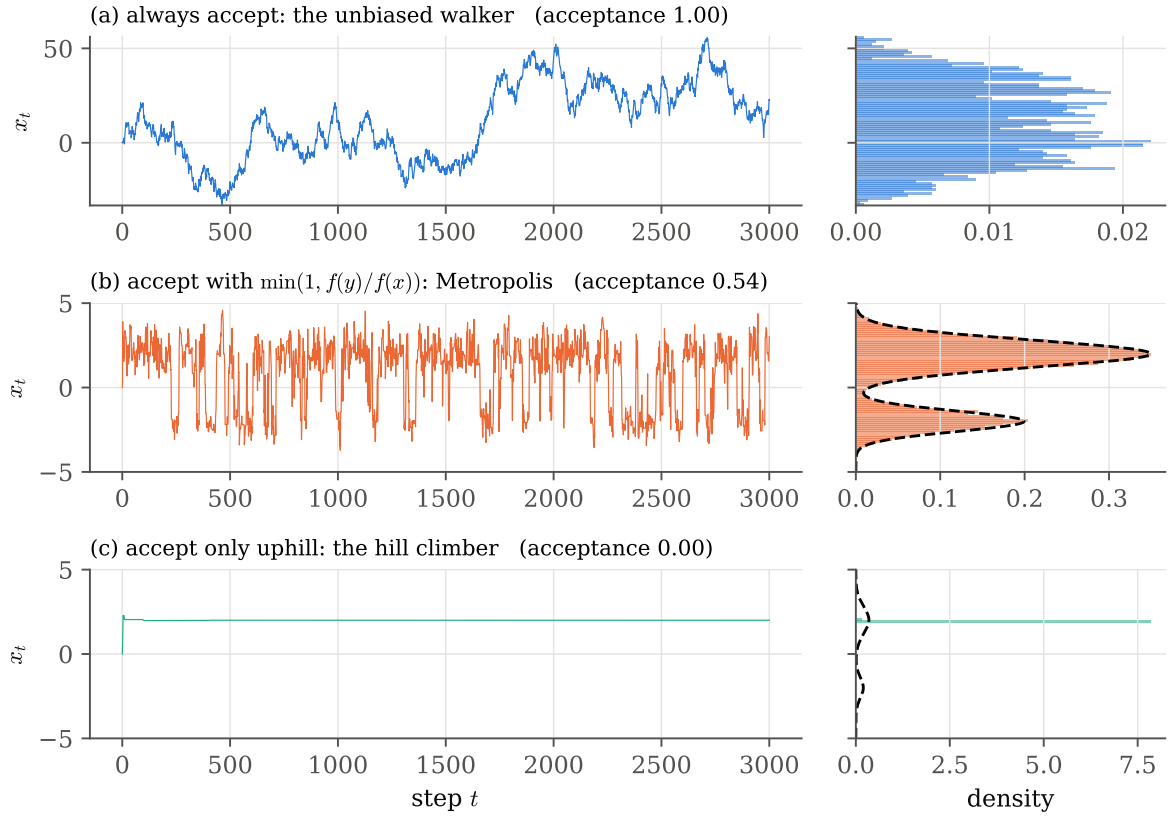

Figure 9.20: Three walkers with the same Gaussian proposals and three decision rules, on the two-bump density (9.57). Left: the first 3000 steps. Right: histograms, with the target dashed. (a) The drunkard wanders off; its histogram is not a density of anything stable. (b) The Metropolis walker hops between the bumps and its long-run histogram is the target. (c) The hill climber reaches the top of the nearest bump and freezes there.

Why the ratio $f(y)/f(x)$, and not, say, its square? Here is the plausibility argument; the proof comes with detailed balance (Section 9.9). Suppose many walkers are already spread out as f, the way the crowd of politicians was spread over the islands in proportion to the populations (Section 9.4). Take two points x and y with $f(y) < f(x)$. The number of walkers who move from x to y in one step is (number at x) $\times$ (chance of proposing y) $\times$ (chance of accepting). The number moving back is (number at y) $\times$ (chance of proposing x) $\times$ (chance of accepting). The proposal is symmetric, so the two proposal chances are equal. The walkers at x outnumber those at y by $f(x)/f(y)$. For the two flows to cancel, which is detailed balance, the acceptance from x to y must be smaller than the acceptance from y to x by exactly the factor $f(y)/f(x)$. Accepting every uphill move and downhill moves with probability $f(y)/f(x)$ does precisely that, and nothing else in the rule refers to f.

Key idea: The biased random walker

A random walk alone samples nothing: it diffuses forever. What turns it into a sampler is a bias, and the accept–reject step is that bias. Uphill proposals are always taken, a downhill proposal is taken with probability equal to the ratio of the target densities, and a refused proposal leaves the walker where he is for one more tick. The walker then spends more time where the probability is higher, in exact proportion to it. Without the accept–reject

step we would simply be simulating the random walk [Wasserman p. 415].

Written as a recipe, this is the algorithm that Metropolis et al. [36] published for the statistical mechanics of interacting particles, and that Hastings [143] generalised to asymmetric proposals (Section 9.9.1).

Working definition 9.8 (random-walk Metropolis)

Given a function returning $\ln f(x)$ up to a constant, a starting point x_0 with $f(x_0) > 0$, and a step length s:

1. *Propose* $y = x_t + s\,z$ with $z \sim \mathcal{N}(0,1)$ [the drunkard's step, symmetric in x and y].
2. *Compare*: compute $R = f(y)/f(x_t)$ [the only place the target enters].
3. *Decide*: draw $U \sim \text{Uniform}(0,1)$. If $U < R$ set $x_{t+1} = y$ [this happens with probability $\min(1, R)$]. Otherwise set $x_{t+1} = x_t$ [the old point is recorded again, it is not skipped].

The list $x_0, x_1, x_2, \ldots$, after the first stretch is discarded, is a correlated sample from f [Wasserman pp. 411–412], [Kruschke §7.3], [Padilla eq. 56]. *Operational test:* the fraction of accepted proposals is between about 0.2 and 0.5, and long runs from different starts give the same histograms (Sections 9.11 and 9.13).

9.8.1 Only ratios enter: the denominator of Bayes cancels

The rule needs $f(y)/f(x)$ and nothing else. To see why that is such good news, run once more through the reasoning of Chapter 5 that produces a posterior, in its usual order. *What did we observe?* The whole data vector $\boldsymbol{d}$, all of it at once, is the one observed event. *What could have produced it?* Each value of the parameter vector $\boldsymbol{\theta}$ is a candidate explanation, one hypothesis about how nature was set up. *How readily would each have produced it?* For every candidate the likelihood $p(\boldsymbol{d} \mid \boldsymbol{\theta})$ answers: had nature been set up this way, how plausible would it have been to get exactly this $\boldsymbol{d}$? *How do we update?* Bayes' theorem multiplies that likelihood by the prior plausibility of the candidate and divides by the evidence $Z = p(\boldsymbol{d})$, the sum of likelihood times prior over every candidate. That denominator is the one quantity that needs every hypothesis at once.

The walker never asks for a posterior on its own. At each tick it holds two candidate explanations side by side, the present point and the proposal, and asks only how much more weight one has than the other. A ratio of two weights that share the same denominator does not contain the denominator. Write the target as the posterior of a parameter vector $\boldsymbol{\theta}$ given data $\boldsymbol{d}$, with likelihood $\mathcal{L}(\boldsymbol{\theta}) = p(\boldsymbol{d} \mid \boldsymbol{\theta})$ and prior $p(\boldsymbol{\theta})$. For a current point $\boldsymbol{\theta}$ and a proposal $\boldsymbol{\theta}'$,

$$R \overset{(1)}{=} \frac{p(\boldsymbol{\theta}' \mid \boldsymbol{d})}{p(\boldsymbol{\theta} \mid \boldsymbol{d})} \overset{(2)}{=} \frac{\mathcal{L}(\boldsymbol{\theta}')\,p(\boldsymbol{\theta}')/Z}{\mathcal{L}(\boldsymbol{\theta})\,p(\boldsymbol{\theta})/Z} \overset{(3)}{=} \frac{\mathcal{L}(\boldsymbol{\theta}')\,p(\boldsymbol{\theta}')}{\mathcal{L}(\boldsymbol{\theta})\,p(\boldsymbol{\theta})},$$

$$\ln R \overset{(4)}{=} \big[\ln \mathcal{L}(\boldsymbol{\theta}') + \ln p(\boldsymbol{\theta}')\big] - \big[\ln \mathcal{L}(\boldsymbol{\theta}) + \ln p(\boldsymbol{\theta})\big]. \tag{9.58}$$

(1) The target density f is the posterior.
(2) Bayes' theorem (Chapter 5) at each of the two points, with the same $Z = \int \mathcal{L}(\boldsymbol{\theta})\,p(\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{\theta}$ in both.
(3) Z does not depend on the point at which the posterior is evaluated, so it cancels.
(4) Logarithm of a ratio is a difference of logarithms; the decision $U < R$ becomes $\ln U < \ln R$.

The walker needs "likelihood times prior" at two points, both of which we can always compute, and never the integral over all points, which we usually cannot: the evidence is the same number for both candidates, so it drops out. The same cancellation will appear in statistical

mechanics, where the target is the Boltzmann weight $e^{-E/kT}/Z$ and the normalisation Z is the partition function (Section 9.15).

Example: the coin. Kruschke's coin [Kruschke §7.3.1] landed heads $z = 14$ times in $N = 20$ flips. With a flat prior on the bias $\theta \in (0,1)$ the posterior is $p(\theta \mid \boldsymbol{d}) = \theta^z(1-\theta)^{N-z}/B(z+1, N-z+1)$, where B is the beta function. From $\theta = 0.6$ a proposal $\theta' = 0.75$ has

$$\ln R \overset{(1)}{=} 14 \ln \frac{0.75}{0.6} + 6 \ln \frac{0.25}{0.4} \overset{(2)}{=} 14 \times 0.2231 + 6 \times (-0.4700) = 3.124 - 2.820 = 0.304,$$

(1) The beta function, the evidence of this problem, cancels; the flat prior is 1 at both points.
(2) $\ln 1.25 = 0.2231$ and $\ln 0.625 = -0.4700$.

so $R = e^{0.304} = 1.36 > 1$ and the move is taken. The reverse proposal, from 0.75 to 0.6, has $R = 1/1.36 = 0.74$ and is taken 74 times in a hundred. The walker therefore sits near 0.75 a little more often than near 0.6, by the factor 1.36, which is the ratio of the posterior densities at the two points.

Example: why we never compute Z instead. The evidence is a D-dimensional integral. A grid with n points per axis costs n^D evaluations, 10^{12} for $n = 100$ and $D = 6$ (Chapter 5). Plain acceptance–rejection sampling (Chapter 6) does no better in many dimensions. To sample uniformly inside the unit ball in D dimensions by drawing points in the enclosing cube of side 2 and keeping those inside, the acceptance is the volume ratio $V_D/2^D = (\sqrt{\pi}/2)^D/\Gamma(1 + D/2)$: $\pi/4 \simeq 0.79$ for $D = 2$, about 0.0025 for $D = 10$, and about 10^{-70} for $D = 100$ [HobsonBMC §3.2.2, p. 61]. Most of a high-dimensional box is corners. A walker that moves locally and only compares neighbouring points never pays this price, because it never looks at the empty corners at all.[1]

Example: why logarithms. A likelihood built from many data points is a product of many factors and underflows. For a Gaussian likelihood of 10^4 data points with $\chi^2 \simeq 10^4$, $\mathcal{L} \propto e^{-\chi^2/2} = e^{-5000}$, far below the smallest positive double-precision number, $e^{-745} \simeq 5 \times 10^{-324}$. Every point would evaluate to zero and every ratio to $0/0$. The difference $\ln \mathcal{L}(\boldsymbol{\theta}') - \ln \mathcal{L}(\boldsymbol{\theta}) = -(\chi'^2 - \chi^2)/2$ is an ordinary number of order one. Every sampler below therefore works with $\ln f$ and accepts when $\ln U < \ln f(y) - \ln f(x)$, which is the advice of Chapter 5 to sum log-likelihoods and never multiply raw ones.

9.9 Why the rule is $\min(1, R)$: detailed balance

The walker of Section 9.8 took every uphill proposal and a downhill one with probability $f(y)/f(x)$, and on the two-bump density (9.57) its histogram came out right. We justified the rule with a crowd of walkers whose flows between two points cancel. That argument used one special feature, a symmetric proposal, and it left open whether other rules would also work. Both points matter in practice. Parameters with a boundary, such as a rate that must be positive, need proposals that are not symmetric, and among the rules that work we want the one that wastes the fewest proposals.

The question. Fix a way of proposing moves: from x, a candidate y is drawn from a density $q(y \mid x)$. With what probability $a(x, y)$ should we accept it so that the target f is the stationary distribution of the resulting chain?

[1] The source quotes ~ 0.025 for $n = 10$; the formula it gives evaluates to $(\sqrt{\pi}/2)^{10}/\Gamma(6) = 0.0025$.

The one-step law of the chain. Two things can happen in one step from x. Either a candidate y is proposed *and* accepted, which has density $q(y \mid x)\, a(x, y)$ in y; or the candidate is refused and the chain stays at x. The second possibility has total probability

$$r(x) = 1 - \int q(y \mid x)\, a(x, y)\, \mathrm{d}y, \tag{9.59}$$

because the proposal certainly produces some y and the step either accepts or refuses it. The transition kernel of Section 9.4.3 therefore has a smooth part and a spike at the starting point:

Working definition 9.9 (Metropolis–Hastings kernel)

The probability that one step from x lands in a small set $\mathrm{d}y$ is

$$P(x, \mathrm{d}y) = q(y \mid x)\, a(x, y)\, \mathrm{d}y \;+\; r(x)\, \delta_x(\mathrm{d}y), \tag{9.60}$$

where δ_x [the point mass at x, probability one on the point itself] carries the refusals, and the acceptance probability is

$$a(x, y) = \min\bigl(1, R_H(x, y)\bigr), \qquad R_H(x, y) = \frac{f(y)\, q(x \mid y)}{f(x)\, q(y \mid x)}. \tag{9.61}$$

R_H is the **Hastings ratio** [target ratio times the ratio of the reverse to the forward proposal density]; for a symmetric proposal, $q(x \mid y) = q(y \mid x)$, it reduces to $f(y)/f(x)$ [Wasserman p. 412], [HobsonBMC §3.2.4, p. 63], [Padilla eqs. 55–56].

Deriving the acceptance from detailed balance. Recall from Section 9.4.2 that a chain is in *detailed balance* with f when the probability flow from x to y equals the flow from y to x, for every pair. For $y \neq x$ only the smooth part of (9.60) moves probability, so we ask

$$\begin{aligned} & f(x)\, q(y \mid x)\, a(x, y) \overset{(1)}{=} f(y)\, q(x \mid y)\, a(y, x) \\ \Longleftrightarrow \quad & \frac{a(x, y)}{a(y, x)} \overset{(2)}{=} \frac{f(y)\, q(x \mid y)}{f(x)\, q(y \mid x)} \overset{(3)}{=} R_H(x, y). \end{aligned} \tag{9.62}$$

(1) Flow from x to y: density of being at x, times density of proposing y, times the chance of accepting; and the same for the reverse flow.
(2) Divide both sides by $f(x)\, q(y \mid x)\, a(y, x)$, assuming these are nonzero.
(3) Definition (9.61). Note that $R_H(y, x) = 1/R_H(x, y)$.

Detailed balance fixes only the *ratio* of the two acceptances, not each one. So let the acceptance be some function of the Hastings ratio, $a(x, y) = g\bigl(R_H(x, y)\bigr)$, with values in $[0, 1]$. Because $R_H(y, x) = 1/R_H(x, y)$, condition (9.62) becomes a condition on g alone:

$$g(R) = R\, g(1/R) \qquad \text{for every } R > 0. \tag{9.63}$$

Many functions satisfy it. Two classic ones are the Metropolis choice and Barker's choice:

$$\begin{aligned} g_{\mathrm{M}}(R) = \min(1, R): \quad & \text{for } R \geq 1, \;\; R\, g_{\mathrm{M}}(1/R) = R \cdot \tfrac{1}{R} = 1 = g_{\mathrm{M}}(R), \\ & \text{for } R < 1, \;\; R\, g_{\mathrm{M}}(1/R) = R \cdot 1 = R = g_{\mathrm{M}}(R); \\ g_{\mathrm{B}}(R) = \frac{R}{1 + R}: \quad & R\, g_{\mathrm{B}}(1/R) = R\, \frac{1/R}{1 + 1/R} = \frac{R}{R + 1} = g_{\mathrm{B}}(R). \end{aligned}$$

The Metropolis choice is the largest. Any admissible g satisfies two bounds: $g(R) \le 1$, because it is a probability, and $g(R) = R\,g(1/R) \le R \cdot 1 = R$, by (9.63) and the first bound applied to $g(1/R)$. Hence

$$g(R) \le \min(1, R) = g_{\mathrm{M}}(R) \qquad \text{for every admissible } g. \tag{9.64}$$

Metropolis accepts every proposal with the largest probability that detailed balance allows (Figure 9.21). Fewer refusals mean fewer wasted steps and less stickiness, and Peskun [145] showed that, for a given proposal, this choice also gives the smallest asymptotic variance of chain averages among such rules.

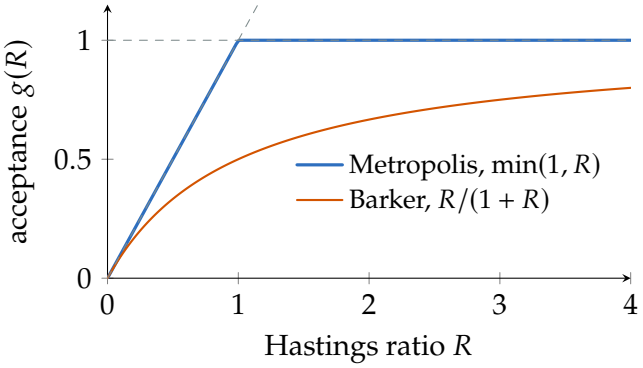

Figure 9.21: Two acceptance rules that both satisfy detailed balance. Every admissible rule lies below the line $g = R$ and below $g = 1$ (both dashed); the Metropolis rule runs along these two bounds, so it refuses as few proposals as possible.

From detailed balance to stationarity, with the refusals included. Detailed balance (9.62) concerns $y \neq x$. The refusals in (9.60) keep probability at x, and they must be counted when we check that f is stationary, that is, that a crowd of walkers spread as f is still spread as f after one step. The density of walkers at y after the step is the flow into y from everywhere else plus the walkers already at y who stayed:

$$\begin{aligned}\int f(x)\,q(y\,|\,x)\,a(x,y)\,\mathrm{d}x + f(y)\,r(y) &\overset{(1)}{=} \int f(y)\,q(x\,|\,y)\,a(y,x)\,\mathrm{d}x + f(y)\,r(y) \\ &\overset{(2)}{=} f(y)\Big[\int q(x\,|\,y)\,a(y,x)\,\mathrm{d}x + r(y)\Big] \overset{(3)}{=} f(y).\end{aligned} \tag{9.65}$$

(1) Detailed balance (9.62) for each pair (x, y) inside the integral.
(2) $f(y)$ does not depend on the integration variable x.
(3) By (9.59) at the point y, the probability of leaving y plus the probability of staying is one.

Wasserman checks (9.62) case by case [Wasserman pp. 413–414, (24.7)–(24.9)]: if $f(x)q(y\,|\,x) > f(y)q(x\,|\,y)$, then $a(x,y) = R_H < 1$ and $a(y,x) = 1$, so $f(x)\,q(y\,|\,x)\,a(x,y) = f(y)\,q(x\,|\,y) = f(y)\,q(x\,|\,y)\,a(y,x)$; the other case is the same with x and y exchanged.

Stationarity is half of what a sampler needs; the other half is that the chain actually gets there from any start. The results of Sections 9.5 and 9.6 supply it once the chain is irreducible and aperiodic. A Gaussian proposal has $q(y\,|\,x) > 0$ for every y, so any region where $f > 0$ can be reached in a single step: the chain is irreducible. And whenever some proposals are refused, the chain can stay put, which removes any cycle: it is aperiodic. Then the distribution of X_t converges to f from any starting point, and chain averages converge to averages over f (the ergodic theorem, Section 9.6).[2]

[2]For a continuous state space the full statement needs a little more measure theory (Harris recurrence); for the targets of this book, with f continuous and positive on a connected region and Gaussian proposals, it holds.

Example: two states, Metropolis against Barker. Take two states with target $f = (\frac{1}{3}, \frac{2}{3})$ and a proposal that always suggests the other state, so q is symmetric and the Hastings ratio is just the target ratio. A walker in state 1 is offered state 2, with $R = f_2/f_1 = 2$; a walker in state 2 is offered state 1, with $R = f_1/f_2 = \frac{1}{2}$. Each rule turns these two ratios into acceptance probabilities:

$$\begin{aligned} &\text{from state 1 } (R = 2): \quad a_{\mathrm{M}} \overset{(1)}{=} \min(1, 2) = 1, && a_{\mathrm{B}} \overset{(2)}{=} \frac{2}{1+2} = \frac{2}{3}, \\ &\text{from state 2 } (R = \tfrac{1}{2}): \quad a_{\mathrm{M}} \overset{(1)}{=} \min\bigl(1, \tfrac{1}{2}\bigr) = \tfrac{1}{2}, && a_{\mathrm{B}} \overset{(2)}{=} \frac{1/2}{1+1/2} = \frac{1}{3}. \end{aligned}$$

(1) The Metropolis rule $g_{\mathrm{M}}(R) = \min(1, R)$.
(2) Barker's rule $g_{\mathrm{B}}(R) = R/(1 + R)$.

An accepted proposal switches state; a refused one keeps it, so each row of the transition matrix is (refuse, accept) or (accept, refuse). With rows labelled by where the walker is and columns by where it goes,

$$P_{\mathrm{M}} = \begin{pmatrix} 0 & 1 \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix}, \qquad P_{\mathrm{B}} = \begin{pmatrix} \frac{1}{3} & \frac{2}{3} \\ \frac{1}{3} & \frac{2}{3} \end{pmatrix}.$$

Both leave f unchanged: $(\frac{1}{3}, \frac{2}{3})P_{\mathrm{M}} = (\frac{1}{3}, \frac{2}{3})$, and every row of P_{B} is already f.

Which is the better sampler? Both are correct, so the question is how many steps each needs for a given precision. The two-state chain with $p_{12} = a$ and $p_{21} = b$ has autocorrelation λ^k with $\lambda = 1 - a - b$ and integrated autocorrelation time $\tau = (1 + \lambda)/(1 - \lambda)$, from (9.45). Barker has $a = \frac{2}{3}$, $b = \frac{1}{3}$, $\lambda = 0$ and $\tau = 1$: its draws are independent. Metropolis has $a = 1$, $b = \frac{1}{2}$, $\lambda = -\frac{1}{2}$ and

$$\tau_{\mathrm{M}} = \frac{1 - \frac{1}{2}}{1 + \frac{1}{2}} = \frac{1}{3}.$$

What τ buys. The variance of a chain average is $\sigma^2\tau/N$ by (9.44), where σ^2 is the variance of one value. Independent draws have $\tau = 1$, so N_{ind} of them give $\sigma^2/N_{\mathrm{ind}}$. The two variances are equal when $N_{\mathrm{ind}} = N/\tau$, which for $\tau_{\mathrm{M}} = \frac{1}{3}$ is $3N$: N Metropolis steps estimate the fraction of time in state 1 as well as $3N$ independent draws would.

Why the chain beats independence. From state 1 the move to state 2 is uphill, and Metropolis never refuses an uphill move, so the walker leaves state 1 at every visit. The chain switches state as often as detailed balance allows, and a value in state 1 is followed by a value in state 2 more often than chance would have it. Successive values are anticorrelated ($\lambda < 0$), and their errors in the running average partly cancel instead of adding up. Barker refuses the uphill move one time in three and loses this. The general statement, proved by Peskun [145] for any target and any fixed proposal, is that a rule which refuses less never gives a larger asymptotic variance; the two-state matrices above are that theorem in its smallest case.

Example: the tempered family. What if the walker accepts with probability $\min\bigl(1, R^\beta\bigr)$ for some exponent $\beta \geq 0$? Since

$$R^\beta = \left(\frac{f(y)}{f(x)}\right)^\beta = \frac{f(y)^\beta}{f(x)^\beta},$$

this is exactly the Metropolis rule for the target f^β, so by (9.65) the walker samples $f^\beta / \int f^\beta$. The family interpolates between the two failures of Section 9.8: $\beta = 0$ is the drunkard ($f^0 = 1$ is flat and not normalisable on the line) and $\beta \to \infty$ is the hill climber (f^β piles up at the highest point). Figure 9.22 checks the claim on the two-bump density with 2×10^5 steps: the fraction of time at $x > 0$ is 0.5929 for $\beta = 0.3$ (exact, from $f^{0.3}$ normalised on a grid: 0.5915), 0.6937 for

$\beta = 1$ (0.6957) and 0.8742 for $\beta = 3$ (0.8772). If $f = e^{-E}$ then $f^\beta = e^{-\beta E}$, a Boltzmann weight at temperature $1/\beta$: lowering β heats the target and flattens its barriers. Simulated annealing (raising β slowly to find a global maximum) and parallel tempering (running several β at once and swapping) are built on this observation; the temperature returns as a physical temperature in Section 9.15.

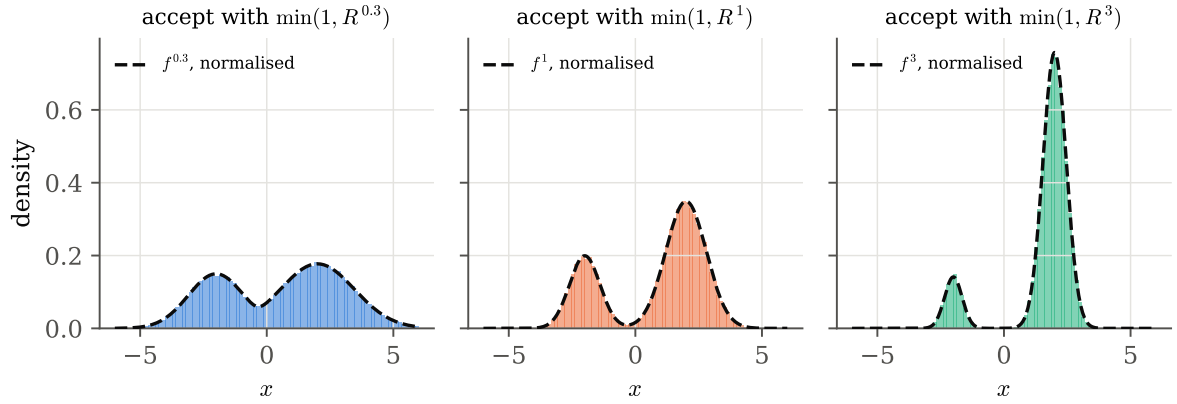

Figure 9.22: A walker that accepts with $\min(1, R^\beta)$ samples f^β, not f. Histograms of three such walkers on the two-bump density, with f^β normalised on a grid (dashed). Small β flattens the target towards the drunkard's flat line; large β sharpens it towards the hill climber's spike.

9.9.1 Asymmetric proposals: the Hastings factor

A Poisson process gave $n = 2$ events in unit exposure. With a flat prior on the rate $\lambda > 0$, the posterior is $f(\lambda) \propto \lambda^2 e^{-\lambda}$, a Gamma density with shape 3, mean 3, and probability 0.01439 below $\lambda = 0.5$. Rates, variances, masses and amplitudes all live on a half-line, and near the wall at $\lambda = 0$ a Gaussian proposal of width $s = 2$ often suggests a negative rate.

The question. What should the walker do with a proposal on the wrong side of the wall, and what changes if we choose proposals that never cross it?

We try five samplers, each run for 200 000 steps (Figure 9.23), and ask of each whether it satisfies (9.62).

A: Gaussian step, stay put if $y < 0$. The target is $f(y) = 0$ there, so $R = 0$ and the proposal is refused like any other bad proposal. Nothing about the rule has changed, so it is exact: mean 3.008, and a fraction 0.01464 of the time below 0.5.

B: Gaussian step, redraw until $y > 0$, no correction. This feels harmless but changes the proposal. *The redrawn proposal density.* An untruncated step $y = x + sZ$ has density $\phi\big((y - x)/s\big)/s$, where ϕ and Φ are the standard Gaussian density and cumulative distribution. The step lands on the allowed side with probability $\mathrm{P}(x + sZ > 0) = \mathrm{P}(Z > -x/s) = \Phi(x/s)$, the last step because Z is symmetric about zero. Redrawing until $y > 0$ keeps only those draws, so it renormalises the Gaussian over $y > 0$ by dividing by that probability:

$$q(y \mid x) = \frac{\phi\big((y - x)/s\big)}{s\,\Phi(x/s)}, \qquad y > 0. \tag{9.66}$$

Close to the wall, $\Phi(x/s)$ is near $\frac{1}{2}$ (half of all steps are thrown back); far from it, $\Phi(x/s)$ is near 1. So the denominator differs between the two directions of a move.

Which flow is unbalanced? Take a point x near the wall and a point y farther out. Sampler B accepts with $\min\big(1, f(y)/f(x)\big)$, as if the proposal were symmetric. The two flows of (9.62) are then

$$\frac{\text{flow } x \to y}{\text{flow } y \to x} \overset{(1)}{=} \frac{f(x)\, q(y \mid x) \min\big(1, f(y)/f(x)\big)}{f(y)\, q(x \mid y) \min\big(1, f(x)/f(y)\big)} \overset{(2)}{=} \frac{q(y \mid x)\ \min\big(f(x), f(y)\big)}{q(x \mid y)\ \min\big(f(y), f(x)\big)} \overset{(3)}{=} \frac{\Phi(y/s)}{\Phi(x/s)}.$$

(1) Density at the start, times the proposal density, times the acceptance, for each direction.
(2) Take $f(x)$ and $f(y)$ inside the minimum: $f(x)\min(1, f(y)/f(x)) = \min(f(x), f(y))$.
(3) The two minima are the same number. In the ratio of the two densities (9.66) the ϕ factors are equal, because ϕ is even, and only the denominators are left.

For x nearer the wall than y, $\Phi(y/s) > \Phi(x/s)$ and the ratio exceeds one. With $s = 2$, $x = 0.2$ and $y = 2$ it is $\Phi(1)/\Phi(0.1) = 0.841/0.540 \simeq 1.56$: probability leaves the neighbourhood of the wall about one and a half times as fast as it comes back. Detailed balance fails in one direction for every such pair, so the walker settles into a stationary law that is depleted near zero. That is what the run measures: it spent only 0.009384 of its time below 0.5, and its mean came out at 3.183.

C: as B, with the Hastings factor. From (9.66), the ϕ factors are equal because ϕ is even, and

$$\frac{q(x \mid y)}{q(y \mid x)} = \frac{\phi\big((x-y)/s\big)/[s\,\Phi(y/s)]}{\phi\big((y-x)/s\big)/[s\,\Phi(x/s)]} = \frac{\Phi(x/s)}{\Phi(y/s)}.$$

Multiplying the target ratio by this factor, as (9.61) instructs, restores balance: mean 2.975, fraction below 0.5 0.01402.

D: multiplicative steps with the Hastings factor. Propose $y = x\, e^{\sigma Z}$ with $\sigma = 1$ and $Z \sim \mathcal{N}(0, 1)$: a Gaussian step in $\ln \lambda$, which can never cross zero. This is Lambert's log-normal proposal [Lambert §13.8]. Its density is

$$\begin{aligned} q(y \mid x) &\overset{(1)}{=} \frac{1}{y\,\sigma\sqrt{2\pi}} \exp\Big[-\frac{(\ln y - \ln x)^2}{2\sigma^2}\Big], \\ \frac{q(x \mid y)}{q(y \mid x)} &\overset{(2)}{=} \frac{1/x}{1/y} = \frac{y}{x}. \end{aligned} \tag{9.67}$$

(1) $\ln y = \ln x + \sigma Z$ is Gaussian; the density of y picks up the Jacobian $|\mathrm{d} \ln y/\mathrm{d}y| = 1/y$ (change of variables, Chapter 2).
(2) The exponential is symmetric in x and y and cancels; only the Jacobian factors remain.

With the factor y/x the sampler is exact: mean 3.012, fraction below 0.5 0.01366.

E: as D, without the factor. Here the walker uses $\min\big(1, f(y)/f(x)\big)$ although the proposal is not symmetric in λ. What does it sample? In the variable $u = \ln \lambda$ the proposal $u \to u + \sigma Z$ *is* symmetric, and the decision uses $f(e^{u'})/f(e^u)$. So, as a chain in u, it is an honest Metropolis sampler of the density $h(u) \propto f(e^u)$. Back in λ,

$$p_E(\lambda) \overset{(1)}{=} h(\ln \lambda) \left|\frac{\mathrm{d}u}{\mathrm{d}\lambda}\right| \overset{(2)}{=} \frac{f(\lambda)}{\lambda} \overset{(3)}{=} \lambda\, e^{-\lambda}. \tag{9.68}$$

(1) Change of variables from u to $\lambda = e^u$.
(2) $h(\ln \lambda) \propto f(\lambda)$ and $\mathrm{d}u/\mathrm{d}\lambda = 1/\lambda$.
(3) $f(\lambda) \propto \lambda^2 e^{-\lambda}$.

The forgotten factor costs one power of λ: the walker samples a Gamma density with shape 2 and mean 2. It returned mean 1.989 and fraction 0.09093 below 0.5, against $1 - 1.5\, e^{-0.5} = 0.090$

for that wrong target. The Hastings factor is the Jacobian of the proposal's own geometry; leaving it out is the same mistake as forgetting a Jacobian when changing variables. This is also Wasserman's advice for bounded parameters, "transform to $\ln X$" [Wasserman p. 415]: sampling $u = \ln \lambda$ with symmetric steps is fine provided the target in u includes the Jacobian, $h(u) = f(e^u)\, e^u$, which is exactly the factor y/x of D.

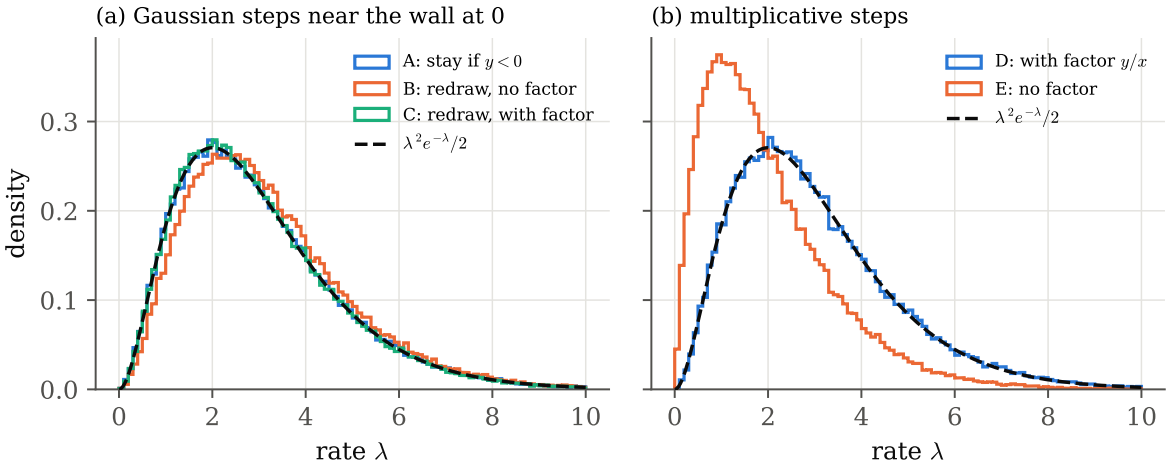

Figure 9.23: Five ways to sample a positive rate with posterior $\lambda^2 e^{-\lambda}/2$ (dashed). (a) Gaussian steps: staying put when the step crosses zero (A) and redrawing with the Hastings factor (C) are exact; redrawing without it (B) pushes the walker away from the wall. (b) Multiplicative steps: with the factor y/x (D) exact; without it (E) the walker samples $\lambda e^{-\lambda}$, with one power of λ missing.

Sampler A deserves a remark because one textbook warns against it. Lambert writes that if all steps proposing a negative value are rejected, too few samples are generated near zero [Lambert §13.8].[3] What goes wrong is redrawing, not refusing.

Watch out: A refusal repeats the current point

In acceptance–rejection sampling (Chapter 6, [Cowan §3.3]) a rejected candidate is thrown away and a fresh independent one is drawn. In Metropolis–Hastings a refused proposal means the walker stays, and the current point is written into the chain *again*. The repeats are not a nuisance: they are how a high-density point earns its extra weight, by being hard to leave. Recording only the accepted moves, or redrawing until something is accepted, removes that weight and biases every average towards low-density regions [Padilla §4.1.1, step 4].

Example: the independence sampler. The proposal need not depend on x at all. Draw every candidate from a fixed density g, so $q(y \mid x) = g(y)$. Then (9.61) gives

$$R_H(x, y) = \frac{f(y)\, g(x)}{f(x)\, g(y)} = \frac{w(y)}{w(x)}, \qquad w \equiv \frac{f}{g}, \tag{9.69}$$

the ratio of the importance weights of Chapter 6 at the candidate and at the current point [Wasserman p. 415]. A candidate with a larger weight than the current point is always accepted; one with a smaller weight sometimes. When $g = f$ every weight is equal and every proposal is accepted: the chain becomes independent sampling. When g has thinner tails than f, a walker

[3] Lambert's statement and Fig. 13.15 describe what happens when the negative proposals are *discarded and redrawn*, which is our sampler B. If the walker stays where it is and records the current point again, which is how every Metropolis step treats a refusal, the region near zero is sampled correctly; sampler A agrees with the exact answer.

that reaches the tail finds $w(x)$ huge and refuses almost everything for a very long time; for exactly the reason given in Chapter 6 for importance sampling, g must have heavier tails than f.

9.10 The sampler in a dozen lines, and two textbook runs

The biased walker of Section 9.8 needs three operations per step: a Gaussian kick, one evaluation of $\ln f$, and one uniform number. That fits in a short function, and the same function will drive every chain in the rest of the book: the straight-line fit and the CMB likelihood that follow, the comparison with the Fisher matrix in Chapter 10, and the topological summaries of Chapter 12. Before trusting it with any of those, we run it on two published examples whose numbers we did not choose, Wasserman's Cauchy chains and Kruschke's coin.

Listing 9.5: Random-walk Metropolis, the core of `lib_mcmc.py` (`code/ch09/lib_mcmc.py`)

```
def metropolis(logp, x0, n, step, rng, cov=None):
    """Random-walk Metropolis with Gaussian proposal y = x + step * L z,  z ~ N(0, 1).

    L is the Cholesky factor of ``cov`` (identity if None).  The proposal is symmetric,
    q(y|x) = q(x|y), so the acceptance probability is min(1, p(y)/p(x)).
    Returns (chain, logp_chain, acceptance_fraction).
    """
    x = np.atleast_1d(np.asarray(x0, dtype=float))
    D = x.size
    L = np.eye(D) if cov is None else np.linalg.cholesky(np.atleast_2d(cov))
    chain = np.empty((n + 1, D))
    lp_chain = np.empty(n + 1)
    lp = logp(x)
    chain[0], lp_chain[0] = x, lp
    kicks = step * rng.standard_normal((n, D)) @ L.T     # all proposal increments at once
    log_u = np.log(rng.random(n))                          # all uniform draws at once
    accepted = 0
    for t in range(n):
        y = x + kicks[t]                                   # 1. propose: the unbiased walker
        lp_y = logp(y)
        if log_u[t] < lp_y - lp:                           # 2. the bias: accept with
    min(1, p(y)/p(x))
            x, lp = y, lp_y
            accepted += 1
        chain[t + 1], lp_chain[t + 1] = x, lp              # 3. a rejection repeats x
    return chain, lp_chain, accepted / n
```

The function follows the working definition of Section 9.8 line by line, with four practical choices.

- The target enters only through `logp`, the log density up to a constant. A point outside the support returns $-\infty$; then $\ln U < -\infty$ is false and the proposal is refused, which is sampler A of Section 9.9.1.
- The proposal is $y = x + s\,Lz$ with z a vector of independent standard Gaussians and L the Cholesky factor of a matrix $\mathbf{C}$, so $LL^{\mathsf{T}} = \mathbf{C}$. Its covariance is $\mathrm{Cov}(sLz) = s^2 L\ \mathrm{Cov}(z)\, L^{\mathsf{T}} = s^2 LL^{\mathsf{T}} = s^2\mathbf{C}$. With no $\mathbf{C}$ given, the steps are round; shaping them like the target is the subject of Section 9.11.
- All Gaussian kicks and all uniform numbers are drawn at once before the loop. Only the decision, which depends on where the walker is, has to be sequential.
- The value of $\ln f$ at the current point is stored, so each step costs exactly one evaluation of the target, at the proposal. In a cosmological analysis that evaluation is a full likelihood call, and the number of steps is the cost of the analysis.

A refused step writes the current point again (the last line of the loop). The companion function `mh` in the same file takes any proposal together with its log density `log_q` and adds $\ln q(x \mid y) - \ln q(y \mid x)$ to the log ratio, which is the Hastings factor of (9.61); samplers C, D and E of Section 9.9.1 used it.

Watch out: Start where the target is positive

Follow what the function does if the starting point has $f(x_0) = 0$. Its stored log density is then $\ln f(x_0) = -\infty$. If a proposal y lands where $f(y) > 0$, the log ratio is the finite number $\ln f(y)$ minus $-\infty$, which is $+\infty$; the test $\ln U < +\infty$ is true, the move is taken, and from then on the walker is inside the support and everything is normal. But if the proposal also lands where $f = 0$, the log ratio is $(-\infty) - (-\infty)$, which floating-point arithmetic returns as `NaN` ("not a number"). Every comparison with `NaN` is false, so $\ln U <$ `NaN` is false and the proposal is refused, without any warning. A start outside the support with steps too short to reach it, say $\theta_0 = -1$ for a coin bias with steps of 0.02, therefore refuses every proposal: the trace is a flat line and the acceptance is exactly zero. The same happens inside the support if $\ln f$ underflows to $-\infty$ at the start and at all its neighbours. Always start where the posterior is positive [Kruschke §7.3]: inside the prior range, with a finite likelihood.

9.10.1 Wasserman's Cauchy chains

Wasserman's first MCMC example [Wasserman pp. 412–413, Ex. 24.10] makes one point. A Metropolis chain samples a density we cannot draw from directly, and it is correct for every proposal width; but how quickly its histogram comes to resemble the target depends on that width, and a badly chosen width wastes most of the run. He judges this by eye: a chain *mixes well* when its trace wanders over the whole range of the target without creeping or sticking. As target he takes the Cauchy density of Chapter 2,

$$f(x) = \frac{1}{\pi(1 + x^2)},$$

which is a good test for two reasons: every property of it is known exactly, so any run can be checked, and its tails are heavy, so a sampler has to reach far from the centre to get it right.

The ratio the walker uses. His proposal is a Gaussian step, $y \sim \mathcal{N}(x, b^2)$, with b the step width. It is symmetric, so the acceptance needs only the target ratio:

$$R = \frac{f(y)}{f(x)} \overset{(1)}{=} \frac{1/[\pi(1 + y^2)]}{1/[\pi(1 + x^2)]} \overset{(2)}{=} \frac{1 + x^2}{1 + y^2}.$$

(1) The Cauchy density at the proposal and at the present point.
(2) The π cancels, like every normalisation (Section 9.8.1); dividing by a fraction is multiplying by its inverse.

A proposal nearer the centre than x has $R > 1$ and is always taken; one farther out is taken with probability $(1 + x^2)/(1 + y^2)$, which falls like $1/y^2$ for a long jump.

The setup. Wasserman runs three chains that differ only in the width:

	small width	middle width	large width
proposal width b	0.1	1	10
steps N	1000	1000	1000
start	$x_0 = 0$	$x_0 = 0$	$x_0 = 0$

The start is at the centre of the target, so there is no burn-in to discard: everything that goes wrong is caused by the width. The width 0.1 is a tenth of the half-width of the Cauchy peak, and 10 is ten times it.

A number to check against. The trace plots of his Fig. 24.2 carry no numbers, so we need one that a run can be checked with. A convenient one is the fraction of time spent at $|x| < 1$, whose exact value is

$$\mathrm{P}(|X| < 1) \overset{(1)}{=} \int_{-1}^{1} \frac{\mathrm{d}x}{\pi(1+x^2)} \overset{(2)}{=} \frac{1}{\pi}\big[\arctan x\big]_{-1}^{1} = \frac{1}{\pi}\Big(\frac{\pi}{4} + \frac{\pi}{4}\Big) = \frac{1}{2}.$$

(1) Probability of an interval is the integral of the density over it.
(2) $\mathrm{d}(\arctan x)/\mathrm{d}x = 1/(1+x^2)$.

What we compute. The script `13_textbook_chains.py` calls the function `metropolis` listed above with the log target $-\ln(1+x^2)$ (the constant $-\ln\pi$ is dropped), the start [0], and each width in turn. For each width it makes two runs: one of 1000 steps, as Wasserman did, and one of 2×10^5 steps. From each it records the fraction of steps with $|x| < 1$, and from the long run also the acceptance rate and the integrated autocorrelation time τ of the indicator of $|x| < 1$ (Section 9.6.2, estimated as in Section 9.12.2). A chain of N steps with correlation time τ is worth N/τ independent draws.

Side by side. Figure 9.24 shows our three 1000-step chains, laid out as in his Fig. 24.2, and the table puts his verdicts next to our numbers.

proposal width b	0.1	1	10
Wasserman, Fig. 24.2 (by eye)	explores little	mixes well	often stuck
ours, 1000 steps: time at $\lvert x\rvert < 1$	0.8332	0.2478	0.5455
ours, 2×10^5 steps: time at $\lvert x\rvert < 1$	0.5517	0.5032	0.5002
ours, 2×10^5 steps: acceptance	0.9731	0.7723	0.2712
ours, 2×10^5 steps: τ (steps)	608	23.86	15.5

The traces have the features he describes. With $b = 0.1$ the walker takes tiny steps and is still exploring the centre after 1000 of them, so it spends far too much time at $|x| < 1$. With $b = 10$ most proposals land far out in the tail and are refused, and the trace is a staircase of long flat stretches. The $b = 1$ chain looks the liveliest. But in our run it happened to make a long excursion into a tail and spent only 0.2478 of its time at $|x| < 1$, further from the exact $\frac{1}{2}$ than the "stuck" $b = 10$ chain.

Why the verdicts differ. A 1000-step run cannot carry the weight of a ranking. The statistical error of a chain average is $\sigma\sqrt{\tau/N}$ (Section 9.12.2). For the fraction of time at $|x| < 1$, an average of an indicator that is 1 half the time, $\sigma = \frac{1}{2}$. With $N = 1000$ and the long-run τ values of the table, the error is $\frac{1}{2}\sqrt{23.86/1000} \simeq 0.08$ for $b = 1$ and $\frac{1}{2}\sqrt{15.5/1000} \simeq 0.06$ for $b = 10$: two widths whose τ differ by less than a factor of two cannot be told apart by one short run, and any single 1000-step histogram, his or ours, is a noisy copy of the target. Only $b = 0.1$, whose τ is some thirty times larger, is clearly worse in 1000 steps, and that part of his verdict stands.

The long runs are close to converged (each fraction is within two of its errors of $\frac{1}{2}$), and they rank the other two the other way round: $b = 10$ has the shorter τ, so it is at least as good as $b = 1$ although it refuses three proposals in four. The reason is the Cauchy tail: $\mathrm{P}(|X| > 10) = 1 - \frac{2}{\pi}\arctan 10 = 0.063$, so six per cent of the probability sits beyond $|x| = 10$, and only long jumps reach it in reasonable time. A walker with $b = 1$ has to diffuse out there one unit at a time and back again, which is the long excursion its short trace shows. A good step length depends on the shape of the target, not only on the width of its peak.

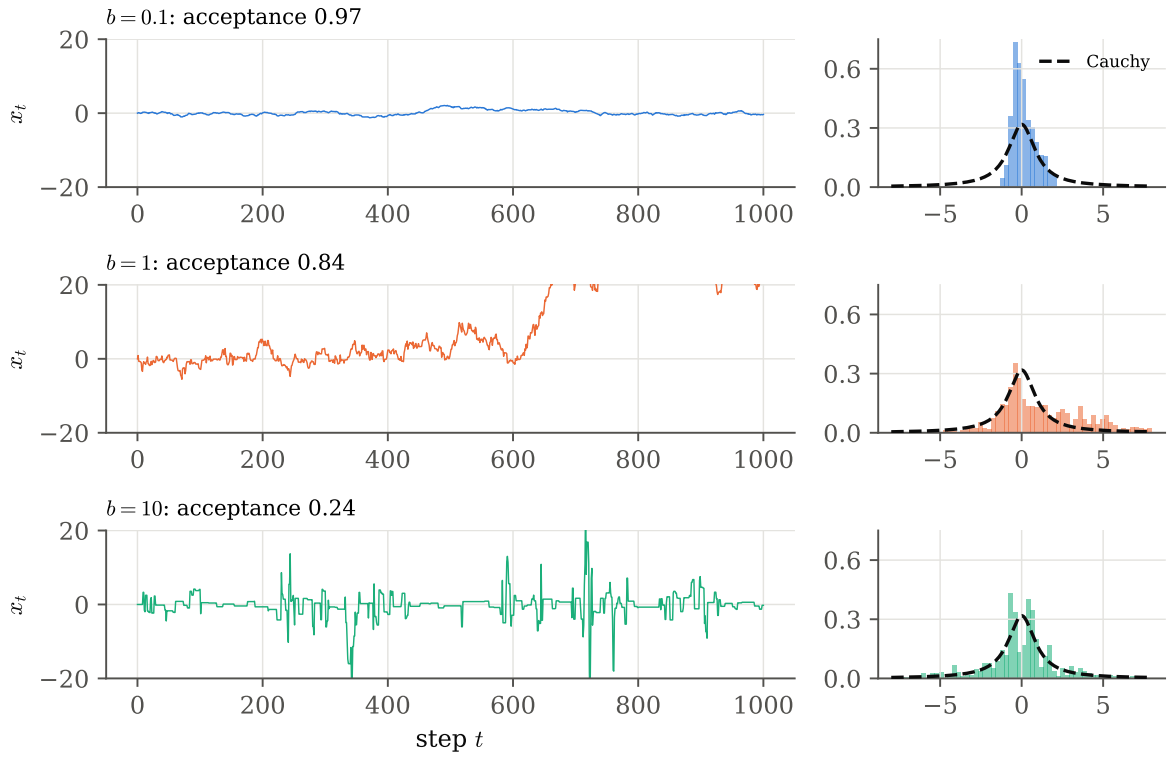

Figure 9.24: Wasserman's Cauchy example: three Metropolis chains of 1000 steps with proposal widths $b = 0.1$, 1 and 10 (left), and their histograms with the Cauchy density (right). Small steps creep; large steps are mostly refused and the trace has flat stretches; in 1000 steps no histogram is yet a good copy of the target.

Note also what we did *not* estimate: the mean of a Cauchy variable does not exist (Chapter 2), and a chain average of x would wander forever however well the chain mixes. A sampler cannot create a moment the distribution does not have.

The lesson. A thousand steps judged by eye can tell a creeping chain from a working one, but they cannot rank two working samplers; that takes τ from a long run.

9.10.2 Kruschke's coin

Kruschke's first Metropolis run [Kruschke §7.3.1, Fig. 7.4] answers a question every user of the method has at the start. A coin was flipped $N = 20$ times and landed heads $z = 14$ times. We want the posterior for its bias θ, the probability of heads, and we do not want to integrate anything: can a walker that only ever compares two values of θ produce that posterior, and what does the choice of proposal width do to the result?

The exact answer, for checking. With the flat prior $\mathrm{Beta}(\theta; 1, 1)$ the posterior can be written down, which is why the problem makes a good test:

$$p(\theta \mid \boldsymbol{d}) \overset{(1)}{=} \frac{\theta^{14}(1-\theta)^{6} \cdot 1}{\int_0^1 t^{14}(1-t)^{6}\,\mathrm{d}t} \overset{(2)}{=} \mathrm{Beta}(\theta; 15, 7),$$

(1) Bernoulli likelihood $\theta^{z}(1-\theta)^{N-z}$ times a flat prior, normalised.

(2) The normalised density $\propto \theta^{a-1}(1-\theta)^{b-1}$ is the beta density with $a = 15$, $b = 7$ (Chapter 5); its mean is $a/(a+b) = 15/22 = 0.6818$ and its standard deviation is 0.097.

The walker does not use this formula. It receives only the log target $14\ln\theta + 6\ln(1-\theta)$ inside $(0,1)$ and $-\infty$ outside, and the integral in the denominator never appears (Section 9.8.1).

A deliberately bad start. Kruschke starts every chain at $\theta = 0.01$, far in the left tail: the posterior density there is smaller than at the mean by a factor

$$\frac{f(0.01)}{f(0.68)} = \exp\left[14\ln\frac{0.01}{0.68} + 6\ln\frac{0.99}{0.32}\right] \simeq e^{-52}.$$

A start there shows the walker finding the posterior before it explores it, the burn-in of Section 9.12.1, and how long that takes for each width.

Three widths. Each chain runs 50 000 steps, and only the width s of the Gaussian proposal changes. Compared with the posterior width of about 0.1:

- $s = 0.02$ is a fifth of the posterior width. Almost every step is a small move to a point of nearly the same density, so almost every step is accepted, but the walker covers ground only by diffusion and creeps.
- $s = 0.2$ is about twice the posterior width. A proposal lands in a region of quite different density about as often as not, so roughly half are taken, and each accepted move is a real jump across the posterior.
- $s = 2$ is twenty times the posterior width, and twice the whole allowed interval. Most proposals land outside $(0,1)$, where the target is zero, or far down a tail, and are refused; the walker sits still for long stretches.

For each chain Kruschke reports two numbers: the acceptance rate, and the **effective sample size** $\text{ESS} = N/\tau$, the number of independent draws that would give the posterior mean as accurately as the N correlated steps do, with τ the integrated autocorrelation time (defined in full, with its estimator, in Section 9.12.2).

Side by side. Our runs use the same start, widths and length, with our own random numbers:

proposal width	0.02	0.2	2
acceptance, ours	0.9334	0.4958	0.06174
acceptance, Kruschke	0.936	0.495	0.0624
effective size, ours	463	11181	2065
effective size, Kruschke	469	11724	2113

How close should they be? Two runs with different random numbers cannot agree exactly; the question is how far apart chance alone puts them. The acceptance rate is an average of N accept-or-refuse indicators, with a spread of order $\sqrt{a(1-a)/N} \simeq 0.002$ for $a = 0.5$ and $N = 50\,000$, a little more because successive decisions are correlated; the three pairs differ by a few thousandths. The estimated τ, and hence the ESS, has a relative spread of about $\sqrt{2(2M+1)/N}$ from one random-number stream to another, with $M \simeq 5\tau$ the window of the estimate (9.79). With $\tau = N/\text{ESS}$ from the table, that is about 4% for width 0.2 (an ESS spread of ±500), 10% for width 2 (±200) and 20% for width 0.02 (±100). The three ESS pairs differ by about 540, 50 and 6: all within what a second stream would give. Kruschke's ESS also comes from a different estimator (the coda package of R), which adds a few per cent of its own.

What each walker did. The 0.02 walker needs hundreds of steps to crawl from 0.01 to the bulk of the posterior (Figure 9.25, top left) and then explores it like a snake; the width-2 walker proposes mostly outside $(0,1)$ and refuses almost all of them. The middle walker, which accepts about half its proposals, is worth 11181 independent draws out of 50 000. Its posterior mean

is 0.6812, against 0.6818, and its central 95% interval is [0.4758, 0.8547] against the exact beta quantiles [0.4782, 0.8541]. (Kruschke's figure quotes the 95% highest-density interval, which for this left-skewed posterior lies slightly to the right of the central one; Chapter 5.) The same coin exercise, with five chains started between 0.1 and 0.9, opens the MCMC section of a cosmology tutorial [Padilla §4.1.2–4.1.3].

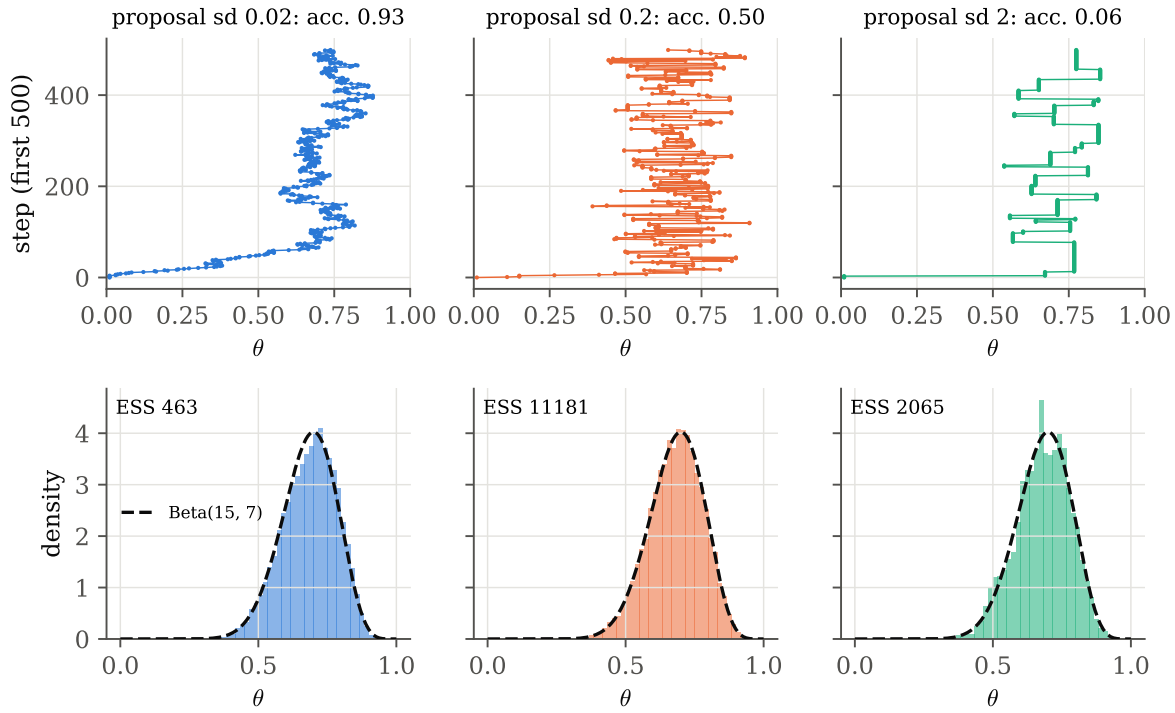

Figure 9.25: Kruschke's coin, reproduced. Top: the first 500 steps of three chains started at $\theta = 0.01$ with proposal widths 0.02, 0.2 and 2 (step number runs upwards). Bottom: histograms of the remaining steps against the exact Beta(15, 7) posterior, with the effective sample size of each chain.

All three coin histograms in Figure 9.25 are close to the beta density. Every proposal width gives the right answer eventually, because each defines a chain with the posterior as its stationary distribution. What differs is how long "eventually" is, more than an order of magnitude in effective sample size between the best and the worst width here.

The lesson. The proposal width never decides whether the answer is right, only what it costs; choosing it well is the subject of Section 9.11.

9.11 How big should the steps be?

Kruschke's three coin walkers of Section 9.10 all converged to the same beta posterior, and yet the best was worth more than ten times as many independent draws as the worst. The two bad ones failed in opposite ways. The walker with tiny steps accepted almost everything but moved like the drunkard, a distance $s\sqrt{t}$ in t steps, so crossing a posterior of width L took about $(L/s)^2$ steps, the diffusive cost met at the end of Section 9.7. The walker with huge steps proposed points far out in the tails, refused them, and sat still for long stretches. In between there must be a best step length, and since the target's width is usually unknown we would like to recognise it from something the chain itself reports.

The question. For a given target, which step length makes the walker produce independent information fastest, and is there a quantity we can monitor, such as the fraction of accepted proposals, that tells us we are there?

9.11.1 The Gaussian in many dimensions: 2.38 and 0.234

The one target where this question has a clean answer is the standard Gaussian in D dimensions, $f(x) \propto e^{-|x|^2/2}$, sampled with round Gaussian steps $y = x + (\ell/\sqrt{D})\, z$, $z \sim \mathcal{N}(0, \mathbb{1}_D)$, where ℓ is a dimensionless step scale. Why divide by $\sqrt{D}$? Because the log ratio is a sum over all D coordinates, and if each coordinate moved by a fixed amount the sum would grow with D and every proposal would be refused. Shrinking the step per coordinate as $1/\sqrt{D}$ keeps the log ratio of order one.

The log ratio becomes Gaussian. For a walker at x and a proposal $y = x + (\ell/\sqrt{D})z$,

$$\begin{aligned} \ln R &\overset{(1)}{=} -\tfrac{1}{2}\big(|y|^2 - |x|^2\big) \overset{(2)}{=} -\frac{\ell}{\sqrt{D}}\, x \cdot z - \frac{\ell^2}{2D}\, |z|^2 \\ &\overset{(3)}{=} -\ell\, \frac{|x|}{\sqrt{D}}\, \zeta - \frac{\ell^2}{2}\, \frac{|z|^2}{D} \xrightarrow{D\to\infty} \Lambda \sim \mathcal{N}\Big(-\frac{\ell^2}{2},\ \ell^2\Big). \end{aligned} \tag{9.70}$$

(1) The normalisation of f cancels; only the exponents differ.
(2) $|x+v|^2 = |x|^2 + 2x\cdot v + |v|^2$ with $v = (\ell/\sqrt{D})z$.
(3) For fixed x, $x \cdot z$ is a sum of independent Gaussians with variance $\sum_i x_i^2 = |x|^2$, so $x \cdot z = |x|\ \zeta$ with $\zeta \sim \mathcal{N}(0,1)$. A walker in equilibrium has $|x|^2/D \to 1$ and $|z|^2/D \to 1$ by the law of large numbers (both are averages of D squared standard Gaussians), so the first term tends to $-\ell\zeta$ and the second to $-\ell^2/2$.

The acceptance rate. Call the limiting log ratio of (9.70) Λ (a capital lambda, for "log ratio"). The acceptance probability of one proposal is $\min(1, R) = \min(1, e^{\Lambda})$, so the mean acceptance is $a(\ell) = \mathbb{E}\big[\min(1, e^{\Lambda})\big]$ with $\Lambda \sim \mathcal{N}(-\sigma^2/2, \sigma^2)$ and $\sigma = \ell$. Split it into the uphill part ($\Lambda > 0$, accepted for sure) and the downhill part:

$$\begin{aligned} a(\ell) &\overset{(1)}{=} \mathrm{P}(\Lambda > 0) + \mathbb{E}\big[e^{\Lambda};\, \Lambda < 0\big] \\ &\overset{(2)}{=} \Phi\Big(-\frac{\sigma}{2}\Big) + \int_{-\infty}^{0} \frac{1}{\sigma\sqrt{2\pi}} \exp\Big[w - \frac{(w+\sigma^2/2)^2}{2\sigma^2}\Big] \mathrm{d}w \\ &\overset{(3)}{=} \Phi\Big(-\frac{\sigma}{2}\Big) + \int_{-\infty}^{0} \frac{1}{\sigma\sqrt{2\pi}} \exp\Big[-\frac{(w-\sigma^2/2)^2}{2\sigma^2}\Big] \mathrm{d}w \overset{(4)}{=} 2\,\Phi\Big(-\frac{\ell}{2}\Big). \end{aligned} \tag{9.71}$$

(1) $\min(1, e^{\Lambda})$ is 1 when $\Lambda > 0$ and e^{Λ} when $\Lambda < 0$; $\mathbb{E}[X; A]$ means the expectation of X restricted to the event A.
(2) $\mathrm{P}(\Lambda > 0) = \mathrm{P}\big(\sigma\zeta - \sigma^2/2 > 0\big) = \mathrm{P}(\zeta > \sigma/2) = \Phi(-\sigma/2)$, with Φ the standard Gaussian cumulative distribution; the second term is the Gaussian density of Λ times e^{w}.
(3) Complete the square: $w - (w+\sigma^2/2)^2/2\sigma^2 = -(w^2 - \sigma^2 w + \sigma^4/4)/2\sigma^2 = -(w-\sigma^2/2)^2/2\sigma^2$. Multiplying by e^{w} has moved the Gaussian's mean from $-\sigma^2/2$ to $+\sigma^2/2$.
(4) The integral is the probability that a $\mathcal{N}(\sigma^2/2, \sigma^2)$ variable is negative, which is again $\Phi(-\sigma/2)$; and $\sigma = \ell$.

Small steps give $a \to 2\Phi(0) = 1$; large steps give $a \to 0$. Figure 9.26a shows that chains in $D = 10$ and 50 follow (9.71) closely, and that even $D = 1$ is not far from it.

The best step. *How far does one step move the walker?* When a proposal is accepted, the walker moves by $(\ell/\sqrt{D})z$; when it is refused, by nothing. Write A for the indicator of acceptance (1 if taken, 0 if refused). The mean squared jump per step, summed over coordinates, is

$$\mathbb{E}\,|x_{t+1}-x_t|^2 \overset{(1)}{=} \mathbb{E}\Big[\frac{\ell^2}{D}\,|z|^2\,A\Big] \overset{(2)}{=} \ell^2\,\mathbb{E}\Big[\frac{|z|^2}{D}\,A\Big] \overset{(3)}{\simeq} \ell^2\,\mathbb{E}[A] \overset{(4)}{=} \ell^2\,a(\ell) = 2\ell^2\,\Phi(-\ell/2). \tag{9.72}$$

(1) The squared jump is $\left|(\ell/\sqrt{D})z\right|^2 = (\ell^2/D)\,|z|^2$ if accepted and 0 if not.

(2) Take the constant ℓ^2 out, leaving ℓ^2/D times $|z|^2$ as ℓ^2 times the average $|z|^2/D$.

(3) $|z|^2/D$ is an average of D squared standard Gaussians, so for large D it is 1 with a spread of only $\sqrt{2/D}$; it is then a constant and comes out of the expectation. The acceptance A depends on z only through the one sum $x\cdot z$ of (9.70) and through this same average, so no single z_i matters and nothing correlates A with the size of the jump.

(4) $\mathbb{E}[A]$ is the mean acceptance (9.71).

From jump size to autocorrelation time. Follow one coordinate, x_1. Its share of the mean squared jump is $\ell^2 a(\ell)/D$ per step, and in equilibrium it spreads over a range of standard deviation 1. A coordinate that moves by diffusion forgets where it was once it has travelled about one standard deviation, and a diffusion with mean squared step v needs about $1/v$ steps for that, the cost $(L/s)^2$ of Section 9.7 with $L=1$ and $s^2=v$. So

$$\tau \;\propto\; \frac{D}{\ell^2\,a(\ell)},$$

and the step that maximises the mean squared jump minimises the autocorrelation time. The statement that this is exact as $D\to\infty$ is the theorem of Roberts, Gelman, and Gilks [146]: watched on a clock that ticks D steps at a time, each coordinate of the chain becomes a diffusion (a Langevin process) whose speed is exactly $h(\ell) = 2\ell^2\Phi(-\ell/2)$.

Maximising the speed. Set the derivative of h to zero:

$$0 = \frac{\mathrm{d}h}{\mathrm{d}\ell} \overset{(1)}{=} 4\ell\,\Phi(-\ell/2) - \ell^2\,\phi(\ell/2) \quad\Longleftrightarrow\quad 4\,\Phi(-\ell/2) = \ell\,\phi(\ell/2),$$

(1) Product rule, with $\mathrm{d}\Phi(-\ell/2)/\mathrm{d}\ell = -\frac{1}{2}\phi(\ell/2)$ and ϕ the standard Gaussian density.

whose root, found numerically, is $\ell = 2.381$. The acceptance there is

$$a = 2\,\Phi\Big(-\frac{2.381}{2}\Big) = 2\,\Phi(-1.19) = 2\times 0.117 = 0.2338,$$

so the best walker refuses $1-0.234 \simeq \frac{3}{4}$ of its proposals, three in four.

Why both extremes lose. For small ℓ the acceptance tends to 1 and $h\approx\ell^2$ is small. For large ℓ the acceptance collapses, and the rate follows from the Gaussian tail. For large u,

$$\Phi(-u) \overset{(1)}{=} \int_u^\infty \phi(t)\,\mathrm{d}t \overset{(2)}{=} \phi(u)\int_u^\infty e^{-(t^2-u^2)/2}\,\mathrm{d}t \overset{(3)}{=} \phi(u)\int_0^\infty e^{-u\,v-v^2/2}\,\mathrm{d}v \;\approx\; \frac{\phi(u)}{u} = \frac{e^{-u^2/2}}{u\sqrt{2\pi}}.$$

(1) $\Phi(-u) = \mathrm{P}(Z<-u) = \mathrm{P}(Z>u)$ for a standard Gaussian Z.

(2) $\phi(t) = \phi(u)\,e^{-(t^2-u^2)/2}$.

(3) Put $t = u+v$, so $t^2-u^2 = 2uv+v^2$. For large u the factor e^{-uv} cuts the integral off at $v\sim 1/u$, where $v^2/2$ is negligible, and $\int_0^\infty e^{-uv}\mathrm{d}v = 1/u$.

With $u=\ell/2$ this gives $a(\ell) = 2\Phi(-\ell/2) \approx (4/\ell\sqrt{2\pi})\,e^{-\ell^2/8}$: the acceptance dies like $e^{-\ell^2/8}$, faster than ℓ^2 grows, and h goes to zero. The compromise between the two sits at $\ell = 2.38$.

Key idea: The 2.38 and 0.234 rule

For a target that is roughly Gaussian in D dimensions, the most efficient round random-walk proposal has width $2.38/\sqrt{D}$ in units of the target's standard deviation, and accepts about 23% of its proposals [146]. In one dimension the best acceptance is higher, near one half. The chain then needs of order D steps per independent draw [HobsonBMC §3.2.4, p. 65].

Figure 9.26b measures the mean squared jump of real chains of 4×10^4 steps on a grid of 22 step scales. The best measured acceptances are 0.4583 in $D = 1$, 0.2816 in $D = 10$ and 0.2629 in $D = 50$, approaching 0.234 as D grows. At $\ell = 2.38$ the integrated autocorrelation time of one coordinate, divided by D, is 4.433, 3.353 and 2.98: an independent draw every three to four and a half times D steps. Dunkley et al. [144] found the same for cosmological chains, an inverse efficiency of about $3.3D$ and an optimal acceptance tending to 0.25, and recommended the width $2.4/\sqrt{D}$ that Lewis and Bridle [37] use in CosmoMC. Wasserman's rule of thumb, accept about half the proposals [Wasserman p. 415], is the one-dimensional answer; Kruschke's adaptive phase aims at "a middling value such as 0.5" [Kruschke p. 161]. In many dimensions the target is 0.2–0.3.

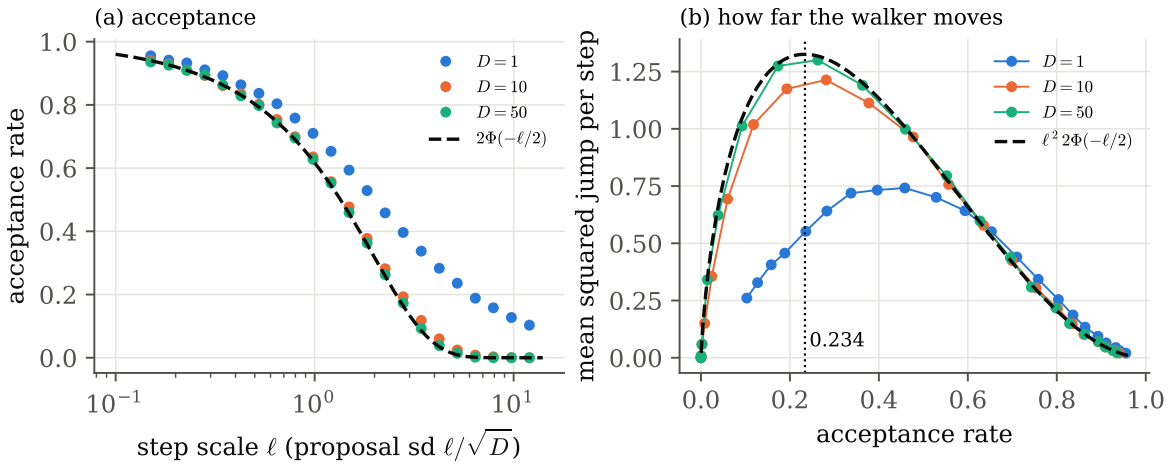

Figure 9.26: Step size on a standard Gaussian target in $D = 1$, 10 and 50 dimensions, with proposal width $\ell/\sqrt{D}$. (a) Measured acceptance against ℓ, with the large-D formula $2\Phi(-\ell/2)$ (dashed). (b) Mean squared jump per step against acceptance: it peaks near acceptance 0.23 in many dimensions (dotted line), and near 0.45 in one dimension.

9.11.2 Correlated targets: shape the steps like the posterior

Real posteriors are rarely round. Two parameters that the data constrain only in combination, such as the amplitude and tilt of a power spectrum, or the matter density and the Hubble rate, give a long thin ellipse. Take the Gaussian with unit variances and correlation $\rho = 0.95$, covariance $\mathbf{C} = \left(\begin{smallmatrix} 1 & \rho \\ \rho & 1 \end{smallmatrix}\right)$. Its principal axes are the eigenvectors of $\mathbf{C}$:

$$\det(\mathbf{C} - \lambda \mathbb{1}) \overset{(1)}{=} (1-\lambda)^2 - \rho^2 = 0 \quad \Longleftrightarrow \quad \lambda_\pm \overset{(2)}{=} 1 \pm \rho,$$

(1) Determinant of a 2×2 matrix.
(2) $1 - \lambda = \mp\rho$; the eigenvectors are $(1, 1)/\sqrt{2}$ for $1 + \rho$ and $(1, -1)/\sqrt{2}$ for $1 - \rho$.

The standard deviation along the ridge is $\sqrt{1.95} = 1.40$ and across it $\sqrt{0.05} = 0.22$, a ratio of about six.

What a round step costs here. A round step cannot be tuned to both widths at once. Suppose we tune it to the narrow one, since that is the direction in which proposals are refused. For a round Gaussian in $D = 2$ the best step is $\ell/\sqrt{D} = 2.38/\sqrt{2} \simeq 1.7$ standard deviations (Section 9.11.1), so here it is about $1.7 \times 0.22 \simeq 0.37$. Along the ridge the walker then diffuses with steps of that size, and by the diffusion cost $(L/s)^2$ of Section 9.7 crossing a distance L takes about $(L/s)^2$ steps:

$$\begin{aligned} \text{ridge, step tuned to the narrow width:} \quad & \left(\frac{1.40}{1.7 \times 0.22}\right)^2 \overset{(1)}{=} \left(\frac{1.40}{0.37}\right)^2 \simeq 14, \\ \text{round target of width 1.40:} \quad & \left(\frac{1.40}{1.7 \times 1.40}\right)^2 \overset{(2)}{=} \frac{1}{1.7^2} \simeq 0.35, \\ \text{ratio:} \quad & \overset{(3)}{=} \left(\frac{1.40}{0.22}\right)^2 \simeq 40. \end{aligned}$$

(1) Ridge length $L = 1.40$, step $s = 1.7 \times 0.22$.
(2) For a round target the best step is 1.7 times its own width, so it crosses in less than one step.
(3) The factor 1.7 cancels: the penalty is the square of the ratio of the two widths.

So a round step sized for the narrow direction makes the walker some forty times slower along the ridge than the same walker on a round target. In practice the best round step is larger than this, a compromise that accepts fewer proposals and moves farther along the ridge when it does, and the penalty is smaller, as the runs below show; but no round step escapes it.

Figure 9.27 shows four walkers of 4×10^4 steps on this ellipse. Tiny round steps ($s = 0.05$) are accepted 0.9286 of the time and creep along the ridge, with integrated autocorrelation time $\tau = 2981$ steps. Huge round steps ($s = 30$) are accepted a fraction 5.750×10^{-4} of the time, $\tau = 1229$. The best round step of a scan, $s = 1.166$, gives acceptance 0.2009 and $\tau = 35.55$. A proposal with the covariance of the target itself, scaled by the 2.38 rule, gives acceptance 0.3554 and $\tau = 9.278$.

Why does shaping work so well? Write the target's covariance as $\mathbf{C} = LL^{\mathsf{T}}$ (Cholesky) and change to whitened coordinates $u = L^{-1}x$, in which the target is round. A shaped proposal $y = x + sLz$ in the original coordinates is, in the new ones,

$$u' \overset{(1)}{=} L^{-1}y = L^{-1}x + sL^{-1}Lz \overset{(2)}{=} u + s\,z,$$

(1) Apply the linear map L^{-1} to the proposal $y = x + sLz$.
(2) $L^{-1}x = u$ and $L^{-1}L = \mathbb{1}$.

a round proposal. And because the map is linear, its Jacobian is a constant that cancels from every ratio. So the shaped walker on the ellipse *is* the round walker on the round Gaussian, and inherits its efficiency: with $\ell = 2.38$ and $D = 2$ the measured $\tau = 9.278$ steps is a few times D, whatever ρ is. In practice the covariance is unknown, so one runs a short pilot chain, estimates the covariance from it, and uses that for the proposal of the real run, repeating if necessary [Padilla §4.1.4], [HobsonBMC §3.2.4, p. 65]. The adaptation must stop before the samples that are kept: a proposal that keeps changing with the chain's own history is no longer a Markov chain with f as its stationary law [HobsonBMC p. 63].

Watch out: A good acceptance rate is not a good chain

The best round walker above accepted 0.2009 of its proposals, right in the recommended range, and was still several times slower than the shaped walker. The acceptance rate measures only whether the step length suits the narrowest direction. It knows nothing about whether the walker moves along the long ones. Judge a chain by its autocorrelation

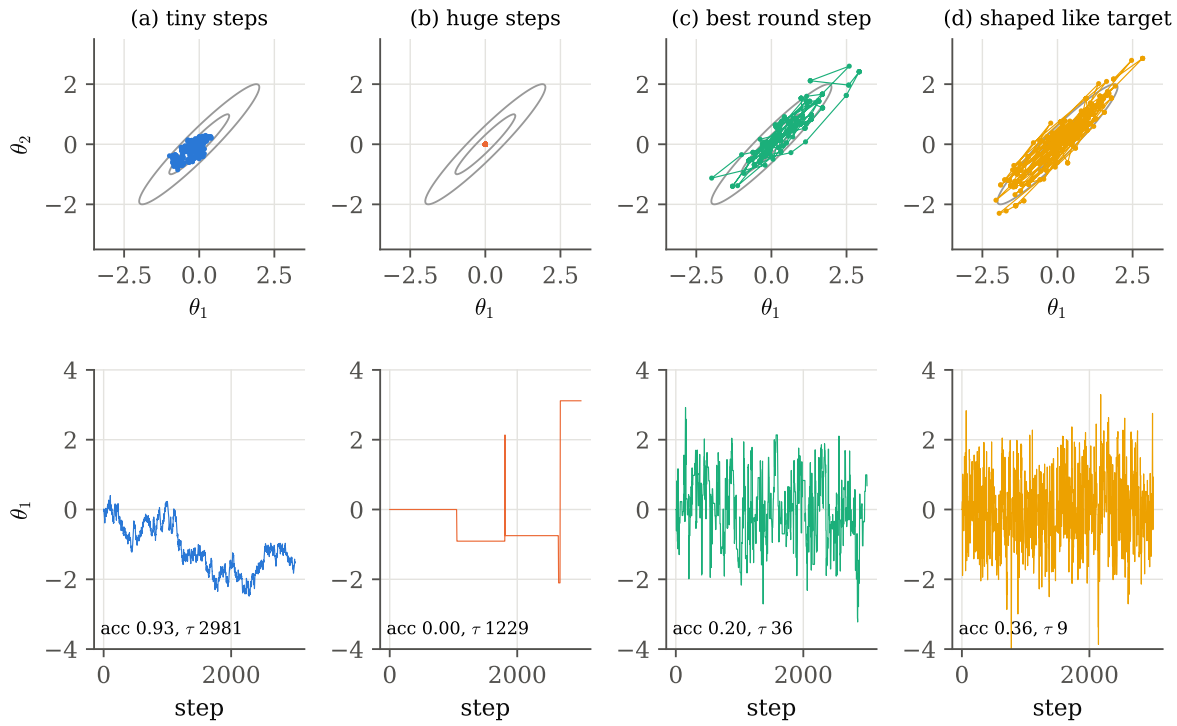

Figure 9.27: Four walkers on a Gaussian with correlation 0.95 (68% and 95% contours in grey). Top: the first 400 steps. Bottom: 3000 steps of θ_1, with acceptance rate and integrated autocorrelation time. (a) Tiny round steps creep. (b) Huge round steps are almost always refused. (c) The best round step still has to diffuse along the ridge. (d) Steps shaped like the target cover it in a few moves.

time or effective sample size (Section 9.12), never by its acceptance rate alone.

9.11.3 Curved targets: change variables

A covariance matrix describes a straight ellipse. Many posteriors are curved, because the data constrain a nonlinear combination of the parameters. The standard test case is the banana

$$p(\theta_1, \theta_2) \propto \exp\Big[-\frac{\theta_1^2}{2} - \frac{(\theta_2 - \theta_1^2)^2}{2\sigma^2}\Big], \qquad \sigma = 0.3. \tag{9.73}$$

Read it as a recipe: $\theta_1 \sim \mathcal{N}(0,1)$, and given θ_1, θ_2 is Gaussian with mean θ_1^2 and standard deviation σ. The exact moments follow from this reading:

$$\begin{aligned}
\mathbb{E}\,\theta_2 &\overset{(1)}{=} \mathbb{E}\big[\mathbb{E}(\theta_2 \mid \theta_1)\big] = \mathbb{E}\,\theta_1^2 = 1, \\
\operatorname{Var}\theta_2 &\overset{(2)}{=} \operatorname{Var}\big(\mathbb{E}(\theta_2 \mid \theta_1)\big) + \mathbb{E}\big[\operatorname{Var}(\theta_2 \mid \theta_1)\big] = \operatorname{Var}(\theta_1^2) + \sigma^2 \overset{(3)}{=} (3-1) + \sigma^2 = 2 + \sigma^2, \\
\operatorname{Cov}(\theta_1, \theta_2) &\overset{(4)}{=} \mathbb{E}\big[\theta_1\, \mathbb{E}(\theta_2 \mid \theta_1)\big] - \mathbb{E}\,\theta_1\, \mathbb{E}\,\theta_2 = \mathbb{E}\,\theta_1^3 = 0.
\end{aligned}$$

(1) Tower rule: average the conditional mean over θ_1.
(2) Law of total variance (Chapter 1).
(3) $\mathbb{E}\,\theta_1^4 = 3$ and $\mathbb{E}\,\theta_1^2 = 1$ for a standard Gaussian.
(4) Odd moments of a standard Gaussian vanish.

The last line is the trap: θ_1 and θ_2 are strongly dependent, yet their linear correlation is exactly zero. A covariance matrix cannot see a symmetric banana.

Figure 9.28 confirms it with 200 000 steps per walker. The best round walker has $\tau = 265.8$. A pilot run's covariance has correlation 0.169, which is only noise, since the true correlation is zero. So the "shaped" proposal does little more than rescale the two axes; it has acceptance 0.07981 and $\tau = 89.19$. Both walkers struggle to get into the arms of the banana. In this run their estimates of Var θ_2 are 2.323 and 1.887, against the exact 2.09. How much of that is luck? Run each walker again 12 times with fresh random numbers: the estimate moves by about 0.28 from run to run for the round walker and 0.31 for the shaped one. A slow chain sees only a few excursions into the arms, and the variance of a long-tailed quantity depends on exactly those.

The cure is to remove the curvature by a change of variables. With $u = \theta_2 - \theta_1^2$ the target becomes $\exp[-\theta_1^2/2 - u^2/2\sigma^2]$, a product of two independent Gaussians. The map $(\theta_1, \theta_2) \mapsto (\theta_1, u)$ has Jacobian determinant $\det\left(\begin{smallmatrix} 1 & 0 \\ -2\theta_1 & 1 \end{smallmatrix}\right) = 1$, so no extra factor appears in the density. A round walker in (θ_1, u), mapped back with $\theta_2 = u + \theta_1^2$, has acceptance 0.3576, $\tau = 7.486$, and Var $\theta_2 = 2.091$, which moves by only 0.05 from run to run. Lewis and Bridle give the same advice for cosmology: when a degeneracy is known, sample in the combination the data constrain well, for example the angular size of the sound horizon instead of the Hubble rate, and remember the Jacobian in the prior [HobsonBMC §3.2.4, p. 66].

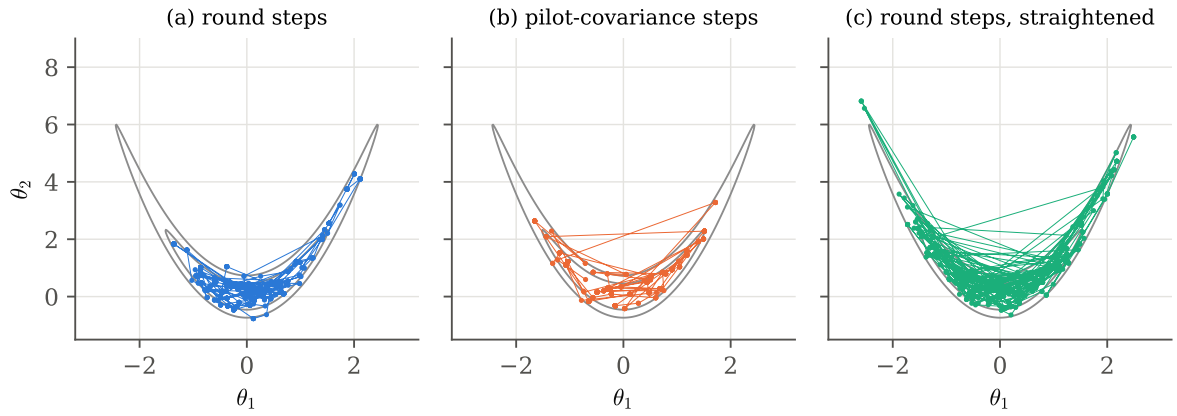

Figure 9.28: Six hundred steps of three walkers on the banana (9.73). (a) Round steps and (b) steps shaped by a pilot covariance both crawl along the curved ridge. (c) Round steps in the straightened variables $(\theta_1, \theta_2 - \theta_1^2)$, mapped back, jump across the whole banana.

Cross-check against a standard library. The affine-invariant ensemble sampler `emcee` [147], described in Section 9.16, runs many walkers that propose moves along the lines joining them. With 32 walkers and 20000 steps each on the banana it accepts 0.5143 of its moves and reports an autocorrelation time of 192.9 steps, far longer than the 7.486 of the straightened walker: an affine-invariant method is blind to linear correlations, but a banana is not linear. Its Var θ_2 is 1.861 in this run and moves by about 0.20 from run to run. The triangle plot of Figure 9.29, drawn with our own `corner` function, overlays the straightened Metropolis chain and the `emcee` chain; the cores agree, and the tips of the arms, where few samples land, are noisy in both.

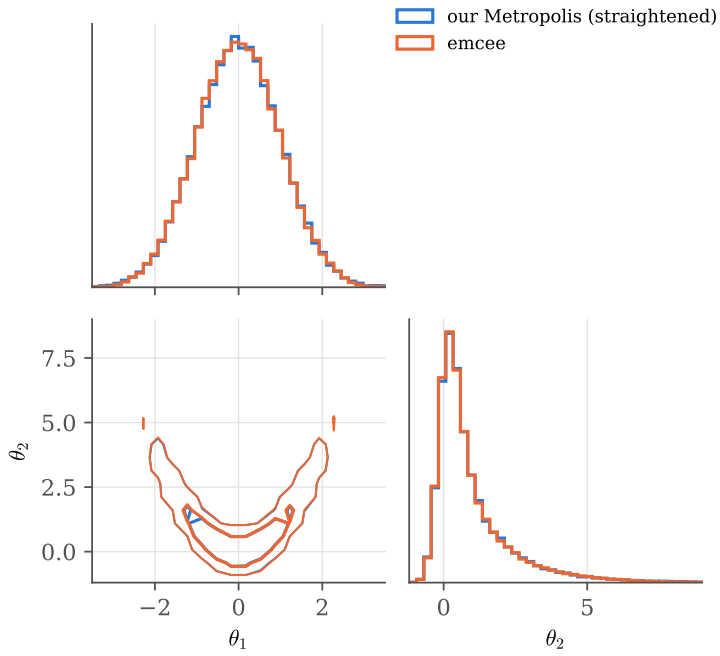

Figure 9.29: Triangle plot of the banana: one-dimensional marginal histograms on the diagonal, 68% and 95% regions of the two-dimensional histogram below it. Blue: our Metropolis sampler in the straightened variables. Orange: `emcee` in the original variables.

9.12 Reading a chain: burn-in, autocorrelation and effective sample size

A finished run is a list of numbers, one row per step. Before quoting any average from it we have to answer two questions [Kruschke §7.5]. Which part of the list is still remembering the arbitrary starting point, and must be thrown away? And how much information is in the rest: how many independent draws is it worth, and how accurate are the averages computed from it? The chain itself has to answer both, because in a real problem nothing else knows the answer.

9.12.1 Burn-in: where does equilibrium start?

Start a Metropolis walker for the standard Gaussian in $D = 10$ dimensions at the point $(10, 10, \ldots, 10)$, ten standard deviations out in every coordinate, with the 2.38 step of Section 9.11.1. The quantity that shows the approach to equilibrium most clearly is the log density along the chain, $\ln f(\theta_t)$, here $-|\theta_t|^2/2$ up to a constant. It starts at -500 and climbs (Figure 9.30b).

The question. When has the walker arrived? The tempting answer, "when it reaches the peak", is wrong, and seeing why is the most useful fact about high-dimensional posteriors.

In equilibrium $\theta \sim \mathcal{N}(0, \mathbb{1}_D)$, so $|\theta|^2 = \sum_i \theta_i^2$ is a sum of D squared standard Gaussians, a χ^2_D variable (Chapter 2). Therefore

$$\mathbb{E}\big[\ln f(\theta)\big] \overset{(1)}{=} -\tfrac{1}{2}\,\mathbb{E}\,\chi^2_D = -\frac{D}{2}, \qquad \mathrm{sd}\big[\ln f(\theta)\big] \overset{(2)}{=} \tfrac{1}{2}\sqrt{\mathrm{Var}\,\chi^2_D} = \tfrac{1}{2}\sqrt{2D} = \sqrt{D/2}. \tag{9.74}$$

(1) $\mathbb{E}\,\theta_i^2 = 1$ for each of the D terms.

(2) $\mathrm{Var}\,\theta_i^2 = \mathbb{E}\,\theta_i^4 - 1 = 3 - 1 = 2$, and the D terms are independent.

For $D = 10$ the equilibrium walker lives at $\ln f = -5 \pm 2.2$, never at the peak value 0. The chain agrees: after step 10 000 its $\ln f$ averages -4.995 with standard deviation 2.29, and the highest value it ever reached was -0.6265.

Why the walker avoids the peak. The reason is volume. Ask how probable it is to find the walker at a distance between r and $r + \mathrm{d}r$ from the centre. The density there is the same at every point, $e^{-r^2/2}$ up to a constant, and the points form a thin spherical shell whose volume is its area times its thickness. The area of a sphere of radius r in D dimensions grows as r^{D-1} (a circle's length as r, a sphere's area as r^2, and so on). So the radius has the density

$$p(r) \overset{(1)}{=} (\text{area} \propto r^{D-1}) \times (\text{density } e^{-r^2/2}) \propto r^{D-1} e^{-r^2/2},$$
$$\frac{\mathrm{d} \ln p}{\mathrm{d}r} \overset{(2)}{=} \frac{D-1}{r} - r = 0 \quad \Longrightarrow \quad r^2_{\text{peak}} \overset{(3)}{=} D - 1 \approx D. \tag{9.75}$$

(1) Probability in a thin shell is density times shell volume, and the shell volume is area times $\mathrm{d}r$.
(2) $\ln p = (D-1)\ln r - r^2/2 + \text{const}$; set its derivative to zero to find the most probable radius.
(3) Multiply by r and solve.

The first factor is zero at the centre and grows; the second is largest at the centre and dies quickly; their product peaks at $r \approx \sqrt{D}$. At that radius $\ln f = -r^2/2 \approx -D/2$, the equilibrium mean of (9.74). For $D = 10$ the most probable radius is $\sqrt{9} = 3$, where $\ln f = -4.5$, against the chain's average -4.995; the peak of f at $r = 0$ has no volume around it at all. The bulk of the probability sits on a thin shell away from the mode. Lambert calls this region the **typical set**, and describes MCMC as two phases, first finding the typical set and then exploring it [Lambert §13.7.1].

Burn-in therefore ends when $\ln f$ stops climbing and starts fluctuating around a steady level, not when it reaches the maximum. Here the trace first crossed its equilibrium median at step 147 (Figure 9.30b). A popular rule in cosmology discards the start of a chain while $p/p_{\max} < 0.1$ [144]. Read literally with the true peak, it must be scaled with dimension. For a Gaussian posterior, $-2\ln(p/p_{\max})$ is exactly the $|\theta|^2$ above, a χ^2_D variable, so the fraction of equilibrium draws that satisfy $p/p_{\max} \geq 0.1$ is $\mathrm{P}(\chi^2_D \leq 2\ln 10)$: 0.9 for $D = 2$, 0.08405 for $D = 10$, and 8.033×10^{-18} for $D = 50$. In fifty dimensions an equilibrium chain essentially never comes within a factor of ten of the peak. Any threshold on $\ln p$ has to be judged against the spread (9.74) of $\ln p$ in equilibrium. Two practical rules are common: look at the trace of $\ln p$ and of each parameter and cut where they become stationary; or, with several chains, discard the first half of each by default [Lambert §13.9.5], [Kruschke §7.5.1]. Multiple chains make the cut checkable (Section 9.13).

9.12.2 Autocorrelation and the integrated autocorrelation time

Once the burn-in is gone, the remaining N steps $x_1, \ldots, x_N$ of one parameter are a stationary but correlated series: every x_t has the same variance σ^2, and the covariance $C_k = \mathrm{Cov}(x_t, x_{t+k}) = \sigma^2 \rho_k$ depends only on the lag k, with ρ_k the autocorrelation. How accurate is the chain average $\bar{x} = \frac{1}{N}\sum_t x_t$? The derivation of Section 9.6.2, repeated in three lines:

$$\mathrm{Var}(\bar{x}) \overset{(1)}{=} \frac{1}{N^2} \sum_{s=1}^{N} \sum_{t=1}^{N} C_{|t-s|} \overset{(2)}{=} \frac{\sigma^2}{N} \left[1 + 2 \sum_{k=1}^{N-1} \left(1 - \frac{k}{N}\right) \rho_k \right] \overset{(3)}{=} \frac{\sigma^2}{N}\, \tau, \qquad \tau = 1 + 2\sum_{k=1}^{\infty} \rho_k. \tag{9.76}$$

(1) The variance of a sum is the sum of all the covariances of its terms.
(2) The N pairs with $s = t$ give $N\sigma^2$; the $2(N-k)$ ordered pairs at lag $k \geq 1$ give $2(N-k)\sigma^2\rho_k$; divide by N^2.

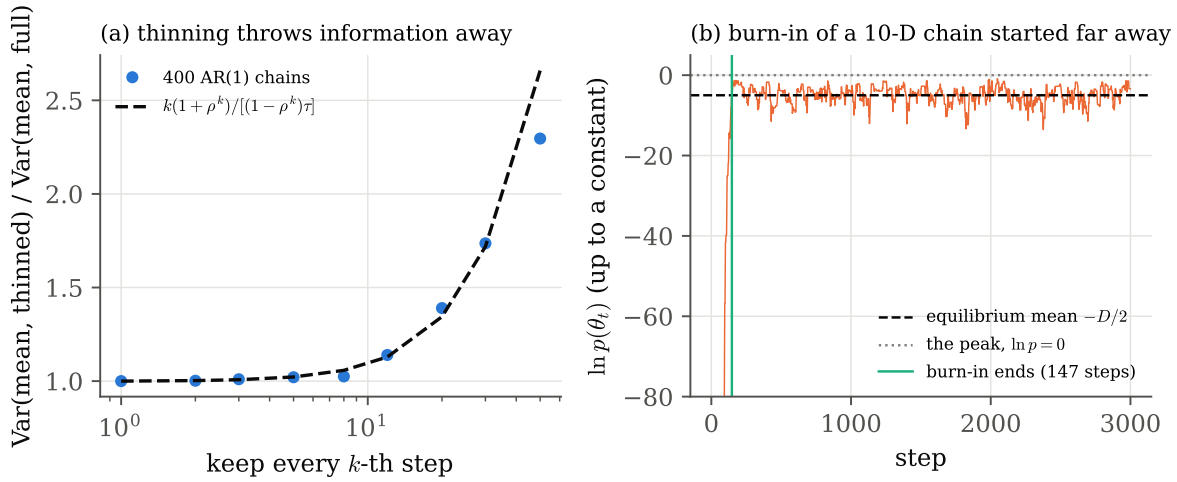

Figure 9.30: (a) Thinning an AR(1) chain with $\rho = 0.9$ by keeping every kth step: the variance of the mean of the thinned chain, relative to the full chain, measured over 400 chains (dots) and predicted (dashed). It is never below one. (b) $\ln p$ along a 10-dimensional chain started far out: it climbs from -500 and settles around $-D/2$ (dashed), well below the peak value 0 (dotted).

(3) For N much longer than the range of the correlations, k/N is negligible wherever ρ_k is not, and the sum can run to infinity.

With independent draws $\tau = 1$ and this is the familiar σ^2/N; correlation replaces N by N/τ, so the chain is worth N/τ independent draws. In Section 9.6 we computed τ exactly from the transition matrix; now we must estimate it from the series alone.

Estimating the autocorrelation. The natural estimator of the lag-k covariance averages the products of deviations k steps apart,

$$\hat{C}_k = \frac{1}{N}\sum_{t=1}^{N-k}(x_t - \bar{x})(x_{t+k} - \bar{x}), \qquad \hat{\rho}_k = \hat{C}_k/\hat{C}_0, \tag{9.77}$$

the **autocorrelation function** (ACF) of the chain [Kruschke §7.5.2]. It is computed for all lags at once with a fast Fourier transform (`acf` in `lib_mcmc.py`). One might now plug every $\hat{\rho}_k$ into (9.76). That gives exactly zero, for any data:

$$N\Big[\hat{C}_0 + 2\sum_{k=1}^{N-1}\hat{C}_k\Big] \overset{(1)}{=} \sum_{s=1}^{N}\sum_{t=1}^{N}(x_s - \bar{x})(x_t - \bar{x}) \overset{(2)}{=} \Big[\sum_{t=1}^{N}(x_t - \bar{x})\Big]^2 \overset{(3)}{=} 0. \tag{9.78}$$

(1) Group the N^2 ordered pairs (s,t) by their lag $|t-s| = k$: lag 0 gives $N\hat{C}_0$ and each lag $k \geq 1$ appears twice, giving $2N\hat{C}_k$.
(2) A double sum of products of the same terms is the square of the single sum.
(3) Deviations from the sample mean sum to zero.

So $1 + 2\sum_{k\geq 1}\hat{\rho}_k = 0$ identically; our script finds it to be zero to within 1.4×10^{-14}, rounding error. The estimated autocorrelations at large lags are almost pure noise, and they are forced to cancel the real correlation at small lags. The sum must be cut off at a window M beyond which the true ρ_k is negligible but the noise is not yet large.

Choosing the window. Kruschke stops the sum at the first lag with $\hat{\rho}_k < 0.05$ [Kruschke eq. 7.11]. Stan, following Geyer, stops when the sum of two consecutive estimates first turns negative

[Lambert §13.10]. Our library uses Sokal's self-consistent window: the smallest M with $M \geq c\,\hat{\tau}(M)$, where $\hat{\tau}(M) = 1 + 2\sum_{k=1}^{M} \hat{\rho}_k$ and $c \simeq 5$ [148]. The window then grows with the correlation time itself, so that slowly decaying correlations are not cut short.

Why the window scales with τ, and why $c \simeq 5$. Cutting the sum at M makes two errors that pull in opposite directions. The first is the correlation left out. If the true autocorrelation decays as $\rho_k \simeq e^{-k/T}$ over some number of steps T, the sum gives $\tau \simeq 2T$ and the omitted tail is $2\sum_{k>M} e^{-k/T} \simeq 2T\, e^{-M/T}$, a fraction $e^{-M/T}$ of τ. The second is noise. Each $\hat{\rho}_k$ fluctuates by about $1/\sqrt{N}$ (a little more for a correlated series), and adding M of them adds noise that grows like $\sqrt{M}$; the careful calculation [148] gives

$$\frac{\mathrm{Var}(\hat{\tau})}{\tau^2} \simeq \frac{2(2M+1)}{N}. \tag{9.79}$$

The omitted part shrinks exponentially in M/T, the noise grows only like $\sqrt{M}$, so the right window is a few times the correlation length, and since T is not known the estimate $\hat{\tau}$ itself is used as the ruler: $M = c\hat{\tau}$. With $c = 5$ the omitted fraction is e^{-10} for a single exponential and stays below $e^{-5} \simeq 0.7\%$ even if a slow component makes T as long as τ, while the relative noise is $\sqrt{2(10\tau+1)/N}$, still small once N is a few hundred times τ. For the AR(1) test below, $\tau = 19$ and $N = 10^4$ give $M \simeq 95$ and a predicted spread of $\sqrt{191 \times 2/10^4} \times 19 \simeq 3.7$ in $\hat{\tau}$.

Listing 9.6: Integrated autocorrelation time with Sokal's window (`code/ch09/lib_mcmc.py`)

```
def tau_int(x, c=5.0):
    """Integrated autocorrelation time tau = 1 + 2 sum_{k=1}^{M} rho_k with Sokal's window:
    the smallest M such that M >= c * tau(M).  Returns (tau, M)."""
    rho = acf(x)
    taus = 2.0 * np.cumsum(rho) - 1.0                    # taus[M] = 1 + 2 sum_{k=1}^{M} rho_k
    ok = np.arange(rho.size) >= c * taus
    M = int(np.argmax(ok)) if ok.any() else rho.size - 1
    return float(taus[M]), M
```

Example: calibrating on a chain with known τ. The AR(1) chain $x_{t+1} = \rho x_t + \sqrt{1-\rho^2}\, z_t$ of Section 9.7.4 has $\rho_k = \rho^k$ exactly, so

$$\tau = 1 + 2\sum_{k\geq 1} \rho^k = 1 + \frac{2\rho}{1-\rho} = \frac{1+\rho}{1-\rho},$$

which is 19 for $\rho = 0.9$. Over 300 chains of 10 000 steps, Kruschke's rule gives $\hat{\tau} = 18.33 \pm 1.779$ (mean and spread over the chains), slightly low because it drops the tail of the correlation; Sokal's window gives 18.95 ± 3.412, unbiased but noisier (Figure 9.31a), with a spread close to the 3.7 that (9.79) predicts. The prediction (9.76) itself checks out: across the same kind of chains, $N\,\mathrm{Var}(\bar{x})/\sigma^2 = 18.84$ against $\tau = 19$. As a cross-check against a standard library, `emcee`'s estimator `integrated_time`, applied to a Metropolis chain of 2×10^5 steps on a standard Gaussian, returns $\tau = 4.336$, and ours returns 4.336.

Working definition 9.10 (effective sample size and Monte Carlo standard error)

For a chain of N steps of one quantity with integrated autocorrelation time τ, the **effective sample size** is

$$\mathrm{ESS} = \frac{N}{\tau} = \frac{N}{1 + 2\sum_{k\geq 1} \rho_k}$$

[the number of independent draws that would give the mean with the same accuracy]
[Kruschke eq. 7.11], [Lambert §13.10], and the **Monte Carlo standard error** of the chain average is $\mathrm{MCSE} = \mathrm{SD}/\sqrt{\mathrm{ESS}} = \mathrm{SD}\sqrt{\tau/N}$ [Kruschke eq. 7.12], with SD the standard deviation of the chain. *Operational recipe:* discard the burn-in, estimate τ with a window (`tau_int`), and quote ESS for every parameter; the smallest one counts.

Note the difference between the two numbers in the box. The MCSE is the error of our *computation* of the posterior mean, the error that a longer run would reduce. The SD is the width of the posterior itself, the uncertainty about the parameter that no amount of computing removes. A run is long enough when the first is small compared with the second.

Example: Kruschke's coin chains. Figure 9.31b shows the ACFs of the three coin chains of Section 9.10. With proposal width 0.02 the ACF is still high after 60 steps; with width 2 it decays slowly too, because the chain repeats the same value for long stretches; with width 0.2 it falls to near zero within ten lags. These shapes are why the three effective sizes differed so much. For the middle chain, ESS ≈ 11181 and the posterior SD is about 0.1, so the posterior mean is computed to MCSE $\approx 0.1/\sqrt{11181} \approx 0.001$, far below the SD. Kruschke recommends an ESS of about 10 000 when the limits of a 95% interval are wanted, since tails are sampled more sparsely than the centre [Kruschke §7.5.2].

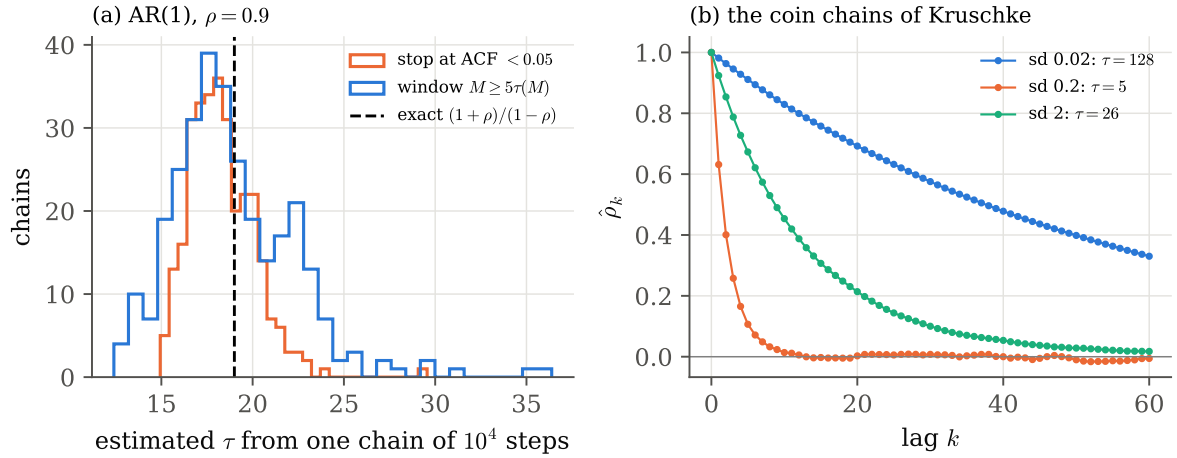

Figure 9.31: (a) Estimates of τ from single AR(1) chains of 10^4 steps with exact $\tau = 19$ (dashed): stopping at the first $\hat{\rho}_k < 0.05$ is slightly biased low, Sokal's self-consistent window is centred on the truth. (b) Autocorrelation functions of Kruschke's three coin chains, with their estimated τ.

9.12.3 Thinning

Keeping only every kth step makes the stored points look less correlated, and is often done. Does it make the averages better? For the AR(1) chain $x_{t+1} = \rho x_t + \sqrt{1-\rho^2}\, z_t$ (Section 9.12.2, with z_t independent standard Gaussians) the answer can be computed exactly.

The thinned chain is again AR(1). Apply the recursion k times:

$$x_{t+k} \overset{(1)}{=} \rho^k x_t + \sqrt{1-\rho^2} \sum_{j=0}^{k-1} \rho^j z_{t+k-1-j},$$

$$\operatorname{Var}\Big(\sqrt{1-\rho^2}\sum_{j=0}^{k-1}\rho^j z_{t+k-1-j}\Big) \overset{(2)}{=} (1-\rho^2)\frac{1-\rho^{2k}}{1-\rho^2} = 1-\rho^{2k}.$$

(1) Substitute $x_{t+k-1} = \rho x_{t+k-2} + \dots$ into itself k times; each earlier kick arrives multiplied by one more factor ρ.

(2) The kicks are independent with variance 1, so the variances add: $(1-\rho^2)\sum_{j=0}^{k-1}\rho^{2j}$, a geometric sum.

So the kept points obey $x_{t+k} = \rho^k x_t + \sqrt{1-\rho^{2k}}\,z'$ with a fresh standard Gaussian z', built from kicks that no other kept step uses: the same AR(1) form with coefficient ρ^k. Its stationary variance is still $\sigma^2 = 1$, as it must be, since every x_t in equilibrium has the same distribution whichever steps we keep. The thinned chain has N/k points. By (9.76) with the AR(1) τ,

$$\frac{\operatorname{Var}(\bar{x}_{\text{thinned}})}{\operatorname{Var}(\bar{x}_{\text{full}})} \overset{(1)}{=} \frac{\dfrac{\sigma^2 k}{N}\dfrac{1+\rho^k}{1-\rho^k}}{\dfrac{\sigma^2}{N}\dfrac{1+\rho}{1-\rho}} \overset{(2)}{=} \frac{k\coth(ka/2)}{\coth(a/2)} \overset{(3)}{\geq} 1, \qquad \rho = e^{-a}. \tag{9.80}$$

(1) Numerator: N/k points with correlation time $(1+\rho^k)/(1-\rho^k)$. Denominator: N points with $\tau = (1+\rho)/(1-\rho)$.

(2) $(1+e^{-b})/(1-e^{-b}) = \coth(b/2)$, used with $b = ka$ and $b = a$.

(3) The function $u\coth u$ increases for $u > 0$: its derivative is $\coth u - u/\sinh^2 u = (\tfrac{1}{2}\sinh 2u - u)/\sinh^2 u > 0$, because $\sinh v > v$ for $v > 0$. Hence $(ka/2)\coth(ka/2) \geq (a/2)\coth(a/2)$ for $k \geq 1$; multiply by $2/a$.

Thinning never helps the average; it can only lose information. For $\rho = 0.9$ and $k = 20$ the predicted ratio is 1.344 and 400 simulated chains give 1.39 (Figure 9.30a). The variance grows by a third although only one point in twenty was kept; when the steps are strongly correlated the discarded ones carried little, but never nothing.

Watch out: Thinning is for storage, not accuracy

Thinning a chain does not make it "more independent" in any useful sense: the thinned average is never more accurate than the full one (9.80). Thin only to save memory or disk, for example when each step stores a whole map [Lambert §13.10.1], [Padilla §4.1.4], and report the ESS of what you kept.

9.13 Many chains from far apart: the Gelman–Rubin statistic

A single chain can look perfectly healthy and be wrong. If the posterior has a second region of high probability that the walker never found, the trace is stationary, the ACF decays, the ESS is large, and every number in Section 9.12 is computed from the wrong distribution. Nothing inside one chain can reveal a region the chain has never visited. The remedy is to send out several walkers from starting points spread far wider than the posterior is expected to be, and to see whether they end up telling the same story [Padilla §4.1.3], [Kruschke §7.5.1].

The question. This was the question Gelman and Rubin [38] set out to answer: given M chains of N steps each, started far apart, how can we tell from the chains alone that none of them still remembers where it started? Put differently, how do we turn "they agree" into a number, and how close to its ideal value must the number be?

Example: four walkers on the two bumps. Take again the two-bump density (9.57), with bumps at $x = -2$ and $x = +2$, and start four Metropolis walkers (step 1.5) at $x_0 = -30$, -10, $+10$ and $+30$, ten to fifteen posterior widths away. Figure 9.32a shows that within a hundred steps all four have fallen into the region of the bumps and are hopping between them. The histograms of the second halves of the four chains, 20 000 steps each, lie on top of one another and of f (Figure 9.32b). Their four means range from 0.7282 to 0.8603, around the exact 0.8.

Within and between. Index the chains by $j = 1, \dots, M$ and the steps by $i = 1, \dots, N$, so θ_{ij} is step i of chain j; let $\bar\theta_j$ be the mean of chain j and $\bar\theta$ the mean of everything. Two quantities summarise the spread [Padilla eqs. 57–60], [Lambert §13.9.3]:

$$W = \frac{1}{M}\sum_{j=1}^{M} s_j^2, \quad s_j^2 = \frac{1}{N-1}\sum_{i=1}^{N}(\theta_{ij}-\bar\theta_j)^2, \qquad \frac{B}{N} = \frac{1}{M-1}\sum_{j=1}^{M}(\bar\theta_j-\bar\theta)^2. \tag{9.81}$$

W is the average variance *within* a chain. B/N is the variance *between* the chain means. The sources write these with slightly different letters:

	here	Gelman and Rubin [38], Lambert	Padilla, eq. 59
variance of the chain means	B/N	B/N (their B is N times it)	B
average within-chain variance	W	W	W

Gelman and Rubin multiply the variance of the means by N so that their B is comparable with the variance of single draws; we keep their B and always write it as B/N. If the chains have not mixed, each one has explored only part of the posterior: W is too small, because no chain has seen the full spread, and B/N is too large, because the chains sit in different places.

How are W and B/N related when the chains *are* all in equilibrium? Write σ^2 for the posterior variance and $v = \mathrm{Var}(\bar\theta_j)$ for the variance of a chain mean, which by (9.76) is $\sigma^2\tau/N$. Then

$$\mathbb{E}\Big[\frac{N-1}{N}W\Big] \overset{(1)}{=} \mathbb{E}\Big[\frac{1}{N}\sum_{i=1}^{N}(\theta_{ij}-\bar\theta_j)^2\Big] \overset{(2)}{=} \mathbb{E}\Big[\frac{1}{N}\sum_{i}(\theta_{ij}-\mu)^2\Big] - \mathbb{E}(\bar\theta_j-\mu)^2 \overset{(3)}{=} \sigma^2 - v,$$
$$\mathbb{E}\Big[\frac{B}{N}\Big] \overset{(4)}{=} v, \qquad \text{so} \qquad \mathbb{E}\Big[\frac{N-1}{N}W + \frac{B}{N}\Big] = \sigma^2. \tag{9.82}$$

(1) Definition of s_j^2; all chains have the same expectation.

(2) With μ the posterior mean, $\sum_i(\theta_{ij}-\bar\theta_j)^2 = \sum_i(\theta_{ij}-\mu)^2 - N(\bar\theta_j-\mu)^2$, the parallel-axis theorem for the sum of squares.

(3) Each θ_{ij} has variance σ^2; $\mathbb{E}(\bar\theta_j-\mu)^2 = v$. This holds for correlated draws as well: correlation only changes v from σ^2/N to $\sigma^2\tau/N$.

(4) Independent chains: the chain means are M independent draws with variance v, and (9.81) is their unbiased sample variance.

So the pooled estimate $\hat\sigma_+^2 = \frac{N-1}{N}W + \frac{B}{N}$ is unbiased for the posterior variance once the chains are in equilibrium. From here Gelman and Rubin's statistic follows in three moves.

Before equilibrium, the two estimates err in opposite directions. Started overdispersed, the chain means are spread not only by the noise v of (9.82) but also by the memory of their starting points, which were chosen wider than the posterior. That extra spread enters B/N, so $\hat\sigma_+^2$ is too *large*. At the same time each chain has explored only the part of the posterior near where it is, and the sample variance s_j^2 of a chain that has not yet seen the whole posterior is too *small*; so is

their average W. The true σ^2 lies between the two:

$$\mathbb{E}\,W \;\lesssim\; \sigma^2 \;\lesssim\; \mathbb{E}\,\hat{\sigma}_+^2,$$

and both inequalities become equalities as the chains forget their starts.

The uncertainty of the centre. The pooled estimate describes the spread of draws around the true posterior mean μ. But μ is not known; it is estimated by the grand mean $\bar{\theta}$, the average of M chain means, each with variance B/N. Its variance is therefore $B/(MN)$, and the spread of a draw around the *estimated* centre is

$$\hat{V} \overset{(1)}{=} \hat{\sigma}_+^2 + \frac{B}{MN} \overset{(2)}{=} \frac{N-1}{N}\,W + \Big(1+\frac{1}{M}\Big)\frac{B}{N}.$$

(1) The variance of a draw around $\bar{\theta}$ is the variance around μ plus the variance of $\bar{\theta}$ itself: variances of independent pieces add, and one draw out of MN barely moves $\bar{\theta}$, so the two are very nearly independent.
(2) Collect the two terms in B/N.

With few chains the centre is poorly known and the correction matters: for $M = 4$ it adds a quarter to the between-chain term.

The ratio, in units of a standard deviation. $\hat{V}$ errs high and W errs low, so $\hat{V}/W$ is above 1 while the chains still remember their starts and tends to 1 as they mix. Its square root compares two standard deviations instead of two variances: it is the factor by which the present estimate of the posterior's *scale* could still shrink if the chains ran forever, hence the name [38].

Working definition 9.11 (potential scale reduction factor $\hat{R}$)

For M chains of N post-burn-in steps of one parameter, with W and B/N as in (9.81),

$$\hat{V} = \frac{N-1}{N}\,W + \Big(1+\frac{1}{M}\Big)\frac{B}{N}, \qquad \hat{R} = \sqrt{\hat{V}/W} \tag{9.83}$$

[by how much the estimated posterior spread could still shrink if the chains ran forever]. $\hat{R} \to 1$ from above as the chains mix. *Operational test:* compute $\hat{R}$ for every parameter, on the second halves of the chains, and keep running until all are below a threshold. Kruschke worries above 1.1 [Kruschke §7.5.1]; current practice often asks for 1.01. Splitting every chain into two halves before computing $\hat{R}$ ("split-$\hat{R}$") also catches a single chain that is still drifting [Lambert §13.9.4].

Padilla's version [Padilla eq. 61] is the ratio $\hat{V}/W$ without the square root, with the criterion $0.97 < \hat{R} < 1.03$; since $\sqrt{1+\epsilon} \simeq 1+\epsilon/2$, a threshold of 1.03 on $\hat{V}/W$ is roughly 1.015 on $\sqrt{\hat{V}/W}$. When reading a paper, check which is meant.

How close to 1 is close enough? Even perfectly converged chains give $\hat{R} > 1$, because W and B are estimated from finite chains. Using (9.82) with $\mathbb{E}\,W = \frac{N}{N-1}(\sigma^2 - v)$,

$$\hat{R}^2 \overset{(1)}{=} \frac{\hat{V}}{W} \simeq \frac{N-1}{N}\,\frac{\sigma^2 + v/M}{\sigma^2 - v} \overset{(2)}{=} \Big(1-\frac{1}{N}\Big)\frac{1+\tau/(MN)}{1-\tau/N} \overset{(3)}{=} 1 + \Big[\Big(1+\frac{1}{M}\Big)\tau - 1\Big]\frac{1}{N} + O\big((\tau/N)^2\big),$$

$$\hat{R} - 1 \overset{(4)}{=} \frac{(1+1/M)\,\tau - 1}{2N} \simeq \Big(1+\frac{1}{M}\Big)\frac{1}{2\,\mathrm{ESS}_{\mathrm{chain}}}. \tag{9.84}$$

(1) Replace each estimate by its expectation: $\hat{V} \simeq \sigma^2 + v/M$ and $W \simeq \frac{N}{N-1}(\sigma^2 - v)$.
(2) $v = \sigma^2\tau/N$; divide numerator and denominator by σ^2.

(3) $1/(1-\epsilon) \simeq 1+\epsilon$ for small $\epsilon = \tau/N$, and multiply out, keeping terms of order $1/N$. The $-1/N$ comes from the factor $(N-1)/N$; it is as large as the other terms when τ is a few, so it cannot be dropped.

(4) $\sqrt{1+\epsilon} \simeq 1+\epsilon/2$. The last form holds when $\tau \gg 1$; $\mathrm{ESS}_{\mathrm{chain}} = N/\tau$ is the effective sample size of one chain.

In equilibrium $\hat{R}-1$ is about half the inverse effective size per chain. A threshold of 1.01 with four chains therefore asks for at least $1.25/(2\times 0.01) \simeq 60$ effective draws per chain; a threshold of 1.1 asks for only about six, which is why it is too lax for quoting tails. A calibration with 200 replicate sets of $M=4$ chains of $N=2000$ steps on a standard Gaussian, all started in equilibrium, with mean $\tau = 4.338$, gives an average $\hat{R}-1 = 0.00111 \pm 7.644\times 10^{-5}$, against 0.001106 from the first form of (9.84).

Back to the four walkers on the two bumps. Figure 9.32c shows $\hat{R}-1$ computed from steps $n/2$ to n as the chains grow. After 100 steps $\hat{R}$ is still 1.618, dominated by the starting points; $\hat{R}-1$ falls below 0.01 after 847 steps and ends at $\hat{R}=1.001$ (split-$\hat{R}=1.002$).

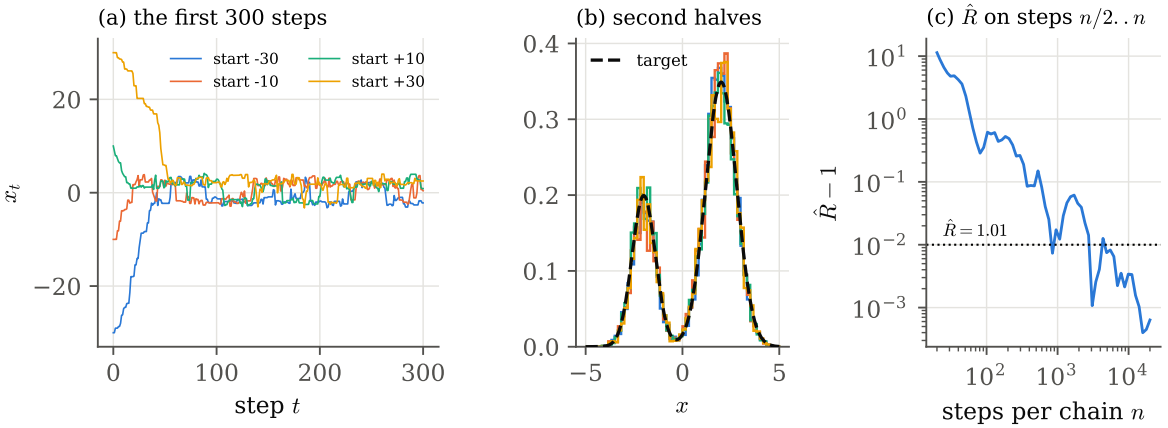

Figure 9.32: Four Metropolis chains on the two-bump density, started at −30, −10, +10 and +30. (a) The first 300 steps: every chain falls into the bumps and starts hopping between them. (b) Histograms of the second halves of the four chains, with the target (dashed). (c) $\hat{R}-1$ on the second half of the steps so far, falling through the 1.01 line.

Example: what $\hat{R}$ sees, and what it cannot see. Now move the bumps to $x=\pm 6$, keep their widths, and use short steps of 0.5. The valley between the bumps is now so deep that a walker essentially never crosses it. Four walkers from −30, −10, +10 and +30 settle into the bump on their own side and stay there (Figure 9.33a). Each chain on its own looks excellent: its trace is stationary, and its autocorrelation time is only about 19.55 steps. Only the comparison between chains reveals the problem: $\hat{R}=11.1$.

Then start all four walkers on the right, at 8, 12, 20 and 30 (Figure 9.33b). They all fall into the right bump and agree perfectly: $\hat{R}=1.000$. Their common mean is 6.008, while the true mean of the target is $0.3\times(-6)+0.7\times 6 = 2.4$. Thirty per cent of the probability is in a bump that none of the walkers has seen, and no statistic computed from them can know.

Watch out: $\hat{R} \simeq 1$ is necessary, not sufficient

$\hat{R}$ compares chains with each other. It detects chains that disagree; it cannot detect chains that agree on the wrong answer because none of them reached part of the posterior [Kruschke §7.5.1]. Start the chains genuinely overdispersed, wider than any plausible

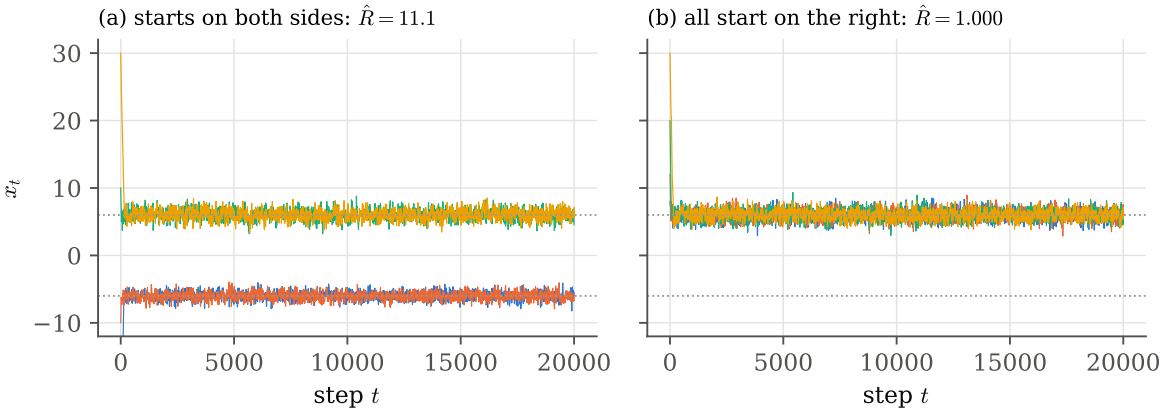

Figure 9.33: The same test on a target with bumps at ±6 (dotted), sampled with short steps. (a) Chains started on both sides stay on their own side; $\hat{R}$ is far above one and exposes the problem. (b) Chains all started on the right agree with each other perfectly and $\hat{R}$ is one, yet all of them miss the left bump.

posterior and on all sides of it, and be most suspicious when the posterior may have several separated modes. The same trap reappears in physics as broken ergodicity: a double well at low temperature (Section 9.15).

Lambert distinguishes the two ways chains can fail to converge [Lambert §13.9.4]: poor mixing *between* chains, as in Figure 9.33a, which ordinary $\hat{R}$ catches; and poor mixing *within* a chain, a chain whose first half and second half disagree because it is still drifting, which only split-$\hat{R}$ catches. Brooks and Gelman [149] extended the diagnostic to many parameters at once; modern practice computes split-$\hat{R}$ for every parameter, together with the ESS of Section 9.12.2.

9.14 Forgetting the start is not forgetting the prior

Two things in an MCMC analysis are chosen before any step is taken, and both are sometimes loosely called "initial conditions": the point where the walker starts, and the prior. It is easy to think that a long enough chain forgets both. It forgets only one of them.

The starting point is forgotten by the chain. That is ergodicity (Section 9.5): for an irreducible aperiodic chain the distribution of X_t approaches the stationary distribution geometrically fast from any start (the Doeblin contraction of Section 9.5.3), and the three crowds of the AR(1) chain, started twenty standard deviations apart, ended with the same histogram (Section 9.7.4). The four walkers of Section 9.13 did the same on the two bumps.

The prior is not part of the walk; it is part of the target. The walker samples $f(\boldsymbol{\theta}) \propto \mathcal{L}(\boldsymbol{\theta})\, p(\boldsymbol{\theta})$, and a different prior is a different f. A chain run with a wrong prior converges, faithfully and from any start, to the posterior of that wrong prior. Running it longer only makes the wrong answer more precise. What forgets the prior is more *data*: the likelihood is a product over data points and grows sharper as their number N grows, while the prior stays as it is, so for large N the posterior is governed by the likelihood. That is the Bernstein–von Mises statement of Chapter 5.

A physicist has met this distinction before. A gas in a box forgets its initial microstate as it thermalises. It does not forget its Hamiltonian: an external potential added to the Hamiltonian changes the equilibrium state, and waiting longer only brings the gas closer to the equilibrium of that Hamiltonian. In the language of Section 9.8.1, $-\ln f = -\ln \mathcal{L} - \ln p$ plays the role of the

energy, and the prior is a fixed external potential $-\ln p$ that the data's potential $-\ln \mathcal{L}$, growing in proportion to N, eventually overwhelms.

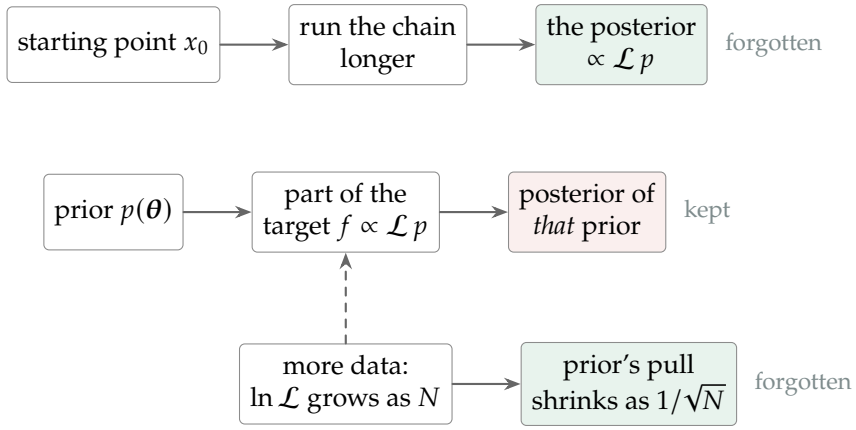

Figure 9.34: Two different kinds of forgetting. Top: the starting point is erased by running the chain (ergodicity). Middle: the prior is built into the target, so running the chain longer leads to the posterior of that prior. Bottom: only more data, through a likelihood that sharpens with N, reduce the prior's influence.

The question. Can we see both statements in one experiment? Same data; two priors, one sensible and one confidently wrong; several chains from wildly different starting points; few data and many data.

The experiment. A detector counts events from a Poisson process with true rate $\lambda = 4$ per unit exposure; this is the counting situation of a collider bin or a photon detector (Chapter 2). We observe N exposures with counts $n_1, \ldots, n_N$ and total $S = \sum_i n_i$. Two priors for λ:

A: flat on $\lambda > 0$;

B: confident and wrong, $\ln \lambda \sim \mathcal{N}(\ln 10, 0.2^2)$, that is, "$\lambda$ is 10, give or take 20%".

The log posterior, up to a constant, is

$$\ln f(\lambda) = \underbrace{S \ln \lambda - N\lambda}_{\ln \mathcal{L}} + \ln p(\lambda), \qquad \ln p_B(\lambda) = -\ln \lambda - \frac{(\ln \lambda - \ln 10)^2}{2 \times 0.2^2}, \tag{9.85}$$

where the Poisson likelihood $\prod_i e^{-\lambda} \lambda^{n_i}/n_i!$ contributes $S \ln \lambda - N\lambda$ after dropping the $n_i!$, which do not depend on λ, and $\ln p_B$ includes the Jacobian $1/\lambda$ of the log-normal density. Under prior A the posterior is known exactly:

$$p_A(\lambda \mid \boldsymbol{d}) \overset{(1)}{=} \frac{\lambda^S e^{-N\lambda}}{\int_0^\infty t^S e^{-Nt}\,\mathrm{d}t} \overset{(2)}{=} \frac{N^{S+1}}{S!}\, \lambda^S e^{-N\lambda}, \qquad \mathbb{E}_A(\lambda \mid \boldsymbol{d}) \overset{(3)}{=} \frac{S+1}{N}.$$

(1) Likelihood times a flat prior, normalised.

(2) $\int_0^\infty t^S e^{-Nt}\mathrm{d}t = S!/N^{S+1}$ (substitute $u = Nt$; Gamma integral).

(3) The mean of a Gamma density with shape $S+1$ and rate N; the same integral with $S+1$ in place of S.

Under prior B the posterior is computed by one-dimensional quadrature on a fine grid, as the reference. For each prior and each data set we run four Metropolis–Hastings chains of 20 000 steps with multiplicative steps $\lambda \to \lambda e^{sZ}$ and the Hastings factor y/x of Section 9.9.1, started at $\lambda_0 = 0.05$, 1, 40 and 200, four decades apart.

Few data: the start is forgotten, the prior is not. With $N = 3$ exposures the counts were $(3, 3, 1)$, $S = 7$; these happen to be low for a true rate of 4, as three Poisson counts easily are. Within some tens of steps the four chains from four decades apart have merged (Figure 9.35a), and their second-phase means differ by only 0.03322; $\hat{R} = 1.000$ for prior B and 1.000 for prior A. The starting points are gone. The priors are not. The posterior mean is 2.669 under A (exact $(S + 1)/N = 2.667$) and 6.297 under B (quadrature: 6.291), 3.83 posterior standard deviations apart (Figure 9.35c). Running prior B ten times longer, 200 000 steps, gives 6.303: no movement at all towards the truth, because there is nothing for it to move towards. The chain has already found its target.

Many data: the likelihood takes over. With $N = 300$ exposures, $S = 1183$. The chains again forget their starts, more slowly now because the posterior is narrow and the steps small (Figure 9.35b). And now the two priors nearly agree: 3.947 under A (exact 3.947) and 4.018 under B, only 0.621 posterior standard deviations apart, both close to the true 4 (Figure 9.35d). The data have outweighed even a prior that claimed 10 within 20%.

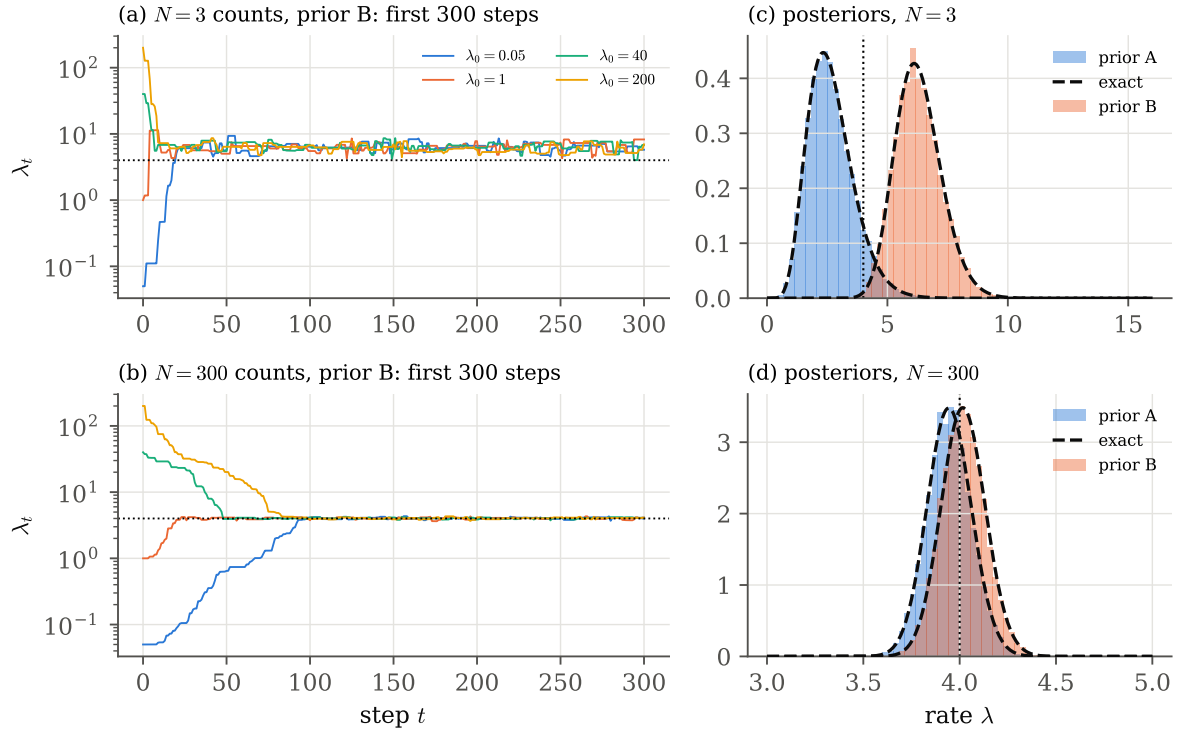

Figure 9.35: Starting point versus prior for a Poisson rate (true value 4, dotted). Left: the first 300 steps of four chains under the wrong prior B, started at $\lambda_0 = 0.05$, 1, 40 and 200 (logarithmic axis); with 3 counts (a) and 300 counts (b) they merge, so the start is forgotten. Right: posteriors from the chains (histograms) and exact (dashed) under the flat prior A and the wrong prior B. With 3 counts (c) the two priors give different answers; with 300 counts (d) they nearly agree.

How fast is the prior forgotten? The rate can be predicted by expanding the log posterior around the peak of the likelihood. The log likelihood $S \ln \lambda - N\lambda$ peaks at $\hat{\lambda} = S/N$ with curvature $-S/\hat{\lambda}^2 = -N/\hat{\lambda}$, so near the peak it is a Gaussian of variance $\sigma_L^2 = \hat{\lambda}/N$. Add the log prior, approximated by its tangent line at $\hat{\lambda}$:

$$\ln f(\lambda) \overset{(1)}{=} \text{const} - \frac{(\lambda - \hat{\lambda})^2}{2\sigma_L^2} + (\ln p)'(\hat{\lambda})\,(\lambda - \hat{\lambda})$$

$$\overset{(2)}{=} \text{const}' - \frac{\left[\lambda - \hat{\lambda} - \sigma_L^2 (\ln p)'(\hat{\lambda})\right]^2}{2\sigma_L^2},$$

$$\frac{\text{shift}}{\text{width}} \overset{(3)}{=} \frac{\sigma_L^2 (\ln p)'(\hat{\lambda})}{\sigma_L} = \sqrt{\frac{\hat{\lambda}}{N}}\,(\ln p)'(\hat{\lambda}). \tag{9.86}$$

(1) Second-order Taylor expansion of $\ln \mathcal{L}$ at its maximum, first-order expansion of $\ln p$, valid when the posterior is narrow compared with the scale on which the prior changes.
(2) Complete the square; the constant absorbs everything independent of λ.
(3) The posterior peak moves by $\sigma_L^2 (\ln p)'$ while its width stays σ_L.

The prior's pull, measured in posterior widths, shrinks as $1/\sqrt{N}$.

The slope of the wrong prior. To use (9.86) for prior B we need the derivative of its log density, $\ln p_B(\lambda) = -\ln \lambda - (\ln \lambda - \ln 10)^2/(2 \times 0.2^2)$, at the true rate $\lambda \simeq 4$:

$$(\ln p_B)'(\lambda) \overset{(1)}{=} -\frac{1}{\lambda} - \frac{2(\ln \lambda - \ln 10)}{2 \times 0.2^2} \cdot \frac{1}{\lambda} \overset{(2)}{=} -\frac{1}{\lambda} - \frac{\ln \lambda - \ln 10}{0.04\,\lambda},$$

$$(\ln p_B)'(4) \overset{(3)}{=} -0.25 - \frac{-0.916}{0.04 \times 4} = -0.25 + 5.73 \simeq 5.5.$$

(1) The first term is the Jacobian $1/\lambda$ of the log-normal density, whose log has derivative $-1/\lambda$. The second is a square: chain rule, with $\mathrm{d}(\ln \lambda)/\mathrm{d}\lambda = 1/\lambda$.
(2) $2 \times 0.2^2/2 = 0.2^2 = 0.04$, the prior's variance in $\ln \lambda$.
(3) $\ln 4 - \ln 10 = \ln 0.4 = -0.916$.

The Jacobian term is small; the second term dominates because $\lambda = 4$ lies $0.916/0.2 \simeq 4.6$ prior standard deviations below the prior's centre at 10. The slope is positive: the prior pulls the posterior peak upwards, towards 10. With $N = 300$, $\hat{\lambda} \simeq 3.94$, (9.86) predicts a shift of $\sqrt{3.94/300} \times 5.5 \simeq 0.63$ widths, matching the 0.621 found by the chains. For $N = 3$ the expansion is not valid (the posterior is as wide as the prior), and the chains are the only honest answer. The result is the one-parameter form of the Bernstein–von Mises theorem of Chapter 5.

Key idea: Two kinds of forgetting

A Markov chain forgets its starting point because it is ergodic, and running it longer completes the forgetting. It does not forget the prior, because the prior is part of the distribution it samples; running longer only converges more precisely to the posterior of that prior. The prior's influence fades only as the data accumulate, as $1/\sqrt{N}$ in units of the posterior width.

Two practical consequences follow. First, a convergence diagnostic such as $\hat{R}$ tests the chain, never the prior: in the experiment above $\hat{R}$ was 1.000 for the wrong prior with three counts. Checking a prior is a modelling question, answered by trying alternatives and seeing how much the posterior moves (a prior sensitivity analysis), or by importance-reweighting the existing chain to the new prior (Chapter 6) when the two posteriors overlap. Second, the experiment explains why cosmological analyses report which priors they used on poorly constrained parameters, such as the optical depth to reionisation in a CMB analysis without large-scale polarisation: there the data are "few" for that parameter, and the prior still shows in the answer.

Watch out: "Burn-in will take care of the prior"

Burn-in removes the memory of the starting point, nothing else. If two analyses of the same data with different priors disagree, no amount of running will reconcile them; only

more informative data will, and only to the extent (9.86) allows.

9.15 Back to statistical mechanics: sampling the canonical ensemble

Recall the oscillator of fixed energy (Section 9.1): a mass on a spring, $x(t) = A\cos(\omega t + \varphi)$, looked at at random instants. Its own motion did the sampling. Every point of the energy ellipse in phase space is visited once per period, the time spent near x is proportional to $1/|v|$, and the histogram of x is the arcsine law $1/(\pi\sqrt{A^2 - x^2})$ of (9.1). That is the **microcanonical** ensemble: the energy is fixed, and the states on the energy shell are weighted by the time the motion spends in them.

Now put the same oscillator in contact with a heat bath at temperature T, a large reservoir it can exchange energy with. Its energy is no longer fixed. Statistical mechanics says that the probability density of a phase-space point (x, p) is then the **canonical**, or Boltzmann, density

$$\rho(x,p) = \frac{e^{-H(x,p)/kT}}{Z}, \qquad Z = \int e^{-H(x,p)/kT}\,\mathrm{d}x\,\mathrm{d}p, \tag{9.87}$$

with H the Hamiltonian, k Boltzmann's constant and Z the partition function. In this section ρ is this Boltzmann density (not an autocorrelation) and p is the momentum (not a prior or posterior). The oscillator's own Hamiltonian motion cannot produce this density. Hamilton's equations conserve H, so a trajectory started on one energy shell stays on it forever and never visits the others. In nature the energy changes through collisions with the bath. On a computer something else must change it, and that something is the Metropolis walker. This is the problem for which Metropolis et al. [36] invented the algorithm: to compute canonical averages, an equation of state, for a system of interacting particles, where neither the partition function nor a direct way to draw configurations is available.

	microcanonical	canonical
what is fixed	energy E	temperature T (energy exchanged with a bath)
distribution	uniform on the shell $H = E$, weighted by time	$e^{-H/kT}/Z$ over all of phase space
who samples it	the system's own dynamics (if ergodic)	a Metropolis walker; physically, the bath
oscillator's x	arcsine law on $\lvert x\rvert < A$	Gaussian, variance $kT/m\omega^2$

The question. Run Metropolis on $e^{-H/kT}$. Does it reproduce what statistical mechanics predicts where we can calculate (the oscillator), and how does it behave where we cannot (a double well, and a lattice of interacting spins)?

The decision ratio of the walker is

$$R = \frac{\rho(y)}{\rho(x)} = \frac{e^{-H(y)/kT}/Z}{e^{-H(x)/kT}/Z} = e^{-[H(y)-H(x)]/kT}\,: \tag{9.88}$$

a move that lowers the energy is always taken, and a move that raises it by ΔH is taken with probability $e^{-\Delta H/kT}$. The partition function cancels exactly as the evidence did in (9.58). The two problems are the same problem in two vocabularies:

Bayesian inference	statistical mechanics
posterior $p(\boldsymbol{\theta} \mid \boldsymbol{d})$	Boltzmann density ρ
$-\ln\big[\mathcal{L}(\boldsymbol{\theta})\,p(\boldsymbol{\theta})\big]$	energy in units of kT, H/kT
evidence $Z = \int \mathcal{L}\,p\,\mathrm{d}\boldsymbol{\theta}$	partition function $Z = \int e^{-H/kT}$
tempered target f^{β} (Section 9.9)	Boltzmann weight at temperature $1/\beta$
maximum a posteriori point	ground state
posterior mean of g	thermal average $\langle g \rangle$

9.15.1 The harmonic oscillator in a heat bath

For $H = p^2/2m + m\omega^2 x^2/2$ the canonical density factorises into two Gaussians, so every prediction can be written down. (We write the spring as $m\omega^2$ to keep the letter k for Boltzmann's constant.)

$$\rho(x,p) \overset{(1)}{=} \frac{1}{Z}\exp\!\Big(-\frac{p^2}{2mkT}\Big)\exp\!\Big(-\frac{x^2}{2kT/m\omega^2}\Big),$$
$$\Big\langle \frac{p^2}{2m}\Big\rangle \overset{(2)}{=} \frac{mkT}{2m} = \frac{kT}{2}, \qquad \Big\langle \frac{m\omega^2 x^2}{2}\Big\rangle \overset{(3)}{=} \frac{m\omega^2}{2}\,\frac{kT}{m\omega^2} = \frac{kT}{2}, \qquad \langle H\rangle = kT. \tag{9.89}$$

(1) $e^{-H/kT} = e^{-p^2/2mkT}\,e^{-m\omega^2x^2/2kT}$: p and x are independent Gaussians with variances mkT and $kT/m\omega^2$.
(2) $\langle p^2\rangle$ is the variance of p, since its mean is zero.
(3) Likewise for x. Each quadratic term in H carries $kT/2$: equipartition.

The distribution of the energy itself follows from the area of phase space at each energy. The region $H \le E$ is an ellipse with semi-axes $\sqrt{2E/m\omega^2}$ in x and $\sqrt{2mE}$ in p, so its area is $\mathcal{A}(E) = \pi\sqrt{2E/m\omega^2}\sqrt{2mE} = 2\pi E/\omega$, and the area between E and $E + \mathrm{d}E$ is $\mathcal{A}'(E)\,\mathrm{d}E = (2\pi/\omega)\,\mathrm{d}E$, the same for every E: the one-dimensional oscillator has a constant density of states. Hence

$$p(E) \propto e^{-E/kT}\,\frac{2\pi}{\omega} \quad\Longrightarrow\quad p(E) = \frac{1}{kT}\,e^{-E/kT}, \qquad \mathrm{P}(E > 2kT) = e^{-2} = 0.135. \tag{9.90}$$

Canonical from microcanonical. The two ensembles are not unrelated: the canonical one is a mixture of microcanonical shells, each weighted by its Boltzmann probability (9.90). On the shell of energy E the position follows the arcsine law with amplitude $A = \sqrt{2E/m\omega^2}$. Averaging it over E should give back the Gaussian of (9.89). In units with $m\omega^2 = 1$ (so $A^2 = 2E$):

$$p(x) \overset{(1)}{=} \int_{x^2/2}^{\infty} \frac{e^{-E/kT}}{kT}\,\frac{1}{\pi\sqrt{2E - x^2}}\,\mathrm{d}E \overset{(2)}{=} \frac{e^{-x^2/2kT}}{2\pi kT}\int_0^{\infty} e^{-u/2kT}\,u^{-1/2}\,\mathrm{d}u$$
$$\overset{(3)}{=} \frac{e^{-x^2/2kT}}{2\pi kT}\,\Gamma\!\big(\tfrac12\big)\sqrt{2kT} \overset{(4)}{=} \frac{e^{-x^2/2kT}}{\sqrt{2\pi kT}}. \tag{9.91}$$

(1) Law of total probability over the energy: $p(x) = \int p(E)\,p(x \mid E)\,\mathrm{d}E$; only shells with $A > |x|$, that is $E > x^2/2$, reach x.
(2) Substitute $u = 2E - x^2$, so $E = (u + x^2)/2$ and $\mathrm{d}E = \mathrm{d}u/2$; the factor $e^{-x^2/2kT}$ comes out of the integral.
(3) $\int_0^{\infty} e^{-u/c}u^{-1/2}\mathrm{d}u = \Gamma(\tfrac12)\sqrt{c}$ with $c = 2kT$.
(4) $\Gamma(\tfrac12) = \sqrt{\pi}$, and $\sqrt{\pi}\sqrt{2kT}/(2\pi kT) = 1/\sqrt{2\pi kT}$.

The arcsine laws, each piled up at its own turning points, add up to a Gaussian peaked at the centre. The same Hamiltonian gives two different distributions of x because the sampling prescription is different: a random instant at fixed energy, or a random state at fixed temperature.

The walker in phase space. A Metropolis walker in the plane (x, p), with $m = \omega = 1$, $kT = 1$, round steps of width $2.38/\sqrt{2}$, started at $(3, -3)$ and run for 200 000 steps, accepted 0.355 of its proposals (Figure 9.36). It never uses Z and knows nothing about shells or equipartition. It gives $\mathrm{Var}\, x = 1.008$ and $\mathrm{Var}\, p = 1.008$ (exact: $kT = 1$), kinetic and potential energies $\langle p^2/2 \rangle = 0.5039$ and $\langle x^2/2 \rangle = 0.5039$ (exact: $1/2$ each), $\langle H \rangle = 1.008$, a fraction 0.1394 of states with $E > 2kT$ (exact $e^{-2} = 0.1353$), and a correlation of -0.004609 between x and p (exact 0). Drawing instead an energy from $p(E)$ and a uniform phase on that shell, as in (9.91), gives $\mathrm{Var}\, x = 0.9943$: the mixture of microcanonical ensembles is the canonical one.

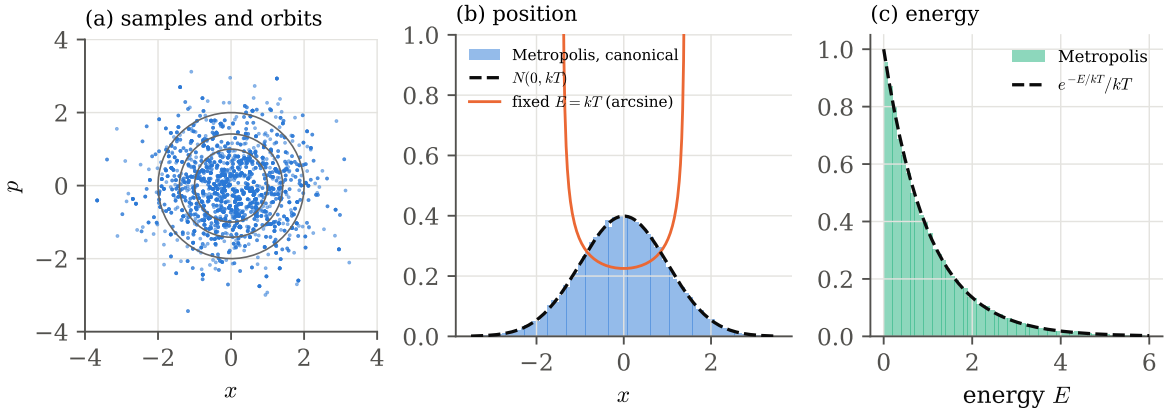

Figure 9.36: Metropolis for the oscillator at $kT = 1$. (a) The first 3000 states in phase space, with three energy shells: the walker crosses shells freely, which the Hamiltonian motion never does. (b) Position: the canonical histogram is the Gaussian $\mathcal{N}(0, kT)$ (dashed), not the arcsine law of a single shell at $E = kT$ (orange). (c) Energy: exponential, $e^{-E/kT}/kT$.

Key idea: Dynamics samples the shell, Metropolis samples the ensemble

Hamiltonian motion conserves energy, so at best it samples one microcanonical shell, uniformly in time. The canonical density $e^{-H/kT}/Z$ is a mixture of all shells weighted by $e^{-E/kT}$ times the density of states. A Metropolis walker samples it directly, because its acceptance rule $\min(1, e^{-\Delta H/kT})$ plays the part of the heat bath: it lets the energy change, and makes rises in energy exponentially rare. The partition function, like the evidence, never appears.

9.15.2 A double well: no formula, and a barrier

Replace the spring by the potential $V(x) = \Delta V\,(x^2 - 1)^2$, with minima at $x = \pm 1$ and a barrier of height $\Delta V = 1$ at $x = 0$: a particle in a symmetric double well, the shape of a molecule with two conformations or of an order parameter below a phase transition. The momentum part of $e^{-H/kT}$ is the same Gaussian as before and factorises away, so the question is the position density $\rho(x) \propto e^{-V(x)/kT}$. Its normalisation $\int e^{-V/kT} \mathrm{d}x$ has no elementary closed form. In one dimension we can still compute it by quadrature as a check; in a thousand dimensions we could not, but the walker would not notice the difference.

With 400 000 steps of width 0.15 the walker reproduces $e^{-V/kT}$ at all temperatures (Figure 9.37a): $\langle x^2 \rangle = 0.8294$ at $kT = 1$ (quadrature 0.8327) and 0.919 at $kT = 0.25$ (0.9177), with fractions 0.4953 and 0.5109 of the time in the right well (exact $\frac{1}{2}$ by symmetry). But the way it gets there changes with temperature. At $kT = 0.25$ the barrier is four times kT, and the walker spends long stretches in one well before hopping to the other (Figure 9.37b): 56.5 hops per 10^5 steps, against 395.8 at $kT = 1$.

How rare are the hops? A walker that moves in small steps behaves like a diffusing particle, and the rate at which it crosses the barrier follows the same reasoning as a thermally activated chemical reaction. To hop, the walker must first be near the top of the barrier, and must then diffuse across it. We estimate the two pieces separately and multiply.

How often is the walker at the top? Call the strip of width w around the top of the barrier, centred on $x = 0$, the top region. In equilibrium the probability of being in it is the Boltzmann weight integrated over the strip, divided by the integral over everything. The denominator is dominated by the two wells. Near a minimum, $V(x) \simeq V''(1)(x-1)^2/2$ (the minimum value is 0), so each well contributes a Gaussian integral:

$$\mathrm{P(top)} \overset{(1)}{=} \frac{\int_{\text{strip}} e^{-V(x)/kT}\,\mathrm{d}x}{\int e^{-V(x)/kT}\,\mathrm{d}x} \overset{(2)}{=} \frac{e^{-\Delta V/kT}\,w}{2Z_{\text{well}}}, \qquad Z_{\text{well}} \overset{(3)}{=} \int e^{-V''(1)(x-1)^2/2kT}\,\mathrm{d}x = \sqrt{\frac{2\pi kT}{V''(1)}}.$$

(1) The fraction of time in a region is the integral of the normalised density $\rho(x)$ over it.
(2) Inside the strip V is within about kT of its maximum ΔV, so $e^{-V/kT} \simeq e^{-\Delta V/kT}$ up to a factor of order one, and the integral is that value times the width. The two wells each contribute Z_{well}.
(3) The Gaussian integral $\int e^{-u^2/2\sigma^2}\mathrm{d}u = \sqrt{2\pi}\,\sigma$ with $\sigma^2 = kT/V''(1)$.

How wide is the top? Near $x = 0$ the potential is a downward parabola, $V(x) \simeq \Delta V - |V''(0)|\,x^2/2$. The top region is where the walker is within kT of the summit, where nothing pushes it strongly either way:

$$\frac{|V''(0)|\,x^2}{2} \le kT \quad\Longleftrightarrow\quad |x| \le \sqrt{\frac{2kT}{|V''(0)|}}, \qquad w = 2\sqrt{\frac{2kT}{|V''(0)|}}.$$

A hotter walker has a wider top, $w \propto \sqrt{kT}$.

How long does it take to cross? A Metropolis walker with steps s much smaller than the scale of V accepts nearly every step, and so moves like the drunkard of Section 9.7: its mean squared displacement after t steps is $s^2 t$. Writing that as $2Dt$ defines its diffusion constant $D = s^2/2$ per step (here D is a diffusion constant, not a dimension). Crossing a strip of width w by diffusion takes about $t_{\text{cross}} = w^2/2D$ steps, the diffusive cost $(L/s)^2$ again.

Multiply. The hop rate per step is the probability of being at the top divided by the time it takes to cross it:

$$\begin{aligned}\text{rate} &\overset{(1)}{=} \frac{\mathrm{P(top)}}{t_{\text{cross}}} = \frac{e^{-\Delta V/kT}\,w}{2Z_{\text{well}}}\cdot\frac{2D}{w^2} = \frac{D\,e^{-\Delta V/kT}}{w\,Z_{\text{well}}} \\ &\overset{(2)}{=} \frac{D\,e^{-\Delta V/kT}}{2\sqrt{2kT/|V''(0)|}\,\sqrt{2\pi kT/V''(1)}} \overset{(3)}{=} \frac{\sqrt{|V''(0)|\,V''(1)}}{4\sqrt{\pi}}\,\frac{D}{kT}\,e^{-\Delta V/kT}.\end{aligned} \tag{9.92}$$

(1) A walker in the strip leaves it, to one side or the other, after about t_{cross} steps, so the strip is crossed about $\mathrm{P(top)}/t_{\text{cross}}$ times per step.
(2) Insert w and Z_{well}.
(3) $\sqrt{kT}\times\sqrt{kT} = kT$: the two square roots, one from the width of the top and one from the width of a well, combine into a single $1/kT$; everything else is a constant of the potential and of the step size.

The prefactor $1/(4\sqrt{\pi}) \simeq 0.14$ comes from our rough choice of the strip; a careful treatment of the same problem replaces it by $1/(2\pi) \simeq 0.16$, and leaves the dependence on temperature unchanged. The result is the form of Kramers' rate for an overdamped particle [150]. Taking logarithms, $\ln(\text{rate}\times kT) = \text{const} - \Delta V/kT$, so plotted against $\Delta V/kT$ it is a straight line of slope

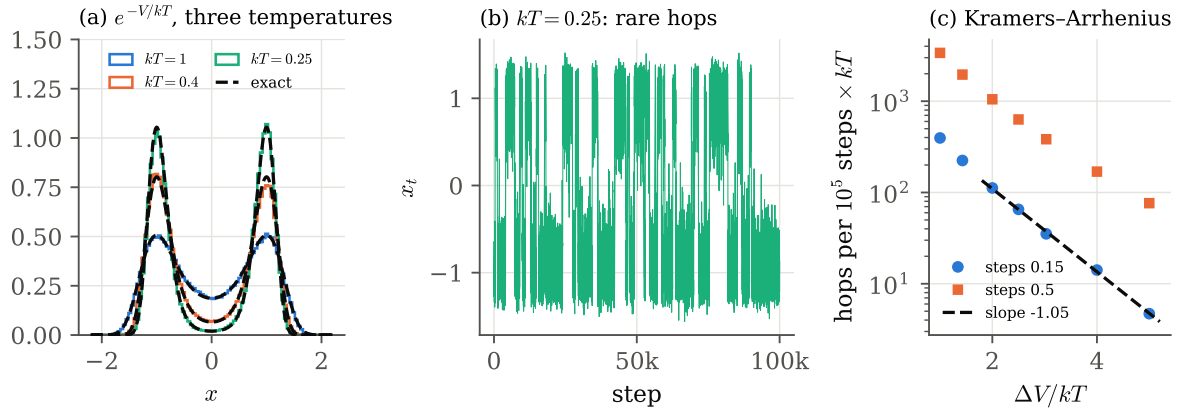

Figure 9.37: Metropolis on the double well $V = (x^2 - 1)^2$. (a) Histograms at three temperatures against $e^{-V/kT}$ normalised by quadrature (dashed). (b) At $kT = 0.25$ the walker stays in one well for long stretches. (c) Hop rate times kT against $\Delta V/kT$: small steps (dots) follow the Kramers–Arrhenius line of slope -1 (dashed); large steps (squares) hop far more often.

-1: every additional kT of barrier height makes hops $e \simeq 2.7$ times rarer. The walker gives slope -1.047 for $kT \leq 0.5$ (Figure 9.37c): Arrhenius's law, recovered from a sampling algorithm.

The squares in Figure 9.37c are walkers with steps of 0.5 instead of 0.15. They sample the same $e^{-V/kT}$ but hop far more often: 677.2 hops per 10^5 steps at $kT = 0.25$, with a fitted slope of only -0.8675. A step of that size can jump from $x \simeq -0.6$ straight to $x \simeq +0.6$, where $V = 0.4096$, without ever visiting the top of the barrier. A Metropolis walker is not a physical particle, and its steps are not physical time. That is a strength for sampling, since moves that no real particle could make may cross barriers cheaply (parallel tempering and cluster moves exploit this), and a warning for dynamics: rates and time correlations read off an MCMC run are properties of the algorithm, not of the system.

Watch out: MCMC time is not physical time

The stationary distribution of a Metropolis chain is the Boltzmann (or posterior) density; its *path* is not a trajectory of the physical system. Equilibrium averages from the chain are physical; hop rates, relaxation times and autocorrelations depend on the proposal and are diagnostics of the sampler. At low temperature the slow hops are also a sampling hazard: a chain that has not hopped often enough is the broken-ergodicity trap of Figure 9.33.

9.15.3 The Ising model: a distribution nobody can sample directly

An $L \times L$ square lattice carries a spin $s_i = \pm 1$ at each site, with periodic boundaries. Neighbouring spins prefer to align; the energy of a configuration $s = (s_1, \ldots, s_{L^2})$ is

$$E(s) = -J \sum_{\langle ij \rangle} s_i s_j, \tag{9.93}$$

where $\langle ij \rangle$ runs over nearest-neighbour pairs and $J > 0$. For $L = 32$ there are $2^{1024} \simeq 10^{308.3}$ configurations. The partition function is a sum over all of them, and no method of drawing configurations directly from $e^{-E/kT}/Z$ is known for general temperatures. A grid in configuration space is not even conceivable.

The exact answer we compare with. Yet the model has been solved exactly, in a limit: an infinite lattice in zero external field. Onsager [151] computed its partition function per spin, by writing

the sum over configurations row by row as a product of transfer matrices and finding their largest eigenvalue; from the free energy follows the energy per spin $u = \langle E\rangle/L^2$, measured in units of J. Yang [152] computed the spontaneous magnetisation, the mean spin $M = \langle s_i\rangle$ that the lattice keeps on its own when no field is applied. Both calculations run to many pages and we do not repeat them: we use their results as targets. They say that below the critical temperature

$$kT_c = \frac{2J}{\ln(1+\sqrt{2})} = 2.269\,J \tag{9.94}$$

the spins order, with magnetisation per spin $M(T) = \left[1-\sinh^{-4}(2J/kT)\right]^{1/8}$, and above it $M = 0$. This is a perfect test: a distribution with no direct sampler and an exact answer.

The single-spin-flip walker. The walker proposes to flip one spin, $s_i \to -s_i$; the proposal is symmetric (flipping it back is equally likely). Only the four bonds that touch site i change. Before the flip they contribute $-Js_ih_i$, with $h_i = \sum_{j\,\mathrm{nb}\,i} s_j$ the sum of the four neighbours; after it, $+Js_ih_i$. So

$$\Delta E = 2Js_ih_i \in \{-8J,-4J,0,4J,8J\}, \qquad a = \min\!\left(1, e^{-\Delta E/kT}\right), \tag{9.95}$$

a local computation that never needs Z. The code visits the sites in order:

Listing 9.7: One Metropolis sweep of the Ising lattice (`code/ch09/20_ising.py`)

```
def sweep(s, beta, u):
    """One sweep: visit every site once (in order) and propose to flip its spin.
    dE = 2 J s_i (sum of the 4 neighbours), J = 1.  Accept with min(1, exp(-beta dE)).
    Each single-site update satisfies detailed balance, so each preserves the Boltzmann
    law."""
    L = s.shape[0]
    acc = 0
    k = 0
    for i in range(L):
        for j in range(L):
            nb = s[(i + 1) % L, j] + s[(i - 1) % L, j] + s[i, (j + 1) % L] + s[i, (j - 1) %
    L]
            dE = 2.0 * s[i, j] * nb
            if dE <= 0.0 or u[k] < np.exp(-beta * dE):
                s[i, j] = -s[i, j]
                acc += 1
            k += 1
    return acc
```

A systematic sweep is not one reversible chain, but it does not need to be. Each single-site update satisfies detailed balance with $e^{-E/kT}$ and therefore leaves it stationary, and a sequence of updates that each leave a distribution unchanged leaves it unchanged as a whole: if $\pi P_1 = \pi$ and $\pi P_2 = \pi$, then $\pi P_1P_2 = \pi P_2 = \pi$.

The run. On a finite lattice the sign of the magnetisation flips now and then, so we record the mean of its absolute value, $\langle|m|\rangle$ with $m = \frac{1}{L^2}\sum_i s_i$, and the mean energy per spin. The settings are

lattice	$L = 32$, 1024 spins, periodic boundaries
start	all spins up, at the lowest temperature
temperatures	twelve, from $kT = 1.5J$ to $3.5J$, denser near T_c; each starts from the last configuration of the one before (heating)
burn-in	2000 sweeps at each temperature
measurement	6000 sweeps at each temperature

A sweep is one pass of the code above, one proposed flip per site.

Side by side. Figure 9.38 shows the whole scan; at one temperature on each side of T_c the numbers are

	$kT = 1.8J$ (ordered)		$kT = 3J$ (disordered)	
	exact	ours	exact	ours
$\langle\lvert m\rvert\rangle$	0.9569	0.9566	0	0.08438
u/J	−1.859	−1.859	−0.8173	−0.8158
accepted flips		0.04152		0.4615

The snapshots show what the numbers mean: an ordered sea with a few flipped spins at $1.8J$, domains of every size at $2.3J \approx T_c$, and short-range disorder at $3J$. At $1.8J$ almost every proposed flip breaks four aligned bonds, $\Delta E = 8J$ in (9.95), and is refused.

Why they differ. *Statistical noise.* At $1.8J$ the magnetisations differ by 3×10^{-4}, and at $3J$ the energies by 1.5×10^{-3}. The energy per spin of a lattice of a thousand spins fluctuates by a few hundredths from sweep to sweep, and 6000 correlated sweeps average that down to about 10^{-3}: both differences are of the size of the run's own noise.

A magnetisation above T_c. The exact $M = 0$ is for an infinite lattice. A finite one has a net magnetisation m that fluctuates about zero, and the mean of its absolute value is positive. If the L^2 spins were independent, m would have standard deviation $1/L$ and $\langle|m|\rangle = \sqrt{2/\pi}/L \simeq 0.025$ for $L = 32$. At $3J$ each spin is correlated with its neighbours over a few lattice spacings, which enlarges the fluctuation to the measured 0.08438. Either way it falls like $1/L$: a lattice twice as wide would give about half.

Rounding near T_c. At T_c the infinite lattice has domains of every size; ours cannot hold a domain wider than $L = 32$. The sharp corner of $M(T)$ is therefore smeared over a range of temperatures in which the correlation length of the infinite lattice exceeds L, a few per cent of T_c for $L = 32$, visible in Figure 9.38a as the dots leaving the exact curve before T_c and not reaching zero after it.

The ordered start. A random start at low temperature would not reproduce Yang's curve. The lattice orders locally into domains of both signs, and a band of down spins that wraps around the periodic lattice can only be removed by moving its walls one spin at a time, which at $1.8J$ may not happen within the run; $\langle|m|\rangle$ would then come out far below 0.96. Starting ordered and heating keeps the lattice in the equilibrium state at every step of the scan.

The lesson. A walker that knows only the energy change of a single flip reproduces Onsager's and Yang's infinite-lattice answers to the noise of the run, as long as the temperature is not so close to T_c that the lattice size itself matters.

The whole scan takes seconds on a laptop: about 10^8 spin updates, compiled with `numba`. Research studies of the same model use lattices of 10^3–10^4 sites per side, many more sweeps near T_c, where the single-flip walker becomes very slow because domains of all sizes must be rearranged one spin at a time, and cluster algorithms that flip whole domains at once; they extract critical exponents from how the results change with L. Underneath, the method is the same: a biased random walk through a space far too large to enumerate, guided only by energy differences.

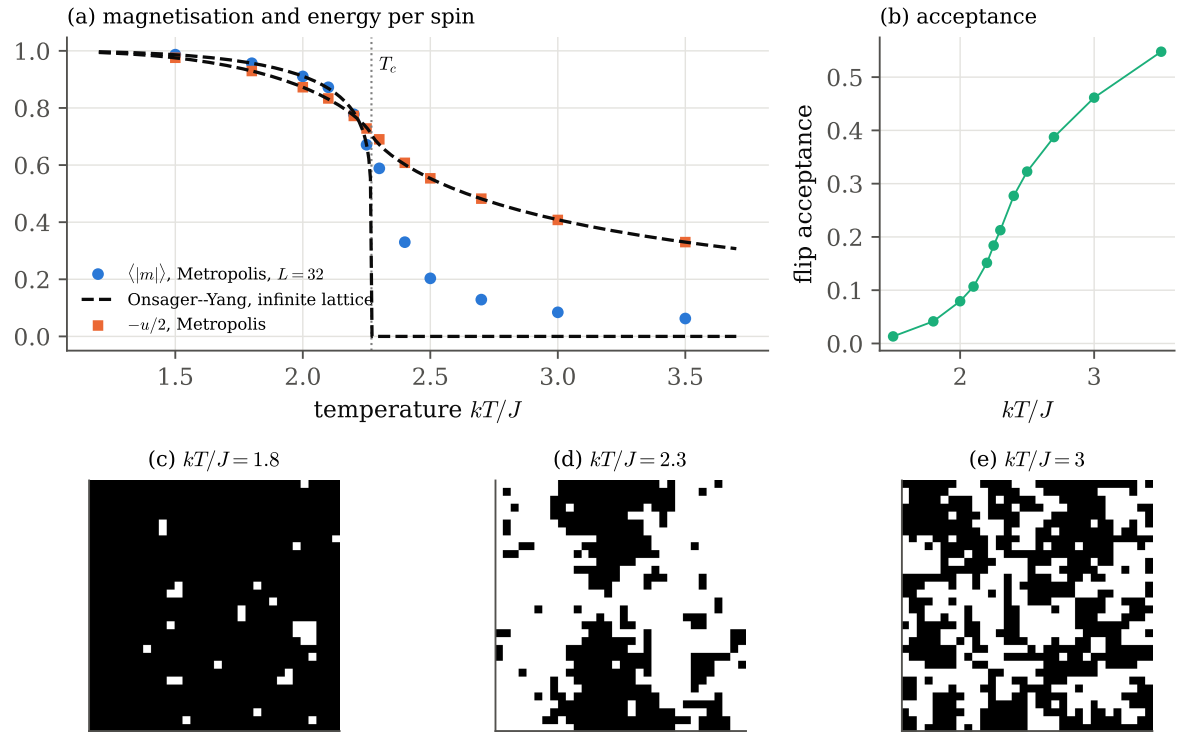

Figure 9.38: The two-dimensional Ising model on a 32×32 lattice by single-spin-flip Metropolis. (a) Mean absolute magnetisation per spin (dots) and minus half the energy per spin (squares) against temperature, with the exact infinite-lattice results of Onsager and Yang (dashed); the dotted line is T_c. (b) Fraction of accepted flips. (c)–(e) Configurations at three temperatures (black and white are the two spin values).

9.16 Relatives of the biased walker: Gibbs, Hamiltonian and ensemble samplers

Every walker so far proposed a random step and corrected it with the Metropolis–Hastings decision. Its weakness was visible on the correlated ellipse of Section 9.11.2: the step must be small enough for the narrowest direction, and along the long direction the walker then diffuses, paying the $(L/s)^2$ cost of the free walk. Three relatives keep the decision rule of (9.61), which guarantees the right stationary distribution, and change only the proposal, so as to be accepted more often or to travel further. A fourth method addresses the one quantity MCMC was designed to avoid, the evidence.

The question. Can a proposal be accepted every time? Can it travel far along the posterior and still be accepted? Can it adapt to the posterior's shape without being tuned?

9.16.1 Gibbs sampling: proposals that are always accepted

Suppose that, although we cannot draw from the joint density $f(\theta_1,\theta_2)$, we can draw each coordinate from its conditional given the other. Gibbs sampling updates the coordinates in turn, drawing θ_1 from $f(\theta_1\mid\theta_2)$ with θ_2 held at its current value, then θ_2 from $f(\theta_2\mid\theta_1)$ with the new θ_1, and repeats [Wasserman p. 416], [Kruschke §7.4.4]. It was introduced by Geman and Geman [153] for restoring images, whose pixels have simple conditionals given their neighbours, and is named after the Gibbs distributions of statistical mechanics.

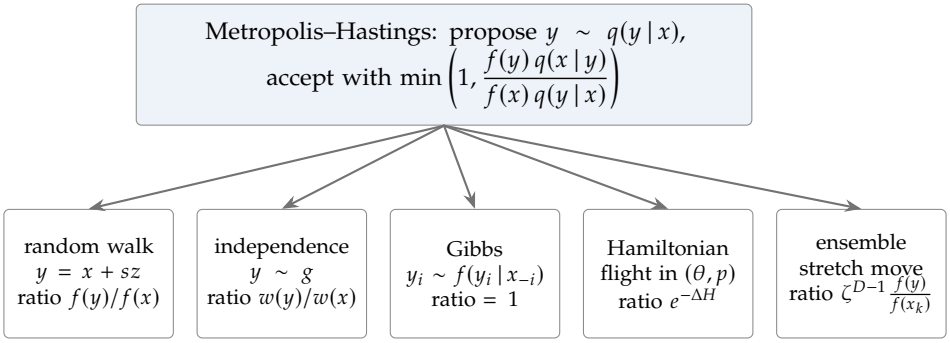

Figure 9.39: One decision rule, several proposals. Each sampler is Metropolis–Hastings with a particular way of proposing y; the ratio shown is what its Hastings ratio reduces to. $w = f/g$ is the importance weight, x_{-i} means all coordinates except the ith, ΔH is the energy error of the numerical flight, and ζ is the stretch factor of the ensemble move.

Why does it need no accept–reject step? Treat the update of θ_1 as a Metropolis–Hastings proposal $y = (y_1, x_2)$ from $x = (x_1, x_2)$ with $q(y \mid x) = f(y_1 \mid x_2)$. Its Hastings ratio is

$$R_H \overset{(1)}{=} \frac{f(y_1, x_2)\; f(x_1 \mid x_2)}{f(x_1, x_2)\; f(y_1 \mid x_2)} \overset{(2)}{=} \frac{f(y_1 \mid x_2)\, f_2(x_2)\; f(x_1 \mid x_2)}{f(x_1 \mid x_2)\, f_2(x_2)\; f(y_1 \mid x_2)} = 1. \tag{9.96}$$

(1) Definition (9.61); the reverse proposal draws x_1 from the same conditional, because the second coordinate is the same x_2 before and after.
(2) Write each joint density as conditional times marginal, $f(\theta_1, x_2) = f(\theta_1 \mid x_2)\, f_2(x_2)$; every factor cancels.

Every Gibbs proposal is accepted [HobsonBMC §3.2.5, p. 66]. When a conditional cannot be sampled directly, a single Metropolis step for that coordinate, with the others held fixed, takes its place (slice sampling, which draws a point uniformly under the graph of the conditional, is another substitute [HobsonBMC §3.2.5]); Wasserman calls this Metropolis within Gibbs [Wasserman p. 419].

Example: the correlated Gaussian. For the Gaussian with unit variances and correlation ρ of Section 9.11.2, the exponent $-(\theta_1^2 - 2\rho\theta_1\theta_2 + \theta_2^2)/2(1-\rho^2)$, viewed as a function of θ_1 alone, is $-(\theta_1 - \rho\theta_2)^2/2(1-\rho^2)$ plus terms without θ_1 (complete the square). So $\theta_1 \mid \theta_2 \sim \mathcal{N}(\rho\theta_2, 1-\rho^2)$, and symmetrically for θ_2. One sweep from $(\theta_1^{(t)}, \theta_2^{(t)})$ is

$$\begin{aligned} \theta_1^{(t+1)} &\overset{(1)}{=} \rho\, \theta_2^{(t)} + \sqrt{1-\rho^2}\; z_t \overset{(2)}{=} \rho\left[\rho\, \theta_1^{(t)} + \sqrt{1-\rho^2}\; z'_{t-1}\right] + \sqrt{1-\rho^2}\; z_t \\ &= \rho^2\, \theta_1^{(t)} + (\text{fresh noise}), \qquad \tau_{\text{Gibbs}} \overset{(3)}{=} \frac{1+\rho^2}{1-\rho^2}. \end{aligned} \tag{9.97}$$

(1) Draw from the conditional of θ_1 given the current θ_2.
(2) The current $\theta_2^{(t)}$ was itself drawn in the previous sweep from its conditional given $\theta_1^{(t)}$, with a noise z'_{t-1} independent of z_t.
(3) The sequence $\theta_1^{(t)}$ is an AR(1) chain with coefficient ρ^2, whose τ was found in Section 9.12.2.

For $\rho = 0.95$ that is 19.51 sweeps; a chain of 50 000 sweeps gives 18.73. Every proposal was accepted, and yet the chain is no faster than the best round Metropolis walker of Section 9.11.2 and slower than the shaped one. The reason is visible in Figure 9.40a: Gibbs moves only parallel to the axes, and a ridge at 45° must be climbed as a staircase of short steps. Gibbs is excellent when the coordinates are nearly independent given each other, and as slow as a random walk when they are strongly correlated [Lambert §14.6].

Gibbs shines in hierarchical models, where the conditionals have known forms even though the joint does not. Wasserman's example [Wasserman pp. 416–418, Ex. 24.11] has disease rates in k cities. The log-odds ψ_i of city i is drawn from a population $\mathcal{N}(\mu, 1)$, and what we observe is an estimate $Z_i \sim \mathcal{N}(\psi_i, \sigma_i^2)$ of it, with a known standard error σ_i; the population mean μ has a flat prior. We keep his letters; in this paragraph Z_i is the estimate for city i, not an evidence. The joint posterior of $(\mu, \psi_1, \dots, \psi_k)$ is proportional to $\prod_i \mathcal{N}(Z_i; \psi_i, \sigma_i^2)\,\mathcal{N}(\psi_i; \mu, 1)$, and Gibbs needs its conditionals.

The conditional of one city. Hold μ and the other cities fixed. Only two factors contain ψ_i, so, writing ψ for ψ_i,

$$\ln p(\psi \mid \text{rest}) \overset{(1)}{=} -\frac{(Z_i-\psi)^2}{2\sigma_i^2} - \frac{(\psi-\mu)^2}{2} + \text{const}$$
$$\overset{(2)}{=} -\frac{1}{2}\Big[\Big(\frac{1}{\sigma_i^2}+1\Big)\psi^2 - 2\Big(\frac{Z_i}{\sigma_i^2}+\mu\Big)\psi\Big] + \text{const} \overset{(3)}{=} -\frac{(\psi-e_i)^2}{2d_i^2} + \text{const},$$

(1) The log of the two Gaussian factors that contain ψ; all others are constants here.
(2) Expand the squares and keep only the terms with ψ.
(3) Complete the square. A log density $-\frac{1}{2}(A\psi^2 - 2B\psi)$ is a Gaussian with precision A and mean B/A; here $A = 1/\sigma_i^2 + 1$ and $B = Z_i/\sigma_i^2 + \mu$.

so $\psi_i \mid \text{rest} \sim \mathcal{N}(e_i, d_i^2)$ with

$$e_i = \frac{Z_i/\sigma_i^2 + \mu}{1/\sigma_i^2 + 1}, \qquad d_i^2 = \frac{1}{1/\sigma_i^2 + 1}.$$

Each city's rate is a precision-weighted average of its own data (precision $1/\sigma_i^2$) and the population mean (precision 1), the shrinkage of Chapter 5: a city with a poor estimate (large σ_i) is pulled most of the way to μ.

The conditional of the population mean. Hold all ψ_i fixed. With the flat prior, μ appears only in the k population factors:

$$\ln p(\mu \mid \text{rest}) \overset{(1)}{=} -\frac{1}{2}\sum_{i=1}^{k}(\psi_i-\mu)^2 + \text{const} \overset{(2)}{=} -\frac{1}{2}\big[k\mu^2 - 2\mu\textstyle\sum_i \psi_i\big] + \text{const} \overset{(3)}{=} -\frac{k}{2}(\mu-\bar\psi)^2 + \text{const},$$

(1) The k factors $\mathcal{N}(\psi_i; \mu, 1)$.
(2) Expand and keep the terms with μ.
(3) Complete the square with $A = k$ and $B = \sum_i \psi_i = k\bar\psi$, where $\bar\psi$ is the mean of the ψ_i.

so $\mu \mid \text{rest} \sim \mathcal{N}(\bar\psi, 1/k)$: the k city log-odds act as k independent measurements of μ, each with unit variance. Gibbs sampling is just cycling through these $k+1$ Gaussian draws.

9.16.2 Hamiltonian Monte Carlo: the oscillator's dynamics as a proposal

The canonical oscillator of Section 9.15 suggests a better proposal. Treat $V(\theta) = -\ln f(\theta)$ as a potential energy, as V was for the double well of Section 9.15.2, give the walker a momentum p of the same dimension (in this subsection p is a momentum, not a prior), and define $H(\theta, p) = V(\theta) + |p|^2/2$. The joint density e^{-H} is $f(\theta)$ times a standard Gaussian in p, so its θ-marginal is the target. One iteration of **Hamiltonian Monte Carlo** [154, 155] has three parts:

1. *Kick.* Draw a fresh momentum $p \sim \mathcal{N}(0, \mathbb{1})$. This is an exact draw from the conditional of p given θ (a Gibbs step), the heat bath's contribution.

2. *Flight.* Follow Hamilton's equations $\dot\theta = p$, $\dot p = -\nabla V$ for a time $t_f = n_{\text{leap}}\varepsilon$, using n_{leap} steps of size ε of the leapfrog integrator: $p \leftarrow p - \frac{\varepsilon}{2}\nabla V(\theta)$, $\theta \leftarrow \theta + \varepsilon p$, $p \leftarrow p - \frac{\varepsilon}{2}\nabla V(\theta)$. This is microcanonical motion on an energy shell, exactly what the oscillator of Section 9.1 did.
3. *Decide.* Accept the end point with probability $\min(1, e^{-\Delta H})$, where ΔH is the change of H along the numerical flight.

Exact Hamiltonian motion conserves H, so it would always be accepted; the decision only corrects the small errors of the integrator.

Why the decision is this simple. The proposal has no randomness in it once p is drawn. Write S for the whole flight, the map that takes the phase-space point $x = (\theta, p)$ to the end point after n_{leap} leapfrog steps, and $F(\theta, p) = (\theta, -p)$ for a flip of the momentum. The proposal is $y = G(x)$ with $G = F \circ S$: fly, then reverse the momentum. Two properties of G do all the work.

- *It undoes itself.* Starting from y, flying, and flipping returns to x: $G(G(x)) = x$. Each leapfrog step run with reversed momentum retraces the step it came from, so flying from the flipped end point retraces the whole path and arrives at x with reversed momentum, which the final flip restores. So the reverse proposal, from y back to x, is the same map G.
- *It keeps volumes.* Each sub-step changes p by an amount that depends only on θ, or θ by an amount that depends only on p. Such a shear has a Jacobian matrix with ones on the diagonal and zeros on one side of it, so its determinant is one; the flip has determinant ± 1. The determinant of G is a product of these, so $|\det \partial G/\partial x| = 1$.

For a deterministic proposal, detailed balance is a statement about small regions. Let A be a small region around x; the walker in A moves to $G(A)$, and the walker in $G(A)$ moves back to A. The two flows must be equal:

$$\int_A e^{-H(x)} a(x)\,\mathrm{d}x \overset{(1)}{=} \int_{G(A)} e^{-H(y)} a(y)\,\mathrm{d}y \overset{(2)}{=} \int_A e^{-H(G(x))} a(G(x)) \left|\det \frac{\partial G}{\partial x}\right| \mathrm{d}x \overset{(3)}{=} \int_A e^{-H(G(x))} a(G(x))\,\mathrm{d}x,$$

(1) Probability that leaves A for $G(A)$ equals probability that leaves $G(A)$ for A; a is the acceptance probability of the move from that point.
(2) Change variables $y = G(x)$.
(3) The flight keeps volumes.

This holds for every small A if $e^{-H(x)}a(x) = e^{-H(y)}a(y)$, which is the condition (9.63) with ratio $R = e^{-H(y)}/e^{-H(x)} = e^{-\Delta H}$, and the Metropolis choice $a = \min(1, e^{-\Delta H})$ satisfies it. No Hastings factor is left over, because the proposal is the same map in both directions and does not stretch volumes [155]. The final flip is harmless: H depends on p only through $|p|^2$, so flipping does not change e^{-H}, and the next kick draws a fresh momentum anyway.

On the correlated Gaussian with $\varepsilon = 0.15$ and $n_{\text{leap}} = 15$, the flights travel an average distance 1.646 per iteration, the energy error averages $|\Delta H| = 0.05734$, and 0.9737 of the proposals are accepted. The integrated autocorrelation time is 0.9427 iterations, below one: successive samples are slightly *anti*correlated, as for the two-state Metropolis chain of Section 9.9 (Figure 9.40b,c). The momentum carries the walker along the ridge in a straight sweep instead of a diffusion, which is what HMC buys in many dimensions. A flight of n_{leap} steps moves a distance of order $n_{\text{leap}}\varepsilon$, where a random walk of as many steps would move only $\sqrt{n_{\text{leap}}}$ times its step. For a target of D independent Gaussians, Neal [155] shows that the step size needed to keep the acceptance fixed shrinks only as $D^{-1/4}$, so an independent sample costs of order $D^{1/4}$ gradient

evaluations, against of order D target evaluations for random-walk Metropolis (Section 9.11.1). The price is the gradient $\nabla \ln f$ at every leapfrog step, and two tuning parameters, ε and n_{leap}. [HobsonBMC §3.2.5, p. 67] describes the method in the cosmological context; Stan's default sampler is an adaptive version of it.

The oscillator thus closes its loop. Its own motion sampled one energy shell; a heat bath moves it between shells with Boltzmann weights; HMC alternates the two: deterministic flights on a shell, and random momentum kicks between shells.

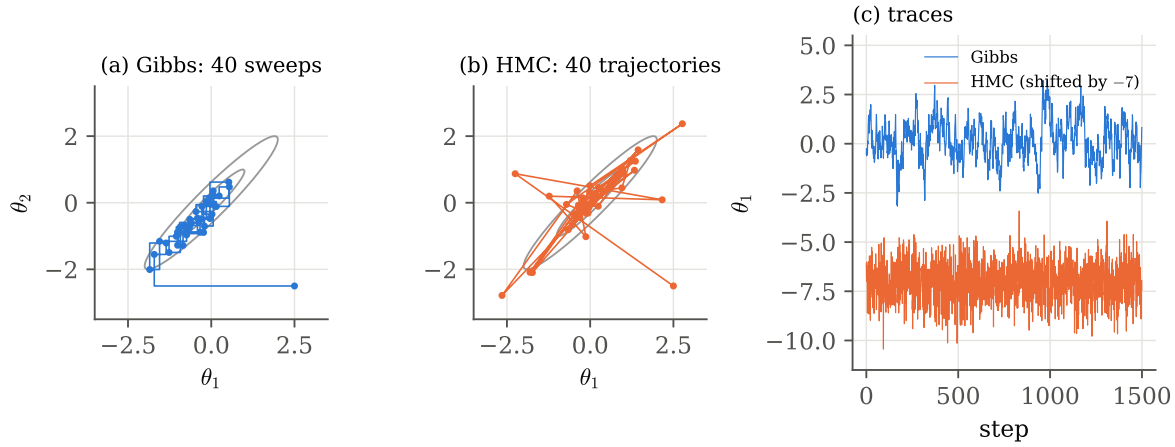

Figure 9.40: Gibbs and Hamiltonian Monte Carlo on the Gaussian with correlation 0.95, both started at $(2.5, -2.5)$. (a) Forty Gibbs sweeps: every move is parallel to an axis, so the ridge is climbed as a staircase. (b) Forty HMC iterations (end points of the flights): each jumps across a large part of the ellipse. (c) Traces of θ_1: Gibbs (top) wanders slowly; HMC (bottom, shifted down by 7) decorrelates in about one iteration.

9.16.3 Ensembles of walkers, and the evidence

A different way to avoid tuning a proposal covariance is to let many walkers propose moves for each other. In the affine-invariant ensemble sampler of Goodman and Weare [156], implemented in `emcee` [147], walker k at x_k picks another walker x_j at random and proposes the *stretch move*

$$y = x_j + \zeta\,(x_k - x_j), \qquad g(\zeta) \propto \frac{1}{\sqrt{\zeta}} \text{ on } [1/a, a], \qquad \text{accept with } \min\!\Big(1, \zeta^{D-1}\frac{f(y)}{f(x_k)}\Big), \tag{9.98}$$

with $a = 2$ by default. The candidate lies on the line through the two walkers, and the **stretch factor** ζ says how far along it: $\zeta > 1$ moves walker k away from walker j, $\zeta < 1$ towards it. (Goodman and Weare call it Z; we write ζ because Z is the evidence and the partition function elsewhere in this chapter.)

Where ζ^{D-1} comes from. Hold every other walker fixed, and measure positions from x_j. Write the present position of walker k in polar form, $x_k - x_j = r\,\omega$, with $r > 0$ its distance from x_j and ω a unit vector. The stretch keeps ω and replaces r by $r' = \zeta r$: it is a one-dimensional move in r. In polar coordinates the volume element is $r^{D-1}\mathrm{d}r\,\mathrm{d}\omega$ (the area of a sphere of radius r times its thickness, as in (9.75)), so the target, as a density in (r, ω), is $f\,r^{D-1}$. Two things are then needed. First, the proposal density of r' given r, and the reverse, which must stretch by $1/\zeta$ to come back:

$$\frac{q(r\,|\,r')}{q(r'\,|\,r)} \overset{(1)}{=} \frac{g(1/\zeta)/r'}{g(\zeta)/r} \overset{(2)}{=} \frac{g(1/\zeta)}{\zeta\,g(\zeta)} \overset{(3)}{=} \frac{\sqrt{\zeta}}{\zeta/\sqrt{\zeta}} = 1.$$

(1) $r' = \zeta r$ with $\zeta \sim g$ has density $g(r'/r)/r$ in r' (change of variable); the reverse move needs the factor $r/r' = 1/\zeta$.
(2) $r'/r = \zeta$.
(3) With $g(\zeta) \propto 1/\sqrt{\zeta}$: $g(1/\zeta) \propto \sqrt{\zeta}$ and $\zeta g(\zeta) \propto \sqrt{\zeta}$. The range $[1/a, a]$ is unchanged by $\zeta \to 1/\zeta$, so the constants agree too.

This is why g is chosen $\propto 1/\sqrt{\zeta}$: it is the choice that makes the stretch symmetric in r, so no proposal factor is left. Second, the target ratio, in the same coordinates:

$$\frac{f(y)\,(\zeta r)^{D-1}}{f(x_k)\,r^{D-1}} = \zeta^{D-1}\frac{f(y)}{f(x_k)},$$

which is the acceptance ratio of (9.98). The factor ζ^{D-1} is the volume of the larger sphere on which the stretched point sits.

Why linear correlations do not matter. Apply a linear change of variables $x \to Ax + b$ to every walker. Then $y - x_j = \zeta(x_k - x_j)$ becomes $A(y - x_j) = \zeta\, A(x_k - x_j)$: the same ζ produces the image of the same move. The transformed target differs from the original by the constant factor $1/|\det A|$, which cancels from the ratio. So every run in the new variables is the image of a run in the old ones, with the same acceptances: a correlated Gaussian is sampled exactly as efficiently as a round one, with no covariance to estimate. That is why `emcee` is so popular in astrophysics. A curved banana is not a linear transformation of anything round, and Section 9.11.3 showed `emcee` struggling on it, just like our walkers.

All these samplers share the property of Section 9.8.1: they never compute the normalisation Z of the target. That is their strength for parameter estimation and their blind spot for model comparison, where the evidence is exactly what a Bayes factor needs (Chapter 5). **Nested sampling** [39] attacks Z directly. It rewrites $Z = \int \mathcal{L}\, p\, \mathrm{d}\boldsymbol{\theta}$ as a one-dimensional integral $Z = \int_0^1 \mathcal{L}(X)\, \mathrm{d}X$ over the prior mass X enclosed by each likelihood contour, and estimates it with a set of "live" points that are repeatedly replaced by new points of higher likelihood, so that the enclosed prior mass shrinks at each replacement by a factor whose distribution is known [HobsonBMC §1.4.1, pp. 21–27]. Drawing the replacement point from the prior inside the current contour is itself usually done with a short Markov chain. Chapter 5 works through the method; the posterior samples come as a by-product.

Taxonomy: Which sampler when

random-walk Metropolis	any target you can evaluate; few parameters, or a good proposal covariance from a pilot run; no gradients needed
Metropolis–Hastings with asymmetric q	bounded parameters (log or logit steps with the Hastings factor); independence proposals from a good approximation
Gibbs	conditionals easy to sample (conjugate hierarchical models); weakly correlated blocks
Hamiltonian Monte Carlo	many parameters, smooth target, gradients available (automatic differentiation)
ensemble (`emcee`)	moderate dimension, linear degeneracies, no gradients, little tuning
tempering / nested sampling	several separated modes; the evidence Z is wanted

Every example since Section 9.8 was chosen so that the answer was known in advance: a beta posterior, a Gamma posterior, Gaussians, Onsager's solution. That made them verifications of the machinery. The machinery earns its keep where no answer is known.

How this is used in real research: MCMC in cosmological parameter estimation

Verification versus research. Every chain above checked the sampler against an exact answer. In research the posterior is unknown, and the sampler, with its diagnostics, is the instrument that produces the published constraints.
What is run. The workhorse for CMB and large-scale-structure likelihoods is still Metropolis–Hastings, as in CosmoMC [37] and its successor Cobaya: a Gaussian proposal with the covariance of a previous run, scaled by about $2.4/\sqrt{D}$; "fast" nuisance parameters (foreground amplitudes, calibrations) updated more often than "slow" cosmological ones, because changing them does not require a new Boltzmann calculation; several chains run in parallel, with $\hat{R} - 1$ of a few hundredths or less as the stopping rule. `emcee` is common in astrophysics for models with up to a few tens of parameters; HMC (through Stan, NumPyro or similar) is used when the model is differentiable; nested samplers are run when the evidence is needed. Lattice QCD runs on HMC, where it was invented [154].
Laptop versus cluster. Our chains are 10^4–10^5 steps of targets that cost microseconds. A Planck-like run evaluates a likelihood that needs a Boltzmann-code calculation of order a second per step, for 10^5 or more steps per chain and several chains: days on a cluster. The CMB analysis that follows keeps the laptop scale by replacing the Boltzmann code with a fast emulator; the statistics, the sampler and the diagnostics stay the same.

Whichever sampler produced the chain, the same three questions are put to its output. Has it forgotten where it started (burn-in and $\hat{R}$, Sections 9.12.1 and 9.13)? How many independent draws does it hold (τ and the effective sample size, Section 9.12.2)? And is the density it samples the one we meant, prior included (Section 9.14)? The samplers differ only in how they propose; none of them changes the answers to these questions.

Recap

- The unbiased random walker samples nothing; Metropolis–Hastings adds the bias. Propose $y \sim q(y \mid x)$, accept with $\min(1, R_H)$, $R_H = f(y)q(x \mid y)/[f(x)q(y \mid x)]$; a refusal repeats the current point. Without the accept–reject step it is a random walk.
- Only ratios of f enter, so the evidence of a posterior and the partition function of a Boltzmann weight cancel. Work with $\ln f$.
- Detailed balance fixes only the ratio of forward and backward acceptances; $\min(1, R_H)$ is the largest admissible choice (Peskun). Accepting with $\min(1, R^\beta)$ samples f^β. Asymmetric proposals need the Hastings factor, which is the Jacobian of the proposal (for $y = xe^{sZ}$ it is y/x); redrawing illegal proposals without it biases the chain.
- Step size: in D dimensions the best round step is $2.38/\sqrt{D}$ target widths, with acceptance ≈ 0.23 (about 0.45 in one dimension), and an independent draw every few D steps. Correlated targets need a proposal shaped by the target's covariance; curved ones need a change of variables. A good acceptance rate does not imply a good chain.
- Burn-in ends when $\ln f$ fluctuates about its equilibrium level, $\simeq \ln f_{\max} - D/2$ for a Gaussian, not at the peak. $\tau = 1 + 2\sum \rho_k$ is estimated with a window (the full sum is identically zero); ESS $= N/\tau$, MCSE $= \mathrm{SD}\sqrt{\tau/N}$; thinning never improves an average.
- Several chains from overdispersed starts: $\hat{R} = \sqrt{\hat{V}/W} \to 1$; in equilibrium $\hat{R} - 1 \simeq (1 + 1/M)\tau/2N$. $\hat{R}$ catches chains that disagree, never a mode that no chain found.

- The chain forgets its start (ergodicity); it never forgets the prior, which is part of the target. The prior's pull fades only with more data, as $1/\sqrt{N}$ posterior widths.
- Metropolis was invented for the canonical ensemble $e^{-H/kT}/Z$: it reproduces equipartition and the exponential energy law of the oscillator (a Boltzmann mixture of arcsine shells), Kramers' barrier-crossing rate in a double well, and Onsager's Ising solution on a lattice with 10^{308} states. MCMC time is not physical time.
- Relatives with the same decision rule: Gibbs (always accepted, slow on correlations), HMC (Hamiltonian flights plus momentum kicks, accepted with $e^{-\Delta H}$), affine-invariant ensembles (`emcee`); nested sampling computes the evidence that MCMC avoids.

9.17 A straight line: the chain against the exact answer

The biased random walker of Section 9.8 has so far sampled densities that we wrote down for the purpose: a Gaussian, a banana, a Boltzmann weight. Now it meets data. The first data set is the simplest one a physicist ever fits, points scattered about a straight line, and it is chosen for one reason: here the posterior is known exactly, so every number the chain produces can be checked. Once the chain has passed that test on a line, we can trust the same code on a posterior nobody can write down, the one of cosmological parameters from a CMB spectrum.

The data. We repeat the first example of Padilla et al. [Padilla §5.1][40]. A theory says that a measured quantity y depends on a control variable x through a straight line, $y = a + bx$. Two experiments measure it at 16 values of x each. Experiment D_1 has Gaussian errors of standard deviation $\sigma_1 = 0.3$, experiment D_2 has $\sigma_2 = 0.2$. The data are simulated from the line with $a = 3$, $b = 2$, at x values drawn as $3 \times \mathcal{N}(0, 1)$, which is how the analysis notebook of the repository the paper cites generates them. Our realisation is in Figure 9.41a.

The question in words. The event is the whole set of $N = 32$ measured y_i. The candidate explanations are the straight lines, one for every pair (a, b). For each candidate we ask: if this line were the truth, how probable is it that the experiments would have returned exactly these y_i? That probability, read as a function of (a, b), is the likelihood; multiplied by the prior and normalised it is the posterior, and the posterior is what the chain will sample. This is the reasoning of Chapter 5 applied to a two-dimensional space of hypotheses.

9.17.1 The likelihood from its inputs

The inputs are of two kinds. The *physical* ones: (i) each measurement is the true value of the line plus an error, $y_i = a + bx_i + \epsilon_i$; (ii) the errors of different points are independent (no common calibration error); (iii) each error is Gaussian with mean zero and a known standard deviation σ_i (0.3 or 0.2); (iv) the x_i are known exactly. The *mathematical* one is only that the prior density on (a, b) exists. Everything else follows. Given (a, b), the only random thing in y_i is ϵ_i, so y_i is Gaussian with mean $a + bx_i$ and variance σ_i^2. Then

$$p(\boldsymbol{d} \mid a, b) \overset{(1)}{=} \prod_{i=1}^{N} p(y_i \mid a, b) \overset{(2)}{=} \prod_{i=1}^{N} \frac{1}{\sqrt{2\pi}\,\sigma_i} \exp\Big[-\frac{(y_i - a - bx_i)^2}{2\sigma_i^2}\Big]$$

$$\overset{(3)}{=} \left(\prod_i \frac{1}{\sqrt{2\pi}\,\sigma_i} \right) e^{-\chi^2(a,b)/2}, \qquad \chi^2(a,b) = \sum_{i=1}^{N} \frac{(y_i - a - b x_i)^2}{\sigma_i^2}. \tag{9.99}$$

(1) Input (ii): independent errors make the joint density a product.
(2) Inputs (i), (iii), (iv): y_i is the fixed number $a + bx_i$ plus a $\mathcal{N}(0, \sigma_i^2)$ error.
(3) The product of exponentials is the exponential of the sum; the prefactor does not depend on (a, b).

This is Padilla's eq. (70). In the words of Chapter 3, $e^{-\chi^2/2}$ measures how plausible is the particular noise realisation $\epsilon_i = y_i - a - bx_i$ that the candidate line needs in order to turn its prediction into the data we saw. A line that misses the points by many error bars needs an improbable noise realisation and gets a small likelihood.

The prior follows Padilla's eq. (69): flat in the box $0 < a < 5$, $0 < b < 3$, zero outside, chosen because a glance at the data excludes anything outside it. Inside the box the posterior is therefore

$$\ln p(a, b \mid \boldsymbol{d}) = -\tfrac{1}{2}\chi^2(a, b) + \text{const}, \tag{9.100}$$

and outside it $\ln p = -\infty$. This one line is all the sampler needs.

9.17.2 The exact posterior: complete the square

Because the model is linear in the parameters, χ^2 is a quadratic function of (a, b), and the exponential of minus a quadratic is a Gaussian. To find which Gaussian, write the model in matrix form. Collect the parameters in $\boldsymbol{\theta} = (a, b)^{\mathsf{T}}$, the data in $\boldsymbol{y}$, and build the $N \times 2$ **design matrix** $\mathbf{A}$ [row i is $(1, x_i)$, so $\mathbf{A}\boldsymbol{\theta}$ is the vector of the line's predictions] and the weight matrix $\mathbf{W} = \mathrm{diag}(1/\sigma_i^2)$. Then $\chi^2 = (\boldsymbol{y} - \mathbf{A}\boldsymbol{\theta})^{\mathsf{T}}\mathbf{W}(\boldsymbol{y} - \mathbf{A}\boldsymbol{\theta})$, and with $\mathbf{F} \equiv \mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A}$ and $\hat{\boldsymbol{\theta}} \equiv \mathbf{F}^{-1}\mathbf{A}^{\mathsf{T}}\mathbf{W}\boldsymbol{y}$,

$$\begin{aligned}
\chi^2(\boldsymbol{\theta}) &\overset{(1)}{=} \boldsymbol{y}^{\mathsf{T}}\mathbf{W}\boldsymbol{y} - 2\boldsymbol{\theta}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{W}\boldsymbol{y} + \boldsymbol{\theta}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A}\boldsymbol{\theta} \\
&\overset{(2)}{=} \boldsymbol{y}^{\mathsf{T}}\mathbf{W}\boldsymbol{y} - 2\boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\hat{\boldsymbol{\theta}} + \boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\boldsymbol{\theta} \\
&\overset{(3)}{=} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}}\mathbf{F}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \left[\boldsymbol{y}^{\mathsf{T}}\mathbf{W}\boldsymbol{y} - \hat{\boldsymbol{\theta}}^{\mathsf{T}}\mathbf{F}\hat{\boldsymbol{\theta}}\right] \overset{(4)}{=} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}}\mathbf{F}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \chi^2_{\min}.
\end{aligned} \tag{9.101}$$

(1) Multiply out; $\boldsymbol{y}^{\mathsf{T}}\mathbf{W}\mathbf{A}\boldsymbol{\theta}$ is a number and equals its transpose $\boldsymbol{\theta}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{W}\boldsymbol{y}$, so the two cross terms combine.
(2) By the definitions, $\mathbf{A}^{\mathsf{T}}\mathbf{W}\boldsymbol{y} = \mathbf{F}\hat{\boldsymbol{\theta}}$ and $\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A} = \mathbf{F}$.
(3) Add and subtract $\hat{\boldsymbol{\theta}}^{\mathsf{T}}\mathbf{F}\hat{\boldsymbol{\theta}}$; $\mathbf{F}$ is symmetric, so $(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}}\mathbf{F}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) = \boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\boldsymbol{\theta} - 2\boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\hat{\boldsymbol{\theta}} + \hat{\boldsymbol{\theta}}^{\mathsf{T}}\mathbf{F}\hat{\boldsymbol{\theta}}$.
(4) The bracket does not depend on $\boldsymbol{\theta}$; setting $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$ shows it is the minimum of χ^2.

So $p(\boldsymbol{\theta} \mid \boldsymbol{d}) \propto e^{-(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}}\mathbf{F}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})/2}$: a Gaussian with mean $\hat{\boldsymbol{\theta}}$, the weighted least-squares line, and covariance $\mathbf{F}^{-1}$. (The flat prior box cuts it off, but the box edges lie dozens of standard deviations away, so the truncation is invisible.) The matrix $\mathbf{F}$ is the Fisher matrix of Chapter 10; for a linear model with Gaussian errors the Fisher forecast is not an approximation but the exact posterior covariance.

Example: the 2×2 matrix written out. Name the weighted sums $S = \sum_i \sigma_i^{-2}$, $S_x = \sum_i x_i \sigma_i^{-2}$, $S_{xx} = \sum_i x_i^2 \sigma_i^{-2}$, and $\Delta = S S_{xx} - S_x^2$. Then

$$\begin{aligned}
\mathbf{F} &= \begin{pmatrix} S & S_x \\ S_x & S_{xx} \end{pmatrix}, & \mathbf{F}^{-1} &\overset{(1)}{=} \frac{1}{\Delta}\begin{pmatrix} S_{xx} & -S_x \\ -S_x & S \end{pmatrix}, \\
\sigma_a^2 &= \frac{S_{xx}}{\Delta} \overset{(2)}{=} \frac{1}{S}\,\frac{1}{1 - \bar{x}_w^2/\overline{x^2}_w}, & \rho_{ab} &\overset{(3)}{=} \frac{-S_x}{\sqrt{S S_{xx}}} = -\frac{\bar{x}_w}{\sqrt{\overline{x^2}_w}},
\end{aligned} \tag{9.102}$$

where $\bar{x}_w = S_x/S$ and $\overline{x^2}_w = S_{xx}/S$ are the error-weighted means of x and x^2.

(1) The inverse of $\left(\begin{smallmatrix} p & q \\ q & r \end{smallmatrix}\right)$ is $\left(\begin{smallmatrix} r & -q \\ -q & p \end{smallmatrix}\right)/(pr - q^2)$.
(2) Divide numerator and denominator by SS_{xx}: $\Delta/S_{xx} = S(1 - S_x^2/SS_{xx})$.
(3) $\rho = \mathrm{Cov}(a,b)/(\sigma_a\sigma_b) = (-S_x/\Delta)/\sqrt{S_{xx}S/\Delta^2}$.

Two facts drop out. The intercept can never be known better than $1/\sqrt{S}$, the error of a weighted mean of the y_i, and it reaches that floor when the weighted mean of x is zero. Here $S = 16/0.3^2 + 16/0.2^2$, so $1/\sqrt{S} = 0.0416$, and because our x values are scattered about zero the exact width is $\sigma_a = 0.0417$, essentially the floor. And the correlation of slope and intercept is set by where the data sit relative to $x = 0$ (Section 9.17.6). For our data

$$a = 2.999 \pm 0.0417, \qquad b = 1.9810 \pm 0.0134, \qquad \rho_{ab} = -0.06,$$

and the best line has $\chi^2_{\min} = 33.0$ for $32 - 2$ degrees of freedom, a perfectly ordinary value.

9.17.3 The chain

The sampler is the random-walk Metropolis algorithm of Section 9.8, in the compact form imported by every script of the analyses that follow:

Listing 9.8: A compact random-walk Metropolis sampler (`code/ch09/lib_mcmc9c.py`)

```
def mh(logpost, x0, cov, n, rng, scale=None):
    """Random-walk Metropolis: propose y = x + L z (z ~ N(0,1), L L^T = scale^2 cov),
    accept with probability min(1, p(y)/p(x)).  The proposal is symmetric, so q cancels.

    Returns (chain, logp, acceptance fraction).  scale defaults to 2.38/sqrt(d).
    """
    x = np.array(x0, dtype=float)
    d = x.size
    s = 2.38 / np.sqrt(d) if scale is None else scale
    L = np.linalg.cholesky(np.atleast_2d(cov)) * s
    chain = np.empty((n, d))
    lp = np.empty(n)
    lx = logpost(x)
    z = rng.standard_normal((n, d)) @ L.T          # all proposal steps drawn at once
    logu = np.log(rng.random(n))                   # all accept-reject coins drawn at once
    acc = 0
    for t in range(n):
        y = x + z[t]
        ly = logpost(y)
        if logu[t] < ly - lx:                      # the biasing step: uphill always,
    downhill sometimes
            x, lx = y, ly
            acc += 1
        chain[t] = x
        lp[t] = lx
    return chain, lp, acc / n
```

It proposes $y = x + Lz$ with z a vector of independent standard Gaussians and LL^T equal to the proposal covariance times $(2.38/\sqrt{d})^2$, the optimal scaling of Section 9.11.1. Since the proposal is symmetric the Hastings factor is one, and the move is accepted when $\ln u < \ln p(y) - \ln p(x)$ for a uniform u: uphill always, downhill with probability $p(y)/p(x)$. A refusal writes the current point again. All the proposals and all the uniforms are drawn before the loop, which changes nothing in the statistics and makes the loop faster. The target is (9.100):

Listing 9.9: The log posterior of the straight line (`code/ch09/40_line_fit.py`)

```python
def logpost_K(th):
    """Known errors: ln p(a, b | d) = -chi^2/2 + const inside the flat prior box."""
    a, b = th
    if not inside(a, b):
        return -np.inf
    r = (y - a - b * x) / sig
    return -0.5 * r @ r
```

Listing 9.10: Five chains, as in Padilla et al. (`code/ch09/40_line_fit.py`)

```python
NCH, NST, BURN = 5, 10000, 1000
starts = np.c_[rng.uniform(*PRIOR["a"], NCH), rng.uniform(*PRIOR["b"], NCH)]
prop = np.diag([0.05 ** 2, 0.015 ** 2])            # a rough guess of the widths, not the answer
ch, lp, acc = mc.run_chains(logpost_K, starts, prop, NST, rng)
post = ch[:, BURN:, :].reshape(-1, 2)
m_mc, s_mc, R_mc = mc.summary(post)
R = mc.rhat(ch[:, BURN:, :])
taus = [mc.tau_int(ch[0, BURN:, k]) for k in range(2)]
ess_tot = [sum(mc.ess(ch[c, BURN:, k]) for c in range(NCH)) for k in range(2)]
```

As in the paper we run five chains of 10000 steps, started at random points of the prior box. The proposal covariance is a rough guess, $\mathrm{diag}(0.05^2, 0.015^2)$, not the answer; in a real problem it would come from a short exploratory run (Section 9.11.2). We drop the first 1000 steps of each chain as burn-in, leaving 45000 samples.

The diagnostics of Section 9.12 come first, before any number is quoted. The acceptance rate is 0.31; the Gelman–Rubin statistic is $\hat{R} = 1.0013$ for a and 1.0012 for b; the integrated autocorrelation times are $\tau = 6.7$ and 8.1 steps, so the five chains hold about 6326 and 5658 effective samples. The Monte Carlo error of the posterior mean of b is then $\sigma_b\sqrt{\tau/N} = 0.00018$, a hundred times smaller than the posterior width. The chain can be trusted, and it reports

$$a = 2.999 \pm 0.0416, \qquad b = 1.9811 \pm 0.0136, \qquad \rho_{ab} = -0.05,$$

against the exact 2.999 ± 0.0417, 1.9810 ± 0.0134, -0.06. The library sampler `emcee` [147], run on the same log posterior, gives $a = 2.998 \pm 0.0422$ and $b = 1.9804 \pm 0.0129$. In Figure 9.41b the chain's 68 and 95 per cent contours lie on top of the exact ellipses.

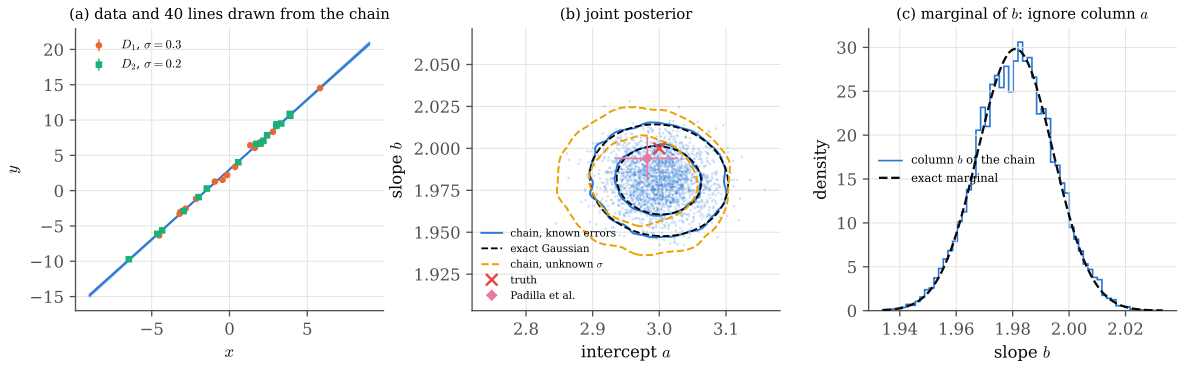

Figure 9.41: The straight line. (a) The two data sets and 40 lines whose (a, b) were picked at random from the chain; they all pass through the bulk of the points. (b) The joint posterior: chain samples (dots) with their 68 and 95 per cent contours (solid), the exact Gaussian (black dashed), the posterior when the noise level is an unknown parameter (orange dashed), the truth (cross) and the result of Padilla et al. (diamond with error bars). (c) The histogram of the b column of the chain against the exact marginal density of b.

9.17.4 Marginalising by ignoring a column

The chain is a table with one row per step and one column per parameter. Suppose we care only about the slope. Its marginal posterior is $p(b \mid \boldsymbol{d}) = \int p(a, b \mid \boldsymbol{d})\, \mathrm{d}a$: the joint density with the nuisance parameter a averaged out, exactly the operation that Chapter 1 introduced to isolate one variable of a joint distribution. With a chain we never do that integral. We take the b column, throw the a column away, and histogram what is left (Figure 9.41c, Figure 9.42).

Key idea: A column of the chain is a sample of the marginal

If the rows (a_t, b_t) are draws from $p(a, b \mid \boldsymbol{d})$, the numbers b_t alone are draws from $p(b \mid \boldsymbol{d})$. Marginalising over any nuisance parameter costs nothing: drop its column.

Why is this true? Take any interval B of slopes and ask how often a row of the chain has its slope in B, whatever its intercept:

$$\mathrm{P}(b_t \in B) \overset{(1)}{=} \int\!\!\int \mathbb{1}_B(b)\, p(a, b \mid \boldsymbol{d})\, \mathrm{d}a\, \mathrm{d}b \overset{(2)}{=} \int_B \Big[\int p(a, b \mid \boldsymbol{d})\, \mathrm{d}a \Big] \mathrm{d}b \overset{(3)}{=} \int_B p(b \mid \boldsymbol{d})\, \mathrm{d}b. \qquad (9.103)$$

(1) The row (a_t, b_t) is distributed as the joint posterior, and the event "$b_t \in B$" puts no condition on a_t: its indicator $\mathbb{1}_B(b)$ is one for every a when $b \in B$.
(2) The indicator restricts the b integral to B; the a integral is done first.
(3) The inner integral is the marginal density, by definition.

A histogram counts rows with b_t in each bin, so by (9.103) and the ergodic theorem (Section 9.6) it converges to the marginal. The column does the integral for us because the rows with large $|a - \hat{a}|$ already appear less often, in proportion to their posterior weight. The same holds in any dimension: from a chain in 6 or 30 parameters, every one- and two-dimensional marginal is a histogram of one or two columns. This is how the marginals of Figure 9.41, and all the triangle plots that follow, are made [HobsonBMC p. 71].

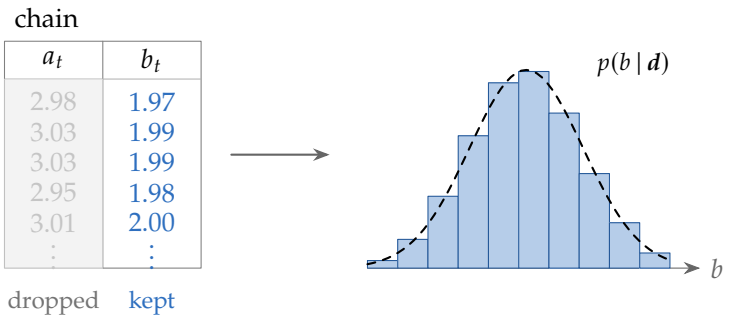

Figure 9.42: Marginalising with a chain. Each row of the chain is a draw from the joint posterior. Dropping the column of the nuisance parameter a and histogramming the column b gives the marginal density of b (dashed), with a integrated out.

Example: marginal is not conditional. It is tempting to report the width of b "at the best a", that is, the width of the slice $p(b \mid a = \hat{a}, \boldsymbol{d})$. Is that the same number? (9.101) answers it. Hold a fixed in the quadratic form $(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}} \mathbf{F} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})$; what is left is a quadratic in b whose b^2 coefficient is $F_{bb} = S_{xx}$, and completing the square in b once more turns it into $S_{xx}(b - b_0)^2$ plus terms free of b. So the slice is a Gaussian of variance $1/S_{xx}$, whatever the value at which a was fixed. The marginal variance is the bb element of $\mathbf{F}^{-1}$ in (9.102), $\sigma_b^2 = S/\Delta$. To compare the two,

multiply the marginal by $1-\rho^2$:

$$\sigma_b^2(1-\rho^2) \overset{(1)}{=} \frac{S}{\Delta}\left(1-\frac{S_x^2}{SS_{xx}}\right) \overset{(2)}{=} \frac{S}{\Delta}\,\frac{SS_{xx}-S_x^2}{SS_{xx}} \overset{(3)}{=} \frac{1}{S_{xx}}. \tag{9.104}$$

(1) $\sigma_b^2 = S/\Delta$ and $\rho^2 = S_x^2/(SS_{xx})$, both from (9.102).
(2) Common denominator.
(3) The numerator is Δ by its definition, and it cancels.

So the slice has standard deviation $\sigma_b\sqrt{1-\rho^2}$, while the marginal has σ_b: fixing a forgets the uncertainty in a, which, through the correlation, would have spread b. With our data $\rho = -0.06$ and the two agree to a fraction of a per cent. With the same data plotted against $x+10$ (next subsection) the correlation becomes $\rho = -0.955$, so $1-\rho^2 \approx 0.088$ and the slice is $\sqrt{1-\rho^2} \approx 0.30$ times the marginal width: reporting it would claim the slope three times better than the data know it. The column histogram cannot make this mistake, because it never fixes a.

Example: the lines the posterior believes. Each row of the chain is a whole line, so a random selection of rows draws the family of lines compatible with the data (Figure 9.41a; Kruschke calls these the credible regression lines [Kruschke §17.2.4]). At a new x the predicted mean $a+bx$ has variance

$$\mathrm{Var}(a+bx) = \sigma_a^2 + 2x\ \mathrm{Cov}(a,b) + x^2\sigma_b^2,$$

smallest near the weighted centre of the data and growing quadratically away from it. With our numbers the band is ± 0.0417 wide at $x=0$ and about $\sqrt{0.042^2 + 10^2 \times 0.013^2} \approx 0.14$ at $x=10$, outside the measured range: the lines fan out where there are no data to pin them. The chain gives this without any error propagation: compute $a_t + b_t x$ row by row and take the spread.

9.17.5 Reproducing Padilla et al.: why their error bars are wider

Their question. Padilla et al. use this straight line as the first test of a sampler written for cosmology [Padilla §5.1]. They wanted to know whether a short Metropolis run recovers the two parameters of a line measured by two experiments, and what the error bars it reports mean. The first half of the question has the answer "yes" in their paper and in ours. The second half is the interesting one, because their error bars turn out to answer a different question from ours.

Their setup, one item at a time. *The data:* two sets of 16 points from the line $y = 3+2x$, at x values drawn as $3 \times \mathcal{N}(0,1)$, one set with Gaussian errors of 0.3 and one with 0.2. This is our experiment exactly, but a different random realisation of it. *The prior:* flat in the box $0 < a < 5$, $0 < b < 3$, as ours. *The noise:* here the two analyses part. The paper's text gives the two error bars, but the analysis notebook in the repository the paper cites does not use them. It describes the noise of all 32 points by one common standard deviation σ, which it treats as unknown, with a flat prior on $0 < \sigma < 1.5$. So σ is a third parameter: the chain samples (a, b, σ), and the numbers reported for a and b come from the first two columns.

Their key equation: the line with the noise level integrated out. In our notation the change is one substitution. Set every σ_i of (9.99) equal to the one unknown σ. The exponent becomes $-\mathrm{RSS}(a,b)/2\sigma^2$, with the **residual sum of squares** $\mathrm{RSS} = \sum_i (y_i - a - bx_i)^2$ [the χ^2 of the line with all errors set to one], and the prefactor $\prod_i (\sqrt{2\pi}\,\sigma_i)^{-1}$ becomes $(2\pi)^{-N/2}\sigma^{-N}$. That prefactor could be dropped when the σ_i were known; now it depends on a parameter and must stay. With the flat priors, $\ln p(a,b,\sigma \mid \boldsymbol{d}) = -N\ln\sigma - \mathrm{RSS}(a,b)/2\sigma^2 + \text{const}$. The noise level is a nuisance

parameter, and integrating it out (the upper prior limit is far out in the tail and can be sent to infinity) gives

$$
\begin{aligned}
p(a,b\mid \boldsymbol{d}) &\overset{(1)}{=} \int_0^\infty \sigma^{-N} e^{-\mathrm{RSS}/2\sigma^2}\,\mathrm{d}\sigma \overset{(2)}{=} \frac{1}{2}\Big(\frac{2}{\mathrm{RSS}}\Big)^{(N-1)/2} \int_0^\infty u^{(N-3)/2} e^{-u}\,\mathrm{d}u \\
&\overset{(3)}{=} \frac{1}{2}\,\Gamma\Big(\frac{N-1}{2}\Big)\Big(\frac{2}{\mathrm{RSS}}\Big)^{(N-1)/2} \;\propto\; \mathrm{RSS}(a,b)^{-(N-1)/2} \\
&\overset{(4)}{=} \Big[1+\frac{(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}_0)^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}_0)}{\mathrm{RSS}_{\min}}\Big]^{-(\nu+2)/2}, \qquad \nu = N-3.
\end{aligned}
\tag{9.105}
$$

(1) Flat prior in σ; dropped constants. Marginalising σ is integrating it out.

(2) Substitute $u = \mathrm{RSS}/2\sigma^2$: $\sigma = (\mathrm{RSS}/2u)^{1/2}$, $\mathrm{d}\sigma = -\frac{1}{2}(\mathrm{RSS}/2)^{1/2}u^{-3/2}\mathrm{d}u$, and $\sigma^{-N} = (2u/\mathrm{RSS})^{N/2}$; the powers of u combine to $u^{(N-3)/2}$, and the minus sign is absorbed by swapping the limits.

(3) $\int_0^\infty u^{s-1}e^{-u}\mathrm{d}u = \Gamma(s)$ with $s = (N-1)/2$.

(4) (9.101) with $\mathbf{W} = \mathbb{1}$: $\mathrm{RSS} = \mathrm{RSS}_{\min} + (\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}_0)^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}_0)$, $\hat{\boldsymbol{\theta}}_0$ the ordinary least-squares line; divide by $\mathrm{RSS}_{\min}$ and write $(N-1)/2 = (\nu+2)/2$.

The last line is a two-dimensional Student t density with $\nu = 29$ degrees of freedom (Chapter 2), centred on the ordinary least-squares line, with covariance $\mathrm{RSS}_{\min}(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}/(\nu-2)$. Set it beside the known-error posterior of Section 9.17.2. There the covariance was $(\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A})^{-1}$, which for one known noise level σ ($\mathbf{W} = \mathbb{1}/\sigma^2$) is $\sigma^2(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}$. The symbol map is therefore short: their σ^2 is not given but estimated, and in the covariance it is replaced by $\mathrm{RSS}_{\min}/(\nu-2)$, the scatter the data actually show about the best line; the Gaussian becomes a Student t, with heavier tails, because that estimate is itself uncertain. The widths now depend on the data through $\mathrm{RSS}_{\min}$. The common σ must absorb the larger scatter of D_1, and the data put it at $\sqrt{\mathrm{RSS}_{\min}/(N-2)} = 0.276$, above the 0.2 of the better experiment.

What we compute. Two posteriors for our realisation: the known-error one of Section 9.17.3, and the unknown-σ one, sampled by a chain in (a,b,σ) whose σ column is then ignored (Section 9.17.4) and checked against the exact Student t of (9.105). The chain gives $a = 2.976 \pm 0.0516$, $b = 1.9805 \pm 0.0171$ (acceptance 0.37, largest $\hat{R} = 1.0013$), against the exact 2.977 ± 0.0514 and 1.9805 ± 0.0172; the data say $\sigma = 0.287 \pm 0.038$. Because their realisation differs from ours, one data set cannot settle which model they used, so we also simulate 20000 replications of the whole design, new x_i and new y_i each time, and record the widths each model would report.

Side by side. Padilla et al. report $a = 2.982 \pm 0.047$ and $b = 1.994 \pm 0.013$ [Padilla §5.1].

	a	b	noise model
Padilla et al. [Padilla §5.1]	2.982 ± 0.047	1.994 ± 0.013	as published
ours, chain, known σ_i	2.999 ± 0.0416	1.9811 ± 0.0136	0.3 and 0.2 known
ours, exact, known σ_i	2.999 ± 0.0417	1.9810 ± 0.0134	(9.101)
ours, chain, one unknown σ	2.976 ± 0.0516	1.9805 ± 0.0171	σ column ignored
ours, exact, one unknown σ	2.977 ± 0.0514	1.9805 ± 0.0172	Student t (9.105)
typical width, unknown σ	0.0412–0.0545	0.0133–0.0193	20000 replications

Why they differ. *The centres.* Their data are a different random realisation of the same experiment, so their centres must differ from ours by amounts of order one standard deviation, and they do.

The widths cannot come from the known errors. With known errors the posterior covariance $\mathbf{F}^{-1}$ depends on the x_i and σ_i only, not on the y_i (9.102), and σ_a can exceed its floor $1/\sqrt{S}$ only through the factor $(1-\bar{x}_w^2/\overline{x^2}_w)^{-1/2}$. How large would that factor have to be? Write $r^2 = \bar{x}_w^2/\overline{x^2}_w$ for the squared ratio of the weighted mean of the x_i to their weighted root-mean-square. Then

$$\frac{0.047}{0.0416} \approx 1.13 \overset{(1)}{=} \frac{1}{1-r^2} = 1.13^2 \approx 1.28 \overset{(2)}{=} r^2 \approx 0.22, \qquad r \approx 0.47. \tag{9.106}$$

(1) The floor is $1/\sqrt{S}$ with $S = 16/0.3^2 + 16/0.2^2 = 578$, so $1/\sqrt{S} = 0.0416$; by (9.102) the ratio $\sigma_a\sqrt{S}$ is $(1-r^2)^{-1/2}$. Square it.
(2) Solve: $r^2 = 1 - 1/1.28$.

So the weighted mean of the x_i would have to be about half their root-mean-square. For 32 points drawn from $3 \times \mathcal{N}(0,1)$ the root-mean-square is about 3, while the mean scatters about zero with standard deviation about $3/\sqrt{32} \approx 0.53$; a typical r is therefore $0.53/3 \approx 0.18$, and 0.47 is more than two and a half times that. The replications confirm it: the known-error width σ_a has median 0.0420 with 68 per cent between 0.0416 and 0.0432, and 99 per cent of replications give less than Padilla's 0.047. Their posterior is not the posterior of (9.100).

The widths do come from one unknown σ. Over the same 20000 replications the unknown-σ model gives σ_a between 0.0412 and 0.0545 (68 per cent) and σ_b between 0.0133 and 0.0193; Padilla's widths sit at the 46th and 13th percentiles, perfectly ordinary.[4]

The lesson. It is not about this paper. Two analyses of the same kind of data can both be correct and quote different error bars because they put different hypotheses in the likelihood: "the errors are 0.3 and 0.2" is a stronger statement than "there is some common noise level", and the stronger statement buys tighter constraints. When reproducing a published number, find the model first.

9.17.6 Centring the predictor: the same posterior, a different chain

Kruschke points out that a regression chain can become very slow for a reason that has nothing to do with the physics: the arbitrary position of $x = 0$ [Kruschke §17.2.1.1]. Move the origin of x far from the data, and every line that goes through the data has to trade its slope against its intercept, because tilting a line about the data cloud moves its value at the distant $x = 0$ by a lot. Equation (9.102) puts a number on it. With x shifted by s, the weighted means become $\bar{x}_w = s$ and $\overline{x^2}_w = s^2 + v$, where $v = 2.99^2$ is the variance of our x values, so

$$\rho_{ab} = -\frac{s}{\sqrt{s^2+v}} = -\frac{10}{\sqrt{100+2.99^2}} \approx -0.96 \quad \text{for } s = 10,$$

and the intercept width grows from 0.0416 to 0.141. The simulation, with the same data plotted against $x - \bar{x} + 10$, gives $\rho = -0.955$.

The posterior is the same physical statement in both coordinates: the intercept at the new origin is the old one minus s times the slope, a linear change of variables [Kruschke eq. 17.2]. The chain is not the same. Run both with the same round proposal, of radius equal to the centred intercept width: the centred chain accepts 0.30 of its moves and has $\tau = 5.7$ steps; the shifted one accepts 0.12 and has $\tau = 342$ steps, a factor of about 60 in run time for the same precision (Figure 9.43). This is the narrow-diagonal problem of Section 9.11.2: a round proposal on a

[4] The paper also says the chains were run "with temperature $T = 2$". Read literally, a tempered chain samples $\mathcal{L}^{1/2}$ and would widen the known-error posterior by $\sqrt{2}$, to about 0.059 and 0.019; neither those numbers nor the known-error ones match the published widths, while the unknown-σ model does.

thin tilted ellipse must take steps of the ellipse's short width and then diffuses slowly along its length. There are two cures, and both are standard. Reparametrise so that the posterior is round (centre or standardise x, as Kruschke does, then transform back with eq. 17.2), or keep the parameters and give the proposal the shape of the posterior covariance, which is what CosmoMC does with the covariance of a previous run [37].

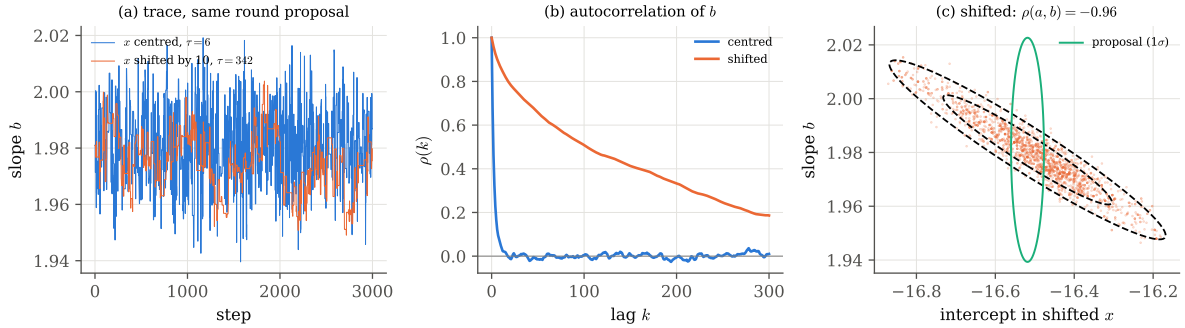

Figure 9.43: The same straight-line posterior sampled with the same round proposal in two coordinate systems. (a) Traces of the slope: with x centred the chain jumps freely; with the origin of x moved ten units from the data it creeps. (b) Their autocorrelation functions. (c) In shifted coordinates the posterior (ellipse, 68 and 95 per cent) is a thin diagonal ridge, and the proposal (green circle, one standard deviation) can only take steps of its short width.

9.18 A decaying source: curved posteriors and nuisance parameters

The straight line had a Gaussian posterior because the model was linear in its parameters. Most physical models are not. A radioactive source, a cooling body, a charging capacitor, the light curve of a supernova: each is an exponential in time, and the decay time enters inside the exponential. For such models the posterior has no closed form, a Gaussian fitted at the peak is only an approximation, and the chain becomes the instrument rather than a check. The same models also bring the most common nuisance parameter of all, an unknown noise level.

The data. A source is read once an hour for fifteen hours. The count rate falls as $y(t) = Ae^{-t/\tau}$, and each reading has a Gaussian error of standard deviation σ. We simulate $N = 15$ readings at $t = 0, 1, \ldots, 14\,\mathrm{h}$ with $A = 100\,\mathrm{s}^{-1}$, $\tau = 4\,\mathrm{h}$ and $\sigma = 6\,\mathrm{s}^{-1}$ (Figure 9.44a). The prior is flat in $0 < A < 300\,\mathrm{s}^{-1}$ and $0.1 < \tau < 30\,\mathrm{h}$. With σ known, the derivation of (9.99) goes through unchanged with $a + bx_i$ replaced by $Ae^{-t_i/\tau}$:

$$\ln p(A, \tau \mid \boldsymbol{d}) = -\frac{\chi_0^2(A, \tau)}{2\sigma^2} + \text{const}, \qquad \chi_0^2(A, \tau) = \sum_{i=1}^{N} \left(y_i - Ae^{-t_i/\tau}\right)^2, \tag{9.107}$$

where χ_0^2 is the residual sum of squares, not yet divided by σ^2.

9.18.1 How far from Gaussian? The Laplace approximation and the chain

The question. Is a Gaussian centred at the best fit a good description of this posterior, and if not, does the chain notice? The Gaussian in question is the **Laplace approximation** [the Gaussian whose log matches $\ln p$ to second order at its peak]. It comes from a Taylor series of

$\ln p$ about the maximum $\hat{\boldsymbol{\theta}}$:

$$\ln p(\boldsymbol{\theta}) \overset{(1)}{=} \ln p(\hat{\boldsymbol{\theta}}) + (\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}} \nabla \ln p\big|_{\hat{\boldsymbol{\theta}}} + \tfrac{1}{2}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}} \big[\nabla\nabla^{\mathsf{T}} \ln p\big]_{\hat{\boldsymbol{\theta}}} (\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}) + \dots$$
$$\overset{(2)}{=} \ln p(\hat{\boldsymbol{\theta}}) - \tfrac{1}{2}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}} \mathbf{H} (\boldsymbol{\theta}-\hat{\boldsymbol{\theta}}) + \dots, \qquad H_{ij} = -\frac{\partial^2 \ln p}{\partial\theta_i \partial\theta_j}\Big|_{\hat{\boldsymbol{\theta}}}. \tag{9.108}$$

(1) Taylor's theorem in two variables.
(2) At a maximum the gradient vanishes. Defining $\mathbf{H}$ with a minus sign makes it positive definite there.

Dropping the dots leaves a Gaussian with mean $\hat{\boldsymbol{\theta}}$ and covariance $\mathbf{H}^{-1}$, the same object as $\mathbf{F}^{-1}$ in (9.101). For the line the dots were exactly zero. Here we find the peak with a simplex optimiser and $\mathbf{H}$ by finite differences: $A = 97.0 \pm 4.7$, $\tau = 4.31 \pm 0.34\,\mathrm{h}$, $\rho = -0.63$. Four chains of 20000 steps, with the Laplace covariance as the proposal shape, give $A = 96.8 \pm 4.7$, $\tau = 4.35 \pm 0.34\,\mathrm{h}$, $\rho = -0.63$ (acceptance 0.36). The widths agree with Laplace. The centre of τ does not: the posterior mean is above the peak. On a 400×400 grid, where the exact posterior can be normalised and its A direction summed out, the marginal of τ has mean 4.35 h, standard deviation 0.34 h and skewness 0.26; the chain's column of τ has skewness 0.32 (Figure 9.44c). The joint contours are bent, a banana in miniature (Figure 9.44b).

Example: why the tail is on the long-τ side. At the time $t = 4\,\mathrm{h}$ the model predicts $100e^{-1} = 36.8\,\mathrm{s}^{-1}$ for $\tau = 4\,\mathrm{h}$. Lower τ by one hour and the prediction falls to $100e^{-4/3} = 26.4$, a change of 10.4; raise it by one hour and it rises to $100e^{-4/5} = 44.9$, a change of only 8.1. The data resist a shorter decay time more strongly than a longer one, so the likelihood falls faster on the short side and leaves a longer tail on the long side. The reason is that τ enters as $1/\tau$ in the exponent, and $1/\tau$ compresses large values. A different parameter choice, the decay rate $\lambda = 1/\tau$, would give a more symmetric posterior, but then a flat prior in λ is a different prior from a flat prior in τ (the Jacobian $|\mathrm{d}\tau/\mathrm{d}\lambda| = 1/\lambda^2$ of Chapter 2), and the question "which is flat?" must be answered with the physics, not with convenience.

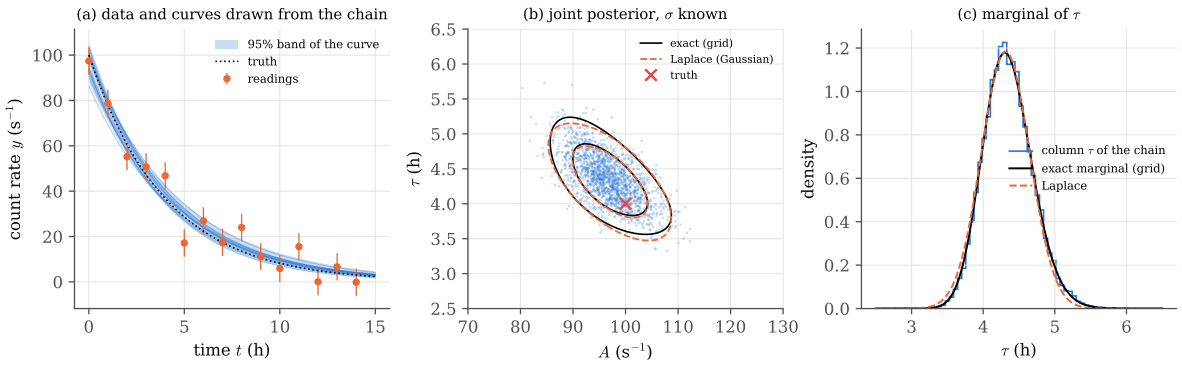

Figure 9.44: The decaying source with known noise. (a) The fifteen readings, the true curve (dotted), fifteen curves whose (A, τ) were drawn from the chain, and the band containing 95 per cent of the drawn curves at each time. (b) The joint posterior: chain samples, the exact contours computed on a grid (black), and the Laplace ellipses (dashed), which miss the bend. (c) The marginal of τ: the chain's column, the exact marginal and the Laplace Gaussian, which puts the centre too low and misses the tail at large τ.

9.18.2 The unknown noise level: three ways to treat a nuisance

So far σ was given. In a real measurement it is often known only roughly, and it matters: by (9.107) every posterior width is proportional to it. There are three things one can do with it.

Fix it at a guess. If the guess is wrong, every width is wrong by the same factor. With $\sigma = 3$ instead of 6, the marginal of τ has standard deviation 0.17 h instead of 0.34, and nothing in the output signals the problem (Figure 9.45a, dashed).

Integrate it out analytically. Hobson et al. do this for a model with the same structure [HobsonBMC eqs. 2.25–2.26]. With the prior $p(\sigma) \propto 1/\sigma$ (flat in $\ln\sigma$, the Jeffreys prior for a scale, Chapter 5),

$$p(A,\tau \mid \boldsymbol{d}) \overset{(1)}{=} \int_0^\infty (2\pi\sigma^2)^{-N/2} e^{-\chi_0^2/2\sigma^2} \frac{\mathrm{d}\sigma}{\sigma} \overset{(2)}{=} (2\pi)^{-N/2} \frac{1}{2}\Big(\frac{2}{\chi_0^2}\Big)^{N/2} \int_0^\infty u^{N/2-1} e^{-u}\,\mathrm{d}u$$
$$\overset{(3)}{=} \frac{\Gamma(N/2)}{2\,\pi^{N/2}} \left[\chi_0^2(A,\tau)\right]^{-N/2}. \tag{9.109}$$

(1) The likelihood (9.107) with its normalisation $(2\pi\sigma^2)^{-N/2}$ restored, because it depends on σ, times the prior $1/\sigma$ (its normalisation over a finite range of σ is a constant and is dropped).
(2) The substitution $u = \chi_0^2/2\sigma^2$ of (9.105), now with one more power of $1/\sigma$ from the prior: $\sigma^{-N-1}\mathrm{d}\sigma = \frac{1}{2}(2/\chi_0^2)^{N/2} u^{N/2-1}\mathrm{d}u$.
(3) The Gamma integral with $s = N/2$; $(2\pi)^{-N/2}2^{N/2} = \pi^{-N/2}$.

The shape $[\chi_0^2]^{-N/2}$ is exactly Hobson's eq. (2.26); their prefactor is the large-N form of ours, from Stirling's formula for $\Gamma(N/2)$. Compare with the line: a flat prior on σ gave the power $-(N-1)/2$ in (9.105), the scale prior $1/\sigma$ gives $-N/2$. Either way the unknown noise turns $e^{-\chi^2/2}$ into a power law in χ^2, which has heavier tails: the data must now also estimate their own scatter, and every parameter is a little less certain. On the grid the marginal of τ from (9.109) has mean 4.36 h and standard deviation 0.39 h, wider than the 0.34 h of the known-noise case.

Sample it and ignore its column. Add $\ln\sigma$ to the chain as a third parameter with a flat prior (the same $1/\sigma$ prior, written in the variable in which it is flat) and run:

Listing 9.11: Three parameters, or σ integrated out (`code/ch09/41_exponential.py`)

```
def lp_three(th):
    """(A, tau, ln sigma): flat in ln sigma is the Jeffreys prior 1/sigma."""
    A, tau, ls = th
    if not (-5 < ls < 5):
        return -np.inf
    base = lp_known((A, tau), 1.0)                # -chi0^2 / 2
    if not np.isfinite(base):
        return -np.inf
    return -N * ls + base * np.exp(-2 * ls)

def lp_marg(th):
    """sigma integrated out analytically: (N/2) ln chi0^2 with a minus sign."""
    A, tau = th
    if not (PRIOR["A"][0] < A < PRIOR["A"][1] and PRIOR["tau"][0] < tau < PRIOR["tau"][1]):
        return -np.inf
    return -0.5 * N * np.log(chi2_0(A, tau))
```

The function `lp_three` is $-N\ln\sigma - \chi_0^2/2\sigma^2$ in the variable $\ln\sigma$, and `lp_marg` is (9.109). By the key idea of Section 9.17.4, the τ column of the three-parameter chain is a sample of $p(\tau \mid \boldsymbol{d})$ with σ integrated out, so it must agree with the grid built on (9.109). It does: mean 4.36 h, standard deviation 0.39 h (four chains, acceptance 0.33, largest $\hat{R} = 1.0009$; Figure 9.45a). The analytic integral and the ignored column are two routes to the same marginal; the second needs no algebra and works for any prior.

The column we ignored is not useless either: it is the posterior of the noise level (Figure 9.45b), $\sigma = 6.4$ with 68 per cent between 5.4 and 8.0 s^{-1}. That is the honest statement of how well

fifteen readings determine their own scatter, and its width is the reason the marginal of τ widened. Hobson et al. use the same device for error bars that may be too small, scaling every σ_i by one unknown factor and marginalising it [HobsonBMC p. 52]; Padilla's notebook did exactly that for the straight line of Section 9.17.5.

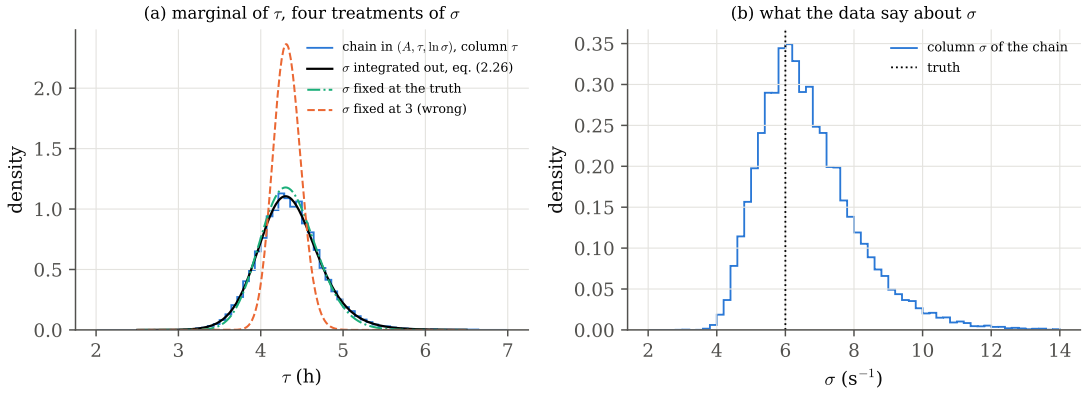

Figure 9.45: The noise level as a nuisance parameter. (a) The marginal of τ four ways: the τ column of the chain in $(A, \tau, \ln\sigma)$, which overlays the analytic marginal (9.109); σ fixed at its true value (narrower, since the uncertainty in σ is ignored); and σ fixed at a wrong value, half the truth (far too narrow). (b) The σ column of the same chain: what the data say about their own scatter.

Watch out: A fixed nuisance parameter is a hidden assumption

Fixing a nuisance parameter is marginalising it with a delta-function prior [HobsonBMC p. 42]. It is legitimate when the parameter really is known; when it is not, every width inherits the error of the guess, and the chain cannot tell. Before quoting a constraint, list what was held fixed. Section 9.22 will show that the error bar on $\ln(10^{10}A_s)$ from a CMB temperature spectrum changes by a factor of nine depending on whether one parameter is fixed.

9.18.3 Data sets that disagree: hyperparameters

Two laboratories measure the same quantity, each quotes an error bar, and the two results do not overlap. One of them has underestimated its errors, or both have, and nobody knows which. Averaging them with their stated weights gives a number with a small error bar that may be far from the truth; throwing one away by judgement is arbitrary. Padilla et al. pose this for the straight line [Padilla §§3.10, 5.2].

The question. When two data sets disagree and we do not know which is wrong, can the analysis itself discover that one does not belong and down-weight it, and can the data tell us whether doing so was justified?

The setup. Two cases, each with 16 points per data set and x drawn as $3 \times \mathcal{N}(0,1)$ as before:

	data set D_1	data set D_2
case 1 (agree)	$y = 3 + 2x$, $\sigma = 0.3$	$y = 3 + 2x$, $\sigma = 0.2$
case 2 (disagree)	$y = 3 + 2x$, $\sigma = 0.3$	$y = 3.5 + 1.5x$, $\sigma = 0.5$

Case 1 is the experiment of Section 9.17, in a new realisation. In case 2 the two sets come from different lines, but the analysis is not told so. Two models of the data are compared.

H_0: both data sets as stated. One line, and every point has the error bar its experiment quotes. This is the likelihood (9.99) of the straight line applied to all 32 points. In case 2 the single line lands between the two truths and fits neither; for our realisation $a = 3.276 \pm 0.066$, $b = 1.864 \pm 0.024$, with a best-fit $\chi^2 \approx 158$ for 32 points (Figure 9.46a, b). The posterior is confident and wrong, because the likelihood was told that both data sets have the stated errors and describe the same line.[5]

H_1: each data set may have its errors scaled by an unknown factor. Still one line, but data set k gets a weight α_k that multiplies its χ^2_k, which is the same as dividing its error bars by $\sqrt{\alpha_k}$. With $\alpha_k = 1$ the errors are as stated; a small α_k says "these error bars are underestimated". The weights are unknown and are marginalised, one per data set: this is the **hyperparameter method** [one extra weight per data set, unknown and integrated out]. We keep Padilla's letters: α_k for the weight, n_k for the number of points and χ^2_k for the χ^2 of data set k alone, as in (9.99); their covariance $\mathbf{V}$ of one data set is our $\mathrm{diag}(\sigma_i^2)$.

The prior on a weight. All we want to say about α is that it is positive and that the stated errors are right on average, $\mathbb{E}\,\alpha = 1$; nothing about how far a given experiment may stray. The least committal density with that one property is the maximum-entropy density of Section 2.11.3 with a flat measure on $\alpha > 0$. Maximise $-\int p \ln p \, \mathrm{d}\alpha$ subject to $\int p \, \mathrm{d}\alpha = 1$ and $\int \alpha \, p \, \mathrm{d}\alpha = 1$:

$$p(\alpha) \overset{(1)}{=} \frac{1}{Z} e^{-\lambda\alpha} \overset{(2)}{=} \lambda \, e^{-\lambda\alpha} \overset{(3)}{=} e^{-\alpha}, \qquad \alpha > 0. \tag{9.110}$$

(1) (2.69) with one constraint, $f(\alpha) = \alpha$, and a flat measure; λ is its Lagrange multiplier.
(2) Normalisation: $Z = \int_0^\infty e^{-\lambda\alpha} \mathrm{d}\alpha = 1/\lambda$.
(3) The mean of $\lambda e^{-\lambda\alpha}$ is $1/\lambda$, and it must be one, so $\lambda = 1$.

A mean of one centres the weights on "the errors are as quoted"; the exponential then lets an individual weight be small (errors underestimated) without any further assumption.

Their key equation: the likelihood with the weight integrated out. For one data set of n points,

$$\begin{aligned} p(D_k \mid \boldsymbol{\theta}, H_1) &\overset{(1)}{=} \int_0^\infty \frac{\alpha^{n/2}}{(2\pi)^{n/2}|\mathbf{V}|^{1/2}} \, e^{-\alpha\chi^2/2} \, e^{-\alpha} \, \mathrm{d}\alpha \overset{(2)}{=} \frac{1}{(2\pi)^{n/2}|\mathbf{V}|^{1/2}} \, \frac{\Gamma(n/2+1)}{(\chi^2/2+1)^{n/2+1}} \\ &\overset{(3)}{=} \frac{2\,\Gamma(n/2+1)}{\pi^{n/2}|\mathbf{V}|^{1/2}} \, (\chi^2+2)^{-(n/2+1)}. \end{aligned} \tag{9.111}$$

(1) Errors $\sigma_i/\sqrt{\alpha}$: each of the n Gaussian factors gains $\sqrt{\alpha}$ in its normalisation and α in its exponent. Times the prior (9.110).
(2) $\int_0^\infty \alpha^{s-1} e^{-c\alpha} \mathrm{d}\alpha = \Gamma(s)/c^s$ with $s = n/2+1$ and $c = \chi^2/2+1$.
(3) $(\chi^2/2+1)^{-(n/2+1)} = 2^{n/2+1}(\chi^2+2)^{-(n/2+1)}$, and $2^{n/2+1}/(2\pi)^{n/2} = 2/\pi^{n/2}$.

This is Padilla's eq. (50), and the H_1 likelihood of the two data sets is the product of one such factor per set. The Gaussian $e^{-\chi^2/2}$ has become the power law $(\chi^2+2)^{-(n/2+1)}$, the same thing that happened to the unknown σ in (9.109), now once per data set. A power law is forgiving: a line that misses one data set badly is penalised only logarithmically in that set's χ^2, so the posterior can follow the other.

[5] Padilla et al. quote $a = 3.528 \pm 0.056$, $b = 1.795 \pm 0.014$ for their realisation. By (9.102), errors of 0.3 and 0.5 allow no intercept width below $(16/0.3^2 + 16/0.5^2)^{-1/2} = 0.064$ for any choice of the x_i, so the published widths were not computed with these error bars; we do not try to reconstruct their setting.

What the posterior does. Under H_1 the posterior of (a, b) has two peaks (Figure 9.46c): one at the line of D_1, carrying 1.00 of the probability, and one near $(a, b) = (3.71, 1.61)$, towards the line of D_2, whose peak is lower by a factor $e^{7.2}$ and carries a fraction 0.0031. The better data set wins, because its smaller errors make it more informative. These weights come from integrating the posterior on a grid. Six chains started at random in the prior box do not find them: none of the 6 chains crossed between the peaks in 20 000 steps, each spending more than 98 per cent of its steps in a single peak. A chain started near the minor peak would stay there and report it as the whole posterior, and a plot of the points of several chains shows the peaks with whatever density the starting points happened to give them. This is the trap of Section 9.13 in practice. When the posterior is multimodal, histograms of chain points are not evidence about the relative weights of the modes; a tempered or nested sampler, or a direct integral as here, is needed.

Should we use H_1? The evidence ratio. Adding hyperparameters is a choice of model, and Chapter 5 answers such questions with the evidence $Z = \int \mathcal{L}(\boldsymbol{\theta})\, p(\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{\theta}$ and the Bayes factor $K = Z_1/Z_0$. Both models share the flat prior on (a, b), here the box $-5 < a < 8$, $0 < b < 4$, and both Z are two-dimensional integrals, which we do by quadrature on a 1301×801 grid. For the disagreeing data sets (case 2) we find $\ln K = 40.6$, a factor of order 10^{17} in favour of H_1; for the agreeing ones (case 1), $K = 0.59$.

Where does a factor of 10^{17} come from? An integral over a likelihood with one sharp peak is the height of the peak times its width, so $\ln K$ is the difference of the two log-likelihoods at their peaks plus a difference of log-widths (the Occam terms of Chapter 5), which are a few units at most. The heights carry the effect. The normalisation $(2\pi)^{-n_k/2}|\mathbf{V}|^{-1/2}$ is common to the two models and cancels. With $n_k = 16$, so that $n_k/2 + 1 = 9$ and $\ln \Gamma(9) = \ln 40\,320 = 10.6$, case 2 gives:

- H_0 at its best line: $-\chi^2_{\min}/2 = -158/2 = -79$. An acceptable fit of 32 points would have χ^2 near 32 (the mean of a χ^2 is its number of degrees of freedom), so the single line is worse than an acceptable fit by $e^{-(158-32)/2} = e^{-63}$.
- H_1 at its main peak, the line of D_1: by line 2 of (9.111) each set contributes $\ln\Gamma(9) - 9\ln(\chi^2_k/2 + 1)$. D_1 fits its own line, $\chi^2_1 \approx 16$, giving $10.6 - 9\ln 9 = -9.2$. D_2 misses that line by $(3.5 + 1.5x) - (3 + 2x) = 0.5(1 - x)$, whose mean square over $x \sim 3 \times \mathcal{N}(0, 1)$ is $0.25(1 + 9) = 2.5$; adding the noise variance 0.25 and dividing by 0.5^2 gives about 11 per point, $\chi^2_2 \approx 176$, and a contribution $10.6 - 9\ln 89 = -29.8$. In all, -39.

The difference is $-39 - (-79) = 40$, against the quadrature's 40.6. The decisive item is the treatment of D_2: under H_0 a misfit of $\chi^2_2 \approx 176$ costs $176/2 = 88$ in $\ln \mathcal{L}$, under H_1 it costs $9\ln 89 \approx 40$ less a constant, because the power law charges the logarithm of χ^2 rather than χ^2 itself. No Occam penalty from two extra parameters can compensate for that. The same count for case 1, where both sets fit their common line with $\chi^2_k \approx 16$ each, gives H_1 two terms of -9.2 against H_0's $-32/2 = -16$, a difference of about -2: the weights buy nothing when the errors are right and cost a little. The power law's broader peak gives back part of that in the width term, and the quadrature gives $\ln K = -0.53$, mildly in favour of H_0.

Side by side. Padilla et al. quote Bayes factors for both cases.

	case 1 (data sets agree)	case 2 (data sets disagree)
Padilla et al., K [Padilla eqs. 71–72]	3	37
ours, $K = Z_1/Z_0$ by quadrature	0.59 ($\ln K = -0.53$)	$\ln K = 40.6$
verdict [33]	barely worth a mention	decisive for H_1

Why they differ. The verdicts agree; the case-2 numbers differ by $\ln(4\times10^{17}/37)\approx 37$ e-folds. The published values come from Padilla's eq. (51), which is not an evidence ratio. To see what it should have been as a ratio of likelihoods, divide (9.111) by the Gaussian likelihood of the same data set at the same $\boldsymbol{\theta}$:

$$\begin{aligned}\frac{p(D_k\,|\,\boldsymbol{\theta},H_1)}{p(D_k\,|\,\boldsymbol{\theta},H_0)} &\overset{(1)}{=} \frac{2\,\Gamma(n/2+1)\,\pi^{-n/2}|\mathbf{V}|^{-1/2}(\chi^2+2)^{-(n/2+1)}}{(2\pi)^{-n/2}|\mathbf{V}|^{-1/2}e^{-\chi^2/2}}\\ &\overset{(2)}{=} 2\,(2\pi)^{n/2}\pi^{-n/2}\,\Gamma(n/2+1)\,(\chi^2+2)^{-(n/2+1)}\,e^{+\chi^2/2}\\ &\overset{(3)}{=} 2^{n/2+1}\,\Gamma(n/2+1)\,(\chi^2+2)^{-(n/2+1)}\,e^{+\chi^2/2}. \end{aligned}\tag{9.112}$$

(1) Numerator (9.111); denominator the Gaussian likelihood (9.99) written with $\mathbf{V}=\mathrm{diag}(\sigma_i^2)$.
(2) $|\mathbf{V}|^{-1/2}$ cancels; dividing by $e^{-\chi^2/2}$ is multiplying by $e^{+\chi^2/2}$.
(3) $2\,(2\pi)^{n/2}/\pi^{n/2}=2\cdot 2^{n/2}=2^{n/2+1}$.

For two data sets the ratio is the product over k. Eq. (51) as printed reads $K=\prod_k 2^{n_k/2+1}\Gamma(n_k/2+1)e^{-\chi_k^2/2}/(\chi_k^2+2)$. Three things separate it from $K=Z_1/Z_0$, each sized here for case 2 at the H_0 best fit, where the two χ_k^2 add up to 158:

1. *The power of* (χ_k^2+2): 1 in print, $n_k/2+1=9$ in (9.112). The missing factor $(\chi_k^2+2)^{-8}$ per set is $8\sum_k\ln(\chi_k^2+2)$ e-folds, between 46 and 70 however the 158 is split between the two sets.
2. *The sign of* $\chi_k^2/2$: $e^{-\chi_k^2/2}$ in print, $e^{+\chi_k^2/2}$ in (9.112). Together the two sets differ by $e^{\sum_k\chi_k^2}=e^{158}$.
3. *A ratio at one point is not a ratio of integrals.* Even corrected, (9.112) compares the two likelihoods at one $\boldsymbol{\theta}$, while Z_1/Z_0 integrates each over its own prior, and the two models peak at different lines. At the H_0 best fit the corrected ratio is $\sum_k[9\ln 2+\ln\Gamma(9)-9\ln(\chi_k^2+2)]+79$, between 34 and 61 e-folds depending on the split, against $\ln K=40.6$; at another $\boldsymbol{\theta}$ it would be another number.

We cannot say which combination of these produced the published 37, since the paper does not give the point at which eq. (51) was evaluated.

The lesson. A Bayes factor is a ratio of integrals over the whole prior, and a likelihood ratio at one point, however carefully written, is a different number, here by tens of e-folds. A direct integral (or, in more dimensions, nested sampling or the importance-sampling identity of their eq. 48, Section 9.23.1) is the way to compute it.

9.19 The likelihood of a CMB power spectrum

The straight line and the decaying source had data that were measurements of the model plus noise. The CMB is different in kind. Cosmology does not predict the temperature in any direction of the sky; it predicts the *statistics* of the temperature field, its power spectrum C_ℓ, and the sky we see is one random realisation of it (Chapter 7). The data are therefore the measured spectrum $\widehat{C}_\ell$ of that one realisation, and the likelihood has to say how probable this $\widehat{C}_\ell$ is if the true spectrum were C_ℓ. On the full sky the answer is exact and short, and every practical CMB likelihood is an approximation to it, so we derive it first and then test the approximations against it.

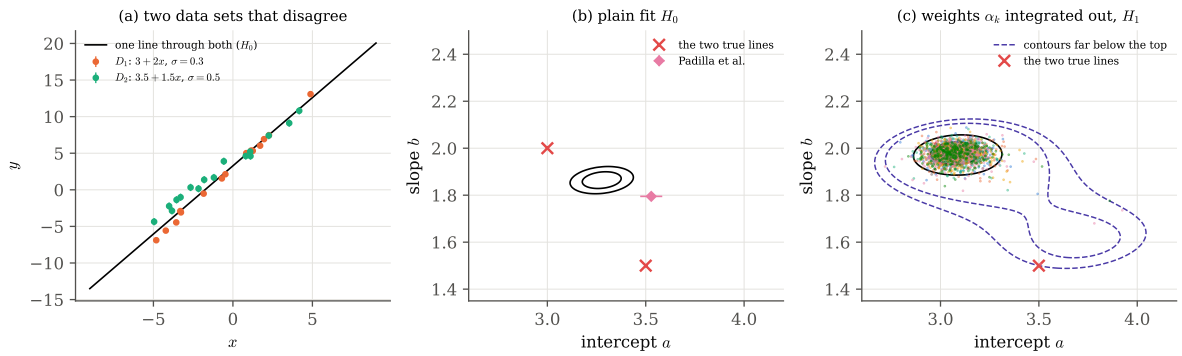

Figure 9.46: Two data sets drawn from different lines. (a) The data and the single line of H_0, which fits neither. (b) The H_0 posterior (68 and 95 per cent), far from both true lines (crosses), with the published result of Padilla et al. for their realisation. (c) With one marginalised weight per data set (H_1): the posterior concentrates on the line of the more precise data set; contours drawn far below the top (dashed) reveal the second, much lower peak towards the other line. Coloured points are the six chains, each confined to a single peak.

The question in words. It is the question of the straight line in Section 9.17, asked in a much larger space of hypotheses. The observed event is the whole data vector, here the measured spectrum $\widehat{C}_\ell$ at every multipole at once, standing in for the map it was computed from. The hypotheses are the cosmological models, one for every value of the ΛCDM parameter vector, as the candidate lines were one for every pair (a, b). To each hypothesis we put the same question: if nature had chosen this model, how probable would it have been to observe exactly this spectrum? That number, read as a function of the parameters, is the likelihood, and Bayes' theorem combines it with the prior into a posterior over the models (Section 5.7). What is new for the CMB is only the first step, the probability of a spectrum given a model.

9.19.1 The chain of dependence: parameters, spectrum, sky

Three levels connect the parameters to the data (Figure 9.47). The parameters $\boldsymbol{\theta}$ (amplitude and tilt of the primordial spectrum, densities, optical depth) fix the angular power spectrum through a Boltzmann code, $C_\ell = C_\ell(\boldsymbol{\theta})$, with no randomness: $C_\ell = \sum_m \int \mathrm{d}k\, T_m(\ell, k) P_m(k)$ in the notation of the cosmology notes, a weighted integral of the primordial power over transfer functions (Chapter T1 maps these objects). The spectrum fixes the *distribution* of the harmonic coefficients, $a_{\ell m} \sim \mathcal{N}(0, C_\ell)$, independent for different ℓ and m (statistical isotropy, Chapter 7). The coefficients give the map, and the map gives the data. Hobson et al. write the posterior of the parameters with the middle level integrated out [HobsonBMC eqs. 10.26–10.28]:

$$
\begin{aligned}
p(\boldsymbol{\theta} \mid \boldsymbol{d}) &\overset{(1)}{=} \int \mathrm{d}C_\ell \; p(\boldsymbol{\theta}, C_\ell \mid \boldsymbol{d}) \overset{(2)}{=} \frac{1}{p(\boldsymbol{d})} \int \mathrm{d}C_\ell \; p(\boldsymbol{d} \mid C_\ell)\, p(C_\ell \mid \boldsymbol{\theta})\, p(\boldsymbol{\theta}) \\
&\overset{(3)}{=} \frac{p(\boldsymbol{\theta})}{p(\boldsymbol{d})} \int \mathrm{d}C_\ell \; p(\boldsymbol{d} \mid C_\ell)\, \delta\big(C_\ell - C_\ell(\boldsymbol{\theta})\big) \overset{(4)}{=} \frac{p(\boldsymbol{\theta})}{p(\boldsymbol{d})}\, p\big(\boldsymbol{d} \mid C_\ell = C_\ell(\boldsymbol{\theta})\big).
\end{aligned}
\tag{9.113}
$$

(1) The spectrum is an intermediate unknown; marginalise it.
(2) Bayes' theorem for the pair $(\boldsymbol{\theta}, C_\ell)$, with the product rule $p(\boldsymbol{d}, C_\ell, \boldsymbol{\theta}) = p(\boldsymbol{d} \mid C_\ell)\, p(C_\ell \mid \boldsymbol{\theta})\, p(\boldsymbol{\theta})$: once the spectrum is known, the data do not depend on how it was produced.
(3) The spectrum is a deterministic function of the parameters, so its conditional density is a delta function [HobsonBMC p. 240].
(4) The delta function picks the value $C_\ell(\boldsymbol{\theta})$.

So the likelihood of the parameters is the likelihood of the spectrum, evaluated at the spectrum

the parameters predict. All the statistics lives in $p(\boldsymbol{d} \mid C_\ell)$, and all the cosmology in the map $\boldsymbol{\theta} \mapsto C_\ell(\boldsymbol{\theta})$.

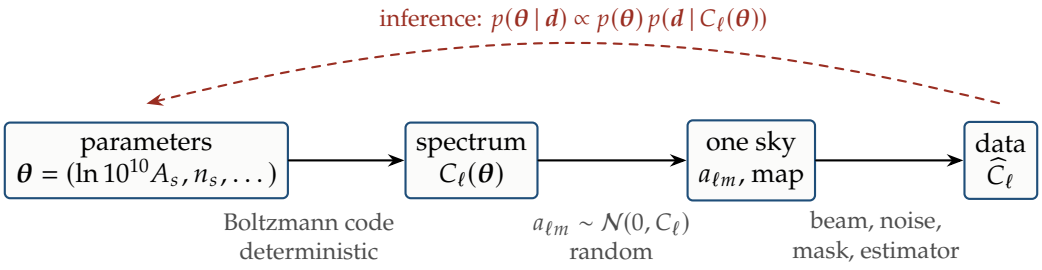

Figure 9.47: The CMB as a chain of dependence. Prediction runs left to right: the parameters fix the spectrum, the spectrum fixes the distribution of the harmonic coefficients, one random sky is drawn and observed. Inference runs back along the dashed arc, and because the first link has no randomness, the likelihood of the parameters is the likelihood of the spectrum at $C_\ell(\boldsymbol{\theta})$.

9.19.2 The exact full-sky likelihood

Take one multipole ℓ of a full, noiseless sky. Its $2\ell+1$ real degrees of freedom are $a_{\ell 0}$, which is real with variance C_ℓ, and the real and imaginary parts x_m, y_m of $a_{\ell m}$ for $m = 1, \dots, \ell$, each with variance $C_\ell/2$ (the $m < 0$ coefficients are their complex conjugates and carry no new information; Chapter 7). The estimator is $\widehat{C}_\ell = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} |a_{\ell m}|^2 = \frac{1}{2\ell+1}\big[a_{\ell 0}^2 + 2\sum_{m\geq 1}(x_m^2 + y_m^2)\big]$. Write $\nu = 2\ell + 1$. The probability of the observed coefficients, given a candidate C_ℓ, is

$$p(\{a_{\ell m}\} \mid C_\ell) \overset{(1)}{=} \frac{e^{-a_{\ell 0}^2/2C_\ell}}{\sqrt{2\pi C_\ell}} \prod_{m=1}^{\ell} \frac{e^{-(x_m^2+y_m^2)/C_\ell}}{\pi C_\ell} \overset{(2)}{=} (2\pi)^{-1/2}\pi^{-\ell}\, C_\ell^{-\nu/2}\, \exp\!\left[-\frac{a_{\ell 0}^2 + 2\sum_{m\geq 1}(x_m^2+y_m^2)}{2C_\ell}\right]$$

$$\overset{(3)}{=} \text{const} \times C_\ell^{-\nu/2}\, e^{-\nu\widehat{C}_\ell/2C_\ell}, \qquad \text{so} \qquad -2\ln\mathcal{L}(C_\ell) = \nu\left[\frac{\widehat{C}_\ell}{C_\ell} + \ln C_\ell\right] + \text{const}. \tag{9.114}$$

(1) Independent Gaussians: $a_{\ell 0}$ with variance C_ℓ; x_m and y_m each with variance $C_\ell/2$, whose two densities multiply to $(\pi C_\ell)^{-1} e^{-(x^2+y^2)/C_\ell}$.

(2) Collect the powers of C_ℓ: $\frac{1}{2} + \ell = \nu/2$; write the exponents over a common denominator $2C_\ell$.

(3) The numerator of the exponent is $\nu\widehat{C}_\ell$ by the definition of $\widehat{C}_\ell$.

This is eq. (6) of Hamimeche and Lewis for one field [16]. Three facts follow at once. *The data enter only through* $\widehat{C}_\ell$. The density (9.114) is a constant times a function of $\widehat{C}_\ell$ and C_ℓ alone, which is the factorised form of Section 3.16.2: on the full sky the spectrum is a **sufficient statistic** [a summary that carries all the information the data have about C_ℓ], and nothing is lost by compressing a map of millions of pixels to one number per ℓ. *The likelihood is largest at* $C_\ell = \widehat{C}_\ell$: set the derivative $\nu[-\widehat{C}_\ell/C_\ell^2 + 1/C_\ell]$ to zero. *Different* ℓ *are independent*, so $-2\ln\mathcal{L}$ of a whole spectrum is the sum of (9.114) over ℓ.

The same density read the other way. At fixed C_ℓ, what is the distribution of the estimate $\widehat{C}_\ell$? The exponent of (9.114) contains $\nu\widehat{C}_\ell = a_{\ell 0}^2 + \sum_{m\geq 1}\big[(\sqrt{2}x_m)^2 + (\sqrt{2}y_m)^2\big]$, a sum of ν squares of independent Gaussians, each of variance C_ℓ ($\sqrt{2}x_m$ has variance $2 \cdot C_\ell/2$). Divided by C_ℓ it is a sum of ν squared standard Gaussians, so $y \equiv \nu\widehat{C}_\ell/C_\ell \sim \chi^2_\nu$ (Section 2.13.2). Change variables

from y to $\widehat{C}_\ell$:

$$p(\widehat{C}_\ell \mid C_\ell) \overset{(1)}{=} \frac{y^{\nu/2-1}e^{-y/2}}{2^{\nu/2}\Gamma(\nu/2)}\,\frac{\mathrm{d}y}{\mathrm{d}\widehat{C}_\ell} \overset{(2)}{=} \frac{1}{2^{\nu/2}\Gamma(\nu/2)}\Big(\frac{\nu\widehat{C}_\ell}{C_\ell}\Big)^{\nu/2-1} e^{-\nu\widehat{C}_\ell/2C_\ell}\,\frac{\nu}{C_\ell}$$
$$\overset{(3)}{=} \text{const} \times \widehat{C}_\ell^{\,(\nu-2)/2}\, C_\ell^{-\nu/2}\, e^{-\nu\widehat{C}_\ell/2C_\ell}. \tag{9.115}$$

(1) The χ^2_ν density of y, times the Jacobian of $y = \nu\widehat{C}_\ell/C_\ell$.
(2) Substitute y and $\mathrm{d}y/\mathrm{d}\widehat{C}_\ell = \nu/C_\ell$.
(3) Collect the powers: $C_\ell^{-(\nu/2-1)}C_\ell^{-1} = C_\ell^{-\nu/2}$; the constant holds ν and the Gamma function.

This is the scaled χ^2_ν law of Chapter 7 (HL eq. 8). As a function of C_ℓ it is (9.114) again: the extra factor $\widehat{C}_\ell^{\,(\nu-2)/2}$ is fixed once the data are fixed and changes nothing in the likelihood.

Several fields. With temperature and E-polarization observed together, each mode is a vector $\boldsymbol{a}_{\ell m}$ of two numbers with a 2×2 covariance $\mathbf{C}_\ell$, and the same three moves give the two-field likelihood. Take as the ν real modes $\boldsymbol{a}_{\ell 0}$ and the real and imaginary parts of the $m \geq 1$ coefficients, each multiplied by $\sqrt{2}$ as above, so that every mode has covariance $\mathbf{C}_\ell$ and density $(2\pi)^{-1}|\mathbf{C}_\ell|^{-1/2}\exp(-\frac{1}{2}\boldsymbol{a}^{\mathsf{T}}\mathbf{C}_\ell^{-1}\boldsymbol{a})$ (Eq. (2.78)). The modes are independent, so

$$-2\ln\mathcal{L} \overset{(1)}{=} \sum_{\text{modes}} \boldsymbol{a}^{\mathsf{T}}\mathbf{C}_\ell^{-1}\boldsymbol{a} + \nu\ln|\mathbf{C}_\ell| + \text{const} \overset{(2)}{=} \mathrm{Tr}\Big(\mathbf{C}_\ell^{-1}\sum_{\text{modes}}\boldsymbol{a}\boldsymbol{a}^{\mathsf{T}}\Big) + \nu\ln|\mathbf{C}_\ell| + \text{const}$$
$$\overset{(3)}{=} \nu\big[\mathrm{Tr}(\widehat{\mathbf{C}}_\ell\mathbf{C}_\ell^{-1}) + \ln|\mathbf{C}_\ell|\big] + \text{const}. \tag{9.116}$$

(1) Minus twice the logarithm of a product of ν Gaussian densities.
(2) A number equals its own trace, and $\mathrm{Tr}(\boldsymbol{a}^{\mathsf{T}}\mathbf{M}\boldsymbol{a}) = \mathrm{Tr}(\mathbf{M}\boldsymbol{a}\boldsymbol{a}^{\mathsf{T}})$ (a trace is unchanged when the factors are cycled); the trace of a sum is the sum of the traces.
(3) The estimate of the spectrum matrix is $\widehat{\mathbf{C}}_\ell = \nu^{-1}\sum_{\text{modes}}\boldsymbol{a}\boldsymbol{a}^{\mathsf{T}}$, and $\mathrm{Tr}(\mathbf{AB}) = \mathrm{Tr}(\mathbf{BA})$.

For one field the trace is $\widehat{C}_\ell/C_\ell$ and the determinant is C_ℓ, and (9.114) comes back (HL eqs. 6–7). The matrix $\nu\widehat{\mathbf{C}}_\ell$ is a sum of outer products of Gaussian vectors, the Wishart matrix met in Section 8.13.2; we use only the one-field form from here on.

Instrumental effects enter simply. White noise of power N_ℓ is another independent Gaussian field, so the observed coefficients have variance $C_\ell + N_\ell$, and (9.114) holds with $C_\ell \to C_\ell + N_\ell$ [HobsonBMC eq. 10.24]; with a beam and pixel window T_ℓ (Chapter 8), $C_\ell \to T_\ell^2 C_\ell + N_\ell$. On a fraction f_{sky} of the sky the number of independent modes is roughly $\nu = (2\ell+1)f_{\text{sky}}$ (Knox's mode count, Chapter 8), and (9.114) with this ν is the standard idealised cut-sky likelihood. It is exact for a sky observed with isotropic noise; for a real mask it is an approximation, since the mask couples multipoles.

Working definition 9.12 (power-spectrum likelihood)

For a Gaussian sky observed with beam and pixel window T_ℓ and isotropic noise N_ℓ on a fraction f_{sky} of the sky, the likelihood of parameters $\boldsymbol{\theta}$ given the observed spectrum $\widehat{C}_\ell$ is

$$-2\ln\mathcal{L}(\boldsymbol{\theta}) = \sum_\ell \nu_\ell\Big[\frac{\widehat{C}_\ell}{T_\ell^2 C_\ell(\boldsymbol{\theta}) + N_\ell} + \ln\big(T_\ell^2 C_\ell(\boldsymbol{\theta}) + N_\ell\big)\Big] + \text{const}, \qquad \nu_\ell = (2\ell+1)f_{\text{sky}},$$

with ν_ℓ [the number of independent real modes at multipole ℓ, exact on the full sky]. *Operational check:* at each ℓ separately it is smallest when the predicted $T_\ell^2 C_\ell + N_\ell$ equals $\widehat{C}_\ell$, and data simulated as $\widehat{C}_\ell = (T_\ell^2 C_\ell + N_\ell)\chi^2_\nu/\nu$ have exactly this likelihood.

Example: the likelihood of the quadrupole is very skewed. As a function of C_ℓ at fixed $\widehat{C}_\ell$, $\mathcal{L} \propto C_\ell^{-\nu/2} e^{-\beta/C_\ell}$ with $\beta = \nu\widehat{C}_\ell/2$, an inverse-gamma shape with index $\alpha = \nu/2 - 1$ and scale β (Chapter 2). Its peak is where the derivative of $\ln\mathcal{L} = -\frac{\nu}{2}\ln C_\ell - \beta/C_\ell$ vanishes, $-\nu/2C_\ell + \beta/C_\ell^2 = 0$, that is at $C_\ell = 2\beta/\nu = \widehat{C}_\ell$. Its mean, with a flat prior on C_ℓ, is a ratio of two integrals of the same kind, each done with the substitution $u = \beta/C_\ell$:

$$\int_0^\infty C_\ell^{-s} e^{-\beta/C_\ell}\,\mathrm{d}C_\ell \overset{(1)}{=} \beta^{1-s}\int_0^\infty u^{s-2}e^{-u}\,\mathrm{d}u \overset{(2)}{=} \beta^{1-s}\,\Gamma(s-1),$$

$$\mathbb{E}[C_\ell] \overset{(3)}{=} \frac{\int C_\ell \cdot C_\ell^{-\nu/2} e^{-\beta/C_\ell}\mathrm{d}C_\ell}{\int C_\ell^{-\nu/2} e^{-\beta/C_\ell}\mathrm{d}C_\ell} \overset{(4)}{=} \beta\,\frac{\Gamma(\nu/2-2)}{\Gamma(\nu/2-1)} \overset{(5)}{=} \frac{\beta}{\nu/2-2} = \frac{\nu\widehat{C}_\ell}{\nu-4} = \widehat{C}_\ell\,\frac{2\ell+1}{2\ell-3}. \tag{9.117}$$

(1) $C_\ell = \beta/u$, $\mathrm{d}C_\ell = -\beta u^{-2}\mathrm{d}u$, and $C_\ell^{-s} = \beta^{-s}u^s$; swapping the limits absorbs the minus sign.
(2) The Gamma integral, which converges for $s > 1$.
(3) The posterior with a flat prior is the normalised likelihood.
(4) Line 2 with $s = \nu/2 - 1$ in the numerator and $s = \nu/2$ in the denominator; the powers of β leave one factor β.
(5) $\Gamma(z+1) = z\,\Gamma(z)$ with $z = \nu/2 - 2$; then $\beta = \nu\widehat{C}_\ell/2$ and $\nu = 2\ell + 1$.

The numerator needs $\nu/2 - 1 > 1$, so the mean exists for $\nu > 4$, that is from the quadrupole up (HL below eq. 8). At $\ell = 5$ the mean is $1.571\,\widehat{C}_\ell$; at the quadrupole, $\ell = 2$ and $\nu = 5$, it is $5\widehat{C}_\ell$, five times the peak. The likelihood has a long tail towards large C_ℓ, because a large true spectrum can produce a small $\widehat{C}_\ell$ by chance much more easily than a small spectrum can produce a large one. The other direction is skewed too. Given C_ℓ, the most probable $\widehat{C}_\ell$ is the peak of (9.115): in the variable $y = \nu\widehat{C}_\ell/C_\ell$ the density is proportional to $y^{\nu/2-1}e^{-y/2}$, whose logarithm has derivative $(\nu/2-1)/y - 1/2$, zero at $y = \nu - 2$. So the most probable $\widehat{C}_\ell$ is $C_\ell(\nu-2)/\nu$: $0.818\,C_\ell$ at $\ell = 5$ and $0.6\,C_\ell$ at the quadrupole. Low multipoles usually come out below their true value, and their likelihood leans upwards to compensate. Figure 9.48 shows the shapes.

9.19.3 Approximations, and what each gets wrong

On a masked sky with anisotropic noise the exact likelihood is a Gaussian in millions of pixels with a covariance that depends on C_ℓ; evaluating it costs $O(N_{\mathrm{pix}}^3)$ operations and is impossible at high ℓ [HobsonBMC p. 238]. Every high-ℓ CMB analysis therefore replaces it by a function of the pseudo-C_ℓ estimates of Chapter 8 that is quadratic in some variable, so that a covariance matrix measured on simulations can be put in. The full sky is where these approximations can be tested, because there the exact answer is (9.114). Normalise it so that it is zero at $C_\ell = \widehat{C}_\ell$ (HL eq. 15) and write $u = \widehat{C}_\ell/C_\ell - 1$ for the fractional mismatch:

$$-2\ln\mathcal{L}_{\mathrm{exact}} \overset{(1)}{=} \nu\big[u - \ln(1+u)\big] \overset{(2)}{=} \nu\Big[\frac{u^2}{2} - \frac{u^3}{3} + \frac{u^4}{4} - \dots\Big]. \tag{9.118}$$

(1) $\widehat{C}_\ell/C_\ell + \ln C_\ell - (1 + \ln\widehat{C}_\ell) = (1+u) - \ln(1+u) - 1$, using $\ln C_\ell - \ln\widehat{C}_\ell = -\ln(1+u)$.
(2) $\ln(1+u) = u - u^2/2 + u^3/3 - \dots$.

The common approximations of HL eqs. (22)–(28) all start from one idea. On the full sky $\widehat{C}_\ell$ has mean C_ℓ and variance $2C_\ell^2/\nu$ (the variance of χ^2_ν is 2ν, and $\widehat{C}_\ell = C_\ell\chi^2_\nu/\nu$). A Gaussian with that mean and variance is quadratic in the data, and a quadratic form is what makes a cut-sky analysis possible: replace the one variance by a covariance matrix of the pseudo-C_ℓ measured on simulations and the formula still works. The approximations differ in where the variance comes from, or in which variable the Gaussian is written:

- $\mathcal{L}_S$, the symmetric Gaussian: variance $2\widehat{C}_\ell^2/\nu$, taken from the data. It costs nothing to evaluate, since the variance does not change with the model.
- $\mathcal{L}_Q$, the quadratic form: variance $2C_\ell^2/\nu$, taken from the model being tested, which is the correct variance at each C_ℓ.
- $\mathcal{L}_f$, the fixed fiducial: variance $2(C_\ell^{\rm f})^2/\nu$ from one fiducial spectrum, computed once; this is what a simulated covariance matrix in a real analysis amounts to.
- The log-normal: a Gaussian in $\ln\widehat{C}_\ell$ with variance $2/\nu$, because $\ln\widehat{C}_\ell$ is closer to Gaussian than $\widehat{C}_\ell$.
- WMAP: a weighted sum of $\mathcal{L}_Q$ and the log-normal [157], with weights fixed below.
- Gaussian$_D$: $\mathcal{L}_Q$ with the normalisation of its Gaussian kept, which adds the logarithm of the model variance, $\ln C_\ell$ once per multipole as HL print it (their eq. 25).
- The cube-root forms: a Gaussian in $\widehat{C}_\ell^{1/3}$, the power of a χ^2 variable whose distribution is most nearly symmetric (HL eq. 28, in two variants labelled $\alpha = \pm 1$).

To compare them with the exact form (9.118), write each in the same variable $u = \widehat{C}_\ell/C_\ell - 1$, so that $\widehat{C}_\ell = C_\ell(1+u)$, and expand to third order. For $\mathcal{L}_S$:

$$-2\ln\mathcal{L}_S \overset{(1)}{=} \frac{\nu}{2}\left(\frac{\widehat{C}_\ell - C_\ell}{\widehat{C}_\ell}\right)^2 \overset{(2)}{=} \frac{\nu}{2}\,\frac{u^2}{(1+u)^2} \overset{(3)}{=} \frac{\nu}{2}\,u^2(1-2u+3u^2-\dots) \overset{(4)}{=} \frac{\nu}{2}u^2 - \nu u^3 + \dots \tag{9.119}$$

(1) A Gaussian in $\widehat{C}_\ell$ with mean C_ℓ and variance $2\widehat{C}_\ell^2/\nu$.
(2) $\widehat{C}_\ell - C_\ell = C_\ell u$ and $\widehat{C}_\ell = C_\ell(1+u)$; C_ℓ cancels.
(3) $(1+u)^{-2} = 1 - 2u + 3u^2 - \dots$.
(4) Keep terms up to u^3.

The others follow in the same way. $\mathcal{L}_Q$ is $\frac{\nu}{2}[(\widehat{C}_\ell - C_\ell)/C_\ell]^2 = \frac{\nu}{2}u^2$ exactly. The log-normal is $\frac{\nu}{2}\ln^2(1+u)$, and $\ln(1+u) = u - u^2/2 + \dots$ squares to $u^2 - u^3 + \dots$.

name	$-2\ln\mathcal{L}$	cubic term in u
exact	$\nu[u - \ln(1+u)]$	$-\nu u^3/3$
$\mathcal{L}_S$, symmetric Gaussian, variance from $\widehat{C}_\ell$	$\frac{\nu}{2}\left[(\widehat{C}_\ell - C_\ell)/\widehat{C}_\ell\right]^2 = \frac{\nu}{2}\frac{u^2}{(1+u)^2}$	$-\nu u^3$
$\mathcal{L}_Q$, variance from the model	$\frac{\nu}{2}\left[(\widehat{C}_\ell - C_\ell)/C_\ell\right]^2 = \frac{\nu}{2}u^2$	0
$\mathcal{L}_f$, variance from a fixed fiducial	$\frac{\nu}{2}\left[(\widehat{C}_\ell - C_\ell)/C_\ell^{\rm f}\right]^2$	(see text)
log-normal	$\frac{\nu}{2}\left[\ln(\widehat{C}_\ell/C_\ell)\right]^2 = \frac{\nu}{2}\ln^2(1+u)$	$-\nu u^3/2$
WMAP	$\frac{1}{3}\mathcal{L}_Q + \frac{2}{3}$ log-normal	$-\nu u^3/3$

Every one of them matches the exact $\nu u^2/2$, so all have the right width near the peak. They differ in the cubic term, which is the skewness of the previous example. What does a cubic term do? A negative u means a model C_ℓ above the measured $\widehat{C}_\ell$, a positive u one below it. A cubic coefficient more negative than the exact $-\nu/3$ adds to $-2\ln\mathcal{L}$ for $u < 0$ and subtracts for $u > 0$, so it penalises models above $\widehat{C}_\ell$ too much and models below too little, and the best fit is pulled low. A coefficient less negative than $-\nu/3$ pulls it high. So $\mathcal{L}_S$ ($-\nu$) biases the spectrum low; $\mathcal{L}_Q$ (0) penalises low C_ℓ too much and biases it high; the log-normal ($-\nu/2$) biases it low again, by less than $\mathcal{L}_S$. The WMAP combination was built to get the cubic term right [157]: weights w_Q and $w_{\rm LN} = 1 - w_Q$ must satisfy $w_Q \cdot 0 + w_{\rm LN}(-\nu/2) = -\nu/3$, so $w_{\rm LN} = 2/3$, which is why the weights are $1/3$ and $2/3$.

Example: how large is the bias of $\mathcal{L}_Q$? Fit an amplitude A, $C_\ell = AC_\ell^{\rm f}$, to a band of L multipoles on a noiseless full sky whose true spectrum is $C_\ell^{\rm f}$, the test of HL §IV A. Write $x_\ell = \widehat{C}_\ell / C_\ell^{\rm f}$, so that $\nu x_\ell \sim \chi^2_\nu$, with $\mathbb{E}\,x = 1$, $\mathrm{Var}\,x = 2/\nu$, $\mathbb{E}\,x^2 = 1 + 2/\nu$ and $\mathbb{E}\,x^3 = (\nu+2)(\nu+4)/\nu^2$ (moments of χ^2, Chapter 2). *The exact best fit.* The exact likelihood is $\sum \nu(x_\ell/A + \ln A)$, with derivative $\sum \nu(-x_\ell/A^2 + 1/A)$; it vanishes at $\hat{A} = \sum \nu x_\ell / \sum \nu$ (HL eq. 17), whose mean is exactly one. *The best fit of $\mathcal{L}_Q$.* $\mathcal{L}_Q$ is $\sum \frac{\nu}{2}(x_\ell/A - 1)^2$. Its derivative is

$$\frac{\mathrm{d}}{\mathrm{d}A} \sum \frac{\nu}{2}\Big(\frac{x_\ell}{A} - 1\Big)^2 = \sum \nu \Big(\frac{x_\ell}{A} - 1\Big)\Big(-\frac{x_\ell}{A^2}\Big),$$

and setting it to zero and multiplying by $-A^2$ gives $\sum \nu x_\ell^2 / A = \sum \nu x_\ell$, so $\hat{A}_Q = \sum \nu x_\ell^2 \big/ \sum \nu x_\ell$, a ratio N/D of two random sums. *The mean of a ratio.* Write $D = \mathbb{E}\,D\,(1+\delta)$ with $\delta = (D - \mathbb{E}\,D)/\mathbb{E}\,D$ small, and expand $1/(1+\delta) = 1 - \delta + \delta^2 - \ldots$:

$$\mathbb{E}\,\frac{N}{D} = \frac{\mathbb{E}[N(1-\delta+\delta^2)]}{\mathbb{E}\,D} + \cdots \simeq \frac{\mathbb{E}\,N}{\mathbb{E}\,D} - \frac{\mathrm{Cov}(N,D)}{(\mathbb{E}\,D)^2} + \frac{\mathbb{E}\,N\ \mathrm{Var}\,D}{(\mathbb{E}\,D)^3},$$

using two facts. Since $\mathbb{E}\,\delta = 0$, the mean $\mathbb{E}[N\delta]$ equals $\mathrm{Cov}(N,D)/\mathbb{E}\,D$; and, to leading order, $\mathbb{E}[N\delta^2] \simeq \mathbb{E}\,N\ \mathrm{Var}\,D/(\mathbb{E}\,D)^2$. With $\Sigma \equiv \sum_\ell \nu_\ell$,

$$\mathbb{E}\,\hat{A}_Q \overset{(1)}{=} \frac{\Sigma + 2L}{\Sigma} - \frac{4\Sigma}{\Sigma^2} + \frac{(\Sigma+2L)\,2\Sigma}{\Sigma^3} \overset{(2)}{=} 1 + \frac{2(L-1)}{\Sigma} + O(\Sigma^{-2}). \tag{9.120}$$

(1) $\mathbb{E}\,N = \sum \nu(1+2/\nu) = \Sigma + 2L$; $\mathbb{E}\,D = \Sigma$; $\mathrm{Var}\,D = \sum \nu^2 \cdot 2/\nu = 2\Sigma$; $\mathrm{Cov}(N,D) = \sum \nu^2\,\mathrm{Cov}(x^2, x) = \sum \nu^2(\mathbb{E}\,x^3 - \mathbb{E}\,x^2) = \sum \nu^2(4/\nu + 8/\nu^2) \simeq 4\Sigma$.
(2) Collect terms: $2L/\Sigma - 4/\Sigma + 2/\Sigma$, dropping terms of order L/Σ^2.

For HL's bins of $L = 10$ starting at $\ell_{\rm min}$, $\Sigma = \sum_{\ell=\ell_{\rm min}}^{\ell_{\rm min}+9}(2\ell+1) = 20\ell_{\rm min} + 100$, so the bias is $18/(20\ell_{\rm min}+100) = 0.9/(\ell_{\rm min}+5)$: about $0.9/\ell$, just inside the tolerance $1/\ell$ of Section 9.19.4. At $\ell_{\rm min} = 1022$ the formula gives 8.8×10^{-4}; the simulation below gives 8.770×10^{-4}, and HL's Fig. 1 shows 9.100×10^{-4}.

The fixed fiducial needs no such calculation. With $C_\ell^{\rm f}$ equal to the truth, $\mathcal{L}_f = \sum \frac{\nu}{2}(x_\ell - A)^2$, with derivative $-\sum \nu(x_\ell - A)$, is maximised at $\sum \nu x_\ell / \sum \nu$, *identical* to the exact $\hat{A}$ in every realisation. The reason is visible in the two derivatives. The exact one is $\sum \nu(A - x_\ell)/A^2$, the fixed-fiducial one $\sum \nu(A - x_\ell)$: they differ by the positive factor $1/A^2$, so they vanish together. The same holds for any parameter. With a general model $C_\ell(\boldsymbol{\theta})$ the exact derivative is $\sum \nu(C_\ell - \widehat{C}_\ell)\,\partial C_\ell / C_\ell^2$ and the fixed-fiducial one is $\sum \nu(C_\ell - \widehat{C}_\ell)\,\partial C_\ell/(C_\ell^{\rm f})^2$, so if the fiducial equals the best-fit model, $C_\ell^{\rm f} = C_\ell(\hat{\boldsymbol{\theta}})$, the two agree term by term at $\hat{\boldsymbol{\theta}}$, and the exact best fit is also a best fit of $\mathcal{L}_f$. This is why a fixed fiducial covariance gives unbiased parameters even though its shape at each ℓ is wrong (HL eqs. 38–39).

Example: what the bias means for a parameter. A relative bias of $0.9/\ell$ in the spectrum is larger at low ℓ than at high ℓ. A parameter that moves power between low and high multipoles, like the tilt n_s, therefore reads it as a tilt: power pushed up at low ℓ looks like a redder spectrum. HL found that $\mathcal{L}_Q$ shifts n_s by about one standard deviation at Planck sensitivity while $\mathcal{L}_f$ does not (HL §III C). We test both statements with our own chains in Sections 9.21.5 and 9.22.6.

9.19.4 Reproducing Hamimeche and Lewis, Fig. 1

Their question. In 2008, with Planck about to fly, every high-ℓ CMB analysis used one of the Gaussian shortcuts of Section 9.19.3, because the exact likelihood cannot be evaluated on a

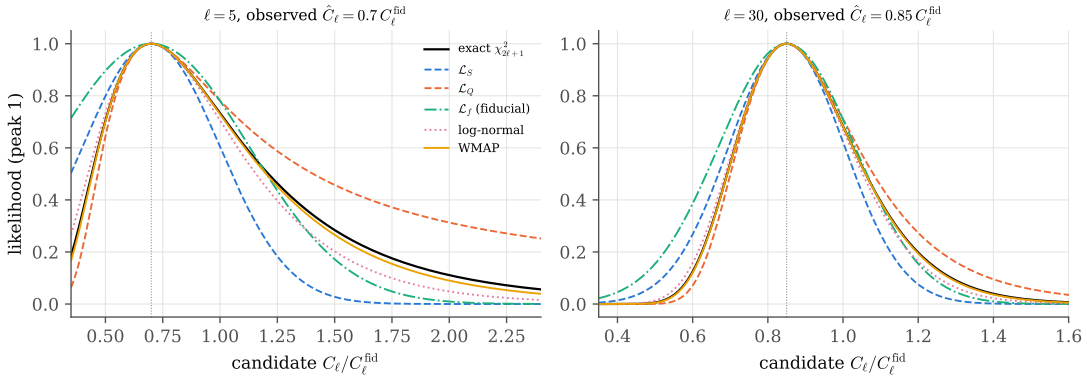

Figure 9.48: Likelihood of the true spectrum, in units of a fiducial one, after observing $\widehat{C}_\ell = 0.7\, C_\ell^{\rm fid}$ at $\ell = 5$ (left) and $0.85\, C_\ell^{\rm fid}$ at $\ell = 30$ (right). The exact likelihood (black) peaks at the observed value with a long tail to the right. The symmetric approximation $\mathcal{L}_S$ is too narrow on the high side; $\mathcal{L}_Q$ has far too heavy a tail there (it tends to a constant as C_ℓ grows); the fixed-fiducial $\mathcal{L}_f$ is symmetric; the WMAP combination is close to exact. At $\ell = 30$ all forms agree better: the distribution of $\widehat{C}_\ell$ becomes Gaussian as ℓ grows.

masked sky. Hamimeche and Lewis asked which of them is safe [16]: which ones return the same spectrum as the exact likelihood, to within an error small enough not to matter at Planck's precision? The cost of a wrong answer is a biased parameter: as the previous example showed, a bias that depends on ℓ reads as a tilt, and for $\mathcal{L}_Q$ it moves n_s by about one standard deviation.

Their setup, one item at a time. *The truth.* A fiducial spectrum $C_\ell^{\rm f}$, and many simulated full, noiseless skies drawn from it. On the full sky the exact likelihood is known, so each approximation can be compared with it sky by sky. *The test statistic.* The data are cut into bins of ten multipoles, $\ell_{\rm min} \le \ell \le \ell_{\rm min} + 9$, and in each bin one amplitude is fitted, $C_\ell = A C_\ell^{\rm f}$, by maximising the exact likelihood and each approximation in turn. An amplitude is the simplest parameter that a bias in the spectrum can move. *Bias and scatter.* For approximation i, the bias is the mean of $A_i - A_{\rm exact}$ over the simulated skies, and the scatter is the root-mean-square of the same difference. The bias says whether the approximation is systematically off; the scatter says how far it is off on a typical sky. *The tolerance.* An error matters only if it is comparable with the cosmic-variance error of the amplitude itself. For an amplitude fitted to all multipoles up to ℓ, the exact $\hat{A} = \sum \nu x_\ell / \sum \nu$ has variance $\sum \nu^2 (2/\nu)/(\sum \nu)^2 = 2/\sum \nu$, and $\sum_{\ell'=2}^{\ell} (2\ell' + 1) = (\ell + 1)^2 - 4 \approx \ell^2$, so its error is about $\sqrt{2}/\ell$. HL take $1/\ell_{\rm min}$ as the line below which a bias in one bin is harmless (their eqs. 19–20).

Their key equations. The exact best fit and the best fits of the approximations are those derived in Section 9.19.3: $\hat{A} = \sum \nu x_\ell / \sum \nu$ for the exact likelihood and for $\mathcal{L}_f$, and $\hat{A}_Q = \sum \nu x_\ell^2 / \sum \nu x_\ell$ for $\mathcal{L}_Q$, whose bias is (9.120) (HL eqs. 17–20). The symbols map directly: x_ℓ is the ratio $\widehat{C}_\ell / C_\ell^{\rm f}$ of the simulated to the fiducial spectrum, $\nu = 2\ell + 1$ the number of modes at ℓ on the full sky, and $L = 10$ the width of a bin.

What we compute. Only x_ℓ matters, and $\nu x_\ell \sim \chi^2_\nu$ exactly ((9.115)), so we draw the x_ℓ directly from χ^2 distributions, 10000 realisations per bin as in the paper, for 70 values of $\ell_{\rm min}$ between 2 and 1500. The best fits of $\mathcal{L}_S$, $\mathcal{L}_Q$ and the log-normal have closed forms; for Gaussian$_D$, WMAP and the cube-root form we use a vectorised golden-section search, as HL did. The likelihood functions are:

Listing 9.12: The exact likelihood and its approximations at one multipole (code/ch09/42_cl_likelihoods.py)

```
def m2lnL(kind, x, A, l):
    """-2 ln L (up to a constant) at multipole l, observed x = C_hat / C_fid, candidate C = A C_fid."""
    nu = 2 * l + 1.0
    if kind == "exact":
        return nu * (x / A + np.log(A))
    if kind == "S":
        return nu / 2 * ((x - A) / x) ** 2
    if kind == "Q":
        return nu / 2 * ((x - A) / A) ** 2
    if kind == "D":
        return nu / 2 * ((x - A) / A) ** 2 + np.log(A)
    if kind == "f":                                  # fixed fiducial in the denominator (24)
        return nu / 2 * (x - A) ** 2
    if kind == "LN":
        return nu / 2 * np.log(x / A) ** 2
    if kind == "WMAP":
        return (1 / 3) * m2lnL("Q", x, A, l) + (2 / 3) * m2lnL("LN", x, A, l)
    if kind == "cube":
        al = -1.0
        c = ((2 * l + al) / nu) ** (1 / 3)
        return nu * 4.5 * c * ((x / A) ** (1 / 3) - c) ** 2 + (1 - al) * np.log(A)
    if kind == "HL":                                 # g(x)^2 form, eq. (44); equals exact - const
        z = x / A
        g2 = 2 * (z - np.log(z) - 1)
        return nu / 2 * g2
    raise ValueError(kind)
```

For the published curves we read the vector paths of HL's Fig. 1 directly from the PDF and convert them to data coordinates with the tick marks.

Side by side. Figure 9.49 overlays the two, and the table compares them at $\ell_{\min} = 1022$ (and the scatter also at $\ell_{\min} = 102$):

	bias $\lvert\langle A_i - A_{\text{exact}}\rangle\rvert$		scatter $\langle (A_i - A_{\text{exact}})^2\rangle^{1/2}$	
	HL Fig. 1	ours	HL Fig. 1	ours ($\ell_{\min} = 102$)
$\mathcal{L}_S$	0.0018	0.00175	0.002	0.00194 (0.0187)
$\mathcal{L}_Q$	9.100×10^{-4}	8.770×10^{-4}	0.001	9.700×10^{-4} (0.00936)
Gaussian$_D$	4.000×10^{-4}	3.890×10^{-4}	5.800×10^{-4}	5.690×10^{-4} (0.00546)
WMAP	noise	5.500×10^{-8}	5.000×10^{-6}	4.480×10^{-6} (1.350×10^{-4})
cube root	noise	6.430×10^{-8}	1.400×10^{-6}	7.510×10^{-7} (2.330×10^{-5})

In units of $1/\ell$ the biases are 1.79 ($\mathcal{L}_S$, outside the tolerance), 0.90 ($\mathcal{L}_Q$, as predicted by (9.120)) and 0.40 (Gaussian$_D$).

Why they differ.

1. *Reading precision.* The symmetric Gaussian, the quadratic form and Gaussian$_D$ agree with the paper to a few per cent, which is the precision of reading a curve off a plot.[6]

[6] For Gaussian$_D$ we used HL's eq. (25) as printed, $\mathcal{L}_Q$ plus $\ln C_\ell$ once per multipole; this is the form that reproduces their curve.

2. *Monte Carlo noise.* The WMAP and cube-root biases are of order 10^{-7}. A mean of 10^4 differences whose scatter is a few times 10^{-6} has a Monte Carlo error of $4\times10^{-6}/\sqrt{10^4} = 4\times10^{-8}$, so these biases are that noise: both curves, the paper's and ours, jitter because they measure nothing but the random draws. The scatter of the WMAP form matches.

3. *An unspecified variant.* Our cube-root scatter, 7.510×10^{-7}, is about half the published 1.400×10^{-6}. HL plot the cube-root form without saying which of their two variants ($\alpha = \pm1$ in eq. 28) is shown, and we used $\alpha = -1$. Either way it is three orders of magnitude inside the tolerance, and the conclusion is the same.

A final check. HL's own new approximation (their eqs. 41–50) is built on $g(x) = \mathrm{sign}(x-1)\sqrt{2(x-\ln x-1)}$, with $x = \widehat{C}_\ell/C_\ell$ the ratio to the model. By (9.118) with $1+u = x$, the exact $-2\ln\mathcal{L}$ minus its minimum is $\nu[(x-1)-\ln x] = \nu(x-\ln x-1)$, and $g(x)^2 = 2(x-\ln x-1)$, so

$$-2\ln\mathcal{L}_{\text{exact}} = \tfrac{\nu}{2}\,g(x)^2.$$

On the full sky the exact likelihood is therefore a Gaussian in the variable g, with variance $2/\nu$: the same quadratic shape as the shortcuts, but in a variable chosen so that it is exact. On a cut sky the variance $2/\nu$ is replaced by a covariance of the g values measured on simulations, as for the other forms. Our best fits with it equal the exact ones to 1.500×10^{-8}, the precision of the search.

The lesson. All the shortcuts are right at the peak; what separates safe from unsafe is the cubic term, and the "biases" of the safe ones in the published figure are Monte Carlo noise, which only rerunning the test reveals.

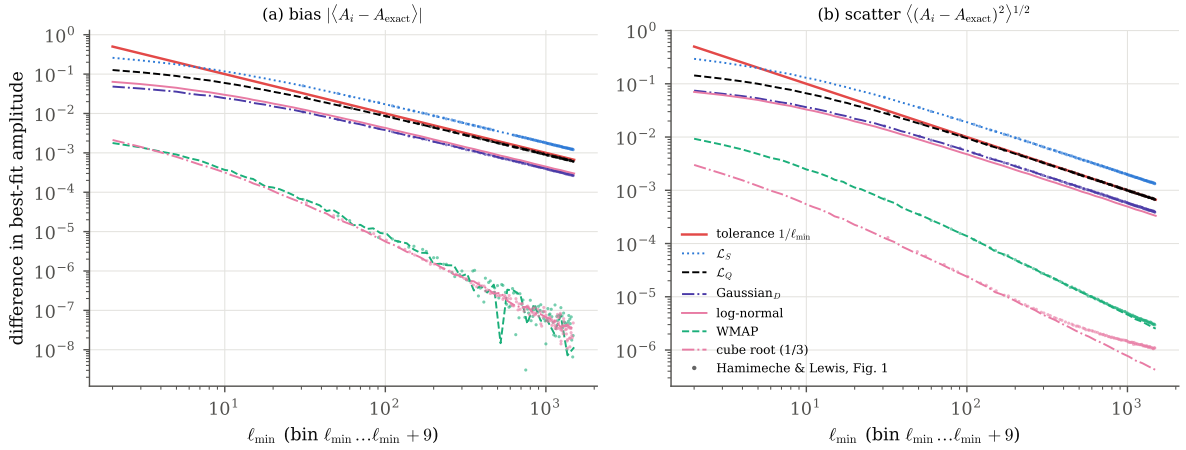

Figure 9.49: Reproduction of Fig. 1 of Hamimeche and Lewis. For bins of ten multipoles starting at $\ell_{\min}$, the bias (a) and the scatter (b) of the best-fit amplitude under each approximation, relative to the exact likelihood, from 10^4 simulated full skies per bin (lines), with the curves read from the published figure (dots) and the tolerance $1/\ell_{\min}$ (red). The symmetric $\mathcal{L}_S$ fails; $\mathcal{L}_Q$ sits on the tolerance; WMAP and the cube-root forms are far inside, and their biases are Monte Carlo noise.

What Planck does. The Planck 2018 temperature likelihood is a hybrid split at $\ell = 30$ [70]. Below it, where the skewness of Figure 9.48 is large, Planck uses the exact likelihood in a form that survives the mask and the noise [158]. Call $\boldsymbol{s}$ the full-sky signal, the sky we would see with no mask and no noise, and $\boldsymbol{d}$ the masked, noisy data. If we knew $\boldsymbol{s}$ the problem would be the one already solved: its spectrum, which we call σ_ℓ (the spectrum of a full sky, as $\widehat{C}_\ell$ was),

would enter (9.114). We do not know $\boldsymbol{s}$, so we average over what the data allow it to be. With a flat prior on C_ℓ,

$$p(C_\ell \mid \boldsymbol{d}) \overset{(1)}{=} \int p(C_\ell \mid \boldsymbol{s}, \boldsymbol{d})\, p(\boldsymbol{s} \mid \boldsymbol{d})\, \mathrm{d}\boldsymbol{s} \overset{(2)}{=} \int p(C_\ell \mid \boldsymbol{s})\, p(\boldsymbol{s} \mid \boldsymbol{d})\, \mathrm{d}\boldsymbol{s}$$
$$\overset{(3)}{=} \frac{1}{N_\mathrm{G}} \sum_{i=1}^{N_\mathrm{G}} p(C_\ell \mid \boldsymbol{s}^i) \overset{(4)}{=} \frac{1}{N_\mathrm{G}} \sum_{i=1}^{N_\mathrm{G}} \prod_{\ell=2}^{29} \frac{\mathrm{const}}{\sigma_\ell^i} \left(\frac{\sigma_\ell^i}{C_\ell}\right)^{\nu/2} e^{-\nu\sigma_\ell^i/2C_\ell}. \tag{9.121}$$

(1) The full sky is an unknown intermediate; marginalise it, with the product rule.
(2) Once the full sky is known, the masked and noisy data add nothing about its spectrum.
(3) Replace the integral over $p(\boldsymbol{s} \mid \boldsymbol{d})$ by an average over N_G samples $\boldsymbol{s}^i$ drawn from it; the average approaches the integral as N_G grows (Section 9.6).
(4) $p(C_\ell \mid \boldsymbol{s})$ depends on $\boldsymbol{s}$ only through its spectrum σ_ℓ, so it is (9.114) with $\widehat{C}_\ell \to \sigma_\ell^i$ and $\nu = 2\ell + 1$, normalised over C_ℓ: the integral $\int C_\ell^{-\nu/2} e^{-\nu\sigma/2C_\ell} \mathrm{d}C_\ell$ is proportional to $\sigma^{1-\nu/2}$ by line 1 of (9.117), so the normalised density carries the factor $\sigma^{\nu/2-1}$, which is written as $(1/\sigma)\,\sigma^{\nu/2}$. Different ℓ are independent given $\boldsymbol{s}$.

The samples $\boldsymbol{s}^i$ come from a Gibbs sampler (Section 9.16.1) that alternates between drawing a full sky given the data and the current spectrum, and drawing a spectrum given that sky; each $\boldsymbol{s}^i$ is one full sky compatible with the masked, noisy map, and σ_ℓ^i is its spectrum. The last line is Planck 2018 V, eq. 2, the Blackwell–Rao estimator: the exact full-sky likelihood averaged over what the mask and the noise hide. The factor $(\sigma_\ell^i)^{\nu/2-1}$, which a single sky could drop because it does not depend on C_ℓ, now matters, because it differs from sample to sample. Above $\ell = 30$ Planck uses a Gaussian in the cross-spectra with a covariance computed for a fixed fiducial model (their eq. 20): the multi-field, cut-sky version of $\mathcal{L}_f$. Their footnote 12 records that the symmetric shape biases n_s by about 0.1σ, and that they ignore it. Section 9.22.6 measures the bias of this choice in our idealised setting.

9.20 A model spectrum fast enough for a chain

Equation (9.113) says that every step of the chain needs the spectrum $C_\ell(\boldsymbol{\theta})$ at the proposed parameters. The honest way to get it is a Boltzmann code. CAMB [8] computes a lensed temperature spectrum to $\ell = 2500$ in about 0.9 s on the laptop. A run of four chains of 40 000 steps, the size used in Section 9.22, would then take some forty hours, and the whole point of a chain is that it can be rerun when something changes. Research codes pay this price on a cluster (Section 9.23). We replace the Boltzmann code by an **emulator** [a cheap function that reproduces the code's output over the region of parameter space the chain will visit], built once from a few dozen CAMB calls and checked against CAMB before it is trusted.

The question. How do we build a function that returns $C_\ell(\boldsymbol{\theta})$ in microseconds, and how do we know it is accurate enough? "Accurate enough" has a precise meaning: the emulator's error must change $-2\ln\mathcal{L}$ by much less than one anywhere the posterior has weight, because a change of one in $-2\ln\mathcal{L}$ is what moves a parameter by one standard deviation.

9.20.1 Expand the logarithm

We use a Taylor series around the fiducial Planck 2018 model $\boldsymbol{\theta}_0$, in six parameters $\boldsymbol{\theta} = (\ln 10^{10} A_s,\, n_s,\, H_0,\, \omega_b,\, \omega_c,\, \tau)$. The first two describe the primordial fluctuations: A_s is their amplitude at the pivot wavenumber k_* and n_s their tilt, how that amplitude changes with

scale (Section 8.7.3). H_0 is the present expansion rate. $\omega_b = \Omega_b h^2$ and $\omega_c = \Omega_c h^2$ are the physical densities of baryons and of cold dark matter, their density parameters times h^2 with $h = H_0/(100\,\mathrm{km\,s^{-1}\,Mpc^{-1}})$, which fix their actual mass per unit volume. τ is the optical depth to reionisation: a CMB photon scatters off a free electron after the Universe was reionised with probability $1 - e^{-\tau} \approx \tau$. The fiducial values, those of CAMB's input everywhere in the book, are

$\ln(10^{10}A_s)$	n_s	H_0 ($\mathrm{km\,s^{-1}\,Mpc^{-1}}$)	ω_b	ω_c	τ
3.044	0.9649	67.36	0.02237	0.1200	0.0544

with $A_s = 2.100 \times 10^{-9}$ at $k_* = 0.05\,\mathrm{Mpc^{-1}}$. The question is: a series for what? Look at how the parameters enter. The primordial power is $P(k) = A_s(k/k_*)^{n_s-1}$ with the pivot $k_* = 0.05\,\mathrm{Mpc^{-1}}$, and the spectrum is a weighted integral of it, $C_\ell = \int \mathrm{d}k\, T(\ell,k)\, P(k)$ with a transfer function $T \geq 0$ (the scalar term of the cosmology notes' $\sum_m \int T_m P_m$). Reionisation multiplies the spectrum at $\ell \gg 10$ by $e^{-2\tau}$ (cosmology notes). So, writing $x = \ln(k/k_*)$,

$$\ln C_\ell \overset{(1)}{=} \ln A_s - 2\tau + \ln \int \mathrm{d}k\, T(\ell,k)\, e^{(n_s-1)x},$$

$$\frac{\partial \ln C_\ell}{\partial n_s} \overset{(2)}{=} \frac{\int \mathrm{d}k\, T\, e^{(n_s-1)x}\, x}{\int \mathrm{d}k\, T\, e^{(n_s-1)x}} \equiv \langle x \rangle_\ell, \qquad \frac{\partial^2 \ln C_\ell}{\partial n_s^2} \overset{(3)}{=} \langle x^2 \rangle_\ell - \langle x \rangle_\ell^2 \geq 0. \tag{9.122}$$

(1) A_s and $e^{-2\tau}$ are overall factors (for $\ell \gg 10$, ignoring lensing, which depends weakly on A_s too), and $(k/k_*)^{n_s-1} = e^{(n_s-1)x}$.

(2) Differentiate the logarithm of the integral: the derivative of the exponent brings down x. The ratio is the average of x over the normalised weight $T\, e^{(n_s-1)x}$, the range of wavenumbers that feed multipole ℓ.

(3) Differentiate the ratio once more (quotient rule): the result is the variance of x under the same weight.

So $\ln C_\ell$ is exactly linear in $\ln A_s$ and τ, and nearly linear in n_s: its curvature in n_s is the variance of $\ln k$ over the wavenumbers that contribute to one multipole, a small number. The spectrum itself is *not* linear in these parameters ($C_\ell \propto A_s$ is linear, but $e^{-2\tau}$ and $e^{(n_s-1)x}$ are not). The expansion we use is therefore

$$\ln C_\ell(\boldsymbol{\theta}) \simeq \ln C_\ell(\boldsymbol{\theta}_0) + \sum_i D_{i\ell}\, \delta\theta_i + \tfrac{1}{2} \sum_{ij} H_{ij\ell}\, \delta\theta_i \delta\theta_j, \qquad D_{i\ell} = \frac{\partial \ln C_\ell}{\partial \theta_i}, \quad H_{ij\ell} = \frac{\partial^2 \ln C_\ell}{\partial \theta_i \partial \theta_j}, \tag{9.123}$$

at first or second order, with all derivatives at $\boldsymbol{\theta}_0$.

Example: the derivatives read as physics. CAMB gives, by central differences, $\partial \ln C_\ell/\partial\tau = -2.00$ averaged over $500 \leq \ell \leq 2000$: the factor $e^{-2\tau}$ exactly. It gives $\partial \ln C_\ell/\partial n_s = 0.55$ at $\ell = 1000$ and -3.61 at $\ell = 10$; by (9.122) these are average values of $\ln(k/k_*)$, so multipole 1000 is fed by wavenumbers about $e^{0.55} \approx 1.7$ times the pivot and multipole 10 by wavenumbers some forty times smaller. Somewhere between, at a multipole of a few hundred, the average is zero: that multipole sees the pivot, and changing n_s leaves it unchanged, which is the meaning of the pivot (Chapter 8). The second derivative at $\ell = 1000$ is 0.08, a spread of about 0.3 in $\ln k$. The second derivative in $\ln A_s$ is at most 0.041 for $30 \leq \ell \leq 2000$: it would be zero without lensing, whose strength also grows with A_s. Figure 9.50 plots all six first derivatives, each multiplied by that parameter's expected error so that the curves show how much one standard deviation of each parameter changes the spectrum.

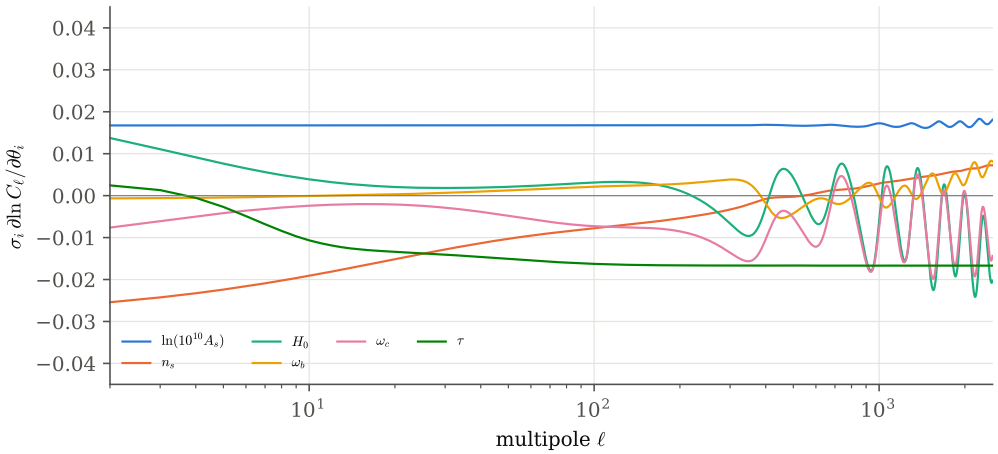

Figure 9.50: What one standard deviation of each parameter does to $\ln C_\ell$. The amplitude (blue) and the optical depth (dark green) give flat, opposite responses above $\ell \approx 30$: a temperature spectrum alone cannot separate them. The tilt n_s (orange) rotates the spectrum about a multipole of several hundred. H_0, ω_b and ω_c move and reshape the acoustic peaks, hence the oscillations.

9.20.2 Building it

The derivatives come from central differences. For one parameter with step h, $f(\theta \pm h) = f \pm hf' + \frac{1}{2}h^2 f'' \pm \frac{1}{6}h^3 f''' + \ldots$, so

$$\frac{f(\theta+h) - f(\theta-h)}{2h} \overset{(1)}{=} f' + \tfrac{1}{6}h^2 f''', \qquad \frac{f(\theta+h) - 2f(\theta) + f(\theta-h)}{h^2} \overset{(2)}{=} f'' + \tfrac{1}{12}h^2 f'''', \quad (9.124)$$

(1) Subtract the two series: even powers cancel.
(2) Add them: odd powers cancel.

both with errors of order h^2. Mixed second derivatives use the four corners $(\pm h_i, \pm h_j)$. For $d = 6$ parameters that is $1 + 2d + 4\binom{d}{2} = 73$ CAMB calls, about a minute; the steps (0.02 in $\ln 10^{10} A_s$, 0.01 in n_s, 0.5 in H_0, 0.0003 in ω_b, 0.003 in ω_c, 0.01 in τ) are those of the finite-difference study of Chapter 8. Evaluating the emulator is two small matrix products:

Listing 9.13: The emulator: ln C to first or second order (`code/ch09/lib_cmbemu.py`)

```
    def cl(self, theta):
        dt = np.asarray(theta, float) - self.fid
        if self.linear_in_C:                          # Taylor series of C itself, first order
            return self.c0 * (1.0 + dt @ self.D)
        x = dt @ self.D
        if self.order == 2:
            x = x + 0.5 * np.einsum("i,ijl,j->l", dt, self.H, dt)
        out = np.exp(self.lnc0 + x)
        out[:2] = 0.0
        return out
```

It takes 54 μs, 16496 times faster than CAMB, which turns forty hours of chain into a few seconds.

9.20.3 How accurate is accurate enough?

To check the emulator we need the scale on which it must be right, and that scale is set by the data. Our target experiment is Planck-like: one channel with a 7.22′ Gaussian beam and

white noise of 33 μK arcmin, the 143 GHz values of Planck 2018 [159], on $f_{\rm sky} = 0.57$ of the sky, $2 \le \ell \le 2500$. Its noise power, deconvolved by the beam, is $N_\ell = \Delta_T^2\, e^{\ell(\ell+1)\sigma_b^2}$, with Δ_T the depth in μK rad and $\sigma_b = \mathrm{FWHM}/\sqrt{8\ln 2}$ (Chapter 8). How far does a model error δC_ℓ move $-2\ln\mathcal{L}$? Expand the exact likelihood (9.114), with $C_\ell \to C_\ell + N_\ell$ and $\nu = (2\ell+1)f_{\rm sky}$, about the true spectrum and average over data; at one multipole, with $C = C_\ell + N_\ell$,

$$\mathbb{E}\Big[-2\ln\mathcal{L}(C+\delta C)\Big] - \mathbb{E}\Big[-2\ln\mathcal{L}(C)\Big] \overset{(1)}{=} \nu\Big[\frac{C}{C+\delta C} + \ln(C+\delta C) - 1 - \ln C\Big]$$
$$\overset{(2)}{=} \nu\Big[-\epsilon + \epsilon^2 + \epsilon - \tfrac{1}{2}\epsilon^2 + O(\epsilon^3)\Big] \overset{(3)}{=} \frac{\nu}{2}\Big(\frac{\delta C}{C_\ell + N_\ell}\Big)^2 + O(\epsilon^3), \tag{9.125}$$

(1) $\mathbb{E}\,\widehat{C}_\ell = C$ (the estimator is unbiased), so the data enter only through their mean.
(2) With $\epsilon = \delta C/C$: $1/(1+\epsilon) = 1 - \epsilon + \epsilon^2 - \dots$ and $\ln(1+\epsilon) = \epsilon - \epsilon^2/2 + \dots$.
(3) The linear terms cancel, because the true spectrum maximises the expected likelihood.

Summed over ℓ this is $\Delta\chi^2 = \sum_\ell \frac{\nu}{2}[\delta C_\ell/(C_\ell + N_\ell)]^2$, the change of $-2\ln\mathcal{L}$ that the emulator error alone produces. The same expansion measures a change of parameters. A small step $\delta\boldsymbol{\theta}$ changes the spectrum by $\delta C_\ell = \sum_i \partial_i C_\ell\, \delta\theta_i$, with $\partial_i \equiv \partial/\partial\theta_i$, and substituting it,

$$\Delta\chi^2 \overset{(1)}{=} \sum_\ell \frac{\nu}{2}\Big(\sum_i \frac{\partial_i C_\ell\, \delta\theta_i}{C_\ell + N_\ell}\Big)^2 \overset{(2)}{=} \sum_{ij} \delta\theta_i\, \delta\theta_j \sum_\ell \frac{\nu}{2}\,\frac{\partial_i C_\ell\, \partial_j C_\ell}{(C_\ell + N_\ell)^2} \overset{(3)}{=} \delta\boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\,\delta\boldsymbol{\theta}, \tag{9.126}$$

(1) (9.125) with $\delta C = \sum_i \partial_i C_\ell\, \delta\theta_i$.
(2) The square of a sum is a double sum, $(\sum_i a_i)^2 = \sum_{ij} a_i a_j$; the $\delta\theta$ do not depend on ℓ and come out of the sum over ℓ.
(3) Name the inner sum F_{ij}.

with the **Fisher matrix**

$$F_{ij} = \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2}\,\frac{\partial_i C_\ell\, \partial_j C_\ell}{(C_\ell + N_\ell)^2}\,\Big[+\frac{1}{\sigma_\tau^2}\ \text{for } i = j = \tau\Big], \tag{9.127}$$

which Chapter 10 develops in full. The bracket is the Gaussian prior on τ, of width $\sigma_\tau = 0.0086$, that stands in for Planck's low-ℓ polarization ("lowE") measurement [25]. A Gaussian prior adds $(\tau - \tau_{\rm obs})^2/\sigma_\tau^2$ to $-2\ln\mathcal{L}$; a step $\delta\tau$ raises that term by $\delta\tau^2/\sigma_\tau^2$, which is $\delta\boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\,\delta\boldsymbol{\theta}$ with $1/\sigma_\tau^2$ added to $F_{\tau\tau}$ alone. Without the prior a temperature spectrum cannot separate A_s from τ (Figure 9.50). The posterior near its peak is then $\propto e^{-\delta\boldsymbol{\theta}^{\mathsf{T}}\mathbf{F}\delta\boldsymbol{\theta}/2}$, a Gaussian with covariance $\mathbf{F}^{-1}$, so the error of parameter i with all the others free is $\sigma_i = \sqrt{(\mathbf{F}^{-1})_{ii}}$, not $1/\sqrt{F_{ii}}$; the second is the error with all the others held fixed, and the two differ whenever parameters are correlated (Section 10.4.1, (10.24)). Holding fixed a parameter that is in fact unknown is what produces the factor of nine in $\ln(10^{10}A_s)$ of Section 9.22. The expected errors σ_i set the natural size of a step: 0.01674 in $\ln 10^{10}A_s$, 0.005293 in n_s, 0.9365 in H_0, 0.0002014 in ω_b, 0.002157 in ω_c and 0.008346 in τ. With only $(\ln 10^{10}A_s, n_s)$ free and the rest fixed, F is the 2×2 corner and the errors shrink to 0.0018 and 0.0026, with correlation -0.73; we return to these numbers in Section 9.22.

Now the test. We compare three emulators, the series in C_ℓ itself to first order, the series in $\ln C_\ell$ to first order, and the series in $\ln C_\ell$ to second order, against direct CAMB calls, at two kinds of points: along each parameter axis at ±1, ±3 and $\pm5\sigma_i$, and at 40 random points drawn from the Fisher Gaussian with its widths doubled, which reach out to 7.3σ from the fiducial.

$\Delta\chi^2$ from the emulator error	axes, $\pm1\sigma$ (max)	axes, $\pm5\sigma$ (max)	random (median)	random (max)
first order in C_ℓ	0.054	35.5	0.0535	2
first order in $\ln C_\ell$	0.0485	33	0.0484	1.98
second order in $\ln C_\ell$	5.290×10^{-5}	0.515	6.550×10^{-4}	0.0964

With six free parameters the first-order series are not good enough: at 5σ along one axis they are wrong by tens in χ^2, and at random points within the posterior they reach $\Delta\chi^2 \approx 2$. Their errors oscillate with the acoustic peaks (Figure 9.51a): H_0, ω_b and ω_c move the peaks sideways, and a sideways shift of an oscillating function is not linear in the size of the shift. The second-order series in $\ln C_\ell$ stays below $\Delta\chi^2 = 0.1$ everywhere we tested (Figure 9.51b). With only $(\ln 10^{10} A_s, n_s)$ free, for which (9.122) promised near-linearity, the first-order series in $\ln C_\ell$ is already enough: its worst error at the four corners $(\pm5\sigma, \pm5\sigma)$ is $\Delta\chi^2 = 2.890 \times 10^{-5}$. These are the two emulators we use: first order for two or three parameters, second order for six.

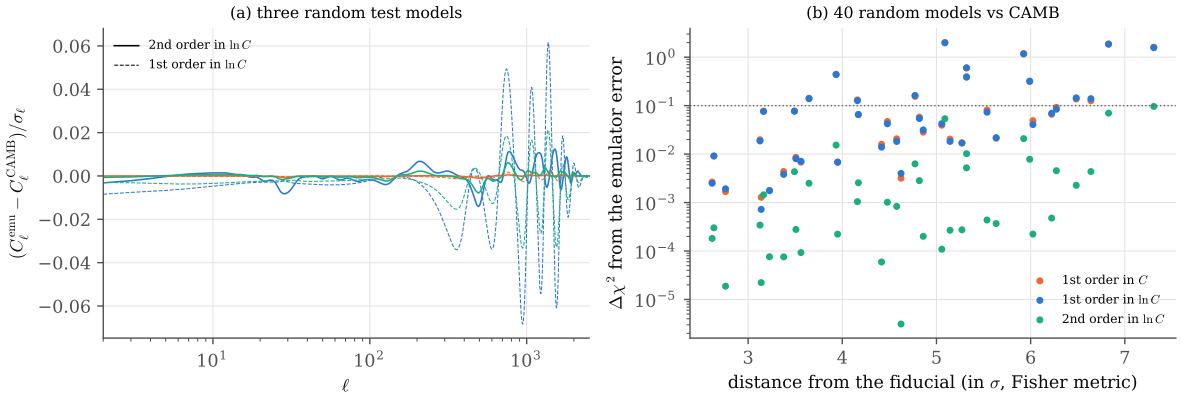

Figure 9.51: Testing the emulator against CAMB. (a) For three random models, the emulator error at each ℓ in units of the error bar of one multipole: second order in $\ln C_\ell$ (solid) against first order (dotted); the first-order errors oscillate with the acoustic peaks. (b) The $\Delta\chi^2$ produced by the emulator error at 40 random models, against their distance from the fiducial; the dotted line is $\Delta\chi^2 = 0.1$.

Example: what $\Delta\chi^2 = 0.1$ does to a posterior. An error $\Delta\chi^2$ in $-2\ln\mathcal{L}$ multiplies the posterior density at that point by $e^{-\Delta\chi^2/2}$. If the error were a constant, it would cancel in the normalisation; what matters is how it varies across the posterior. Errors that vary by 0.1 across the posterior reweight its regions by at most $e^{0.05} \approx 1.05$: a five per cent reweighting of the tails, which moves means by a few hundredths of a standard deviation. Section 9.23.1 measures this directly by reweighting the six-parameter chain with CAMB itself.

Laptop versus research. Our emulator costs 73 Boltzmann calls and is valid only within a few standard deviations of the fiducial model; it could not explore a prior much wider than the posterior or a cosmology far from Planck's. Research analyses either call CAMB or CLASS at every step, with the fast and slow parameters of Section 9.16 updated at different rates [37], or train a neural-network emulator on 10^5 Boltzmann runs spread over the whole prior, as CosmoPower does [160]. Either way the principle is the one used here: validate the fast model against the slow one on the posterior itself.

9.21 Cosmological parameters from one simulated sky

Chapter 8 built a small CMB experiment on the laptop and studied what it does to the power spectrum: a 30′ beam, white noise of 200 μK arcmin, maps at HEALPix resolution $N_{\rm side} = 256$, and a Galactic band $|b| < 20^\circ$ masked with edges tapered over 5°. It produced the sampling distribution of the measured spectrum, including a covariance of the masked bandpowers from 2000 simulated skies. Everything needed for inference is now in place: the likelihood (Section 9.19), a fast model (Section 9.20), and the sampler. We take one simulated sky, observe it three ways, and ask what each observation says about two parameters of the primordial spectrum, the amplitude $\ln(10^{10}A_s)$ and the tilt n_s, with the other four ΛCDM parameters held at their true values.

The question. The reasoning is that of Section 9.19: every candidate pair of amplitude and tilt is a hypothesis about the sky, and the measured spectrum is asked how probable it would have been under each. How does the posterior of $(\ln 10^{10}A_s, n_s)$ change from (a) a perfect, noiseless view of the whole sky, to (b) the same sky seen through the beam and the noise, to (c) the noisy sky behind the Galactic mask? And are the chains' answers the ones the Fisher matrix predicts?

9.21.1 One sky, three observations, three likelihoods

One set of $a_{\ell m}$ is drawn from the fiducial spectrum up to $\ell = 767$, and the analysis uses $2 \le \ell \le 601$ (Figure 9.52). The three data sets and their likelihoods are:

(a) The sky itself. $\widehat{C}_\ell$ is the spectrum of the $a_{\ell m}$ themselves, and the likelihood is the exact full-sky form (9.114) with $\nu = 2\ell + 1$, summed over ℓ.

(b) The full sky with beam and noise. $\widehat{C}_\ell^{\rm obs}$ is the spectrum of the observed map, and the likelihood is the same exact form with the model spectrum replaced by what the instrument should see, $T_\ell^2 C_\ell(\boldsymbol{\theta}) + N_\ell$, where T_ℓ is the beam and pixel window and N_ℓ the white-noise power (Section 9.19.2). Nothing is approximated: on the full sky with isotropic noise this is still exact.

(c) The masked noisy sky. The data are the 30 MASTER bandpowers $\widehat{D}_b$ of Chapter 8, in bins of 20 multipoles, from the masked map ($f_{\rm sky} = 0.658$ of the sky has nonzero weight). The model predicts them through the bandpower windows, $D_b(\boldsymbol{\theta}) = \sum_\ell \mathcal{F}_{b\ell} C_\ell(\boldsymbol{\theta})$, which encode what the binning, the mask deconvolution and the beam do to a theory spectrum [140]. Their distribution is no longer known exactly, so we use a Gaussian with the covariance $\widehat{\mathbf{C}}$ measured on the 2000 simulations of Chapter 8. That covariance is an unbiased estimate, but its inverse, which is what the likelihood uses, is not: inverting magnifies the directions in which the simulations happened to scatter too little, and for n simulations of p bandpowers the inverse comes out too large on average by the factor $(n-1)/(n-p-2)$ (Section 8.13.2, (8.78)). A χ^2 built with it would be too large, and the errors too small. We therefore multiply the inverse by the reciprocal, the Hartlap factor $(n-p-2)/(n-1) = 0.9845$ for $n = 2000$ and $p = 30$ [6]. With two thousand simulations for thirty bins the correction is small: every χ^2 shrinks by 1.5 per cent and every error grows by $1/\sqrt{0.9845} \approx 1.008$, under one per cent. The likelihood is

$$-2\ln\mathcal{L} = \big(\widehat{\boldsymbol{D}} - \boldsymbol{D}(\boldsymbol{\theta})\big)^{\mathsf{T}} \, \frac{n-p-2}{n-1} \, \widehat{\mathbf{C}}^{-1} \, \big(\widehat{\boldsymbol{D}} - \boldsymbol{D}(\boldsymbol{\theta})\big). \tag{9.128}$$

The covariance is fixed, computed once at the fiducial model: this is the $\mathcal{L}_f$ of Section 9.19.3 on a cut sky, the form Planck uses at high ℓ. Binning by 20 makes each bandpower an average of about $20 \times (2\ell+1) f_{\rm sky}$ modes, close to Gaussian except in the first bin or two, where the cost of the approximation is concentrated.

In code the three log-posteriors are three short functions (the prior is a wide box):

Listing 9.14: The three likelihoods of the simulated sky (`code/ch09/44_cmb_mcmc.py`)

```
def lp_full(th):
    if not inprior(th):
        return -np.inf
    c = emu.cl(th)
    return -0.5 * np.sum(nu[use] * (chat_sky[use] / c[use] + np.log(c[use])))

def lp_noisy(th):
    if not inprior(th):
        return -np.inf
    c = T2 * emu.cl(th) + Nw                          # what the instrument's spectrum
    should be
    return -0.5 * np.sum(nu[use] * (chat_obs[use] / c[use] + np.log(c[use])))

def lp_mask(th):
    if not inprior(th):
        return -np.inf
    r = Db - Fwin @ emu.cl(th)
    return -0.5 * r @ Cinv @ r
```

The model spectrum `emu.cl` is the first-order series in $\ln C_\ell$ in the two free parameters, which Section 9.20.3 showed to be accurate to $\Delta\chi^2 < 10^{-4}$ out to five standard deviations.

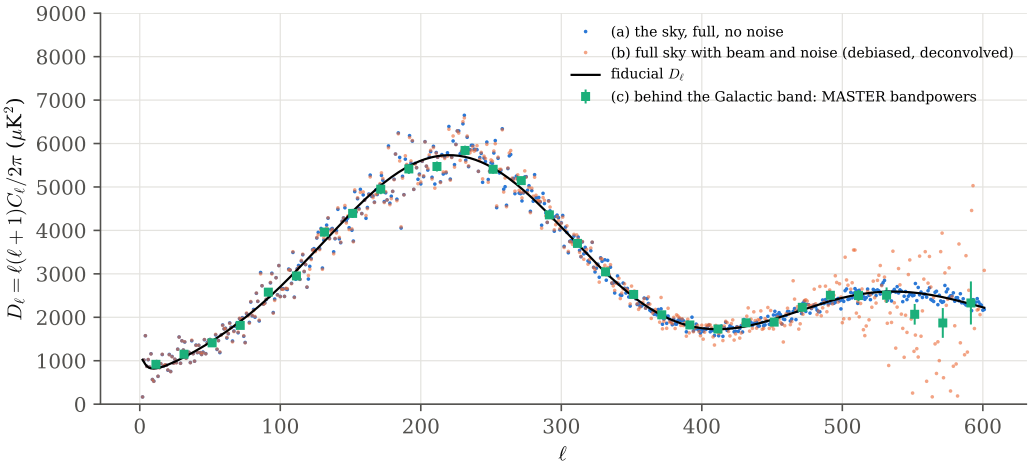

Figure 9.52: The data of the three analyses, as $D_\ell = \ell(\ell+1)C_\ell/2\pi$. (a) The spectrum of the simulated sky itself, scattering about the fiducial model (black) by cosmic variance. (b) The spectrum of the observed full-sky map, with the noise power subtracted and the beam divided out for display; above $\ell \approx 400$ the noise dominates and the scatter grows. (c) MASTER bandpowers from the masked map, with error bars from the 2000 simulations.

9.21.2 The chains and their diagnostics

For each case we run 4 chains of 20000 steps, started at random up to six expected standard deviations from the truth, with the proposal shaped by the Fisher covariance of that case and scaled by $2.38/\sqrt{2}$ (Section 9.11.2), and drop 2000 steps of burn-in. Each case takes about a second. Before reading off any number we look at the diagnostic panel that Kruschke recommends [Kruschke §8.2.5], here for the masked case (Figure 9.53): the traces of the four chains overlap after a few hundred steps; the autocorrelation falls to zero within about thirty steps; $\hat{R}$ for n_s drops below 1.01 well before the end; and the four chains' marginals agree. In

numbers: acceptance 0.36, largest $\hat{R} = 1.0006$, $\tau = 8.0$ steps, about 9336 effective samples of n_s. The other cases look the same (the table below).

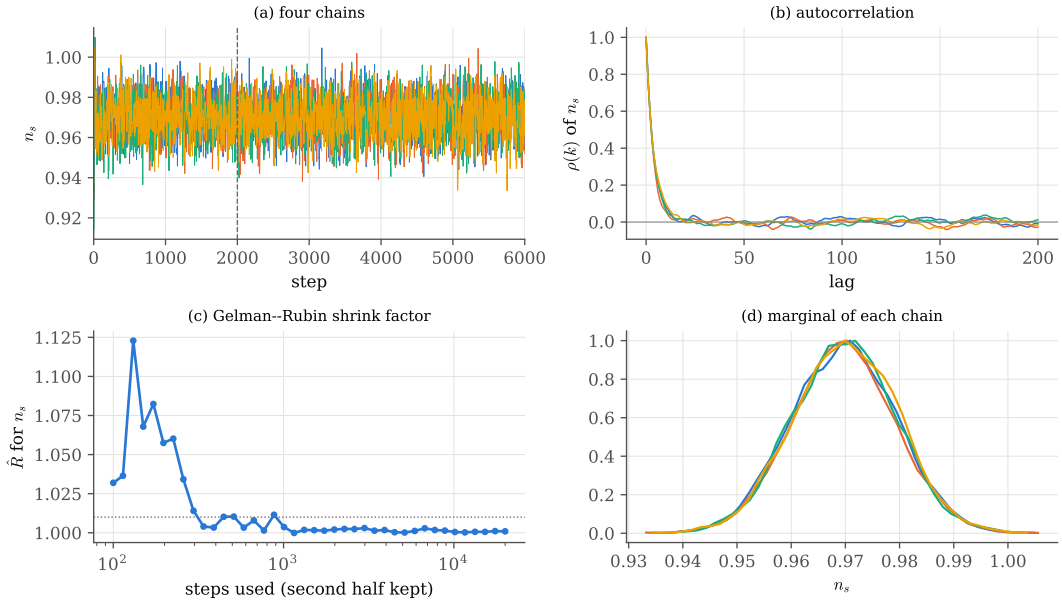

Figure 9.53: Diagnostics of the masked-sky chains, for n_s. (a) Traces of the four chains from dispersed starting points; the dashed line marks the end of burn-in. (b) Autocorrelation functions after burn-in. (c) The Gelman–Rubin $\hat{R}$ computed from the second half of the first n steps, against n; the dotted line is 1.01. (d) The marginal of n_s from each chain separately.

case	$\ln(10^{10}A_s)$	n_s	ρ	Fisher σ's, ρ	acc., $\hat{R}$	τ, ESS
(a) sky	3.0446 ± 0.0029	0.9649 ± 0.0050	0.59	0.0029, 0.0049, 0.59	0.36, 1.0013	8.4, 9471
(b) noisy	3.0400 ± 0.0063	0.9604 ± 0.0072	0.83	0.0063, 0.0072, 0.83	0.36, 1.0005	6.4, 10259
(c) masked	3.0519 ± 0.0083	0.9698 ± 0.0095	0.83	0.0082, 0.0094, 0.83	0.36, 1.0006	8.0, 9336
truth	3.0445	0.9649				

The library cross-checks agree: `emcee` on the masked likelihood gives $\ln(10^{10}A_s) = 3.0518 \pm 0.0083$ and $n_s = 0.9698 \pm 0.0093$, and `getdist` [161], the analysis package of CosmoMC and Cobaya, puts the 68 per cent interval of n_s at $[0.9603, 0.9792]$, the same as our percentiles $[0.9603, 0.9792]$.

9.21.3 Reading the triangle plot

The standard display of a posterior with several parameters is the **triangle plot** [one-dimensional marginals on the diagonal, two-dimensional marginals of each pair below it]. By the key idea of Section 9.17.4 every panel is a histogram of one or two columns of the chain. Ours is written by hand in matplotlib (`triangle` in `lib_mcmc9c.py`) so that nothing is hidden, and two choices in it need a word.

Where to draw the 68 per cent contour. A two-dimensional histogram H of the samples, smoothed slightly, estimates the density on a grid. The 68 per cent region is the set of highest density holding 68 per cent of the samples: sort the cells from the highest down, add up their contents until the total reaches 68 per cent, and the height of the last cell added is the contour level.

Listing 9.15: The contour level that encloses a given probability (`code/ch09/lib_mcmc9c.py`)

```
def hpd_levels(H, probs=(0.68, 0.95)):
    """Heights h_p of a (normalised-histogram) density H such that the region H >= h_p holds
    probability p.  Sort the cells from the highest down and accumulate their mass."""
    flat = np.sort(H.ravel())[::-1]
    cum = np.cumsum(flat) / flat.sum()
    return [flat[np.searchsorted(cum, p)] for p in probs]
```

Where to draw the Fisher ellipse. For a two-dimensional Gaussian with covariance $\mathbf{C}$, the quantity $\Delta\chi^2 = (\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{\theta} - \bar{\boldsymbol{\theta}})$ is a sum of two squared independent standard Gaussians (rotate and rescale to the principal axes), so it follows χ^2_2, whose cumulative distribution is $1 - e^{-c/2}$ (Chapter 2). The ellipse $\Delta\chi^2 = c$ encloses probability p when

$$1 - e^{-c/2} = p \quad \Longleftrightarrow \quad c = -2\ln(1-p): \qquad p = 0.683 \to c = 2.30, \qquad p = 0.954 \to c = 6.18.$$

In two dimensions the "1σ" ellipse is not $\Delta\chi^2 = 1$, which encloses only $1 - e^{-1/2} = 39$ per cent; the one-dimensional 68.3 per cent of $\pm 1\sigma$ needs $\Delta\chi^2 = 2.30$ when two parameters are shown together.

Figure 9.54 shows the three posteriors with the Fisher ellipses of each case centred on the truth.

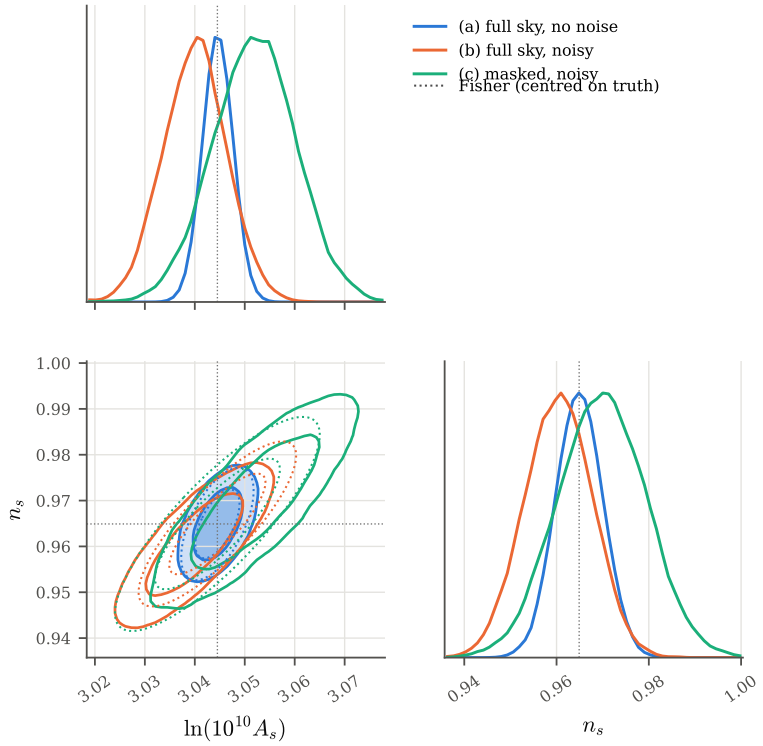

Figure 9.54: Hand-made triangle plot of $(\ln 10^{10}A_s, n_s)$ from one simulated sky observed three ways: the sky itself (filled blue), the full sky with beam and noise (red), and the noisy sky behind the Galactic mask (green). Diagonal: one-dimensional marginals. Lower panel: 68 and 95 per cent contours of the chains, with the Fisher ellipses of each case centred on the truth (dotted) and the true values (dashed lines).

9.21.4 Understanding the three posteriors

The centres. The three analyses see the same sky, so their centres are not independent draws; they move only through what the noise adds and what the mask hides. Relative to their own

widths, the noisy case sits −0.7 and −0.6 standard deviations from the truth in $\ln(10^{10}A_s)$ and n_s, the masked case +0.9 and +0.5: ordinary fluctuations.

The widths. From the sky itself to the noisy sky the error of $\ln(10^{10}A_s)$ grows from 0.0029 to 0.0063, a factor of about two, and that of n_s from 0.0050 to 0.0072, a factor of about one and a half. Where does the information go? The Fisher matrix (9.127) counts it multipole by multipole. With the beam divided out, so that N_ℓ is the deconvolved noise power, each multipole enters with the weight

$$w_\ell = \frac{\nu}{2}\left(\frac{C_\ell}{C_\ell + N_\ell}\right)^2,$$

which is the full-sky $\nu/2$ where the signal dominates and falls as $(C_\ell/N_\ell)^2$ where the noise does. For our experiment, 30′ and 200 μK arcmin, the deconvolved noise $N_\ell = \Delta_T^2 e^{\ell(\ell+1)\sigma_b^2}$ (Section 9.20.3) is below a twentieth of the signal at $\ell = 300$, equals it near $\ell \approx 460$, and is twelve times larger at $\ell = 600$. Because the number of modes $2\ell+1$ grows with ℓ, the multipoles above the crossover carried much of the total: $\sum_\ell w_\ell$, which is the amplitude entry F_{AA}, keeps only 47 per cent of its noiseless value. The tilt's entry F_{nn} keeps 97 per cent, since it weights each multipole also by the square of its lever arm in $\ln k$ (next paragraph), which is largest at the low multipoles the noise does not touch. The tilt's error still grows, through the correlation: with the high multipoles gone, amplitude and tilt can trade more freely. These weights reproduce the chains' widths to about ten per cent; the remainder comes from the pixel window and the other details of the simulation that this count leaves out.

The mask then removes a third of the sky. On a fraction $f_{\rm sky}$ of the sky each multipole has about $(2\ell+1)f_{\rm sky}$ independent modes instead of $2\ell+1$ (Knox's mode count, Section 8.4.2), so every w_ℓ, and with them the whole Fisher matrix, is multiplied by $f_{\rm sky}$, and every error by $1/\sqrt{f_{\rm sky}} = 1/\sqrt{0.658} \approx 1.23$. The chains give $0.0083/0.0063 \approx 1.32$ for both parameters. The extra seven per cent is the taper: pixels near the mask edge are kept with weights below one, so they carry less than their share of modes.

In every case the chain and the Fisher matrix agree to the second decimal. That follows from two facts already shown. By (9.122) the parameters enter $\ln C_\ell$ almost linearly, and a likelihood that is quadratic in a quantity linear in the parameters is a Gaussian in the parameters, as for the straight line; and with hundreds of multipoles each term of the sum is close to its quadratic expansion (9.125). So the posterior is nearly Gaussian, and its covariance is the inverse Fisher matrix.

The correlation: a straight line in disguise. Why is the correlation +0.59, and why does it grow to +0.83 with noise? Give a name to the derivative of (9.122): for each multipole let

$$s_\ell \equiv \frac{\partial \ln C_\ell}{\partial n_s} = \langle \ln(k/k_*) \rangle_\ell,$$

the average distance in $\ln k$ from the pivot of the wavenumbers that feed multipole ℓ (in Section 9.20.1 the integration variable $\ln(k/k_*)$ was called x; s_ℓ is its average, one number per multipole). Near the fiducial model, to first order,

$$\ln C_\ell(\boldsymbol{\theta}) \simeq \ln C_\ell(\boldsymbol{\theta}_0) + \delta \ln A_s + s_\ell\, \delta n_s,$$

a straight line in the variable s_ℓ, with intercept $\delta \ln A_s$ and slope δn_s. Its Fisher matrix follows from (9.127) in two lines:

$$\partial_i C_\ell\, \partial_j C_\ell \overset{(1)}{=} C_\ell^2 \frac{\partial \ln C_\ell}{\partial \theta_i}\frac{\partial \ln C_\ell}{\partial \theta_j} \overset{(2)}{=} C_\ell^2 \begin{pmatrix} 1 & s_\ell \\ s_\ell & s_\ell^2 \end{pmatrix}_{ij}, \qquad F \overset{(3)}{=} \sum_\ell w_\ell \begin{pmatrix} 1 & s_\ell \\ s_\ell & s_\ell^2 \end{pmatrix}. \tag{9.129}$$

(1) $\partial C_\ell = C_\ell\, \partial \ln C_\ell$.
(2) $\partial \ln C_\ell / \partial \ln A_s = 1$ and $\partial \ln C_\ell / \partial n_s = s_\ell$, from the line above.
(3) Put this into (9.127): $\frac{\nu}{2} C_\ell^2/(C_\ell + N_\ell)^2$ is the weight w_ℓ of the previous paragraph.

This is exactly the matrix of the straight-line fit (9.102), with s_ℓ in place of x_i and w_ℓ in place of $1/\sigma_i^2$. So the result of Section 9.17.2 applies unchanged:

$$\rho(\ln A_s, n_s) = -\frac{\bar{s}_w}{\sqrt{\overline{s^2}_w}},$$

with $\bar{s}_w$ and $\overline{s^2}_w$ the w-weighted means of s_ℓ and s_ℓ^2. The pivot $k_* = 0.05\,\mathrm{Mpc}^{-1}$ is the origin $s = 0$ of this line, and it falls at a multipole of a few hundred (Section 9.20.1). Our data stop at $\ell = 601$ and most of their weight is at lower multipoles, where $s_\ell < 0$: the weighted mean is negative and the correlation positive. Noise removes the high multipoles, nearest the pivot, so $\bar{s}_w$ moves further from zero and the correlation grows. A Planck-like experiment measures out to $\ell = 2500$, where $s_\ell > 0$, and the sign flips (Section 9.22). Choosing the pivot is choosing the origin of s, Kruschke's centring of Section 9.17.6 in cosmological dress: a pivot at the weighted centre of the data would make amplitude and tilt uncorrelated.

9.21.5 Do the Gaussian approximations bias n_s?

On the noiseless full sky we know the exact likelihood, so we can test the approximations of Section 9.19.3 on parameters. Running the chain with $\mathcal{L}_Q$ (variance from the model) and with $\mathcal{L}_f$ (variance from the fixed fiducial) instead of the exact form, on the same sky, gives the posteriors of Figure 9.55a: $\mathcal{L}_f$ coincides with the exact one, while $\mathcal{L}_Q$ moves n_s by -1.15 standard deviations. One sky could be a fluke, so we repeat the comparison of best fits on 500 skies drawn from the exact χ^2 distribution. Relative to the exact best fit, $\mathcal{L}_Q$ shifts n_s by -1.25 ± 0.17 standard deviations (mean and scatter over skies) and $\ln(10^{10} A_s)$ by $+0.38$; $\mathcal{L}_f$ shifts n_s by -0.000 ± 0.009 (Figure 9.55b). This is HL's statement, "$\mathcal{L}_Q$ biases parameters like the spectral index by around one sigma, $\mathcal{L}_f$ is unbiased" [16], reproduced on our experiment. The mechanism is the $0.9/\ell$ upward bias of the spectrum derived in (9.120): largest at low ℓ, so it is read as extra power on large scales, a lower n_s and a slightly higher amplitude.

The same 500 skies give a check of the exact analysis itself. Its best-fit n_s scatters about the truth with mean $+0.03$ and standard deviation 1.05 in units of the Fisher error: unbiased, and with error bars that mean what they say, to the precision of 500 skies (about ± 0.03 on the standard deviation).

9.22 Reproducing Planck 2018: the amplitude and tilt of the primordial spectrum

How did the fluctuations that grew into galaxies start out? The simplest models of the early Universe predict a primordial spectrum that is almost a power law, $P(k) = A_s (k/k_*)^{n_s - 1}$, described by two numbers: its amplitude A_s at the pivot wavenumber $k_* = 0.05\,\mathrm{Mpc}^{-1}$ and its tilt n_s (Section 8.7.3). A tilt of exactly one would mean the same strength of fluctuations on every scale; a tilt slightly below one, more on large scales, is what the simplest models of inflation predict. A CMB temperature map is the cleanest view of that spectrum we have: the sky is one realisation of $C_\ell(\boldsymbol{\theta})$, and the spectrum is a weighted integral of $P(k)$ (Section 9.20.1).

The question. How well does Planck's temperature map, with its low-multipole polarization, measure the amplitude and the tilt, and how much of the answer depends on which other

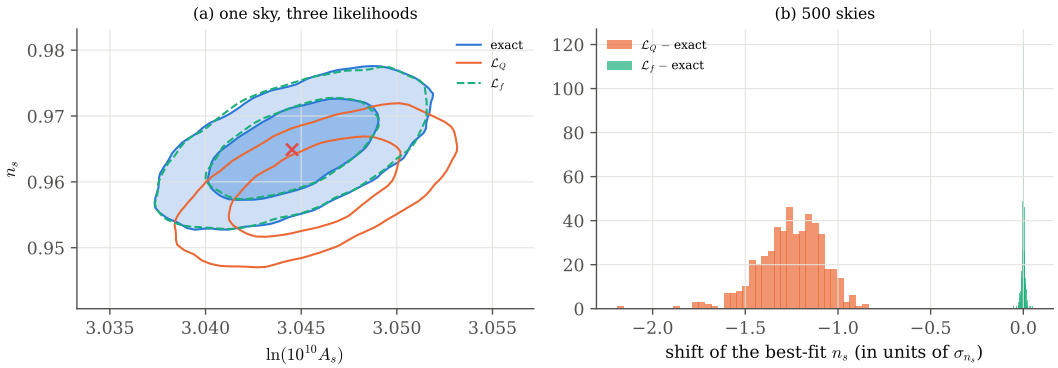

Figure 9.55: Gaussian approximations on the noiseless full sky. (a) One sky, three likelihoods: exact (filled), $\mathcal{L}_Q$ and $\mathcal{L}_f$; $\mathcal{L}_f$ lies on the exact contours, $\mathcal{L}_Q$ is displaced to lower n_s. (b) Over 500 skies, the shift of the best-fit n_s from its exact value, in units of the expected error: $\mathcal{L}_Q$ is off by more than one standard deviation in every sky, $\mathcal{L}_f$ by less than a hundredth.

parameters are left free? We cannot reproduce Planck's centres: they belong to the one real sky. We can reproduce the widths and the correlation, which depend on the experiment and on the model, not on the sky, and we can trace every difference to a cause.

9.22.1 Planck's setup and likelihood

The maps. Planck's high-ℓ temperature likelihood uses three frequency channels, 100, 143 and 217 GHz, each observed in two halves of the mission. Spectra are formed only between different halves, so the noise of one half is uncorrelated with the other and adds no power on average (Section 9.23.2).

The masks. Each channel has its own mask, removing the Galactic plane and point sources, and leaving a different fraction of the sky, because dust emission grows with frequency [70].

The foregrounds and the instrument. What remains on the sky is not only the CMB. Planck describes dust, point sources, the thermal and kinetic Sunyaev–Zeldovich effects, the cosmic infrared background and the relative calibrations of the channels with about fifteen nuisance parameters, sampled alongside the six cosmological ones.

The low multipoles. Below $\ell = 30$, the Blackwell–Rao likelihood of Section 9.19.4 for temperature, and the lowE polarization likelihood, which measures the optical depth $\tau = 0.0506 \pm 0.0086$ on its own [25].

channel	100 GHz	143 GHz	217 GHz
sky fraction of the temperature mask	0.66	0.57	0.47

range	likelihood
$2 \le \ell < 30$	Blackwell–Rao; lowE for τ
$\ell \ge 30$	Gaussian, fiducial covariance

Their key equation. Above $\ell = 30$ Planck's likelihood is a Gaussian in the vector $\widehat{C}$ of all the binned cross-spectra, with a covariance $\mathbf{\Sigma}$ computed once for a fiducial model (Planck 2018 V, eq. 20): $-2\ln\mathcal{L} = (\widehat{C} - C(\theta))^{\mathsf{T}}\mathbf{\Sigma}^{-1}(\widehat{C} - C(\theta)) + \text{const}$, where $C(\theta)$ holds the cosmological spectrum plus the foreground model, scaled by the calibrations. The symbol map to our notation is short. Their $\widehat{C}$ is our $\widehat{C}_\ell$ for one channel and no binning; their $C(\theta)$ is our $C_\ell(\theta)$

plus the noise power N_ℓ (we use one map, whose spectrum contains its noise, where Planck uses cross-spectra without it) and with no foregrounds; their $\mathbf{\Sigma}$ is diagonal for us, with the $f_{\rm sky}$ mode count of Section 9.19.2. Then

$$-2\ln\mathcal{L} \overset{(1)}{=} \sum_\ell \frac{\big(\widehat{C}_\ell - C_\ell(\boldsymbol{\theta}) - N_\ell\big)^2}{\Sigma_{\ell\ell}} \overset{(2)}{=} \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2}\left[\frac{\widehat{C}_\ell - C_\ell(\boldsymbol{\theta}) - N_\ell}{C_\ell^{\rm f} + N_\ell}\right]^2. \tag{9.130}$$

(1) One channel, one spectrum per multipole, and no coupling between multipoles: $\mathbf{\Sigma}$ is diagonal.

(2) The variance of $\widehat{C}_\ell$ is $2(C_\ell+N_\ell)^2/\nu$ with $\nu=(2\ell+1)f_{\rm sky}$ (Section 9.19.3), evaluated once at the fiducial spectrum $C_\ell^{\rm f}$.

This is the fixed-fiducial $\mathcal{L}_f$ of Section 9.19.3, with the noise added. On our idealised data the exact form is available, so our runs use it, and Section 9.22.6 measures what replacing it by (9.130) costs. What we drop, then, is the second and third channels, the mode coupling of a real mask, and all the foreground and calibration parameters.

The numbers to reproduce. With this likelihood, temperature plus lowE gives $\ln(10^{10}A_s) = 3.040 \pm 0.016$ and $n_s = 0.9626 \pm 0.0057$ (Planck 2018 VI, Table 2, column TT+lowE [25]). The covariance matrix that the Planck team distributes with its chains adds the correlation between the two, +0.03, with widths 0.0164 and 0.0057.

9.22.2 The simulated experiment and its likelihood

The spectrum. The true spectrum is computed by CAMB at the fiducial parameters (not by the emulator, so the emulator's error is part of the test). The noise is that of the 143 GHz channel, 7.22′ and 33 μK arcmin [159], and the sky fraction is $f_{\rm sky}=0.57$, the fraction left by Planck's 143 GHz temperature mask [70]. The measured spectrum is drawn as $\widehat{C}_\ell = (C_\ell+N_\ell)\,\chi^2_\nu/\nu$ with $\nu=(2\ell+1)f_{\rm sky}$ at every $2\le\ell\le2500$: the distribution of Section 9.19.2 with the mode count of a partial sky.

The likelihood. For these data the $f_{\rm sky}$-scaled exact form is the true likelihood,

$$-2\ln\mathcal{L}(\boldsymbol{\theta}) = \sum_{\ell=2}^{2500}(2\ell+1)f_{\rm sky}\left[\frac{\widehat{C}_\ell}{C_\ell(\boldsymbol{\theta})+N_\ell} + \ln\big(C_\ell(\boldsymbol{\theta})+N_\ell\big)\right] + \frac{(\tau-\tau_{\rm obs})^2}{\sigma_\tau^2}. \tag{9.131}$$

The last term stands in for Planck's low-ℓ polarization likelihood (lowE), which on its own measures $\tau = 0.0506 \pm 0.0086$ [25]. We simulate that measurement too: $\tau_{\rm obs}$ is drawn from a Gaussian of width $\sigma_\tau = 0.0086$ about the true $\tau = 0.0544$, and the draw gave $\tau_{\rm obs} = 0.0714$, two standard deviations high. In code:

Listing 9.16: The Planck-like log posterior (`code/ch09/45_planck_like.py`)

```
def make_lp(names, order):
    em = ce.Emulator(order=order, names=names, lmax=LMAX)
    it = names.index("tau") if "tau" in names else None
    lo = em.fid - np.array([0.5, 0.1, 10, 0.003, 0.02, 0.06])[[ce.NAMES.index(n) for n in
    names]]
    hi = em.fid + np.array([0.5, 0.1, 10, 0.003, 0.02, 0.06])[[ce.NAMES.index(n) for n in
    names]]
    lo = np.where(np.array(names) == "tau", 0.01, lo)

    def lp(th):
        th = np.asarray(th)
        if np.any(th < lo) or np.any(th > hi):
```

```
            return -np.inf
        c = em.cl(th)[use] + Nl[use]
        out = -0.5 * np.sum(nu[use] * (chat[use] / c + np.log(c)))
        if it is not None:
            out -= 0.5 * ((th[it] - tau_obs) / SIG_TAU) ** 2
        return out
    return lp, em
```

Three runs, each asking a different question:

- P2: *if we knew everything else*, how well would the spectrum fix the amplitude and the tilt? Only $(\ln 10^{10}A_s, n_s)$ are free; H_0, ω_b, ω_c and the optical depth τ are fixed at the truth.
- P3: what changes when the reionisation optical depth τ is left free, constrained only by its lowE prior?
- P6: the full problem, with all six ΛCDM parameters free.

Every run has 4 chains of 40000 steps, a proposal shaped by the Fisher covariance, and 4000 steps of burn-in. The diagnostics of Section 9.12 are below; to keep τ for the optical depth, the integrated autocorrelation time (written τ in Section 9.17.3) is called t_{ac} here.

run	free	emulator	time (s)	acceptance	largest $\hat{R}$	t_{ac} (steps)
P2	$\ln 10^{10}A_s, n_s$	first order	5	0.35	1.0001	8
P3	$+\tau$	first order	5	0.32	1.0004	10
P6	all six	second order	12	0.28	1.0006	up to 23

All three chains can be trusted. Their widths, against Planck's:

	$\sigma(\ln 10^{10}A_s)$	$\sigma(n_s)$	$\rho(\ln A_s, n_s)$
Planck 2018 TT+lowE, Table 2	0.016	0.0057	
Planck chains' covariance	0.0164	0.0057	+0.03
P2: 2 free, others fixed	0.0018	0.0026	−0.73
Fisher	0.0018	0.0026	−0.73
P3: $+\tau$, lowE prior	0.0164	0.0026	−0.06
Fisher	0.0165	0.0026	−0.06
P6: all 6 free	0.017	0.0053	−0.14
Fisher	0.0167	0.0053	−0.15
ratio P6 / Planck	1.04	0.93	

With all six parameters free we recover Planck's widths to within ten per cent. Reading down the table, freeing τ (P2 to P3) multiplies the amplitude's error by nine and leaves the tilt's alone; freeing the other three (P3 to P6) doubles the tilt's error and leaves the amplitude's alone. The next two subsections explain each step, and the third the correlation (Figure 9.56).

9.22.3 Why the amplitude needs τ

Above $\ell \approx 30$ the temperature spectrum depends on A_s and τ only through $A_s e^{-2\tau}$ (Section 9.20.1), that is, through the combination $c = \ln(10^{10}A_s) - 2\tau$. A temperature spectrum measures c precisely and says almost nothing about $\ln A_s$ and τ separately (the opposite flat responses in Figure 9.50). In P3 the chain's column of $\ln(10^{10}A_s) - 2\tau$ has standard deviation

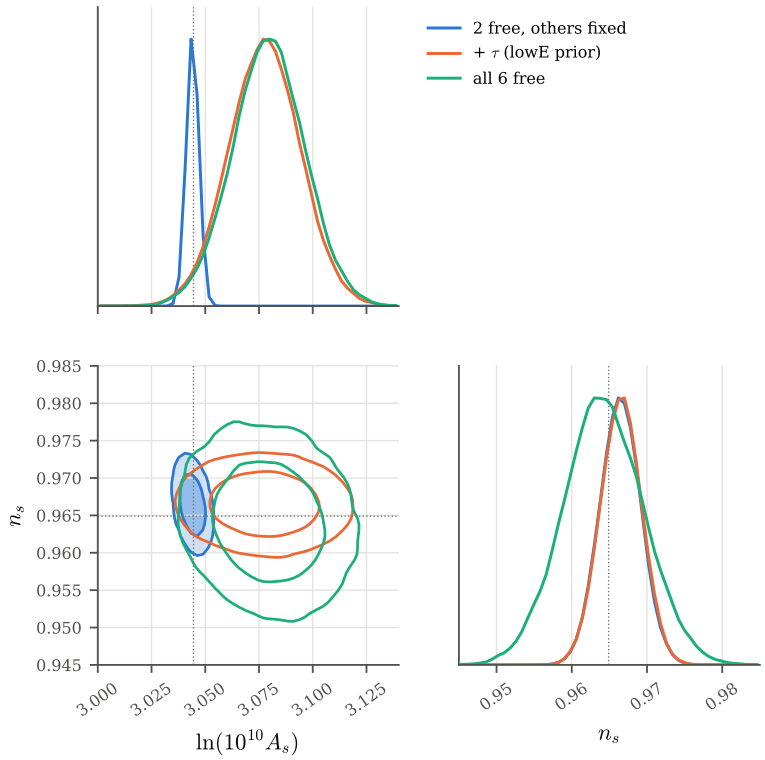

Figure 9.56: $(\ln 10^{10}A_s, n_s)$ from the Planck-like simulated spectrum, with two parameters free and the rest fixed (filled blue), with τ free under the lowE prior (red), and with all six ΛCDM parameters free (green). Dashed lines: the true values. Freeing τ stretches the amplitude ninefold; freeing H_0, ω_b and ω_c doubles the tilt's error and removes most of the correlation.

0.0018, the same as $\sigma(\ln A_s)$ in P2, where τ was fixed and the whole of c was attributed to A_s. The amplitude itself is then pinned only by lowE. Write $\ln(10^{10}A_s) = c + 2\tau$. Are c and τ independent? Change variables from $(\ln 10^{10}A_s, n_s, \tau)$ to (c, n_s, τ), a shift with unit Jacobian, so flat priors stay flat. Above $\ell = 30$ the TT term of (9.131) depends on the amplitude and the optical depth only through c; the lowE term depends only on τ. The likelihood is then a function of (c, n_s) times a function of τ, and with flat priors so is the posterior: c and τ are independent, up to the weak information TT has on τ below $\ell = 30$. The chain agrees: the correlation of its c and τ columns in P3 is -0.05. So

$$\sigma^2(\ln 10^{10}A_s) \overset{(1)}{=} \sigma_c^2 + 4\sigma_\tau^2 \overset{(2)}{=} 0.0018^2 + 4\times 0.0082^2 \quad\Rightarrow\quad \sigma(\ln 10^{10}A_s) \approx 0.0165,$$
$$\rho(\ln A_s, \tau) \overset{(3)}{=} \frac{2\sigma_\tau^2}{\sigma(\ln A_s)\,\sigma_\tau} \approx 0.99. \tag{9.132}$$

(1) The variance of a sum of independent quantities, with the factor 2 squared.
(2) $\sigma_c = 0.0018$ from the chain; $\sigma_\tau = 0.0082$, the posterior width of τ, which is the lowE width slightly narrowed by the weak information TT has on τ at $\ell < 30$.
(3) $\mathrm{Cov}(c + 2\tau, \tau) = 2\sigma_\tau^2$.

The chain gives 0.0164 and +0.99. The published 0.016 is the same calculation with Planck's $\sigma_\tau = 0.0080$: our width is larger by about the ratio of the two τ errors, $0.0082/0.0080 \approx 1.03$, which is the origin of the 1.04 of the table. The amplitude of the primordial spectrum, as measured by the CMB, is a measurement of the optical depth to reionisation.

Example: why our amplitude is high. Our six-parameter chain centres on $\ln(10^{10}A_s) = 3.0794$, while the truth is 3.0445: a shift of two standard deviations. By the same argument it must follow the simulated lowE measurement, which came out high by $\tau_{\rm obs} - \tau_{\rm true} = 0.0714 - 0.0544 = 0.017$; the posterior of τ is 0.070519, and $2 \times (0.0705 - 0.0544) = 0.032$ is the shift of $\ln A_s$. A two-sigma fluctuation of one external measurement moved the amplitude by two sigma, and TT could not object, because TT fixes only c.

9.22.4 Why the tilt needs the other parameters

With ω_b, ω_c and H_0 fixed (P3), $\sigma(n_s) = 0.0026$; with them free (P6), 0.0053, a factor 2.0. How much a parameter's error grows when others are freed can be read from the Fisher matrix (9.127). Split the parameters into n_s and the rest, r. The inverse of a matrix split this way has the Schur-complement form already used in (8.77):

$$\sigma^2(n_s) \overset{(1)}{=} (\mathbf{F}^{-1})_{nn} \overset{(2)}{=} \frac{1}{F_{nn} - \boldsymbol{F}_{nr}\mathbf{F}_{rr}^{-1}\boldsymbol{F}_{rn}} \overset{(3)}{=} \frac{1}{F_{nn}\,(1 - R^2)}, \qquad R^2 \equiv \frac{\boldsymbol{F}_{nr}\mathbf{F}_{rr}^{-1}\boldsymbol{F}_{rn}}{F_{nn}}. \tag{9.133}$$

(1) The marginal error, with all the other free parameters integrated out (Section 9.20.3).
(2) Block inversion: the (n, n) element of the inverse is one over the Schur complement of $\mathbf{F}_{rr}$.
(3) Factor out F_{nn}; $1/\sqrt{F_{nn}}$ is the error with everything else fixed.

R^2 is a number between zero and one: the fraction of the effect of n_s on the spectrum, measured in the Fisher metric, that some combination of the other parameters can reproduce (the multiple correlation of the derivative curves of Figure 9.50). For our experiment $1/\sqrt{F_{nn}} = 0.0018$. With $\ln A_s$ and τ free, $R^2 = 0.53$ and $\sigma(n_s) = 0.0018/\sqrt{0.47} = 0.0026$; with all five free, $R^2 = 0.89$ and $\sigma(n_s) = 0.0018/\sqrt{0.11} = 0.0053$, the chains' values. A doubling of the error is a factor of four in $1 - R^2$: of the part of n_s's effect that amplitude and optical depth cannot mimic, H_0, ω_b and ω_c together mimic three quarters.

Which of them? Freed one at a time (with $\ln A_s$ and τ), each moves $\sigma(n_s)$ by less than four per cent: 0.0027 for H_0 or ω_b, 0.0026 for ω_c. Freed together, H_0 and ω_c give 0.0049, and adding ω_b completes the 0.0053. The physical reading follows from these numbers. Changing H_0 or ω_c alone moves the acoustic peaks sideways in ℓ, which the spectrum measures far too well to allow; changing both together, in the proportion that keeps the angular size of the sound horizon fixed, leaves the peaks in place and changes the matter density, which alters the driving of the oscillations and so the heights of the first peaks relative to the later ones. A change of relative heights across ℓ is what a tilt does, so n_s becomes partly degenerate with that combination; the baryon density, which raises the odd peaks against the even ones, takes a smaller share. This is the pitfall of Section 9.18.2 on a cosmological scale: a nuisance parameter fixed at its true value hides an uncertainty, and the chain cannot tell. The remaining seven per cent between our 0.0053 and Planck's 0.0057 is what we left out (Section 9.22.1): the fifteen foreground and calibration parameters that Planck's official TT chains sample alongside the six (they are listed in the covariance file we used), and three frequency channels with different noise, beams and masks [70]. By (9.133), each nuisance parameter that can mimic part of the effect of n_s at high ℓ widens it a little. Our one clean channel with no foregrounds is slightly too optimistic.

The other widths tell the same story (Figure 9.57b): H_0 to ± 0.93 against Planck's 0.92, ω_b to 0.0002 against 0.00022, ω_c to 0.0022 against 0.0021, τ to 0.0083 against 0.0080, all within about ten per cent.[7]

[7] Planck samples 100 $\theta_{\rm MC}$, the angular size of the sound horizon, where we sample H_0. The marginal of $(\ln A_s, n_s)$ does not care how the integrated-out parameters are labelled: a change of variables $\phi \to \psi(\phi)$ inside $\int p(\boldsymbol{\theta}, \phi)\,\mathrm{d}\phi$

9.22.5 The correlation, and why the pivot is at $0.05\,\mathrm{Mpc}^{-1}$

With the other parameters fixed the correlation is strongly negative, -0.73, the opposite sign to the toy experiment of Section 9.21.4, and the straight-line formula $\rho = -\bar{s}_w/\sqrt{\overline{s^2}_w}$ of that section explains the sign. Planck's information extends to $\ell \approx 2000$, beyond the multipole of a few hundred that sees the pivot, so the weighted mean of $s_\ell = \langle \ln(k/k_*)\rangle_\ell$, the lever arm of multipole ℓ in $\ln k$, is positive and $\rho < 0$; the toy stopped at $\ell = 601$, where $s_\ell < 0$, and had $\rho > 0$. With τ free the correlation drops to -0.06, with all six free to -0.14 (Fisher -0.15), and Planck finds $+0.03$. Why does it nearly vanish?

Moving the pivot. Section 8.7.3 answered this with two lines. The same spectrum read at another wavenumber k', a distance $L = \ln(k'/k_*)$ away in $\ln k$, has amplitude $\ln A(k') = \ln A_s + (n_s - 1)L$, by $P(k) = A_s(k/k_*)^{n_s-1}$; its covariance with the tilt is

$$\mathrm{Cov}\big(\ln A(k'), n_s\big) = \mathrm{Cov}(\ln A_s, n_s) + L\ \mathrm{Var}(n_s), \tag{9.134}$$

zero at $L_{\mathrm{dec}} = -\mathrm{Cov}(\ln A_s, n_s)/\mathrm{Var}(n_s)$ (8.46). Dividing by the two widths, the correlation at the pivot itself is

$$\rho(\ln A_s, n_s) = \frac{\mathrm{Cov}(\ln A_s, n_s)}{\sigma(\ln A_s)\,\sigma(n_s)} = -L_{\mathrm{dec}}\,\frac{\sigma(n_s)}{\sigma(\ln A_s)}. \tag{9.135}$$

So the correlation at k_* is small if the decorrelation wavenumber is close to k_*, *or* if the amplitude's error is large compared with L_{dec} times the tilt's.

The numbers from our chains. In P2, $\sigma(\ln A_s) = 0.0018$, $\sigma(n_s) = 0.0026$ and $\rho = -0.73$ give $L_{\mathrm{dec}} = 0.50$, so $k_{\mathrm{dec}} = 0.05\,e^{0.50} = 0.082\,\mathrm{Mpc}^{-1}$, the value Section 8.7.3 found for a Planck-like experiment by Fisher matrix. In P6, $L_{\mathrm{dec}} = 0.43$ and $k_{\mathrm{dec}} = 0.077\,\mathrm{Mpc}^{-1}$: freeing the other parameters hardly moves the decorrelation scale. What changes is the ratio in (9.135): $0.0026/0.0018 = 1.5$ in P2 but $0.0053/0.017 = 0.32$ in P6, so $\rho = -0.50 \times 1.5 = -0.73$ becomes $-0.43 \times 0.32 = -0.14$. The drop is the factor of nine in the amplitude's error of Section 9.22.3: the optical depth adds the same uncertainty $2\sigma_\tau$ to $\ln A$ at every pivot, and that common part is uncorrelated with the tilt. This is also why P3, with only τ freed, already has $\rho = -0.06$. Planck's own $+0.03$ corresponds to $L_{\mathrm{dec}} = -0.03 \times 0.0164/0.0057 \approx -0.09$, a k_{dec} near $0.046\,\mathrm{Mpc}^{-1}$; their extra nuisance parameters, which absorb high-ℓ power, plausibly move the weighted centre of the tilt's information to lower ℓ, but with ρ this small the difference is within what the two analyses' different ingredients can produce.

A pivot far away. The same formula prices the alternative. At WMAP's pivot, $k' = 0.002\,\mathrm{Mpc}^{-1}$, $L = \ln(0.002/0.05) = -3.2$, and our P6 chain gives $\rho\big(\ln A(k'), n_s\big) = -0.76$ with $\sigma\big(\ln A(k')\big) = 0.025$, half as large again as at k_*; in P2 the correlation there is -0.99. By the centring argument of Section 9.17.6, the amplitude read far from the data's weighted centre swings with every error in the slope.

That is the reason for the convention. The pivot $k_* = 0.05\,\mathrm{Mpc}^{-1}$ defines what A_s means, the amplitude of the primordial spectrum at that wavenumber. Any other choice describes the same spectrum, but a pivot near the centre of the data's information, within a factor of two of k_{dec} in either direction, makes the amplitude and the tilt nearly independent, which makes them easier to quote, to combine and to sample.

9.22.6 Planck's Gaussian approximation, tested

Planck's high-ℓ likelihood is a Gaussian with a fiducial covariance (Section 9.19.4), with the remark that its symmetric shape biases n_s by about 0.1σ [70]. In our setting we can measure

only multiplies the prior by the Jacobian $\left|\mathrm{d}\phi/\mathrm{d}\psi\right|$, so flat priors in different bases differ slightly, and with Planck's data the likelihood dominates.

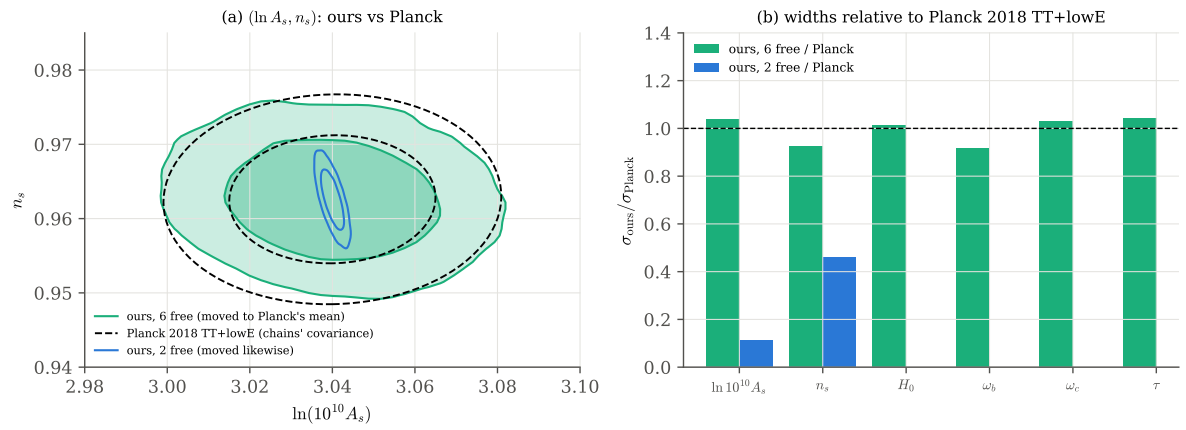

Figure 9.57: Ours against Planck 2018 TT+lowE. (a) The 68 and 95 per cent contours of our six-parameter run (filled green) and two-parameter run (blue), both shifted to Planck's centre since the centres belong to different skies, with the Gaussian of the official chains' covariance (black dashed). (b) Posterior widths of all six parameters divided by Planck's: with everything free (green) they are within about ten per cent; fixing the other four (blue) makes $\ln A_s$ nine times and n_s twice too precise.

the effect of that choice, because we know the exact likelihood. For 300 simulated Planck-like spectra we find the best-fit $(\ln A_s, n_s)$ under the exact likelihood (9.131) (others fixed), under a hybrid that keeps it at $\ell < 30$ and uses a Gaussian with the fixed fiducial variance $2(C_\ell^{\rm f} + N_\ell)^2/\nu$ above, and under the same hybrid with $\mathcal{L}_Q$ above $\ell = 30$. In units of $\sigma(n_s)$, the fixed-fiducial Gaussian shifts n_s by $+0.000 \pm 0.000$ on average (scatter 0.004 between spectra); $\mathcal{L}_Q$ shifts it by -1.307 ± 0.007.

The second number is HL's warning again, now at Planck's sensitivity: the variance must not be taken from the model being tested. The first says that in an idealised experiment the fixed-fiducial Gaussian costs nothing in the best fit, as HL's eqs. (38)–(39) predict. Planck's 0.1σ therefore comes from what our test leaves out: real cut-sky pseudo-spectra whose distribution is not a scaled χ^2 at $30 \le \ell < 100$, a fiducial model that is not exactly the truth, and posterior means from chains rather than best fits (the exact posterior is slightly skewed at low ℓ, the Gaussian is not). We have not reproduced that 0.1σ; we have shown that it is not a property of the Gaussian form itself, and that a tenth of a standard deviation is the scale of effect these choices produce.

quantity	Planck 2018	ours, and why they differ
$\sigma(\ln 10^{10}A_s)$	0.016	0.017: set by σ_τ, ours 0.0083, theirs 0.0080
$\sigma(n_s)$	0.0057	0.0053: no foreground or calibration nuisance parameters
$\rho(\ln A_s, n_s)$	+0.03	−0.14: same reason; small either way (pivot)
$\sigma(n_s)$, others fixed	not quoted	0.0026: a fixed parameter hides uncertainty
bias of the high-ℓ Gaussian on n_s	$\approx 0.1\sigma$ (V, fn. 12)	$+0.000\sigma$ in the ideal case; -1.307σ for $\mathcal{L}_Q$

9.23 How it is done in research

A published constraint is the end of a long pipeline, and the chain is only one stage of it. Once a chain exists, one trick that research pipelines use constantly takes a few lines: reweight the chain instead of rerunning it whenever the data or the theory change a little. Around the chain

sit the data products, the covariance, the likelihood code and the checks, and each of them has a laptop-sized counterpart in the analyses above.

9.23.1 Importance sampling: reusing a chain

A chain is a sample from one posterior, $p_{\text{old}}(\boldsymbol{\theta})$. Often we want averages over a slightly different one, $p_{\text{new}}(\boldsymbol{\theta})$: the same data with a more accurate theory code, or the same data plus a new measurement. The identity of Chapter 6 does it without a new run [Padilla eqs. 45–47]: for any function f,

$$\mathbb{E}_{\text{new}}[f] \overset{(1)}{=} \int f(\boldsymbol{\theta})\,\frac{p_{\text{new}}(\boldsymbol{\theta})}{p_{\text{old}}(\boldsymbol{\theta})}\,p_{\text{old}}(\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{\theta} \overset{(2)}{=} \frac{\sum_t w_t f(\boldsymbol{\theta}_t)}{\sum_t w_t}, \qquad w_t = \frac{\mathcal{L}_{\text{new}}(\boldsymbol{\theta}_t)}{\mathcal{L}_{\text{old}}(\boldsymbol{\theta}_t)}. \tag{9.136}$$

(1) Multiply and divide by p_{old}; this needs $p_{\text{old}} > 0$ wherever $p_{\text{new}} > 0$.
(2) The integral is an average over p_{old}, which the chain samples. The posteriors are known only up to their evidences, so we normalise the weights by their sum (the self-normalised estimator); with the same prior in both, the prior cancels in $p_{\text{new}}/p_{\text{old}}$ and only the likelihood ratio remains.

The price is precision. If N independent draws carry weights w_t, the weighted mean of f has variance $\sigma_f^2 \sum_t w_t^2/(\sum_t w_t)^2$ (the variance of $\sum_t a_t f_t$ with $a_t = w_t/\sum w$ is $\sigma_f^2 \sum a_t^2$), the same as an unweighted mean of

$$N_{\text{eff}} = \frac{\left(\sum_t w_t\right)^2}{\sum_t w_t^2} \tag{9.137}$$

draws, the **effective sample size** of Chapter 6. Equal weights give $N_{\text{eff}} = N$; one dominant weight gives $N_{\text{eff}} \approx 1$. Lewis and Bridle made this a standard part of the CosmoMC workflow [37]: run the chain with a fast approximation, then reweight with the expensive calculation, or add a data set by multiplying in its likelihood.

Example: checking the emulator on the posterior itself. The six-parameter chain of Section 9.22 used the second-order emulator. We pick 400 of its 144000 samples at random, recompute the likelihood with CAMB at each (3.56 s per call, 1422 s in all), and form $w_t = \mathcal{L}_{\text{CAMB}}/\mathcal{L}_{\text{emu}}$. The values of $-2\ln w_t$ scatter with standard deviation 0.044 and never deviate from their mean by more than 0.32 (Figure 9.58a): the effective sample size is 400 of 400, and the reweighted means move by at most 0.00 standard deviations. This is the check promised in Section 9.20.3, done where it matters, on the posterior. Reweighting the whole chain would take 142 hours of CAMB on the laptop, which is why we subsample; a cluster does it in parallel.

Where we have met H_0 before. The supernovae of Section 3.17.4 fixed only $M - 5\log_{10} H_0$; the distance ladder of Section T2.12 supplied M, and the real ladder gives 73.04 ± 1.04, against 67.36 ± 0.54 from Planck's full CMB data, a difference of 4.8σ between two independent Gaussians (Section T2.12.3). The ladder value is the same here, and so is the question, whether the CMB and the ladder can be describing one H_0. Two things are different. The CMB side is our own chain, run P6 of Section 9.22, which sampled H_0 directly from one simulated temperature spectrum and the τ prior. And the ladder enters not as a second number to subtract but as a likelihood that multiplies the posterior, the Bayesian combination of Chapter 5. The numbers differ for one reason: our chain has the width of temperature data alone, 0.93, close to Planck's 0.92 for TT+lowE, where the full data with polarization and lensing give 0.54, and its centre, 67.06, is one draw of a simulated sky about the fiducial 67.36. The same gap measured with a wider error bar is fewer standard deviations, 4.3 instead of 4.8.

Example: adding a measurement of H_0. Our CMB chain says $H_0 = 67.06 \pm 0.93\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$. Suppose an independent experiment reports a Gaussian measurement $H \pm s_H$. The new posterior is the old one times $e^{-(H_0-H)^2/2s_H^2}$, so the weights are exactly that factor. Two cases (Figure 9.58b, c):

- a compatible measurement, 67.0 ± 1.0: $N_{\mathrm{eff}} = 127474$, 88.5 per cent of the chain, and the reweighted $H_0 = 67.02 \pm 0.68$ agrees with a fresh chain run on the combined posterior, 67.03 ± 0.68;
- the SH0ES distance-ladder value 73.04 ± 1.04 [24], 4.3 standard deviations from the CMB value: $N_{\mathrm{eff}} = 634$, 0.4 per cent of the chain. The reweighted $H_0 = 69.74 \pm 0.64$ against the fresh chain's 69.79 ± 0.71. How far can we trust the reweighted numbers? Reweight 8 pieces of the chain separately and see how much they scatter: the centre is uncertain by about 0.083 and the width by about 0.027, against 0.007 and 0.0033 in the compatible case. The centre agrees with the fresh chain, but the width comes out narrower by about twice its own uncertainty. The combined posterior lives in the far tail of the old one, where the chain has few samples, and the samples that are missing are the ones that would widen it.

How small should we expect N_{eff} to be? Take the simplest case: the old posterior of H_0 is a Gaussian $\mathcal{N}(\mu_0, s_0^2)$, and the new measurement multiplies it by $\mathcal{L}(h) = e^{-(h-H)^2/2s_H^2}$, so the weights are $w = \mathcal{L}$. For a long chain the sums in (9.137) become averages over the old posterior, $N_{\mathrm{eff}}/N \to (\mathbb{E}_{\mathrm{old}}\,\mathcal{L})^2/\mathbb{E}_{\mathrm{old}}[\mathcal{L}^2]$, and we need the average of a power $\mathcal{L}^k$ for $k = 1$ and $k = 2$. With $\Delta = \mu_0 - H$ the offset between the old centre and the new measurement,

$$\mathbb{E}_{\mathrm{old}}\big[\mathcal{L}^k\big] \overset{(1)}{=} \int \frac{e^{-(h-\mu_0)^2/2s_0^2}}{\sqrt{2\pi}\,s_0}\, e^{-k(h-H)^2/2s_H^2}\,\mathrm{d}h \overset{(2)}{=} \sqrt{2\pi}\,\frac{s_H}{\sqrt{k}} \int \mathcal{N}\big(h;\mu_0,s_0^2\big)\,\mathcal{N}\big(h;H,s_H^2/k\big)\,\mathrm{d}h$$
$$\overset{(3)}{=} \sqrt{2\pi}\,\frac{s_H}{\sqrt{k}}\,\frac{e^{-\Delta^2/2(s_0^2+s_H^2/k)}}{\sqrt{2\pi(s_0^2+s_H^2/k)}} \overset{(4)}{=} \sqrt{\frac{s_H^2}{s_H^2+ks_0^2}}\; e^{-k\Delta^2/2(s_H^2+ks_0^2)}. \tag{9.138}$$

(1) The average of $\mathcal{L}^k$ over the old Gaussian.
(2) $\mathcal{L}^k$ is a Gaussian in h of variance s_H^2/k, missing its normalisation $1/(\sqrt{2\pi}\,s_H/\sqrt{k})$; put it in and compensate outside.
(3) The integral of a product of two normal densities in h is a normal density in the difference of their centres, with the two variances added (complete the square in h, or read it as the density of the sum of two independent Gaussians).
(4) Cancel $\sqrt{2\pi}$, and multiply numerator and denominator of the variance by k.

Now form the ratio with $k = 1$ in the numerator (squared) and $k = 2$ in the denominator:

$$\frac{N_{\mathrm{eff}}}{N} \overset{(1)}{=} \frac{\dfrac{s_H^2}{s_H^2+s_0^2}\,e^{-\Delta^2/(s_H^2+s_0^2)}}{\sqrt{\dfrac{s_H^2}{s_H^2+2s_0^2}}\,e^{-\Delta^2/(s_H^2+2s_0^2)}} \overset{(2)}{=} \frac{s_H\sqrt{s_H^2+2s_0^2}}{s_H^2+s_0^2}\,\exp\!\left[-\frac{\Delta^2}{s_H^2+s_0^2}+\frac{\Delta^2}{s_H^2+2s_0^2}\right]. \tag{9.139}$$

(1) Square (9.138) at $k = 1$: the square root goes and the exponent doubles to $-\Delta^2/(s_H^2+s_0^2)$. At $k = 2$ the exponent is $-2\Delta^2/2(s_H^2+2s_0^2) = -\Delta^2/(s_H^2+2s_0^2)$.
(2) Prefactor: $\frac{s_H^2}{s_H^2+s_0^2}\cdot\frac{\sqrt{s_H^2+2s_0^2}}{s_H}$; exponent: subtract the denominator's.

The prefactor is the cost of the narrower width alone, the exponential the cost of the offset. Put in the numbers, with $s_0 = 0.93$ from our chain. *The compatible case:* $s_H = 1$ and $\Delta \approx 0$, so the

exponential is one and the prefactor is $1 \times \sqrt{1 + 2 \times 0.865}/(1 + 0.865) = 1.652/1.865 = 0.89$, as found. *The SH0ES case:* $s_H = 1.04$, $s_H^2 = 1.082$, $\Delta = 6.0$. The two variances are $s_H^2 + s_0^2 = 1.946$ and $s_H^2 + 2s_0^2 = 2.811$, the exponent is $-36/1.946 + 36/2.811 = -18.50 + 12.81 = -5.7$, and the prefactor $1.04 \times \sqrt{2.811}/1.946 = 0.90$; together $0.90 \times e^{-5.7} = 0.003$, or 0.3 per cent, against the 0.4 ± 0.1 per cent measured (the error again from the scatter between pieces of the chain). The fraction falls like a Gaussian in the offset Δ: reweighting is safe for new data that are "broadly consistent" with the old posterior, as Padilla et al. put it, and fails quickly for data in tension, where a new run is needed.

The same weights give an evidence ratio. Write the old posterior with its normalisation, the evidence $Z_{\text{old}} = \int \mathcal{L}_{\text{old}}\, \pi \, \mathrm{d}\boldsymbol{\theta}$ of Chapter 5, as $p_{\text{old}} = \mathcal{L}_{\text{old}}\, \pi / Z_{\text{old}}$, with π the prior common to both analyses. The plain average of the weights over the old chain is then

$$\mathbb{E}_{\text{old}}[w] \overset{(1)}{=} \int \frac{\mathcal{L}_{\text{new}}}{\mathcal{L}_{\text{old}}} \frac{\mathcal{L}_{\text{old}}\, \pi}{Z_{\text{old}}} \, \mathrm{d}\boldsymbol{\theta} \overset{(2)}{=} \frac{\int \mathcal{L}_{\text{new}}\, \pi \, \mathrm{d}\boldsymbol{\theta}}{Z_{\text{old}}} \overset{(3)}{=} \frac{Z_{\text{new}}}{Z_{\text{old}}}. \tag{9.140}$$

(1) The definition of the weight, averaged over the normalised old posterior.
(2) $\mathcal{L}_{\text{old}}$ cancels, wherever it is not zero: as for (9.136), p_{old} must be positive wherever p_{new} is.
(3) The numerator is the evidence of the new analysis.

So $\frac{1}{N} \sum_t w_t$ estimates the ratio of the evidences of the two analyses [Padilla eq. 48], the Bayes factor of Section 9.18.3, without a new integral. Its precision is governed by the same spread of weights: when a few samples carry all the weight, N_{eff} is small and the average of the w_t is as unreliable as the reweighted means, so a small N_{eff} also means an untrustworthy evidence ratio.

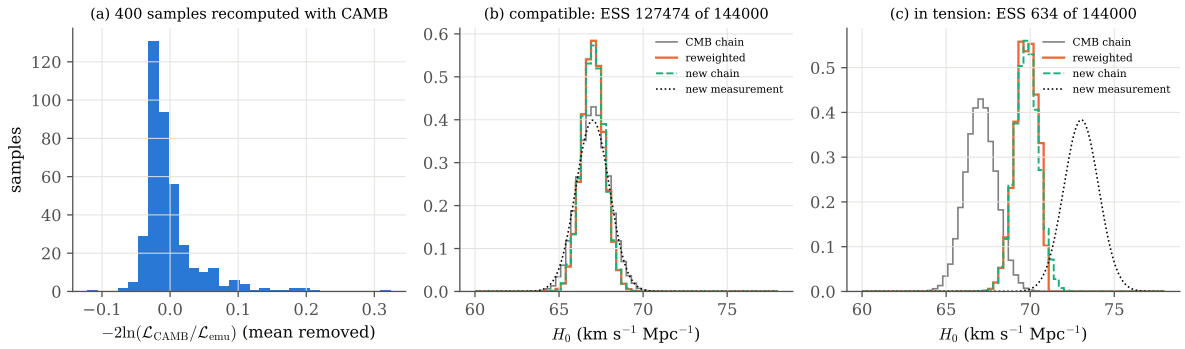

Figure 9.58: Importance sampling a six-parameter CMB chain. (a) $-2\ln(\mathcal{L}_{\text{CAMB}}/\mathcal{L}_{\text{emu}})$ at 400 random samples: a spread of a few hundredths, so the emulator chain needs no correction. (b) Adding a compatible H_0 measurement (dotted): the reweighted chain (red) and a new chain (dashed) agree. (c) Adding a measurement in tension: only 0.4 per cent of the samples carry weight, and the reweighted histogram is noisy and too narrow.

9.23.2 The research pipeline, stage by stage

A CMB temperature-and-polarization analysis of the Planck kind runs in seven stages [25, 70]. Each one produces something definite and is checked in a definite way; the laptop counterpart of every stage is drawn in Figure 9.59 and its cost is tabulated after it.

1. *Data products.* Maps at several frequencies (for Planck's high-ℓ likelihood, 100, 143 and 217 GHz), split into halves of the mission so that cross-spectra have no noise bias; a mask for each frequency (Galactic and point sources); beam window functions; and simulations: 1000 sky realisations and 300 end-to-end simulations of the full instrument and processing (FFP10).

2. *Spectra and covariance.* Cross-spectra of the half-mission maps for every frequency pair, corrected for the mask by a MASTER-type deconvolution, binned (Chapter 8); their covariance computed analytically for a fiducial model and corrected with simulations.

3. *Likelihood.* A hybrid: below $\ell = 30$, the Blackwell–Rao temperature likelihood from Gibbs samples of the sky and a simulation-based polarization likelihood (lowE); above, the Gaussian of Section 9.19.4 with the fiducial covariance, and a model of foregrounds and calibrations with about fifteen nuisance parameters for temperature alone.

4. *Theory.* A Boltzmann code (CAMB or CLASS) called by the sampler for each proposed cosmology, with the nuisance parameters updated more often than the cosmological ones because they are cheap [37].

5. *Sampling.* Metropolis–Hastings with a proposal covariance learned from earlier runs, several chains, and a stopping rule such as $\hat{R} - 1 < 0.01$; a nested sampler when the evidence is needed. The codes are CosmoMC [37], its successor Cobaya [162], and MontePython [163].

6. *Products.* The chains themselves, with tables of marginal means and limits and triangle plots made by `getdist` [161], and the parameter covariance, which is the file we compared with in Section 9.22.

7. *Checks.* The pipeline is run on simulations with known inputs and must recover them on average (the 300 FFP10 simulations); independent likelihood codes (Plik and CamSpec) must agree; results from different multipole ranges and frequency combinations must be consistent; null spectra must be compatible with noise; and importance sampling adds other data (CMB lensing, BAO) or checks the accuracy settings of the Boltzmann code.

How this is used in real research: verification and research

The straight line, the decaying source and the noiseless full sky were *verifications*: the posterior was known exactly (a Gaussian, a grid, a Student t, an exact likelihood) and the chain had to reproduce it, which it did to the precision its effective sample size allows. The masked sky and the six-parameter Planck-like run are the *research* mode: no closed-form posterior exists, the covariance comes from simulations, and the chain with its diagnostics is the instrument that produces the constraint. In real analyses the loop is exactly this one, with a Boltzmann code in place of the emulator: CosmoMC and Cobaya [37, 162] and MontePython [163] propose a cosmology, call CAMB or CLASS, evaluate the Planck likelihood code, and accept or reject with the Metropolis rule; the chains are analysed with `getdist`. Fisher forecasts (Chapter 10) are checked against such chains, and the same machinery, fed with simulated covariances of new summaries, will constrain parameters with topological statistics in Chapter 12.

What each laptop reduction costs. Every reduction trades something for speed, as the table shows.

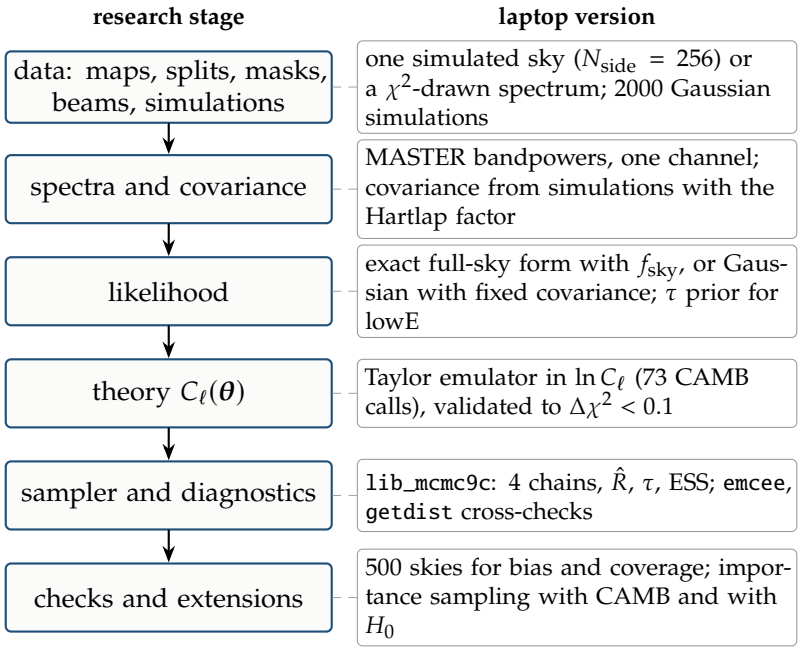

Figure 9.59: The stages of a CMB parameter analysis (left) and the reduced version run on a laptop (right). The statistics, the sampler and the diagnostics are the same; the data, the theory code and the size of the simulations are reduced.

our choice	research version	cost of the reduction
Taylor emulator, 73 CAMB calls	Boltzmann code at every step, or a neural emulator trained over the whole prior	valid only within a few σ of the fiducial model
one simulated χ^2 spectrum, $f_{\rm sky}$ mode count	real cut-sky cross-spectra at three frequencies with a calibrated covariance	no mode coupling or foregrounds: $\sigma(n_s)$ about 7 per cent too small
temperature only, Gaussian prior on τ	TT, TE, EE, lensing; a non-Gaussian lowE likelihood	weaker constraints; a symmetric τ posterior
no nuisance parameters	about fifteen foreground and calibration parameters marginalised	widths and correlations slightly optimistic
toy sky: $N_{\rm side} = 256$, $\ell \le 601$, 2000 Gaussian simulations	$N_{\rm side} = 2048$, $\ell \le 2500$, 300 end-to-end plus 1000 sky simulations	fewer modes; covariance noise of order $\sqrt{2/n}$ on each element
chains of $4 \times (2\text{–}4) \times 10^4$ steps in seconds	chains of 10^5 or more steps, days on a cluster with a Boltzmann code	none at the level of the diagnostics shown
importance check on 400 samples	reweighting the full chain in parallel	a check of the bulk, not of the far tails

Recap

- For a linear model with Gaussian errors the posterior is exactly Gaussian, with mean the weighted least-squares fit and covariance $(\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A})^{-1}$, the Fisher matrix; the chain reproduces it, as does `emcee`.
- A column of a chain is a sample of that parameter's marginal: marginalising a nuisance parameter means ignoring its column. The marginal is wider than the slice at the best fit by $1/\sqrt{1-\rho^2}$.

- Published error bars depend on the noise model: Padilla et al.'s straight-line widths are those of one unknown common σ (a Student-t posterior), not of the stated errors.
- Slope and intercept correlate as $-\bar{x}_w/\sqrt{\overline{x^2}_w}$; centring x (or choosing a pivot) removes the correlation and speeds the chain by orders of magnitude.
- A nonlinear model gives a skewed posterior that the Laplace (peak Gaussian) approximation misses and the chain does not. An unknown noise level, integrated out, turns $e^{-\chi^2/2}$ into $(\chi^2)^{-N/2}$; sampling it and ignoring its column gives the same marginal. Fixing it at a wrong value gives wrong widths without warning.
- Hyperparameters with prior $e^{-\alpha}$ give $(\chi_k^2 + 2)^{-(n_k/2+1)}$ per data set and let a posterior follow the consistent data; the Bayes factor is a ratio of integrals, not of likelihoods at a point. Multimodal posteriors defeat chains that never cross between modes.
- On the full sky the CMB likelihood is exact: $-2\ln\mathcal{L} = \sum_\ell (2\ell+1)[\widehat{C}_\ell/C_\ell + \ln C_\ell]$, with $C_\ell \to T_\ell^2 C_\ell + N_\ell$ for beam and noise and $2\ell+1 \to (2\ell+1)f_{\text{sky}}$ for a partial sky; it is skewed at low ℓ.
- Gaussian approximations differ from it in the cubic term in $\widehat{C}_\ell/C_\ell - 1$. $\mathcal{L}_Q$ biases a spectrum up by $0.9/\ell$ in bins of ten and n_s by more than one standard deviation; a fixed fiducial covariance ($\mathcal{L}_f$, Planck's choice) is unbiased in the ideal case. Hamimeche and Lewis's Fig. 1 is reproduced to a few per cent.
- An emulator in $\ln C_\ell$ is natural ($\ln A_s$ and τ enter linearly, n_s almost) and must be validated with $\Delta\chi^2 = \sum \frac{\nu}{2}[\delta C/(C+N)]^2 \ll 1$: first order for $(\ln A_s, n_s)$, second order for six parameters.
- The amplitude and tilt are a straight-line fit in $x_\ell = \langle \ln k/k_* \rangle_\ell$; the sign of their correlation is the side of the pivot the data lie on.
- A Planck-like TT+lowE simulation reproduces Planck 2018's widths to ten per cent with six parameters free; $\sigma(\ln A_s) \approx 2\sigma_\tau$ because TT measures only $A_s e^{-2\tau}$; fixing the other parameters makes the amplitude nine times and the tilt twice too precise.
- Importance sampling reweights a chain by $\mathcal{L}_{\text{new}}/\mathcal{L}_{\text{old}}$; the effective sample size $(\sum w)^2/\sum w^2$ shows when it works (compatible data, accurate approximations) and when it fails (tension).

Reading the literature

- **Markov chains and MCMC, textbook level.** Wasserman, *All of Statistics*, Chapters 23 (Markov chains) and 24 (Metropolis–Hastings, Gibbs) [Wasserman pp. 381–420]; Kruschke, *Doing Bayesian Data Analysis*, Chapters 7 (MCMC with the island-hopping politician, diagnostics) and 17 (regression, centring, posterior predictive lines) [Kruschke Chs. 7, 8, 17]; Lambert, *A Student's Guide to Bayesian Statistics*, Chapters 12–14 on the typical set, $\hat{R}$ and effective sample size [Lambert Chs. 12–14].

- **Planck.** Planck 2018 V on the likelihoods [70] and VI on the cosmological parameters [25]; Planck 2018 I for the instrument [159]; CAMB [8].

Chapter summary

A posterior that can be evaluated point by point but not integrated is known only in principle. A Markov chain turns it into a sample. The chain is a random walker that remembers only where it is; if the target density is stationary for its hopping rule, the walker forgets where it started and its time averages converge to averages over the target. Metropolis–Hastings supplies such a rule for any target: propose a step, accept it with the ratio of densities, and repeat the current point on refusal. Without the accept–reject step the walker would diffuse forever and sample nothing; the step is the bias that makes it linger where the probability is high, and because only ratios enter, the evidence never has to be computed. A finite chain is trusted only after its diagnostics: burn-in, several chains that agree ($\hat{R}$), and the autocorrelation time that converts N steps into N/τ independent ones. Then every marginal is a histogram of a column, and every constraint is read off. On a straight line, a decaying source and a full-sky spectrum the chain reproduces exact answers; on a masked sky and a six-parameter Planck-like spectrum it is the instrument that produces them, reproducing Planck's published widths once the same parameters are left free. In the pipeline

$$\text{physical model} \to \text{field} \to \text{summary } S \to P(S \mid \theta) \to \boxed{\text{infer physics}},$$

Markov chain Monte Carlo is the last arrow: it turns the sampling distribution of Chapters 7 and 8 into posterior constraints. Chapter 10 gives the fast Gaussian forecast that the chains check, Chapter 12 applies the same chains to topological summaries, and Chapter 13 runs them on Planck data.

Markov chains

concept	operational meaning	used later in
Markov chain	next state drawn from $p(x, \cdot)$ depending only on the current state; rows of P are pmfs	Chapters 12 and 13
stationary distribution	$\pi P = \pi$; probability flowing in balances flowing out	Chapters 10 and 13
detailed balance	$\pi_i p_{ij} = \pi_j p_{ji}$; sufficient for stationarity; no net currents	Chapter 13
irreducible, aperiodic, positive recurrent	every state reachable, no cycles, finite return time: the chain converges	Chapter 13
convergence (forgetting)	$\|p_t - \pi\|_{\mathrm{TV}} \sim \|\lambda_2\|^t$; any start is forgotten	Chapter 13
ergodic theorem	time average along one chain $\to$ average over π	Chapters 10, 12 and 13
autocorrelation time	$\tau = 1 + 2\sum \rho_k$; variance of a chain mean $\sigma^2\tau/N$	Chapters 12 and 13
free random walk	spreads as $\sqrt{t}$, no stationary law: the walker MH must bias	Chapter 11

The biased random walker

concept	operational meaning	used later in
Metropolis–Hastings	propose $y \sim q(y \mid x)$, accept with $\min(1, f(y)q(x \mid y)/f(x)q(y \mid x))$, else repeat x	Chapters 11 to 13
only ratios	evidence and partition function cancel; work with $\ln f$	Chapter 13
Hastings factor	Jacobian of an asymmetric proposal; omitting it samples the wrong target	Chapter 13
step size	round step $2.38/\sqrt{D}$ target widths, acceptance ≈ 0.23; shape the proposal by the covariance	Chapters 10 and 13
burn-in	cut where $\ln p$ settles near $\ln p_{\max} - D/2$, not at the peak	Chapter 13
ESS, MCSE	N/τ effective draws; Monte Carlo error $\mathrm{SD}\sqrt{\tau/N}$; thinning never helps	Chapters 12 and 13
$\hat{R}$	several overdispersed chains; $\sqrt{\hat{V}/W} \to 1$; blind to modes no chain found	Chapter 13
start vs prior	the start is forgotten, the prior is part of the target	Chapters 10 and 13
canonical ensemble	Metropolis samples $e^{-H/kT}$; MCMC time is not physical time	Chapter 12
Gibbs, HMC, ensembles	always-accepted conditional moves; Hamiltonian flights; affine-invariant walkers (`emcee`)	Chapters 11 and 13

MCMC at work

concept	operational meaning	used later in
marginal from a chain	histogram one column, ignore the others	Chapters 10, 12 and 13
linear-Gaussian posterior	exact Gaussian with covariance $(\mathbf{A}^\mathsf{T}\mathbf{W}\mathbf{A})^{-1}$ = inverse Fisher matrix	Chapter 10
centring, pivot	move the origin to the data's weighted centre to decorrelate parameters	Chapters 10 and 13
Laplace approximation	Gaussian from the curvature at the peak; misses skewness of nonlinear models	Chapter 10
nuisance noise level	integrate out $((\chi^2)^{-N/2})$ or sample and ignore; never fix at a guess	Chapters 11 and 13
hyperparameters	one marginalised weight per data set, $(\chi_k^2 + 2)^{-(n_k/2+1)}$; Bayes factor by integration	Chapter 11
exact full-sky C_ℓ likelihood	$\sum(2\ell+1)[\widehat{C}_\ell/C_\ell + \ln C_\ell]$; $C_\ell \to T^2 C_\ell + N$; $\nu \to (2\ell+1) f_{\rm sky}$	Chapters 10 and 13
Gaussian C_ℓ likelihoods	fixed fiducial covariance unbiased; model-dependent variance ($\mathcal{L}_Q$) biases n_s by $\sim 1\sigma$	Chapter 13
emulator	Taylor series of $\ln C_\ell$; validate by $\Delta\chi^2 = \sum \frac{\nu}{2}(\delta C/(C+N))^2 \ll 1$ on the posterior	Chapters 10 and 13
triangle plot	1-D and 2-D marginals; 68/95 per cent levels by sorted cells; $\Delta\chi^2 = 2.30, 6.18$ in 2-D	Chapters 10, 12 and 13
$A_s e^{-2\tau}$ degeneracy	TT measures $\ln A_s - 2\tau$; $\sigma(\ln A_s) \approx 2\sigma_\tau$	Chapters 10 and 13
importance sampling	reweight by $\mathcal{L}_{\rm new}/\mathcal{L}_{\rm old}$; $N_{\rm eff} = (\sum w)^2/\sum w^2$; fails for data in tension	Chapters 11 and 13

Chapter 10

The Fisher Matrix: Forecasting What Data Can Teach

Where this chapter is going

Everything so far has started from data. In Chapter 3 a data set gave a likelihood, the likelihood had a peak, and the width of the peak was the error bar. In Chapter 9 a simulated temperature spectrum gave a posterior over six cosmological parameters, and a Markov chain mapped it out. Now turn the question around. A satellite costs a billion euros and takes fifteen years to build. Before a single photon is collected, a committee wants to know: *if we build this instrument, how well will it measure the parameters we care about?* Which beam size, which noise level, which fraction of the sky? There are no data yet, so there is no likelihood to look at.

What we do have is a model of the experiment: a model of the signal, a model of the noise, and a guess for the true parameters. That is enough to say what the data would look like, on average, and therefore how sharply peaked the likelihood would be, on average. The average sharpness of the peak is a matrix, the **Fisher matrix**: the expected curvature of $-\ln \mathcal{L}$ at the true parameters. Its inverse is the covariance of the parameters that the experiment will deliver. So a forecast costs one matrix inversion instead of a satellite.

Making the idea precise takes a few steps. The Fisher matrix has two faces, the covariance of the score and the average curvature, and they are equal. No unbiased method can beat its inverse (the Cramér–Rao bound), and maximum likelihood reaches it when the data are informative. For Gaussian data there is a closed formula, which splits the information into a part carried by the mean and a part carried by the covariance. Reading the matrix needs care: the error with the other parameters fixed is not the error with them free, and the difference is a Schur complement. Priors and independent experiments are added as matrices, a change of parameters is a Jacobian sandwich, and a nuisance parameter is removed by inverting. Then we forecast the six ΛCDM parameters for a Planck-like experiment, check the forecast against what Planck actually achieved, reproduce Knox's 1995 forecast and the classic degeneracies of the CMB, and test the whole method against the Markov chain of Chapter 9. Part 10b applies the same machinery to gravitational waves. The last part turns it on a tiny twist of the CMB polarization: a forecast of how small a rotation angle a Planck-like map can detect, and a thousand simulated masked skies that check the forecast (Sections 10.15 and 10.17), the rehearsal for the real-data measurement of Chapter 13 (Figure 10.1).

In the pipeline of the book (physical model → field or data set → what matters → summary → sampling distribution → inference), the Fisher matrix lives on the last two arrows, but it uses them *before* the data exist. It takes the sampling distribution $p(\boldsymbol{d} \mid \boldsymbol{\theta})$ of Chapters 7 and 8 and asks how wide the inference of Chapter 9 will be, on average, for an experiment that has not been built.

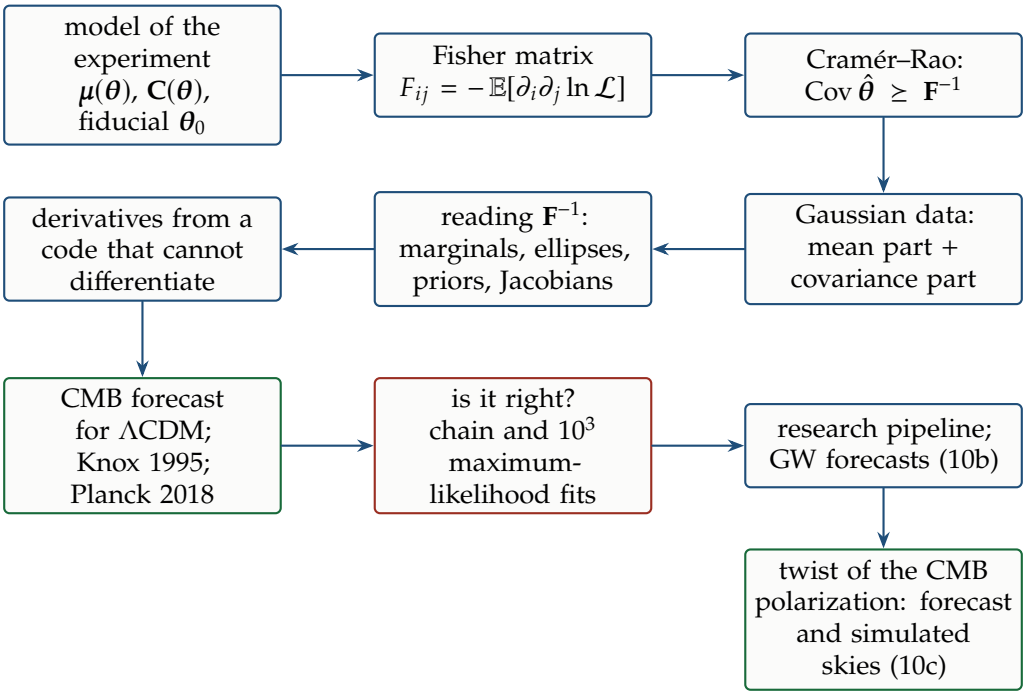

Figure 10.1: The route of the chapter. A model of the experiment and a guess for the truth give the Fisher matrix; the Cramér–Rao bound says what its inverse means; Gaussian data give it in closed form; a short grammar tells us how to read and combine it; finite differences supply the derivatives. The green boxes are the worked applications on the CMB, the last of them a forecast and simulation of a rotation of the polarization; the red box is the test of whether the forecast can be trusted.

10.1 How sharp will the likelihood be? The Fisher matrix

Two teams propose an experiment to measure the angular distribution of a scattering process. The theory says that the cosine $x = \cos\theta$ of the scattering angle has the density

$$f(x;\alpha,\beta) = \frac{1 + \alpha x + \beta x^2}{\mathcal{N}(\alpha,\beta)}, \qquad -0.95 \leq x \leq 0.95, \tag{10.1}$$

where α and β are the two numbers the theory wants measured and $\mathcal{N}$ makes the density integrate to one over the range the detector sees [Cowan §6.8, (6.26)–(6.27)]. One team promises 2000 events, the other 500 events with a wider acceptance. Which proposal will measure β better, and by how much? Nobody has taken data. Yet the answer can be worked out exactly, today, from (10.1) alone. That is what a forecast is: a statement about data nobody has yet taken, computed from the model of the experiment.

The question in words. In Section 3.12 we learned to read an error bar off one data set: the log-likelihood $\ln \mathcal{L}(\theta)$ has a peak at the maximum-likelihood estimate $\hat{\theta}$, and the sharper the peak, the smaller the error. Here there is no data set, so there is no peak to look at. The question becomes: *if the parameters have some definite true value and we run this experiment many times, how sharp will the peak of the log-likelihood be, on average?*

The hidden assumption. The question already contains an assumption: "the parameters have some definite true value". A forecast is always made *at* a chosen point $\boldsymbol{\theta}_0$, the **fiducial model** [the parameter values we assume nature has chosen, used to simulate or average over the data]. The width of the likelihood generally depends on where we sit. For the angular

distribution, a measurement of β near $\beta = 0$ and near $\beta = 5$ are different problems. So every forecast here reads: "*if* the truth is $\boldsymbol{\theta}_0$, the experiment will measure $\boldsymbol{\theta}$ to within ... ". Changing $\boldsymbol{\theta}_0$ changes the answer; for a linear model it does not, and that is the only case where the fiducial does not matter [HobsonBMC p. 107].

10.1.1 From the curvature of one likelihood to the average curvature

Start with one data set $\boldsymbol{d}$ and m parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m)$. Near its maximum $\hat{\boldsymbol{\theta}}$, the log-likelihood $\ell(\boldsymbol{\theta}) = \ln \mathcal{L}(\boldsymbol{\theta})$ is a smooth hill. Expand it in a Taylor series about the top [Sivia (3.17)–(3.19)], [HobsonBMC (5.13)–(5.14)]:

$$\ell(\boldsymbol{\theta}) \overset{(1)}{=} \ell(\hat{\boldsymbol{\theta}}) + \sum_i \frac{\partial \ell}{\partial \theta_i}\Big|_{\hat{\boldsymbol{\theta}}} (\theta_i - \hat{\theta}_i) + \frac{1}{2} \sum_{ij} \frac{\partial^2 \ell}{\partial \theta_i \partial \theta_j}\Big|_{\hat{\boldsymbol{\theta}}} (\theta_i - \hat{\theta}_i)(\theta_j - \hat{\theta}_j) + \ldots$$

$$\overset{(2)}{=} \ell(\hat{\boldsymbol{\theta}}) - \frac{1}{2} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}} \boldsymbol{\mathcal{H}} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \ldots, \qquad \mathcal{H}_{ij} \equiv -\frac{\partial^2 \ell}{\partial \theta_i \partial \theta_j}\Big|_{\hat{\boldsymbol{\theta}}}. \tag{10.2}$$

(1) Taylor's theorem in m variables, to second order.

(2) At the top of the hill every first derivative vanishes, so the linear terms drop out. We collect the second derivatives, with a minus sign, into the matrix $\boldsymbol{\mathcal{H}}$; at a maximum it is positive definite [$\boldsymbol{v}^{\mathsf{T}} \boldsymbol{\mathcal{H}} \boldsymbol{v} > 0$ for every nonzero vector $\boldsymbol{v}$, so the hill falls off in every direction].

Why the curvature is a covariance. Exponentiate (10.2), dropping the higher terms: $\mathcal{L}(\boldsymbol{\theta}) \propto \exp[-\frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}} \boldsymbol{\mathcal{H}} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})]$. Take one parameter first. Then $\boldsymbol{\mathcal{H}}$ is a single positive number $\mathcal{H}$ and the likelihood is $\exp[-\mathcal{H}(\theta - \hat{\theta})^2/2]$. A Gaussian of variance σ^2 has the shape $\exp[-(\theta - \hat{\theta})^2/2\sigma^2]$; the two match when $1/\sigma^2 = \mathcal{H}$, so the variance is $1/\mathcal{H}$. With many parameters, the Gaussian of covariance matrix $\boldsymbol{\Sigma}$ has the shape $\exp[-\frac{1}{2}\boldsymbol{d}^{\mathsf{T}} \boldsymbol{\Sigma}^{-1} \boldsymbol{d}]$ with $\boldsymbol{d} = \boldsymbol{\theta} - \hat{\boldsymbol{\theta}}$, and matching the two exponents term by term gives $\boldsymbol{\Sigma}^{-1} = \boldsymbol{\mathcal{H}}$, that is $\boldsymbol{\Sigma} = \boldsymbol{\mathcal{H}}^{-1}$ [Sivia (3.31)–(3.32)]. This is the many-parameter version of "the curvature is the error bar". The matrix $\boldsymbol{\mathcal{H}}$ is the **observed information**: the curvature of *this* likelihood, at *this* peak.

From one data set to the average. Each new data set has its own peak and its own curvature. To forecast, we average over the data sets the experiment could produce, drawn from $p(\boldsymbol{d} \mid \boldsymbol{\theta}_0)$, and evaluate the second derivatives at the fiducial point rather than at a peak we do not have. Two facts make this a small change for large data sets. First, with n independent observations ℓ is a sum of n terms, so its curvature is a sum of n independent curvatures. By the law of large numbers that sum is n times its average plus a fluctuation whose relative size falls as $1/\sqrt{n}$. Second, the peak $\hat{\boldsymbol{\theta}}$ lies within a distance of order $1/\sqrt{n}$ of $\boldsymbol{\theta}_0$ (consistency, Section 3.13.1), so moving the point of evaluation from $\hat{\boldsymbol{\theta}}$ to $\boldsymbol{\theta}_0$ changes the curvature by a relative amount of the same order. The average curvature at the truth is the Fisher matrix [Wasserman p. 133, (9.18)], [165]:

$$\boxed{F_{ij}(\boldsymbol{\theta}_0) = -\,\mathbb{E}_{\boldsymbol{\theta}_0}\left[\frac{\partial^2 \ln p(\boldsymbol{d} \mid \boldsymbol{\theta})}{\partial \theta_i \, \partial \theta_j}\right]_{\boldsymbol{\theta} = \boldsymbol{\theta}_0}} \tag{10.3}$$

where $\mathbb{E}_{\boldsymbol{\theta}_0}$ is an average over data drawn from the model at $\boldsymbol{\theta}_0$.[1] Read in words: *how fast, on average, does the log-likelihood fall away from the truth?* The two facts above together give $\boldsymbol{\mathcal{H}}(\hat{\boldsymbol{\theta}}) = \mathbf{F}(\boldsymbol{\theta}_0)\,[1 + O(1/\sqrt{n})]$. So the covariance $\boldsymbol{\mathcal{H}}^{-1}$ that one data set would show is, up to corrections of relative size $1/\sqrt{n}$, the matrix $\mathbf{F}^{-1}$ that we can compute before any data exist. The exact statement, that no unbiased estimate can scatter less than $\mathbf{F}^{-1}$, is the Cramér–Rao bound of Section 10.2.

[1] Hobson et al. [HobsonBMC (5.14)–(5.15)] define $H_{ij} = \partial^2 \ln \mathcal{L}/\partial\theta_i \partial\theta_j$ and then write $F_{ij} = \langle H_{ij} \rangle$; with that sign $\mathbf{F}$ would be negative definite. The Hessian there must be that of $-\ln \mathcal{L}$, as in Tegmark et al. [165], eq. (4), who write $\mathcal{L} = -\ln L$.

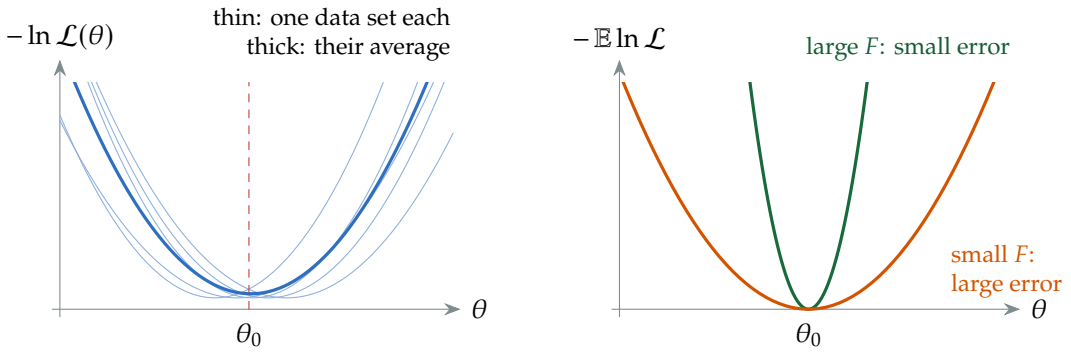

Figure 10.2: Left: every data set the experiment could produce gives its own log-likelihood (thin curves), with its own minimum of $-\ln \mathcal{L}$ near the true value θ_0 and its own curvature; the Fisher information is the curvature of their average (thick curve) at θ_0. Right: the forecast compares experiments by this average curvature, a sharp valley meaning a small error bar.

Working definition 10.1 (Fisher matrix)

For data with density $p(\boldsymbol{d} \mid \boldsymbol{\theta})$ and a fiducial point $\boldsymbol{\theta}_0$, the **Fisher matrix** is the $m \times m$ matrix $F_{ij} = -\mathbb{E}_{\boldsymbol{\theta}_0}[\partial_i \partial_j \ln p(\boldsymbol{d} \mid \boldsymbol{\theta})] = \mathbb{E}_{\boldsymbol{\theta}_0}[S_i S_j]$, where $S_i = \partial_i \ln p(\boldsymbol{d} \mid \boldsymbol{\theta})$ is the **score** [the slope of the log-likelihood in the direction of θ_i, a random quantity because the data are random], all evaluated at $\boldsymbol{\theta}_0$. *Operationally:* write the log-likelihood of the planned experiment, differentiate twice, average over data simulated at $\boldsymbol{\theta}_0$ (or do the average analytically), and change the sign. Its inverse $\mathbf{F}^{-1}$ is the forecast covariance of the parameters.

10.1.2 Two faces of one matrix: average curvature and covariance of the score

For one parameter, Section 3.12.3 proved that the score has mean zero and that its variance equals minus the average curvature. The same two facts hold for many parameters, component by component, and they are worth redoing because the second one is what makes the Fisher matrix a covariance matrix, and hence positive semidefinite.

The score has mean zero. Write $p = p(\boldsymbol{d} \mid \boldsymbol{\theta})$ and $\partial_i = \partial/\partial\theta_i$. For each i,

$$\mathbb{E}[S_i] \overset{(1)}{=} \int \frac{\partial_i p}{p}\, p \, \mathrm{d}\boldsymbol{d} \overset{(2)}{=} \partial_i \int p \, \mathrm{d}\boldsymbol{d} \overset{(3)}{=} \partial_i 1 = 0. \tag{10.4}$$

(1) The expectation is an integral over data weighted by their density at the same $\boldsymbol{\theta}$, and $\partial_i \ln p = \partial_i p / p$.
(2) The p cancels; take the derivative outside the integral. This exchange is the regularity condition: it needs the range of the data not to depend on $\boldsymbol{\theta}$ (Section 3.13.3).
(3) A density integrates to one for every value of $\boldsymbol{\theta}$.

The covariance of the score is minus the average Hessian. Differentiate the identity $\int (\partial_i \ln p)\, p \, \mathrm{d}\boldsymbol{d} = 0$ with respect to θ_j:

$$0 \overset{(1)}{=} \int \Big[(\partial_j \partial_i \ln p)\, p + (\partial_i \ln p)\, \partial_j p \Big] \mathrm{d}\boldsymbol{d} \overset{(2)}{=} \int \Big[\partial_i \partial_j \ln p + (\partial_i \ln p)(\partial_j \ln p) \Big] p \, \mathrm{d}\boldsymbol{d},$$

$$\mathbb{E}[S_i S_j] \overset{(3)}{=} -\mathbb{E}[\partial_i \partial_j \ln p] = F_{ij}. \tag{10.5}$$

(1) Product rule under the integral, again exchanging derivative and integral.

(2) $\partial_j p = (\partial_j \ln p)\, p$.
(3) Split the integral into two expectations. Since $\mathbb{E}\, S_i = 0$ by (10.4), the left side $\mathbb{E}[S_i S_j]$ is the covariance $\mathrm{Cov}(S_i, S_j)$.

So $\mathbf{F}$ is the covariance matrix of the score vector. A covariance matrix is positive semidefinite: $\boldsymbol{v}^\mathsf{T}\mathbf{F}\boldsymbol{v} = \mathrm{Var}(\boldsymbol{v}^\mathsf{T}\boldsymbol{S}) \geq 0$ for every $\boldsymbol{v}$. If it is strictly positive, $\mathbf{F}$ can be inverted. If some combination $\boldsymbol{v}^\mathsf{T}\boldsymbol{S}$ has zero variance, the data never respond to a change of the parameters along $\boldsymbol{v}$: that combination is not measured at all, $\mathbf{F}$ is singular, and no amount of data will fix it (an **exact degeneracy**).

Independent pieces of data add. If the data consist of independent parts, $p(\boldsymbol{d}\,|\,\boldsymbol{\theta}) = \prod_k p_k(\boldsymbol{d}_k\,|\,\boldsymbol{\theta})$, the log-likelihood is a sum, every second derivative is a sum, and so is its average: $\mathbf{F} = \sum_k \mathbf{F}_k$. For n independent, identically distributed observations $\mathbf{F} = n\,\mathbf{F}_1$ [Cowan (6.20)], which is where the familiar $1/\sqrt{n}$ comes from: $\mathbf{F}^{-1} \propto 1/n$, so the error bars shrink as $1/\sqrt{n}$.

Example: a Gaussian sample, mean and width both unknown. Take n independent draws $x_k \sim \mathcal{N}(\mu, \sigma^2)$ and $\boldsymbol{\theta} = (\mu, \sigma)$. Section 3.13.2 averaged the three second derivatives of $\ln f = -\ln\sigma - (x-\mu)^2/2\sigma^2$ and found [Wasserman p. 134, Ex. 9.29]

$$\mathbf{F} = n \begin{pmatrix} 1/\sigma^2 & 0 \\ 0 & 2/\sigma^2 \end{pmatrix}.$$

Seen as a covariance of scores, every entry of this matrix has a plain reason, and it is worth computing them once that way. Write $u_k = x_k - \mu$ for the deviations; each has mean 0 and variance σ^2, and for a Gaussian $\mathbb{E}[u^3] = 0$ and $\mathbb{E}[u^4] = 3\sigma^4$ (the Gaussian fourth moment behind (3.34)). The two scores are $S_\mu = \sum_k u_k/\sigma^2$ and $S_\sigma = \sum_k (u_k^2 - \sigma^2)/\sigma^3$. Then

$$\begin{aligned}
\mathrm{Var}\, S_\mu &\overset{(1)}{=} \frac{n\,\mathrm{Var}\, u}{\sigma^4} = \frac{n}{\sigma^2}, \\
\mathrm{Var}\, S_\sigma &\overset{(2)}{=} \frac{n\,\mathrm{Var}(u^2)}{\sigma^6} \overset{(3)}{=} \frac{n\,(3\sigma^4 - \sigma^4)}{\sigma^6} = \frac{2n}{\sigma^2}, \\
\mathrm{Cov}(S_\mu, S_\sigma) &\overset{(4)}{=} \frac{n\;\mathbb{E}[u\,(u^2 - \sigma^2)]}{\sigma^5} = \frac{n\,(\mathbb{E}\,u^3 - \sigma^2\,\mathbb{E}\,u)}{\sigma^5} \overset{(5)}{=} 0.
\end{aligned}$$

(1) The n terms are independent, so their variances add; dividing a variable by σ^2 divides its variance by σ^4.
(2) The same, with the constant $-\sigma^2$ in each term not changing the variance.
(3) $\mathrm{Var}(u^2) = \mathbb{E}[u^4] - (\mathbb{E}\,u^2)^2 = 3\sigma^4 - \sigma^4 = 2\sigma^4$.
(4) Terms with different k are independent and have mean zero, so only the n terms with the same k survive; both scores have mean zero, so the covariance is the mean of the product.
(5) A Gaussian is symmetric about μ, so its odd moments $\mathbb{E}\,u$ and $\mathbb{E}\,u^3$ vanish.

These are the entries of $\mathbf{F}$ above. The width score has twice the variance of the mean score because u^2 fluctuates by $\sqrt{2}\sigma^2$ about its mean while u fluctuates by σ; the two scores are uncorrelated because one is odd in the deviations and the other even. Since $\mathbf{F}$ is diagonal, its inverse is found entry by entry, $\mathbf{F}^{-1} = \mathrm{diag}(\sigma^2/n,\ \sigma^2/2n)$. The forecast errors are therefore $\sigma/\sqrt{n}$ on the mean and $\sigma/\sqrt{2n}$ on the width, and the two estimates are uncorrelated.

The score cloud in Python. The covariance face of $\mathbf{F}$ can be watched directly. The script `02_score_cloud.py` draws 20000 samples of $n = 20$ points from $\mathcal{N}(0,1)$, computes the score vector (S_μ, S_σ) of each at the true parameters, and plots the cloud (Figure 10.3, left). The mean

score is $(+0.044, +0.001)$, consistent with zero: the simulation noise is $\sqrt{20/20000} \approx \pm 0.03$ on the first entry and $\sqrt{40/20000} \approx \pm 0.05$ on the second. The covariance of the cloud has diagonal $(19.95, 39.96)$ and off-diagonal -0.02; the average of minus the Hessian has diagonal $(20.00, 40.00)$ and off-diagonal $+0.09$; and the formula above gives $(20, 40)$ and 0. Three routes, one matrix.

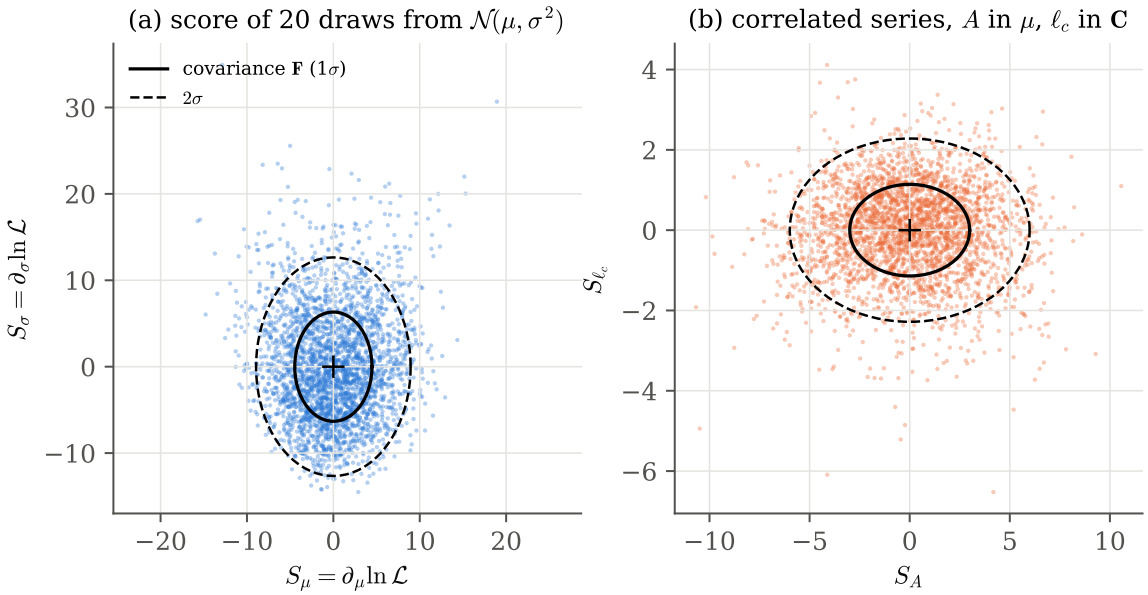

Figure 10.3: The score is a random vector whose covariance is the Fisher matrix. Each point is the slope of the log-likelihood of one simulated data set, evaluated at the true parameters; the solid and dashed ellipses are drawn from $\mathbf{F}$ alone. Left: 20 Gaussian draws, parameters (μ, σ). Right: a correlated time series in which the amplitude A enters the mean and the correlation length ℓ_c enters the covariance (Section 10.3).

10.1.3 Example: forecasting Cowan's angular distribution

Back to the two proposals. Cowan used this very density to ask a question every experimenter meets [Cowan §6.8]: *how precisely can two shape parameters be pulled out of one finite sample, and does the error bar read off a single fit agree with the scatter we would see if the experiment were repeated many times?* The second half matters because in practice there is only one data set, and the error bar quoted from it has to stand in for the scatter of experiments that will never be done.

His setup. The density (10.1), seen through the window $-0.95 \le x \le 0.95$, with true values $\alpha = \beta = 0.5$. He generated one sample of 2000 events, found the maximum of the likelihood, and read the errors and the correlation off the numerical Hessian of that one fit [Cowan (6.28)]. Then he generated 500 further samples of 2000 events, fitted each, and took the standard deviations and the correlation of the 500 estimates [Cowan (6.29)]. His numbers are in the first two rows of Table 10.1. Our question: can we predict them without generating a single event?

The log-density of one event. With $g(x) = 1 + \alpha x + \beta x^2$ and the normalisation over the window $[a, b] = [-0.95, 0.95]$,

$$\mathcal{N}(\alpha, \beta) = \int_a^b g \, \mathrm{d}x = (b - a) + \alpha \frac{b^2 - a^2}{2} + \beta \frac{b^3 - a^3}{3}, \qquad \ln f = \ln g(x) - \ln \mathcal{N}(\alpha, \beta).$$

Its score. Differentiating, $\partial_\alpha \ln f = x/g - \mathcal{N}_\alpha/\mathcal{N}$ and $\partial_\beta \ln f = x^2/g - \mathcal{N}_\beta/\mathcal{N}$, with $\mathcal{N}_\alpha = (b^2 - a^2)/2$ and $\mathcal{N}_\beta = (b^3 - a^3)/3$ the derivatives of the normalisation. *The Fisher matrix per event* is the

covariance of this score, an integral over the model:

$$I_{ij} = \mathbb{E}[\partial_i \ln f \, \partial_j \ln f] = \int_a^b \partial_i \ln f \; \partial_j \ln f \; f(x) \, \mathrm{d}x, \tag{10.6}$$

which we do by numerical quadrature:

Listing 10.1: The Fisher matrix of one event: the covariance of the score, integrated over the model (`code/ch10/01_cowan_two_param.py`)

```
41 def fisher_per_event(a, b):
42     """I_ij = E[d_i ln f d_j ln f] = int (d_i f)(d_j f)/f dx, with d_i f by hand."""
43     n = norm(a, b)
44     dn = np.array([(XMAX**2 - XMIN**2) / 2, (XMAX**3 - XMIN**3) / 3])   # d norm / d(a, b)
45
46     def dlnf(x):
47         g = 1 + a * x + b * x**2
48         return np.array([x / g - dn[0] / n, x**2 / g - dn[1] / n])
49
50     I = np.zeros((2, 2))
51     for i in range(2):
52         for j in range(2):
53             I[i, j] = integrate.quad(lambda x: dlnf(x)[i] * dlnf(x)[j] * pdf(x, a, b),
       XMIN, XMAX)[0]
54     return I
```

Lines 46–48 are the score written above; line 53 is (10.6), one quadrature per matrix element. No random number appears anywhere. It gives $I_{\alpha\alpha} = 0.2250$, $I_{\alpha\beta} = -0.0451$ and $I_{\beta\beta} = 0.0497$.
Many events. The events are independent, so $\mathbf{F} = 2000\,\boldsymbol{I}$, with entries $F_{\alpha\alpha} = 450$, $F_{\alpha\beta} = -90$ and $F_{\beta\beta} = 99$.

The forecast is the inverse. For a symmetric 2×2 matrix the inverse is the swapped diagonal with the off-diagonal negated, divided by the determinant:

$$\mathbf{F}^{-1} = \frac{1}{\det \mathbf{F}} \begin{pmatrix} F_{\beta\beta} & -F_{\alpha\beta} \\ -F_{\alpha\beta} & F_{\alpha\alpha} \end{pmatrix}, \qquad \det \mathbf{F} = F_{\alpha\alpha}F_{\beta\beta} - F_{\alpha\beta}^2, \tag{10.7}$$

as multiplying it by $\mathbf{F}$ confirms. The diagonal entries are the variances and the off-diagonal entry the covariance, so

$$\sigma_\alpha^2 = \frac{F_{\beta\beta}}{\det \mathbf{F}}, \qquad \sigma_\beta^2 = \frac{F_{\alpha\alpha}}{\det \mathbf{F}}, \qquad \rho = \frac{(\mathbf{F}^{-1})_{\alpha\beta}}{\sigma_\alpha \sigma_\beta} = \frac{-F_{\alpha\beta}/\det \mathbf{F}}{\sqrt{F_{\alpha\alpha}F_{\beta\beta}}/\det \mathbf{F}} = -\frac{F_{\alpha\beta}}{\sqrt{F_{\alpha\alpha}F_{\beta\beta}}}.$$

With the numbers above, $\det \mathbf{F} = 450 \times 99 - (-90)^2 \approx 3.6 \times 10^4$, so $\sigma_\alpha = \sqrt{99/\det \mathbf{F}} = 0.052$, $\sigma_\beta = \sqrt{450/\det \mathbf{F}} = 0.111$, and $\rho = -(-90)/\sqrt{450 \times 99} = +0.43$. A negative entry of the Fisher matrix becomes a positive correlation: the sign flips in the inverse.

Our own repeats. To have a second set of repeats with known code, `01_cowan_two_param.py` also generates 500 experiments of 2000 events, fits each by Newton–Raphson, and records the observed Hessian of the first one (Figure 10.4).

Why the rows differ. The scatter of 500 fits is itself an estimate. The standard deviation of N Gaussian numbers has a relative error of $1/\sqrt{2(N-1)}$, which is 3% for $N = 500$, and a correlation coefficient has an error of about $(1-\rho^2)/\sqrt{N} \approx 0.04$. Cowan's repeats differ from the forecast by 2%, 0% and 0.01, all inside these limits; ours by about 4%, 3% and 0.01, about one sampling error. The single-fit rows differ for another reason. The observed Hessian $\boldsymbol{\mathcal{H}}$ is the curvature of one particular likelihood, and it fluctuates from data set to data set by a relative amount of order $1/\sqrt{n}$ (Section 10.1.1); the Fisher matrix is its average. That is why

	σ_α	σ_β	ρ
Cowan, Hessian of one fit	0.052	0.11	0.46
Cowan, scatter of 500 fits	0.051	0.111	0.42
ours, Fisher forecast (no events)	0.052	0.111	0.43
ours, Hessian of one fit	0.053	0.115	0.38
ours, scatter of 500 fits	0.050	0.108	0.44

Table 10.1: Cowan's two-parameter example [Cowan (6.28)–(6.29)], 2000 events at $\alpha = \beta = 0.5$. A standard deviation estimated from 500 fits carries a sampling error of $1/\sqrt{2 \times 499} \approx \pm 3\%$, and a correlation $\pm(1-\rho^2)/\sqrt{500} \approx \pm 0.04$.

Cowan's single fit gives $\rho = 0.46$ and ours 0.38, on either side of 0.43, while their errors stay within a few per cent of the forecast. For 2000 events the fluctuation is small, so his first row and his second row are two estimates of the same thing, and the Fisher matrix is the number both scatter around.

The positive correlation also has a plain reason. Over the window the two shapes x and x^2 both rise towards $x = +0.95$, and since the density must stay normalised, an upward fluctuation in the number of events at large positive x can be absorbed partly by α and partly by β, so the two estimates tend to move together.

The answer to the proposal question is now one line. Errors scale as $1/\sqrt{n}$, so 500 events in the same window would give $\sigma_\beta = 0.111 \times \sqrt{2000/500} \approx 0.22$. A wider window changes $\boldsymbol{I}$ itself, and the same quadrature, with a and b changed, tells us by how much.

The lesson: the forecast and the repeated experiment agree to within the error of the repeats, so the expensive part of Cowan's study, the 500 simulated experiments, could have been replaced by one integral per matrix element; what a single fit adds is a curvature that wobbles about that integral.

Key idea: The Fisher matrix

$F_{ij} = -\mathbb{E}[\partial_i \partial_j \ln \mathcal{L}] = \mathbb{E}[S_i S_j]$, evaluated at the fiducial parameters, is the average curvature of the log-likelihood and the covariance of the score. It needs a model of the experiment, not data. Its inverse is the forecast covariance of the parameters, and independent data sets add their Fisher matrices.

10.2 Nobody beats the inverse Fisher matrix: the Cramér–Rao bound

The forecast of Section 10.1.3 was built from the width of the likelihood. But the analysis team may not use the likelihood at all. They might fit moments of the distribution, or train a network to map histograms to parameters, or use some estimator nobody has thought of yet. Is $\mathbf{F}^{-1}$ a property of one particular method, maximum likelihood, or is it a limit on every method? If it is a limit, a forecast is much more than a guess: it is the best any analysis of that experiment can ever do.

For one parameter the answer was the Cramér–Rao inequality of Section 3.13.3: every unbiased estimator has $\mathrm{Var}\,\hat{\theta} \geq 1/I_n(\theta)$ [CasellaBerger Thm. 7.3.9], [Cowan (6.16)]. With several parameters, a new question appears that the one-parameter bound cannot answer.

The question in words. Can any unbiased method of turning the data into estimates $\boldsymbol{T}(\boldsymbol{d}) = (T_1, \ldots, T_m)$ have, *in some direction of parameter space*, a smaller scatter than $\mathbf{F}^{-1}$ predicts?

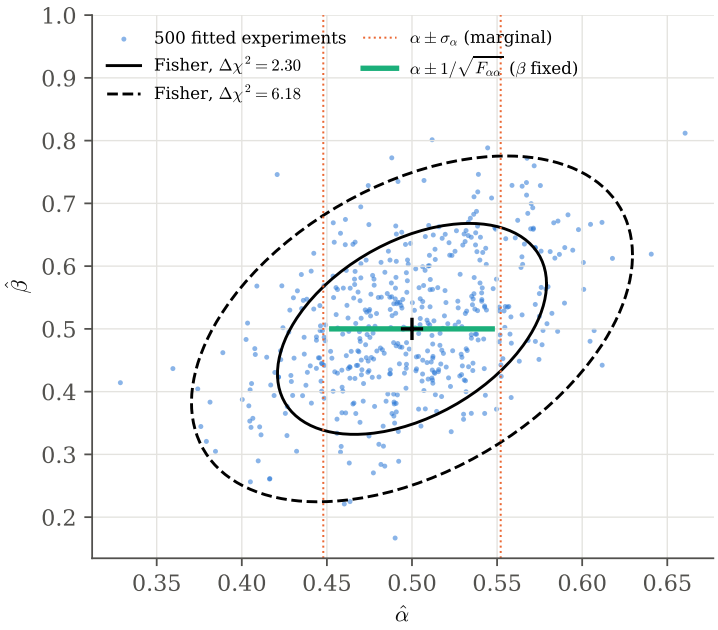

Figure 10.4: Cowan's experiment repeated: each point is the maximum-likelihood fit of one simulated experiment of 2000 events. The ellipses come from the Fisher matrix alone, computed before any event was generated: the solid one should contain 68.3% of the points and the dashed one 95.4% (Section 10.4.2). The dotted vertical lines are $\alpha \pm \sigma_\alpha$; the green bar is the shorter error on α that we would quote if β were known (Section 10.4.1).

And when we quote the error on one parameter, is the limit $1/\sqrt{F_{ii}}$, which looks only at the i-th diagonal element, or $\sqrt{(\mathbf{F}^{-1})_{ii}}$, which involves the whole matrix?

10.2.1 The bound, from one covariance matrix

Let $\boldsymbol{T}$ be unbiased, $\mathbb{E}_{\boldsymbol{\theta}}\, \boldsymbol{T} = \boldsymbol{\theta}$ for every $\boldsymbol{\theta}$, with covariance matrix $\boldsymbol{V} = \operatorname{Cov} \boldsymbol{T}$, and let $\boldsymbol{S}$ be the score of the whole data set. The proof needs one fact about how $\boldsymbol{T}$ and $\boldsymbol{S}$ are related, and one fact about covariance matrices.

How the estimator and the score are correlated. For each pair a, j,

$$\operatorname{Cov}(T_a, S_j) \overset{(1)}{=} \mathbb{E}[T_a\, S_j] \overset{(2)}{=} \int T_a(\boldsymbol{d})\, \frac{\partial_j p(\boldsymbol{d}\,|\,\boldsymbol{\theta})}{p(\boldsymbol{d}\,|\,\boldsymbol{\theta})}\, p(\boldsymbol{d}\,|\,\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{d} \overset{(3)}{=} \partial_j \int T_a(\boldsymbol{d})\, p(\boldsymbol{d}\,|\,\boldsymbol{\theta})\, \mathrm{d}\boldsymbol{d} \overset{(4)}{=} \partial_j \theta_a = \delta_{aj}. \tag{10.8}$$

(1) $\operatorname{Cov}(T_a, S_j) = \mathbb{E}[T_a S_j] - \mathbb{E}\, T_a\ \mathbb{E}\, S_j$, and $\mathbb{E}\, S_j = 0$ by (10.4).
(2) Write the expectation as an integral; $S_j = \partial_j p / p$.
(3) Cancel p and take the derivative out of the integral. T_a depends on the data only, not on $\boldsymbol{\theta}$; the exchange is the same regularity condition as before.
(4) The integral is $\mathbb{E}\, T_a$, which equals θ_a because the estimator is unbiased.

So an unbiased estimator must be correlated with the score in a fixed way: $\operatorname{Cov}(\boldsymbol{T}, \boldsymbol{S}) = \mathbb{1}$. This is the whole content of unbiasedness for the proof. If $\boldsymbol{T}$ did not respond to the data along the directions in which the data respond to $\boldsymbol{\theta}$, it could not follow $\boldsymbol{\theta}$ on average.

Covariance matrices are positive semidefinite. Stack the $2m$ random numbers $(\boldsymbol{T}, \boldsymbol{S})$ into one vector. Its covariance matrix is

$$\boldsymbol{M} = \begin{pmatrix} \boldsymbol{V} & \mathbb{1} \\ \mathbb{1} & \mathbf{F} \end{pmatrix}, \qquad (\boldsymbol{u}^{\mathsf{T}}, \boldsymbol{w}^{\mathsf{T}})\, \boldsymbol{M} \begin{pmatrix} \boldsymbol{u} \\ \boldsymbol{w} \end{pmatrix} = \operatorname{Var}(\boldsymbol{u}^{\mathsf{T}}\boldsymbol{T} + \boldsymbol{w}^{\mathsf{T}}\boldsymbol{S}) \geq 0 \quad \text{for all } \boldsymbol{u}, \boldsymbol{w}, \tag{10.9}$$

where the off-diagonal blocks are (10.8) and the lower block is (10.5).

The bound. Pick any direction $\boldsymbol{a}$ in parameter space and set $\boldsymbol{u} = \boldsymbol{a}$, $\boldsymbol{w} = -\mathbf{F}^{-1}\boldsymbol{a}$:

$$0 \overset{(1)}{\leq} \operatorname{Var}\big(\boldsymbol{a}^{\mathsf{T}}\boldsymbol{T} - \boldsymbol{a}^{\mathsf{T}}\mathbf{F}^{-1}\boldsymbol{S}\big) \overset{(2)}{=} \boldsymbol{a}^{\mathsf{T}}\boldsymbol{V}\boldsymbol{a} - 2\,\boldsymbol{a}^{\mathsf{T}}\mathbf{F}^{-1}\boldsymbol{a} + \boldsymbol{a}^{\mathsf{T}}\mathbf{F}^{-1}\mathbf{F}\mathbf{F}^{-1}\boldsymbol{a} \overset{(3)}{=} \boldsymbol{a}^{\mathsf{T}}\big(\boldsymbol{V} - \mathbf{F}^{-1}\big)\boldsymbol{a}. \tag{10.10}$$

(1) (10.9) with this choice of $\boldsymbol{u}, \boldsymbol{w}$.
(2) Expand the quadratic form block by block: $\boldsymbol{u}^{\mathsf{T}}\boldsymbol{V}\boldsymbol{u} + 2\boldsymbol{u}^{\mathsf{T}}\mathbb{1}\,\boldsymbol{w} + \boldsymbol{w}^{\mathsf{T}}\mathbf{F}\boldsymbol{w}$, using $\mathbf{F}^{-1}$ symmetric.
(3) $\mathbf{F}^{-1}\mathbf{F} = \mathbb{1}$; collect.

Why that choice of $\boldsymbol{w}$? One parameter shows it. Then T and S are two random numbers with $\operatorname{Cov}(T, S) = 1$ by (10.8) and $\operatorname{Var} S = F$. Ask for the multiple cS of the score that comes closest to T, in the sense of the smallest variance of the difference:

$$\operatorname{Var}(T - cS) \overset{(1)}{=} \operatorname{Var} T - 2c\,\operatorname{Cov}(T, S) + c^2 \operatorname{Var} S \overset{(2)}{=} \operatorname{Var} T - 2c + c^2 F,$$

$$\frac{\mathrm{d}}{\mathrm{d}c}\operatorname{Var}(T - cS) = -2 + 2cF = 0 \overset{(3)}{=} c = \frac{1}{F}, \qquad \operatorname{Var}\Big(T - \frac{S}{F}\Big) \overset{(4)}{=} \operatorname{Var} T - \frac{1}{F}.$$

(1) The variance of a difference.
(2) Insert $\operatorname{Cov}(T, S) = 1$ and $\operatorname{Var} S = F$.
(3) The best coefficient is covariance over variance, as in a least-squares regression of T on S.
(4) Put $c = 1/F$ back into the first line: $\operatorname{Var} T - 2/F + 1/F$.

The residual $T - S/F$ is uncorrelated with the score, $\operatorname{Cov}(T - S/F, S) = 1 - F/F = 0$: it is the part of T the score cannot predict. Its variance cannot be negative, so $\operatorname{Var} T \geq 1/F$. The variance of any unbiased T splits into a part $1/F$ that is forced by its correlation with the score and a leftover that a good estimator makes small. With many parameters the same regression of $\boldsymbol{a}^{\mathsf{T}}\boldsymbol{T}$ on the score vector has coefficient vector $\mathbf{F}^{-1}\boldsymbol{a}$ (covariance $\boldsymbol{a}^{\mathsf{T}}\mathbb{1}$ times the inverse of the variance matrix $\mathbf{F}$), which is exactly the $\boldsymbol{w} = -\mathbf{F}^{-1}\boldsymbol{a}$ chosen above, and (10.10) is the matrix version of the last line. Since $\boldsymbol{a}$ was arbitrary,

$$\boxed{\operatorname{Cov}\boldsymbol{T} - \mathbf{F}^{-1} \geq 0 : \qquad \operatorname{Var}(\boldsymbol{a}^{\mathsf{T}}\boldsymbol{T}) \geq \boldsymbol{a}^{\mathsf{T}}\mathbf{F}^{-1}\boldsymbol{a} \text{ for every } \boldsymbol{a}, \qquad \operatorname{Var} T_i \geq (\mathbf{F}^{-1})_{ii},} \tag{10.11}$$

where ≥ 0 means positive semidefinite. The last form is the choice $\boldsymbol{a} = \boldsymbol{e}_i$, the i-th unit vector [Cowan (6.19)], [165]. Positive semidefinite ordering has a picture: the ellipse of $\operatorname{Cov}\boldsymbol{T}$ contains the ellipse of $\mathbf{F}^{-1}$, because the half-width of an ellipse $\{\boldsymbol{x} : \boldsymbol{x}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{x} \leq 1\}$ measured along a unit direction $\boldsymbol{a}$ is $\sqrt{\boldsymbol{a}^{\mathsf{T}}\boldsymbol{V}\boldsymbol{a}}$ (Figure 10.5).

10.2.2 Marginalised or conditional: the second half of the answer

The bound on T_i is $(\mathbf{F}^{-1})_{ii}$, the ii element of the *inverse*. How does it compare with $1/F_{ii}$, the inverse of the ii element? Two tools are needed. *Picking out an element.* Write $\boldsymbol{e}_i$ for the unit vector with 1 in place i and 0 elsewhere; then $\boldsymbol{M}\boldsymbol{e}_i$ is the i-th column of a matrix $\boldsymbol{M}$ and $\boldsymbol{e}_i^{\mathsf{T}}\boldsymbol{M}\boldsymbol{e}_i = M_{ii}$. *A square root of* $\mathbf{F}$. A symmetric matrix can be written as $\mathbf{F} = \boldsymbol{V}\,\operatorname{diag}(\lambda_1, \ldots, \lambda_m)\boldsymbol{V}^{\mathsf{T}}$, with the orthonormal eigenvectors as the columns of $\boldsymbol{V}$ ($\boldsymbol{V}^{\mathsf{T}}\boldsymbol{V} = \mathbb{1}$) and the eigenvalues λ_a on the diagonal; for a positive definite $\mathbf{F}$ all $\lambda_a > 0$. Then $\mathbf{F}^{1/2} \equiv \boldsymbol{V}\,\operatorname{diag}(\sqrt{\lambda_a})\boldsymbol{V}^{\mathsf{T}}$ is symmetric and squares to $\mathbf{F}$, because the inner $\boldsymbol{V}^{\mathsf{T}}\boldsymbol{V}$ is $\mathbb{1}$; likewise $\mathbf{F}^{-1/2} \equiv \boldsymbol{V}\,\operatorname{diag}(1/\sqrt{\lambda_a})\boldsymbol{V}^{\mathsf{T}}$, and $\mathbf{F}^{1/2}\mathbf{F}^{-1/2} = \mathbb{1}$. Then

$$1 \overset{(1)}{=} \big(\boldsymbol{e}_i^{\mathsf{T}}\boldsymbol{e}_i\big)^2 \overset{(2)}{=} \big[(\mathbf{F}^{1/2}\boldsymbol{e}_i)^{\mathsf{T}}(\mathbf{F}^{-1/2}\boldsymbol{e}_i)\big]^2 \overset{(3)}{\leq} \big(\boldsymbol{e}_i^{\mathsf{T}}\mathbf{F}\boldsymbol{e}_i\big)\big(\boldsymbol{e}_i^{\mathsf{T}}\mathbf{F}^{-1}\boldsymbol{e}_i\big) = F_{ii}\,(\mathbf{F}^{-1})_{ii}, \tag{10.12}$$

(1) A unit vector has length one.

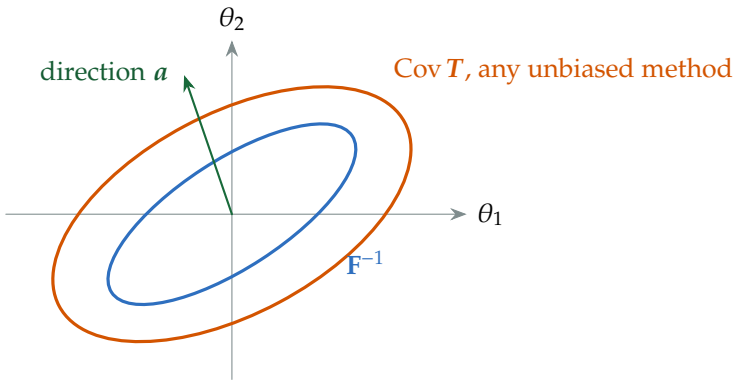

Figure 10.5: The Cramér–Rao bound as a picture. For every direction $\boldsymbol{a}$, the spread of an unbiased estimator along $\boldsymbol{a}$ is at least $\sqrt{\boldsymbol{a}^\mathsf{T}\mathbf{F}^{-1}\boldsymbol{a}}$, so the error ellipse of any method (orange) encloses the ellipse of the inverse Fisher matrix (blue). Maximum likelihood with informative data shrinks its ellipse onto the blue one.

(2) Insert $\mathbf{F}^{1/2}\mathbf{F}^{-1/2} = \mathbb{1}$ between the two factors; both matrices are symmetric.
(3) Cauchy–Schwarz for ordinary vectors, $(\boldsymbol{x}^\mathsf{T}\boldsymbol{y})^2 \le (\boldsymbol{x}^\mathsf{T}\boldsymbol{x})(\boldsymbol{y}^\mathsf{T}\boldsymbol{y})$.

so $(\mathbf{F}^{-1})_{ii} \ge 1/F_{ii}$.

When are the two equal? Cauchy–Schwarz is an equality only when the two vectors are parallel, $\mathbf{F}^{1/2}\boldsymbol{e}_i = c\,\mathbf{F}^{-1/2}\boldsymbol{e}_i$ for some number c. Multiplying both sides by $\mathbf{F}^{1/2}$ turns this into $\mathbf{F}\boldsymbol{e}_i = c\,\boldsymbol{e}_i$: the i-th column of $\mathbf{F}$ has a single nonzero entry, on the diagonal. So $F_{ji} = 0$ for every $j \ne i$, and parameter i shares no information with any other. Then $\mathbf{F}^{-1}\boldsymbol{e}_i = \boldsymbol{e}_i/c$ as well, and $(\mathbf{F}^{-1})_{ii} = 1/F_{ii}$. In every other case the inverse of the matrix gives the larger number. A small example gives the size: for $F_{11} = 2$, $F_{22} = 1$, $F_{12} = 1$ the determinant is 1 and $(\mathbf{F}^{-1})_{11} = F_{22}/\det\mathbf{F} = 1$ by (10.7), so $F_{11}(\mathbf{F}^{-1})_{11} = 2$: the error on θ_1 is $\sqrt{2}$ times larger when θ_2 must be estimated too. This is the content of Tegmark, Taylor and Heavens' statement of the bound [165]: $1/\sqrt{F_{ii}}$ is the smallest error on θ_i *if all the other parameters are known*; if they are estimated from the same data, the smallest error rises to $\sqrt{(\mathbf{F}^{-1})_{ii}}$. We come back to this distinction, the single most common error in quoting forecasts, in Section 10.4.1. In the angular-distribution experiment of Section 10.1.3 (Cowan's two-parameter example) the two numbers for α are $1/\sqrt{F_{\alpha\alpha}} = 0.047$ and $\sqrt{(\mathbf{F}^{-1})_{\alpha\alpha}} = 0.052$ (Figure 10.4, green bar against dotted lines).

10.2.3 When the bound is reached, and what it means

A bound is only useful if someone reaches it. Vallisneri lists three readings of $\mathbf{F}^{-1}$ that are often confused [166]: (i) the Cramér–Rao bound on any unbiased estimator, a statement about the scatter over imagined repetitions of the experiment; (ii) the covariance of the maximum-likelihood estimator, which reaches the bound when the model is linear in $\boldsymbol{\theta}$ over the region where the errors live; (iii) the covariance of the Bayesian posterior from *one* experiment, with a flat prior, in the same limit. The first is always true; the second and third need a condition, and the examples show what the condition means.

When is the bound an equality, and what if the estimator is biased? Equality in (10.10) needs $\mathrm{Var}(\boldsymbol{a}^\mathsf{T}\boldsymbol{T} - \boldsymbol{a}^\mathsf{T}\mathbf{F}^{-1}\boldsymbol{S}) = 0$ for every $\boldsymbol{a}$. A random variable with zero variance is a constant, and since both $\boldsymbol{T}$ and $\boldsymbol{S}$ have the right means ($\boldsymbol{\theta}$ and $\mathbf{0}$) the constant is $\boldsymbol{\theta}$ itself:

$$\boldsymbol{T}(\boldsymbol{d}) = \boldsymbol{\theta} + \mathbf{F}^{-1}\boldsymbol{S}(\boldsymbol{d}) \quad \text{for all data.}$$

So an estimator reaches the bound exactly when the score is a linear function of the estimator. This is the case for the linear-Gaussian model below, where the score is $\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{d}-\boldsymbol{A}\boldsymbol{\theta})$, and it holds only approximately in the other models of this chapter. The ratio $e = \big[(\mathbf{F}^{-1})_{ii}\big] \,/\, \operatorname{Var} T_i \le 1$ is the **efficiency** of the estimator [Cowan §6.6]: how much of the available information it uses.

A biased estimator. Suppose instead $\mathbb{E}\,\boldsymbol{T} = \boldsymbol{\theta} + \boldsymbol{b}(\boldsymbol{\theta})$, with a bias $\boldsymbol{b}$ that may depend on the parameters, and write $B_{aj} = \partial_j b_a$ for its derivatives. Only the last step of (10.8) changes: the integral is now $\mathbb{E}\,T_a = \theta_a + b_a$, so

$$\operatorname{Cov}(T_a, S_j) = \partial_j(\theta_a + b_a) = \delta_{aj} + B_{aj}, \qquad \text{that is} \qquad \operatorname{Cov}(\boldsymbol{T}, \boldsymbol{S}) = \mathbb{1} + \boldsymbol{B},$$

and the off-diagonal blocks of (10.9) become $\mathbb{1} + \boldsymbol{B}$ and $(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}$. Repeat the regression with the new covariance: $\boldsymbol{u} = \boldsymbol{a}$ and $\boldsymbol{w} = -\mathbf{F}^{-1}(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}\boldsymbol{a}$. Then

$$\begin{aligned} 0 &\overset{(1)}{\le} \boldsymbol{a}^{\mathsf{T}}\boldsymbol{V}\boldsymbol{a} + 2\,\boldsymbol{a}^{\mathsf{T}}(\mathbb{1} + \boldsymbol{B})\boldsymbol{w} + \boldsymbol{w}^{\mathsf{T}}\mathbf{F}\boldsymbol{w} \\ &\overset{(2)}{=} \boldsymbol{a}^{\mathsf{T}}\boldsymbol{V}\boldsymbol{a} - 2\,\boldsymbol{a}^{\mathsf{T}}(\mathbb{1} + \boldsymbol{B})\mathbf{F}^{-1}(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}\boldsymbol{a} + \boldsymbol{a}^{\mathsf{T}}(\mathbb{1} + \boldsymbol{B})\mathbf{F}^{-1}\mathbf{F}\mathbf{F}^{-1}(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}\boldsymbol{a} \\ &\overset{(3)}{=} \boldsymbol{a}^{\mathbb{T}}\big[\boldsymbol{V} - (\mathbb{1} + \boldsymbol{B})\mathbf{F}^{-1}(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}\big]\boldsymbol{a}. \end{aligned}$$

(1) The quadratic form of the joint covariance, expanded block by block, is a variance and so not negative.
(2) Insert $\boldsymbol{w}$; its transpose is $-\boldsymbol{a}^{\mathsf{T}}(\mathbb{1} + \boldsymbol{B})\mathbf{F}^{-1}$, since $\mathbf{F}^{-1}$ is symmetric.
(3) $\mathbf{F}^{-1}\mathbf{F} = \mathbb{1}$, so the last term is $\boldsymbol{a}^{\mathsf{T}}(\mathbb{1} + \boldsymbol{B})\mathbf{F}^{-1}(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}\boldsymbol{a}$, and the middle term is -2 times the same number; together they leave minus it once.

Since $\boldsymbol{a}$ is arbitrary,

$$\operatorname{Cov}\boldsymbol{T} \ge (\mathbb{1} + \boldsymbol{B})\,\mathbf{F}^{-1}(\mathbb{1} + \boldsymbol{B})^{\mathsf{T}}, \tag{10.13}$$

which is the information inequality of [Cowan (6.16)] for several parameters. With $\boldsymbol{B} = \mathbf{0}$ it is (10.11) again.

A bias can buy a smaller variance. Take n draws from $\mathcal{N}(\theta, \sigma^2)$ with known σ, so $F = n/\sigma^2$, and shrink the sample mean towards zero: $T = c\,\bar{x}$ with $0 < c < 1$. Its mean is $c\theta$, so the bias is $b = -(1-c)\theta$ and $B = \mathrm{d}b/\mathrm{d}\theta = -(1-c)$, giving $1 + B = c$. The bound (10.13) reads $\operatorname{Var} T \ge c^2/F = c^2\sigma^2/n$, and indeed $\operatorname{Var} T = c^2 \operatorname{Var}\bar{x} = c^2\sigma^2/n$: the shrunk estimator sits on its bound, which is below the unbiased bound $1/F = \sigma^2/n$ by the factor c^2. A bias whose derivative is negative pulls estimates together, and the variance drops below $\mathbf{F}^{-1}$; the price is that T is off by $(1-c)\theta$ on average. This is the loophole of the last example below.

Example: a linear model reaches the bound exactly. Let the data be $\boldsymbol{d} = \boldsymbol{A}\boldsymbol{\theta} + \boldsymbol{n}$ with a known $N \times m$ matrix $\boldsymbol{A}$ (each column a template, for example the columns 1 and x of a straight-line fit) and Gaussian noise $\boldsymbol{n} \sim \mathcal{N}(\mathbf{0}, \mathbf{C})$ with known $\mathbf{C}$. Then $\ln \mathcal{L} = -\tfrac{1}{2}(\boldsymbol{d} - \boldsymbol{A}\boldsymbol{\theta})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{d} - \boldsymbol{A}\boldsymbol{\theta}) + \text{const}$ and

$$\begin{aligned} -\partial_i\partial_j \ln \mathcal{L} &\overset{(1)}{=} (\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{A})_{ij} \equiv F_{ij}, \\ \hat{\boldsymbol{\theta}} &\overset{(2)}{=} (\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{A})^{-1}\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d} = \mathbf{F}^{-1}\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}, \\ \operatorname{Cov}\hat{\boldsymbol{\theta}} &\overset{(3)}{=} \mathbf{F}^{-1}\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}\,\operatorname{Cov}(\boldsymbol{d})\,\mathbf{C}^{-1}\boldsymbol{A}\,\mathbf{F}^{-1} \overset{(4)}{=} \mathbf{F}^{-1}\big(\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{A}\big)\mathbf{F}^{-1} = \mathbf{F}^{-1}. \end{aligned}$$

(1) Differentiate the quadratic form twice: the second derivative is constant, the same for every data set, so no average is needed.
(2) Set the gradient $\boldsymbol{A}^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{d} - \boldsymbol{A}\boldsymbol{\theta})$ to zero: the normal equations of Chapter 3.
(3) $\hat{\boldsymbol{\theta}}$ is a linear map $\boldsymbol{B}\boldsymbol{d}$ of the data, so $\operatorname{Cov}\hat{\boldsymbol{\theta}} = \boldsymbol{B}\operatorname{Cov}(\boldsymbol{d})\boldsymbol{B}^{\mathsf{T}}$; the term $\boldsymbol{A}\boldsymbol{\theta}$ in $\boldsymbol{d}$ is not random.

(4) $\mathrm{Cov}(\boldsymbol{d}) = \mathbf{C}$, and $\mathbf{C}^{-1}\mathbf{C}\mathbf{C}^{-1} = \mathbf{C}^{-1}$.

The bound is reached exactly, at any number of data points. The log-likelihood is an exact parabola in $\boldsymbol{\theta}$, its curvature is the same for every data set, and all three readings of $\mathbf{F}^{-1}$ coincide. Every other situation is this one only approximately: a nonlinear model looks linear when the errors are small compared with the scale on which the model bends, which is what "informative data" or "high signal-to-noise" means.

Example: how fast does Cowan's experiment reach the bound? The angular distribution is not linear in (α, β), because the parameters also sit in the denominator of $\ln g$. `01_cowan_two_param.py` repeats the experiment 2000 times at each of several event numbers n and compares the variance of the fitted $\hat{\alpha}$ and $\hat{\beta}$ with the bound $(\mathbf{F}^{-1})_{ii} = (\boldsymbol{I}^{-1})_{ii}/n$ (Figure 10.6). At $n = 2000$ the ratios are 1.03 and 1.00, one within the simulation error of about ± 0.03. At $n = 50$ they are 1.57 and 1.73, and in 1.5% of the experiments the fit does not converge at all: the likelihood keeps increasing as $\beta \to \infty$, because a handful of events all at large $|x|$ look like a pure x^2 shape. With so little information the log-likelihood is far from a parabola over the range where the estimates scatter, and a Fisher forecast for 50 events would be too optimistic by a quarter in σ_α.

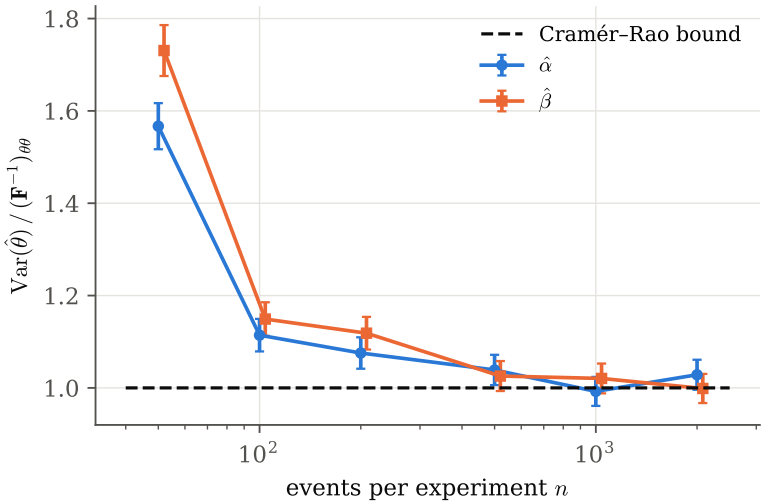

Figure 10.6: The variance of the maximum-likelihood estimates in Cowan's experiment divided by the Cramér–Rao bound, against the number of events. Below a few hundred events the fits scatter more than the bound; from about 500 events on, maximum likelihood reaches it. Error bars are the Monte Carlo uncertainty of a variance estimated from 2000 experiments.

Example: the bound is for unbiased estimators. Two loopholes are worth naming. First, a biased estimator can beat $\mathbf{F}^{-1}$. The posterior mean with an informative prior is one: it is pulled towards the prior, and its scatter is smaller, which is fair because the prior is extra information. In the Fisher language the prior simply adds its own matrix (Section 10.4.4). Second, the bound needs the regularity condition: for Uniform$(0, \theta)$ the maximum of the sample has a variance falling like $1/n^2$ (Section 3.13.3), because a sharp edge in the data is not covered by the derivation. In the other direction, the bound does not promise that a good estimator exists at small n. Take the variance of a Gaussian with unknown mean, now with (μ, σ^2) as parameters instead of (μ, σ). *The bound.* The Jacobian rule (10.27) converts the Fisher entry for σ found in Section 10.1.2 into one for σ^2: with $\sigma = \sqrt{\sigma^2}$, $\mathrm{d}\sigma/\mathrm{d}\sigma^2 = 1/(2\sigma)$, so

$$F_{\sigma^2\sigma^2} = \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\sigma^2}\right)^2 F_{\sigma\sigma} = \frac{1}{4\sigma^2}\,\frac{2n}{\sigma^2} = \frac{n}{2\sigma^4},$$

while $F_{\mu\mu} = n/\sigma^2$ and the off-diagonal entry stay as they were, zero. The matrix is diagonal, so the bound on any unbiased estimator of σ^2 is the inverse of this one entry, $2\sigma^4/n$. *The best unbiased estimator.* The sample variance S^2 has $(n-1)S^2/\sigma^2 \sim \chi^2_{n-1}$, and a χ^2_k variable has variance $2k$, so $\mathrm{Var}\, S^2 = \sigma^4 \cdot 2(n-1)/(n-1)^2 = 2\sigma^4/(n-1)$, as in (3.34). It exceeds the bound by the factor $n/(n-1)$, and no unbiased estimator does better [CasellaBerger Ex. 7.3.14]: the bound is approached only as n grows.

Key idea: Cramér–Rao for many parameters

For any unbiased estimator, $\mathrm{Cov}\, \boldsymbol{T} - \mathbf{F}^{-1}$ is positive semidefinite: no direction of parameter space can be measured better than $\mathbf{F}^{-1}$ allows. The error on one parameter is at least $\sqrt{(\mathbf{F}^{-1})_{ii}} \geq 1/\sqrt{F_{ii}}$, the second value applying only when all other parameters are known. Maximum likelihood reaches the bound exactly for linear-Gaussian models and approximately whenever the data are informative enough that the log-likelihood is a parabola over the scatter of the estimates.

10.3 Gaussian data: the Fisher matrix in closed form

Most data in physics reach the analysis as a Gaussian vector, or are compressed into one. The pixels of a CMB map, its harmonic coefficients $a_{\ell m}$, a binned power spectrum, the Fourier amplitudes of a detector's strain, the points of a fitted line: each is either Gaussian by nature (a Gaussian random field, thermal detector noise) or Gaussian to a good approximation by the central limit theorem (a bin average of many modes, Chapter 2). The parameters reach such data in two different ways. Either they move the *mean*: a peak position, a template amplitude, the shape of a gravitational waveform. Or they change the *covariance*: the CMB temperature has zero mean at every point, and every cosmological parameter acts only through the variance C_ℓ of the $a_{\ell m}$. A forecast formula for Gaussian data must handle both, and it turns out to be one line.

The question. If the data vector $\boldsymbol{d}$ (length N) is Gaussian with a mean $\boldsymbol{\mu}(\boldsymbol{\theta})$ and a covariance $\mathbf{C}(\boldsymbol{\theta})$ that we can compute for any parameters, what is the Fisher matrix, written with nothing but $\boldsymbol{\mu}$, $\mathbf{C}$ and their derivatives?

The inputs. One physical input: the data are Gaussian, with mean and covariance known as functions of the parameters (all the physics of the experiment, signal and noise, sits in these two functions). Two mathematical inputs: $\boldsymbol{\mu}$ and $\mathbf{C}$ are differentiable in $\boldsymbol{\theta}$, and $\mathbf{C}$ is positive definite, hence invertible. Everything else is derived. With $\boldsymbol{r} = \boldsymbol{d} - \boldsymbol{\mu}$ the residual,

$$-2\ln \mathcal{L}(\boldsymbol{\theta}) = \ln\det \mathbf{C} + \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r} + N\ln 2\pi \tag{10.14}$$

[HobsonBMC (5.16)], [165], eq. (7). It is the likelihood in the sense of Chapter 3: the data are the model mean plus noise, $\boldsymbol{d} = \boldsymbol{\mu}(\boldsymbol{\theta}) + \boldsymbol{n}$, and for a given $\boldsymbol{\theta}$ the likelihood asks how plausible the particular noise realisation $\boldsymbol{r} = \boldsymbol{d} - \boldsymbol{\mu}(\boldsymbol{\theta})$ is that would turn the model into the data we have. The second term is the familiar χ^2 of Chapter 3; the first is what is left of the normalisation $(2\pi)^{-N/2}(\det \mathbf{C})^{-1/2}$, and it matters as soon as $\mathbf{C}$ depends on the parameters. We write $\boldsymbol{\mu}_{,i} = \partial_i \boldsymbol{\mu}$, $\mathbf{C}_{,i} = \partial_i \mathbf{C}$, and so on.

10.3.1 Three tools

The derivative of an inverse. Differentiate $\mathbf{C}\mathbf{C}^{-1} = \mathbb{1}$: $\mathbf{C}_{,i}\mathbf{C}^{-1} + \mathbf{C}\,\partial_i(\mathbf{C}^{-1}) = 0$, so

$$\partial_i(\mathbf{C}^{-1}) = -\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}. \tag{10.15}$$

It is the matrix version of $(1/c)' = -c'/c^2$; the order matters because matrices do not commute.

The derivative of a log-determinant. For a small change $\delta\mathbf{C}$,

$$\begin{aligned}\ln\det(\mathbf{C}+\delta\mathbf{C}) &\overset{(1)}{=} \ln\det\mathbf{C} + \ln\det(\mathbb{1} + \mathbf{C}^{-1}\delta\mathbf{C}) \overset{(2)}{=} \ln\det\mathbf{C} + \ln\prod_a(1+\epsilon_a)\\ &\overset{(3)}{=} \ln\det\mathbf{C} + \mathrm{Tr}(\mathbf{C}^{-1}\delta\mathbf{C}) + O(\delta^2),\end{aligned} \tag{10.16}$$

(1) $\mathbf{C} + \delta\mathbf{C} = \mathbf{C}(\mathbb{1} + \mathbf{C}^{-1}\delta\mathbf{C})$, and the determinant of a product is the product of determinants.
(2) ϵ_a are the eigenvalues of the small matrix $\mathbf{C}^{-1}\delta\mathbf{C}$; a determinant is the product of the eigenvalues, and $\mathbb{1} + \boldsymbol{\epsilon}$ has eigenvalues $1 + \epsilon_a$.
(3) $\ln(1+\epsilon_a) = \epsilon_a + O(\epsilon^2)$, and the sum of the eigenvalues is the trace.

Hence $\partial_i \ln\det\mathbf{C} = \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i})$, the matrix version of $(\ln c)' = c'/c$.

The average of a quadratic form. For any fixed matrix $\boldsymbol{B}$ and a residual with $\mathbb{E}\,\boldsymbol{r} = \mathbf{0}$, $\mathbb{E}\,\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}} = \mathbf{C}$:

$$\mathbb{E}[\boldsymbol{r}^{\mathsf{T}}\boldsymbol{B}\boldsymbol{r}] = \mathbb{E}\,\mathrm{Tr}(\boldsymbol{B}\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}}) = \mathrm{Tr}(\boldsymbol{B}\,\mathbb{E}[\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}}]) = \mathrm{Tr}(\boldsymbol{B}\mathbf{C}), \tag{10.17}$$

because a number is its own trace, the trace is cyclic, and both trace and expectation are linear. Terms linear in $\boldsymbol{r}$ average to zero, and terms with three factors of $\boldsymbol{r}$ never appear below.

10.3.2 The derivation

The score. Differentiate (10.14) once. The residual depends on $\boldsymbol{\theta}$ through the mean, $\partial_i\boldsymbol{r} = -\boldsymbol{\mu}_{,i}$, so

$$\partial_i(-2\ln\mathcal{L}) \overset{(1)}{=} \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i}) - 2\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r} - \boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\boldsymbol{r}. \tag{10.18}$$

(1) The first term is (10.16). In the quadratic form, differentiating either of the two $\boldsymbol{r}$ gives $-\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ (the two are equal because $\mathbf{C}^{-1}$ is symmetric), and differentiating $\mathbf{C}^{-1}$ uses (10.15).

Its average is $\mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i}) - 0 - \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}) = 0$ by (10.17): the score has mean zero, as it must.

The second derivative. Differentiate each of the three terms of (10.18) with respect to θ_j, and average at once, dropping every term linear in $\boldsymbol{r}$:

$$\begin{aligned}\mathbb{E}\;\partial_j\,\mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i}) &\overset{(1)}{=} -\mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,j}\mathbf{C}^{-1}\mathbf{C}_{,i}) + \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,ij}),\\ \mathbb{E}\;\partial_j\big(-2\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}\big) &\overset{(2)}{=} 2\,\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\mu}_{,j},\\ \mathbb{E}\;\partial_j\big(-\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\boldsymbol{r}\big) &\overset{(3)}{=} \mathbb{E}\;\boldsymbol{r}^{\mathsf{T}}\big[\mathbf{C}^{-1}\mathbf{C}_{,j}\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1} - \mathbf{C}^{-1}\mathbf{C}_{,ij}\mathbf{C}^{-1} + \mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}\mathbf{C}^{-1}\big]\boldsymbol{r}\\ &\overset{(4)}{=} \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,j}\mathbf{C}^{-1}\mathbf{C}_{,i}) - \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,ij}) + \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}).\end{aligned} \tag{10.19}$$

(1) Product rule on $\mathbf{C}^{-1}\mathbf{C}_{,i}$, with (10.15) for the derivative of $\mathbf{C}^{-1}$. Nothing is random here.
(2) Of the three pieces of the product rule, $-2\boldsymbol{\mu}_{,ij}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ and $+2\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}_{,j}\mathbf{C}^{-1}\boldsymbol{r}$ are linear in $\boldsymbol{r}$ and average to zero; the third comes from $\partial_j\boldsymbol{r} = -\boldsymbol{\mu}_{,j}$.

(3) The terms in which ∂_j hits an $\boldsymbol{r}$ are linear in $\boldsymbol{r}$ and drop out; what is left is the derivative of the middle matrix $\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}$, using (10.15) on each $\mathbf{C}^{-1}$.
(4) (10.17), then $\mathbf{C}^{-1}\mathbf{C} = \mathbb{1}$ at the end of each product.

Add the three lines. The first trace of the first line cancels the first trace of the third line (they are equal by the cyclic property), the two $\mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,ij})$ cancel, and what survives is $2\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\mu}_{,j} + \mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j})$. Dividing by two,

$$\boxed{F_{ij} = \boldsymbol{\mu}_{,i}^{\mathsf{T}}\,\mathbf{C}^{-1}\boldsymbol{\mu}_{,j} + \frac{1}{2}\,\mathrm{Tr}\big[\mathbf{C}^{-1}\mathbf{C}_{,i}\,\mathbf{C}^{-1}\mathbf{C}_{,j}\big]} \tag{10.20}$$

which is Tegmark, Taylor and Heavens' eq. (15), there written $\frac{1}{2}\,\mathrm{Tr}[\boldsymbol{A}_i\boldsymbol{A}_j + \mathbf{C}^{-1}\boldsymbol{M}_{ij}]$ with $\boldsymbol{A}_i = \mathbf{C}^{-1}\mathbf{C}_{,i}$ and $\boldsymbol{M}_{ij} = \boldsymbol{\mu}_{,i}\boldsymbol{\mu}_{,j}^{\mathsf{T}} + \boldsymbol{\mu}_{,j}\boldsymbol{\mu}_{,i}^{\mathsf{T}}$ [165], [HobsonBMC (5.17)].

Three things in (10.20) are worth saying in words. First, *only first derivatives appear*: the second derivatives $\boldsymbol{\mu}_{,ij}$ and $\mathbf{C}_{,ij}$ cancelled. A forecast needs to know how the model responds to each parameter, and nothing more. Second, the information splits into two independent channels (Figure 10.7). The mean part is a dot product of the response vectors $\boldsymbol{\mu}_{,i}$ and $\boldsymbol{\mu}_{,j}$ in the metric $\mathbf{C}^{-1}$: a change of θ_i is detectable if it moves the mean by an amount that is large compared with the noise, in the direction where the noise is small. The covariance part measures how much a change of the parameters reshapes the scatter of the data, in units of the scatter itself. Third, the geometric reading of Tegmark et al.: if two response vectors are nearly parallel in that metric, the two parameters do the same thing to the data, the Fisher matrix is nearly singular, and their errors explode together. That is a degeneracy, now seen at the level of the model.

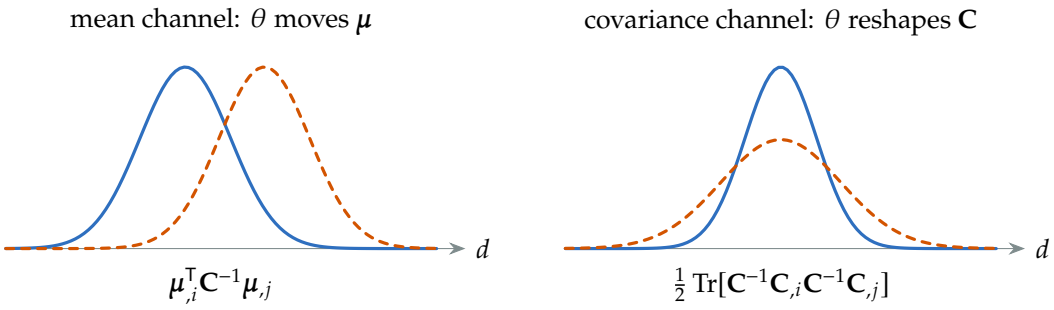

Figure 10.7: The two ways a parameter reaches Gaussian data. Left: changing θ (solid to dashed) shifts the distribution of the data; the information is the squared shift in units of the noise. Right: changing θ leaves the mean at zero and widens the distribution, as cosmological parameters do to the CMB $a_{\ell m}$; the information is the squared fractional change of the variance, with a factor one half.

For simulations it is useful to have the score itself, which is minus one half of (10.18):

$$S_i = \boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r} + \tfrac{1}{2}\big(\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\boldsymbol{r} - \mathrm{Tr}\,\mathbf{C}^{-1}\mathbf{C}_{,i}\big). \tag{10.21}$$

10.3.3 Examples

Example: a template of known shape (mean channel only). A detector sees noise of known covariance $\mathbf{C}$ and possibly a signal $A\boldsymbol{s}$ of known shape $\boldsymbol{s}$ and unknown amplitude A. Then $\boldsymbol{\mu}_{,A} = \boldsymbol{s}$, $\mathbf{C}_{,A} = 0$, and $F_{AA} = \boldsymbol{s}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{s}$, so $\sigma_A = (\boldsymbol{s}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{s})^{-1/2}$. The ratio of the true amplitude to its error is the signal-to-noise ratio of a matched filter, $\mathrm{SNR} = A\sqrt{\boldsymbol{s}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{s}}$. For white noise $\mathbf{C} = \sigma^2\mathbb{1}$ this is $\sqrt{\sum_k s_k^2}/\sigma$ times A: every sample adds the square of its signal-to-noise. Part 10b uses exactly this with $\mathbf{C}$ replaced by the noise power spectrum of a gravitational-wave detector.

Example: estimating a variance (covariance channel only). Let N numbers be drawn independently from $\mathcal{N}(0, v)$ and let the parameter be the variance v. Then $\boldsymbol{\mu} = \mathbf{0}$, $\mathbf{C} = v\mathbb{1}$, $\mathbf{C}^{-1}\mathbf{C}_{,v} = \mathbb{1}/v$, and

$$F_{vv} = \tfrac{1}{2}\,\mathrm{Tr}\big[(\mathbb{1}/v)^2\big] = \frac{N}{2v^2}, \qquad \sigma_v = v\sqrt{\frac{2}{N}}.$$

A variance estimated from N independent Gaussian numbers has a fractional error $\sqrt{2/N}$, however precisely each number is measured. This is the origin of cosmic variance: the $2\ell+1$ coefficients $a_{\ell m}$ at one multipole are $N = 2\ell+1$ such numbers with variance C_ℓ, so $\sigma(C_\ell)/C_\ell = \sqrt{2/(2\ell+1)}$ (Chapter 7). In the parameter $\sigma = \sqrt{v}$ the same information reads $F_{\sigma\sigma} = (\mathrm{d}v/\mathrm{d}\sigma)^2 F_{vv} = 2N/\sigma^2$, the value found directly in Section 10.1.2; this rescaling is a first instance of the Jacobian rule of Section 10.4.5.

Example: both channels at once. Suppose each of n points is $\mathcal{N}(\theta, \theta^2)$: a quantity whose noise grows in proportion to its size. The mean channel gives $1/\theta^2$ per point; in the covariance channel $\mathbf{C} = \theta^2$, $\mathbf{C}^{-1}\mathbf{C}_{,\theta} = 2/\theta$, and $\frac{1}{2}(2/\theta)^2 = 2/\theta^2$. In total $F = 3n/\theta^2$: here the spread of the data carries twice as much information as their average position. With $n = 10$ and $\theta = 2$, the variance of the score (10.21) over 200000 simulated data sets is 7.566, against $3n/\theta^2 = 7.500$.

The same example contains a warning. A Poisson count with mean λ is often approximated by $\mathcal{N}(\lambda, \lambda)$. The formula then gives $1/\lambda$ from the mean and $1/2\lambda^2$ from the variance, while the exact Poisson information is $1/\lambda$ (Section 3.12.3). The Gaussian approximation invents the extra $1/2\lambda^2$: it pretends that the observed scatter is an independent measurement of λ, which for a Poisson variable it is not. For large λ the invented part is negligible; for a few counts per bin it is not, and a forecast built that way is too optimistic.

Example: a correlated time series in Python. A more realistic case separates the two channels cleanly. Forty samples d_k at times t_k spread over two periods carry a signal $A \sin t_k$ on top of correlated noise plus white noise,

$$\mu_k = A \sin t_k, \qquad C_{kl} = s^2 e^{-|t_k - t_l|/\ell_c} + \sigma_n^2 \delta_{kl},$$

with $A = 1$, $s = 0.8$, $\ell_c = 1.5$ and $\sigma_n = 0.5$. The amplitude A is in the mean only, the correlation length ℓ_c is in the covariance only, so (10.20) has no cross term: $F_{AA} = 8.97$, $F_{\ell_c\ell_c} = 1.30$, $F_{A\ell_c} = 0.00$. The script draws 20000 series, evaluates the score (10.21) for each, and finds a covariance with diagonal $(8.85, 1.33)$ and off-diagonal -0.01, equal to the formula within the simulation noise of one to two per cent (Figure 10.3, right).

The same script asks a design question: what if we sampled the same two periods more densely? Figure 10.8 gives the answer. For white noise the error on A would fall as $n^{-1/2}$. Here it falls from 0.420 at 10 samples to only 0.312 at 320, because the correlated part of the noise is common to neighbouring samples and does not average down: once the samples are much closer than ℓ_c, a new sample repeats the noise of its neighbour. The correlation length itself keeps improving (from 1.67 to 0.45), because denser sampling resolves the shape of the correlation at short separations, which is exactly where ℓ_c shows. Before the data are taken, the Fisher matrix tells us which of the two quantities a denser sampling would actually buy.

Key idea: The Fisher matrix of Gaussian data

For $\boldsymbol{d} \sim \mathcal{N}(\boldsymbol{\mu}(\boldsymbol{\theta}), \mathbf{C}(\boldsymbol{\theta}))$, $F_{ij} = \boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\mu}_{,j} + \frac{1}{2}\,\mathrm{Tr}[\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}]$. Only first derivatives of the model enter. Parameters in the mean contribute the squared shift of the mean in units of the noise; parameters in the covariance contribute the squared fractional change of the scatter, with a factor one half.

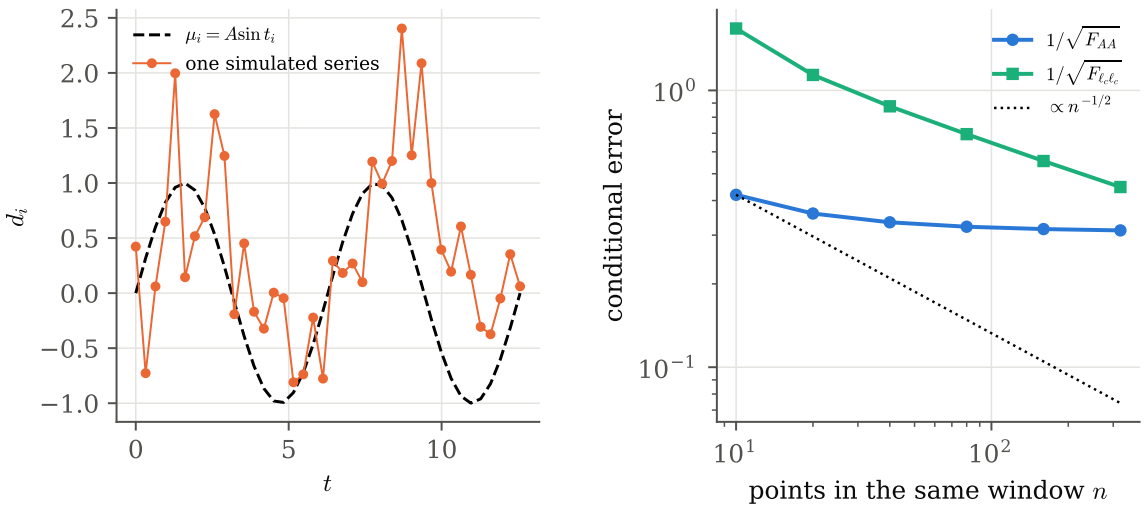

Figure 10.8: Left: one simulated series (points) and its mean $A \sin t$ (dashed). Right: the conditional errors $1/\sqrt{F_{ii}}$ on A and ℓ_c when the same window is sampled with more and more points. Against the white-noise expectation $n^{-1/2}$ (dotted), the amplitude error stalls, because correlated noise does not average down, while the correlation length keeps improving.

10.4 Reading a Fisher matrix

A Fisher matrix for six cosmological parameters is thirty-six numbers. On its own it answers nothing; the questions people actually ask are of a different kind. How well is n_s measured if everything else is also free? Which combination of parameters does the experiment really pin down? What if we add the measurement of τ that another experiment already has? What is the error on H_0, which is not one of the parameters we differentiated with respect to? Each question has a one-line answer in terms of $\mathbf{F}$, and each answer comes from treating $\mathbf{F}$ as what it approximately is: the inverse covariance of a Gaussian in parameter space, $\mathcal{L}(\boldsymbol{\theta}) \propto \exp[-\tfrac{1}{2}(\boldsymbol{\theta}-\boldsymbol{\theta}_0)^{\mathsf{T}}\mathbf{F}(\boldsymbol{\theta}-\boldsymbol{\theta}_0)]$. This section collects those answers and the reasons for them, then condenses them into a recipe.

10.4.1 Marginal and conditional errors

The question. We want the error on one group of parameters $\boldsymbol{a}$ (say n_s), while the others, $\boldsymbol{b}$, are also unknown. "Also unknown" can mean two different things. Either the other parameters are estimated from the same data and we do not care about them: we *marginalise*, averaging the Gaussian over all their values, as in Chapter 1 [integrating a joint distribution over the variables we do not want, to isolate the one we do]. Or someone tells us their values: we *condition* on them, taking a slice of the Gaussian at the known values. Which width does each give?

Split $\boldsymbol{\delta} = \boldsymbol{\theta} - \boldsymbol{\theta}_0$ into $(\boldsymbol{\delta}_a, \boldsymbol{\delta}_b)$ and $\mathbf{F}$ into blocks $\mathbf{F}_{aa}$, $\mathbf{F}_{ab}$, $\mathbf{F}_{ba} = \mathbf{F}_{ab}^{\mathsf{T}}$, $\mathbf{F}_{bb}$. The exponent of the Gaussian is

$$\begin{aligned}\boldsymbol{\delta}^{\mathsf{T}}\mathbf{F}\boldsymbol{\delta} &\overset{(1)}{=} \boldsymbol{\delta}_a^{\mathsf{T}}\mathbf{F}_{aa}\boldsymbol{\delta}_a + 2\boldsymbol{\delta}_a^{\mathsf{T}}\mathbf{F}_{ab}\boldsymbol{\delta}_b + \boldsymbol{\delta}_b^{\mathsf{T}}\mathbf{F}_{bb}\boldsymbol{\delta}_b \\ &\overset{(2)}{=} \big(\boldsymbol{\delta}_b + \mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}\boldsymbol{\delta}_a\big)^{\mathsf{T}}\mathbf{F}_{bb}\big(\boldsymbol{\delta}_b + \mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}\boldsymbol{\delta}_a\big) + \boldsymbol{\delta}_a^{\mathsf{T}}\big(\mathbf{F}_{aa} - \mathbf{F}_{ab}\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}\big)\boldsymbol{\delta}_a. \end{aligned} \tag{10.22}$$

(1) Multiply out the block form; the two cross terms are equal because $\mathbf{F}$ is symmetric.
(2) Complete the square in $\boldsymbol{\delta}_b$: expanding the first product gives back $\boldsymbol{\delta}_b^{\mathsf{T}}\mathbf{F}_{bb}\boldsymbol{\delta}_b + 2\boldsymbol{\delta}_a^{\mathsf{T}}\mathbf{F}_{ab}\boldsymbol{\delta}_b + \boldsymbol{\delta}_a^{\mathsf{T}}\mathbf{F}_{ab}\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}\boldsymbol{\delta}_a$, and the last piece is subtracted again in the second term.

Conditioning sets $\boldsymbol{\delta}_b = \mathbf{0}$ in the original exponent: what remains is $\boldsymbol{\delta}_a^{\mathsf{T}} \mathbf{F}_{aa} \boldsymbol{\delta}_a$, so the conditional covariance of $\boldsymbol{a}$ is $\mathbf{F}_{aa}^{-1}$. *Marginalising* integrates over $\boldsymbol{\delta}_b$. In the second line of (10.22) the first term is a Gaussian in $\boldsymbol{\delta}_b$ centred on $-\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}\boldsymbol{\delta}_a$ with a width that does not depend on $\boldsymbol{\delta}_a$, so its integral is a constant. The marginal is a Gaussian in $\boldsymbol{\delta}_a$ with inverse covariance

$$\widetilde{\mathbf{F}}_{aa} = \mathbf{F}_{aa} - \mathbf{F}_{ab}\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}, \tag{10.23}$$

the **Schur complement** of $\mathbf{F}_{bb}$ [what is left of the information on $\boldsymbol{a}$ after the part that could be confused with changes of $\boldsymbol{b}$ is removed]. The same block also appears when we invert $\mathbf{F}$: multiplying out shows that

$$\mathbf{F}\begin{pmatrix} \widetilde{\mathbf{F}}_{aa}^{-1} \\ -\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}\widetilde{\mathbf{F}}_{aa}^{-1} \end{pmatrix} = \begin{pmatrix} (\mathbf{F}_{aa} - \mathbf{F}_{ab}\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba})\widetilde{\mathbf{F}}_{aa}^{-1} \\ (\mathbf{F}_{ba} - \mathbf{F}_{bb}\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba})\widetilde{\mathbf{F}}_{aa}^{-1} \end{pmatrix} = \begin{pmatrix} \mathbb{1} \\ \mathbf{0} \end{pmatrix},$$

so the aa block of $\mathbf{F}^{-1}$ is $\widetilde{\mathbf{F}}_{aa}^{-1}$. In words: *to marginalise, invert the whole Fisher matrix and read off the block you want* [HobsonBMC p. 107], [167]. The same block-inverse formula gave conditional and marginal variances of a multivariate Gaussian in Chapter 2; here the roles of covariance and inverse covariance are exchanged.

Working definition 10.2 (marginalised and conditional errors)

The **marginalised error** on θ_i is $\sigma_i = \sqrt{(\mathbf{F}^{-1})_{ii}}$, the error when all other parameters are estimated from the same data. The **conditional error** is $1/\sqrt{F_{ii}}$, the error if all other parameters were known exactly. *Operationally:* invert the full matrix and take the square root of the diagonal; never take the inverse square root of the diagonal of $\mathbf{F}$ itself unless the other parameters really are fixed by something outside the experiment.

Since $\mathbf{F}_{ab}\mathbf{F}_{bb}^{-1}\mathbf{F}_{ba}$ is positive semidefinite, $\widetilde{\mathbf{F}}_{aa} \preceq \mathbf{F}_{aa}$: marginalising can only lose information, which is the matrix form of (10.12). For two parameters the loss has a simple form. The 2×2 inverse (10.7), written with indices $1,2$, has $(\mathbf{F}^{-1})_{11} = F_{22}/\det\mathbf{F}$, $(\mathbf{F}^{-1})_{22} = F_{11}/\det\mathbf{F}$ and $(\mathbf{F}^{-1})_{12} = -F_{12}/\det\mathbf{F}$, with $\det\mathbf{F} = F_{11}F_{22} - F_{12}^2$. Then

$$\begin{aligned}
(\mathbf{F}^{-1})_{11} &\overset{(1)}{=} \frac{F_{22}}{F_{11}F_{22} - F_{12}^2} = \frac{1}{F_{11} - F_{12}^2/F_{22}}, \\
\rho &\overset{(2)}{=} \frac{(\mathbf{F}^{-1})_{12}}{\sqrt{(\mathbf{F}^{-1})_{11}(\mathbf{F}^{-1})_{22}}} = \frac{-F_{12}/\det\mathbf{F}}{\sqrt{F_{22}F_{11}}/\det\mathbf{F}} = -\frac{F_{12}}{\sqrt{F_{11}F_{22}}}, \\
F_{11} - \frac{F_{12}^2}{F_{22}} &\overset{(3)}{=} F_{11}\left(1 - \frac{F_{12}^2}{F_{11}F_{22}}\right) = F_{11}\,(1-\rho^2).
\end{aligned}$$

(1) Divide numerator and denominator by F_{22}. The result is the Schur complement (10.23) with $\boldsymbol{a} = \theta_1$ and $\boldsymbol{b} = \theta_2$, as it must be.

(2) The correlation coefficient is the covariance over the product of the two standard deviations; the determinant cancels.

(3) Take F_{11} out, and recognise $F_{12}^2/(F_{11}F_{22}) = \rho^2$ from the line above.

With the conditional error $\sigma_1^{\text{cond}} = 1/\sqrt{F_{11}}$, the marginalised error is therefore

$$\sigma_1^{\text{marg}} = \frac{1}{\sqrt{F_{11} - F_{12}^2/F_{22}}} = \frac{\sigma_1^{\text{cond}}}{\sqrt{1-\rho^2}}, \tag{10.24}$$

Sivia's (3.21) in Fisher notation [Sivia (3.21)–(3.22)]. A correlation of 0.9 more than doubles the error, 0.99 multiplies it by seven.

Figure 10.9 shows the geometry, which Cowan describes in words [Cowan p. 83]. Take the ellipse $\boldsymbol{\delta}^{\mathsf{T}}\mathbf{F}\boldsymbol{\delta} = 1$. *The chord.* On the horizontal line through the centre, $\delta_2 = 0$, the equation is $F_{11}\delta_1^2 = 1$, so the chord ends at $\delta_1 = \pm 1/\sqrt{F_{11}} = \pm\sigma_1^{\text{cond}}$. *The tangents.* The completed square (10.22), with one parameter in each group, writes the same equation as

$$F_{22}\left(\delta_2 + \frac{F_{12}}{F_{22}}\delta_1\right)^2 + \left(F_{11} - \frac{F_{12}^2}{F_{22}}\right)\delta_1^2 = 1.$$

The first term is never negative, so every point of the ellipse has $(F_{11} - F_{12}^2/F_{22})\,\delta_1^2 \le 1$, that is $|\delta_1| \le \sigma_1^{\text{marg}}$; the bound is reached where the first term vanishes, $\delta_2 = -F_{12}\delta_1/F_{22}$. So the ellipse reaches out to $\delta_1 = \pm\sigma_1^{\text{marg}}$ and no further: its vertical tangents sit there. In the angular-distribution experiment of Section 10.1.3 the two errors on α were 0.052 and 0.047 (Figure 10.4).

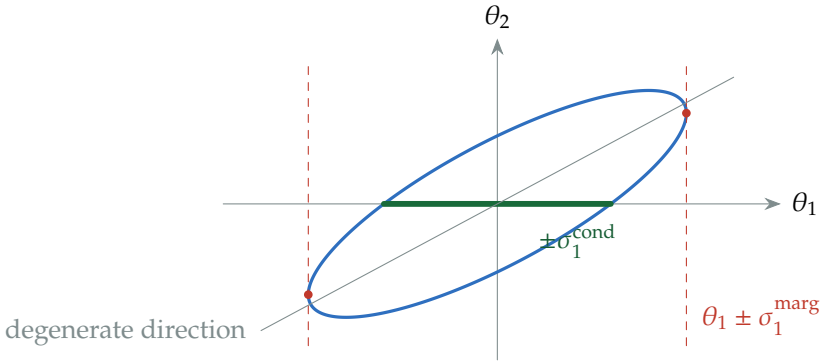

Figure 10.9: The ellipse $\boldsymbol{\delta}^{\mathsf{T}}\mathbf{F}\boldsymbol{\delta} = 1$ for two parameters with correlation $\rho = 0.8$. If θ_2 is known, the error on θ_1 is the half-chord at $\theta_2 = \theta_2^0$ (green). If θ_2 is free, the error is the half-width of the shadow of the ellipse on the θ_1 axis (red tangents), larger by $1/\sqrt{1-\rho^2}$. The long axis (grey) is the combination the data cannot pin down.

Watch out: Quoting the conditional error

$1/\sqrt{F_{ii}}$ is the error on θ_i with every other parameter fixed at its true value. Quoting it as "the error" of a forecast is the classic way to overstate an experiment. In the CMB forecast of Section 10.6, the conditional errors on τ and $\ln A_s$ are fifteen times smaller than the marginalised ones, and the error on ω_c three times smaller.

Nuisance parameters. A calibration factor, a foreground amplitude, a detector gain: parameters we must fit but do not care about [168]. In a forecast they are included in $\mathbf{F}$ like any other parameter and then marginalised by inverting. Fixing them instead ("assume the calibration is perfect") gives the conditional error, which is wrong unless the nuisance really is known. For a Gaussian likelihood, marginalising and profiling agree (Section 3.14.4), so the Fisher answer serves both schools. Section 10.6.3 shows a single nuisance parameter, Planck's calibration, accounting for most of the gap between a naive forecast and the published error on $A_s e^{-2\tau}$.

10.4.2 Confidence ellipses: where 2.30 and 6.18 come from

A two-parameter forecast is usually drawn as an ellipse, and a reader needs to know how much probability it encloses. For a pair of parameters, marginalise the rest. By (10.23) and the inversion rule that follows it, the marginal distribution of the pair is a Gaussian whose covariance is the corresponding 2×2 block of $\mathbf{F}^{-1}$; call that block $\boldsymbol{\Sigma}$. Its inverse defines $\Delta\chi^2 = \boldsymbol{\delta}^{\mathsf{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{\delta}$ for the two-component $\boldsymbol{\delta}$ [Cowan (9.31)–(9.32)].

The question. What fraction p of the Gaussian lies inside the ellipse $\Delta\chi^2 \le q$? *Whiten the variables.* Factor the covariance as $\boldsymbol{\Sigma} = \boldsymbol{L}\boldsymbol{L}^{\mathsf{T}}$ with $\boldsymbol{L}$ lower triangular (the Cholesky factor) and set $\boldsymbol{z} = \boldsymbol{L}^{-1}\boldsymbol{\delta}$, so $\boldsymbol{\delta} = \boldsymbol{L}\boldsymbol{z}$. A linear map transforms a covariance by sandwiching it, so

$$\operatorname{Cov} \boldsymbol{z} = \boldsymbol{L}^{-1}\boldsymbol{\Sigma}\,\boldsymbol{L}^{-\mathsf{T}} = \boldsymbol{L}^{-1}\boldsymbol{L}\boldsymbol{L}^{\mathsf{T}}\boldsymbol{L}^{-\mathsf{T}} = \mathbb{1}.$$

The two components of $\boldsymbol{z}$ are Gaussian, have unit variance and are uncorrelated. For Gaussians that is enough for independence: with covariance $\mathbb{1}$ the density $\propto e^{-(z_1^2+z_2^2)/2}$ has no cross term, so it factorises into a function of z_1 times a function of z_2. The quadratic form becomes a sum of squares,

$$\Delta\chi^2 = (\boldsymbol{L}\boldsymbol{z})^{\mathsf{T}}(\boldsymbol{L}\boldsymbol{L}^{\mathsf{T}})^{-1}(\boldsymbol{L}\boldsymbol{z}) = \boldsymbol{z}^{\mathsf{T}}\boldsymbol{L}^{\mathsf{T}}\boldsymbol{L}^{-\mathsf{T}}\boldsymbol{L}^{-1}\boldsymbol{L}\boldsymbol{z} = \boldsymbol{z}^{\mathsf{T}}\boldsymbol{z} = z_1^2 + z_2^2 \equiv r^2,$$

using $(\boldsymbol{L}\boldsymbol{L}^{\mathsf{T}})^{-1} = \boldsymbol{L}^{-\mathsf{T}}\boldsymbol{L}^{-1}$: a squared radius in the $\boldsymbol{z}$ plane. Then

$$\mathrm{P}(\Delta\chi^2 \le q) \overset{(1)}{=} \int_{r^2\le q} \frac{1}{2\pi} e^{-(z_1^2+z_2^2)/2}\,\mathrm{d}z_1\mathrm{d}z_2 \overset{(2)}{=} \int_0^{2\pi}\int_0^{\sqrt{q}} \frac{1}{2\pi} e^{-r^2/2}\, r\,\mathrm{d}r\,\mathrm{d}\phi \overset{(3)}{=} 1 - e^{-q/2}, \tag{10.25}$$

(1) The joint density of two independent standard normals.
(2) Polar coordinates, $\mathrm{d}z_1\mathrm{d}z_2 = r\,\mathrm{d}r\,\mathrm{d}\phi$.
(3) The ϕ integral gives 2π; $\int_0^{\sqrt{q}} re^{-r^2/2}\mathrm{d}r = [-e^{-r^2/2}]_0^{\sqrt{q}}$.

So $q = -2\ln(1-p)$. For the probability inside $\pm1\sigma$ of a one-dimensional Gaussian, $p = 0.6827$, this gives $q = 2.30$; for $\pm2\sigma$, $p = 0.9545$, $q = 6.18$; for $\pm3\sigma$, $p = 0.9973$, $q = 11.8$.[2] These are the levels in Figure 10.4, and the simulation is a test of (10.25): 0.704 of Cowan's 500 fits fall inside the 2.30 ellipse and 0.974 inside the 6.18 one, against 0.683 and 0.954, with binomial uncertainties ±0.021 and ±0.009.

Two ellipses for two questions. The ellipse $\Delta\chi^2 = 1$ is the one whose tangents mark $\pm\sigma_i^{\mathrm{marg}}$ (Figure 10.9); it is Cowan's contour $\ln\mathcal{L} = \ln\mathcal{L}_{\max} - \frac{1}{2}$ [Cowan (6.25), (6.31)]. But it contains only $1 - e^{-1/2} = 39\%$ of the two-dimensional probability. The ellipse that contains 68.3% is the larger one, $\Delta\chi^2 = 2.30$. How far does it reach along each axis? The tangent argument of Section 10.4.1 applies to any ellipse: on $\boldsymbol{\delta}^{\mathsf{T}}\boldsymbol{M}\boldsymbol{\delta} = q$ the largest $|\delta_1|$ is $\sqrt{q}$ divided by the square root of the Schur complement of $\boldsymbol{M}$, and by the inversion rule after (10.23) the inverse of that Schur complement is $(\boldsymbol{M}^{-1})_{11}$. Here $\boldsymbol{M} = \boldsymbol{\Sigma}^{-1}$, so $(\boldsymbol{M}^{-1})_{11} = \Sigma_{11} = \sigma_1^2$, and the ellipse $\Delta\chi^2 = q$ casts a shadow $\pm\sqrt{q}\,\sigma_i$ on each axis. For $q = 1$ that is $\pm\sigma_i$, as stated; for $q = 2.30$ it is $\pm\sqrt{2.30}\,\sigma_i = \pm1.52\,\sigma_i$. Both are correct; they answer different questions (one parameter at a time, or the pair jointly), and a figure must say which it shows. With m parameters jointly the levels come from χ^2_m [Cowan Table 9.4]; for $m = 6$ the 68.3% region is $\Delta\chi^2 \le 7.04$.

Drawing the ellipse. To draw it we need its axes, their lengths and its tilt. Write the pair covariance as $\boldsymbol{\Sigma} = \left(\begin{smallmatrix} a & b \\ b & c \end{smallmatrix}\right)$ with $a = \sigma_x^2$, $c = \sigma_y^2$, $b = \sigma_{xy}$. *The lengths.* The eigenvalues λ of $\boldsymbol{\Sigma}$ solve $\det(\boldsymbol{\Sigma} - \lambda\mathbb{1}) = (a-\lambda)(c-\lambda) - b^2 = 0$, that is $\lambda^2 - (a+c)\lambda + (ac - b^2) = 0$, the trace and the determinant as coefficients. The quadratic formula gives

$$\lambda_\pm = \frac{a+c}{2} \pm \sqrt{\left(\frac{a+c}{2}\right)^2 - ac + b^2} = \frac{\sigma_x^2+\sigma_y^2}{2} \pm \sqrt{\frac{(\sigma_x^2-\sigma_y^2)^2}{4} + \sigma_{xy}^2}.$$

Let $\boldsymbol{R}$ be the rotation whose columns are the two unit eigenvectors, so $\boldsymbol{\Sigma} = \boldsymbol{R}\,\mathrm{diag}(\lambda_+,\lambda_-)\boldsymbol{R}^{\mathsf{T}}$ and $\boldsymbol{\Sigma}^{-1} = \boldsymbol{R}\,\mathrm{diag}(1/\lambda_+, 1/\lambda_-)\boldsymbol{R}^{\mathsf{T}}$. In the rotated coordinates $(u,v) = \boldsymbol{R}^{\mathsf{T}}\boldsymbol{\delta}$ the ellipse is

[2] Coe [167] and others print 6.17; $-2\ln(1-0.9545) = 6.180$.

$u^2/\lambda_+ + v^2/\lambda_- = q$, an upright ellipse with half-axes $\sqrt{q\lambda_+}$ and $\sqrt{q\lambda_-}$. *The tilt.* With $\boldsymbol{R}$ the rotation by the angle ϑ, the matrix $\boldsymbol{R}^\mathsf{T}\boldsymbol{\Sigma}\boldsymbol{R}$ must be diagonal. Its off-diagonal entry is $(c-a)\sin\vartheta\cos\vartheta + b(\cos^2\vartheta - \sin^2\vartheta) = \frac{c-a}{2}\sin 2\vartheta + b\cos 2\vartheta$, and setting it to zero gives

$$\tan 2\vartheta = \frac{2b}{a-c} = \frac{2\sigma_{xy}}{\sigma_x^2 - \sigma_y^2}$$

for the angle ϑ of the long axis [167], [Cowan (6.32)]. In code it is simpler to map a unit circle through the Cholesky factor, $\boldsymbol{\delta} = \sqrt{q}\,\boldsymbol{L}(\cos t, \sin t)^\mathsf{T}$: by the whitening above this is exactly the set $\boldsymbol{z}^\mathsf{T}\boldsymbol{z} = q$, and it is how every ellipse in the figures is drawn.

10.4.3 Degeneracy directions

The long axis of the ellipse is a combination of parameters the data barely constrain; the short axis is a combination they pin down. For many parameters the same information is in the eigenvectors of $\mathbf{F}$. Write $\mathbf{F} = \boldsymbol{V}\,\mathrm{diag}(\lambda_1,\dots,\lambda_m)\boldsymbol{V}^\mathsf{T}$ with orthonormal eigenvectors $\boldsymbol{v}_a$ as the columns of $\boldsymbol{V}$, as in Section 10.2.2. Since $\boldsymbol{V}^\mathsf{T}\boldsymbol{V} = \mathbb{1}$, the inverse is $\mathbf{F}^{-1} = \boldsymbol{V}\,\mathrm{diag}(1/\lambda_1,\dots,1/\lambda_m)\boldsymbol{V}^\mathsf{T}$, and $\boldsymbol{V}^\mathsf{T}\boldsymbol{v}_a$ is the unit vector $\boldsymbol{e}_a$. The variance of the combination $\boldsymbol{v}_a^\mathsf{T}\boldsymbol{\theta}$, and its covariance with another such combination, follow from the rule $\mathrm{Cov}(\boldsymbol{u}^\mathsf{T}\boldsymbol{\theta}, \boldsymbol{w}^\mathsf{T}\boldsymbol{\theta}) = \boldsymbol{u}^\mathsf{T}\mathbf{F}^{-1}\boldsymbol{w}$:

$$\mathrm{Var}(\boldsymbol{v}_a^\mathsf{T}\boldsymbol{\theta}) = \boldsymbol{v}_a^\mathsf{T}\mathbf{F}^{-1}\boldsymbol{v}_a = \boldsymbol{e}_a^\mathsf{T}\,\mathrm{diag}(1/\lambda)\,\boldsymbol{e}_a = \frac{1}{\lambda_a},$$

$$\mathrm{Cov}(\boldsymbol{v}_a^\mathsf{T}\boldsymbol{\theta}, \boldsymbol{v}_b^\mathsf{T}\boldsymbol{\theta}) = \boldsymbol{e}_a^\mathsf{T}\,\mathrm{diag}(1/\lambda)\,\boldsymbol{e}_b = 0 \quad (a \neq b).$$

So each eigen-combination is measured with error $1/\sqrt{\lambda_a}$, the combinations are mutually uncorrelated [Sivia (3.20), Fig. 3.7], [165], and because the calculation used $\mathbf{F}^{-1}$, this is the marginalised error, with every other combination free. A very small eigenvalue is a **degeneracy**: a direction along which the model hardly changes the data. One caution: the eigenvectors depend on the units of the parameters (rescale θ_1 by 1000 and the directions turn), so they are only meaningful for parameters of comparable kind, or after each parameter is scaled by its expected error.

Example: the straight line and its pivot. Experiment A measures $y = a + bx$ at ten points evenly spread over $0 \le x \le 1$, each with Gaussian noise $\sigma = 0.1$. With $\boldsymbol{\mu}_{,a} = (1,\dots,1)$ and $\boldsymbol{\mu}_{,b} = (x_1,\dots,x_{10})$, the formula (10.20) gives

$$\mathbf{F} = \frac{1}{\sigma^2}\begin{pmatrix} \sum_k 1 & \sum_k x_k \\ \sum_k x_k & \sum_k x_k^2 \end{pmatrix},$$

the matrix of the normal equations (Section 9.17.2). The intercept and slope come out strongly anticorrelated, $\rho = -0.84$, with $\sigma_a = 0.059$, $\sigma_b = 0.099$. The reason is a lever arm: all data sit to the right of $x = 0$, so a steeper line is compensated by a lower intercept. The combination the data really fix is the height of the line in the middle of the data, $y_p = a + bx_p$, for a suitable point x_p. *Which point?* The one at which y_p and b are uncorrelated. Covariance is linear in each argument and x_p is a fixed number, so

$$0 = \mathrm{Cov}(y_p, b) \overset{(1)}{=} \mathrm{Cov}(a,b) + x_p\,\mathrm{Var}(b) \quad\Rightarrow\quad x_p = -\frac{(\mathbf{F}^{-1})_{ab}}{(\mathbf{F}^{-1})_{bb}} \overset{(2)}{=} \frac{F_{ab}}{F_{aa}} \overset{(3)}{=} \frac{\sum_k x_k}{n} = 0.50.$$

(1) The covariances come from $\mathbf{F}^{-1}$: $\mathrm{Cov}(a,b) = (\mathbf{F}^{-1})_{ab}$ and $\mathrm{Var}(b) = (\mathbf{F}^{-1})_{bb}$.

(2) The 2×2 inverse (10.7): $(\mathbf{F}^{-1})_{ab} = -F_{ab}/\det\mathbf{F}$ and $(\mathbf{F}^{-1})_{bb} = F_{aa}/\det\mathbf{F}$; the determinant cancels.

(3) Read the entries off the matrix above, with $n = 10$ points; the common factor $1/\sigma^2$ cancels.

So the pivot is the mean of the x_k. Each point carries the same information here, because all have the same noise; with unequal noise the same steps give the mean of the x_k weighted by $1/\sigma_k^2$, the information each point carries. That is the general statement: the pivot sits at the information-weighted mean of the variable along which the line is drawn. Section 8.7.3 found the same statement for the CMB, with $\ln k$ in place of x and the information of each multipole as the weight, and Section 10.6.2 uses it again.

The pivot as new parameters. Solving $y_p = a + bx_p$ for the old parameter gives $a = y_p - bx_p$, while b stays b. These are the functions $\boldsymbol{\theta}(\boldsymbol{p})$ that Section 10.4.5 turns into a Jacobian, and in the variables (y_p, b) the errors are uncorrelated. This is the reason the CMB amplitude A_s is quoted at a pivot wavenumber.

10.4.4 Priors and independent experiments add

Two independent experiments A and B measuring the same parameters have a joint likelihood $\mathcal{L} = \mathcal{L}_A\mathcal{L}_B$. The log-likelihoods add, so their second derivatives add, so

$$\mathbf{F}_{A+B} = \mathbf{F}_A + \mathbf{F}_B. \tag{10.26}$$

A Gaussian prior $p(\boldsymbol{\theta}) \propto \exp[-\frac{1}{2}(\boldsymbol{\theta}-\boldsymbol{\theta}_0)^{\mathsf{T}}\boldsymbol{P}(\boldsymbol{\theta}-\boldsymbol{\theta}_0)]$ multiplies the likelihood in Bayes' theorem, so in the exponent it adds: the posterior has inverse covariance $\mathbf{F}+\boldsymbol{P}$ [HobsonBMC p. 107]. A prior is one more experiment, and a prior of width σ_p on one parameter adds $1/\sigma_p^2$ to one diagonal element. Two rules make this work. Add the matrices *before* inverting, and write them for the same set of parameters in the same units (padding with zeros a parameter an experiment does not see).

Example: two experiments on one line. Experiment B measures the same line at ten points over $2 \le x \le 3$. On its own it is even more degenerate, $\rho = -0.99$, because its lever arm from $x = 0$ is longer, and its ellipse is tilted at a different angle from A's (Figure 10.10, left). The sum of the two Fisher matrices gives $\sigma_a = 0.039$ and $\sigma_b = 0.021$: the slope is 4.7 times better than either experiment alone. A naive combination of the two *marginalised* slope errors, $1/\sqrt{1/0.099^2 + 1/0.099^2} = 0.070$, would have missed most of the gain, because the long axes of the two ellipses point in different directions and each experiment measures well what the other measures badly.

Example: a prior on the intercept. Suppose a calibration measurement fixes the intercept to ± 0.02. Adding $1/0.02^2$ to F_{aa} of experiment A gives $\sigma_b = 0.060$ instead of 0.099 (Figure 10.10, right): a prior on one parameter improves another through their correlation. This is how a measurement of τ from large-scale polarization improves the CMB amplitude in Section 10.6.

Why the matrices, not the errors, are combined. Two forecasts quoted as marginalised errors cannot be combined by adding inverse variances: the correlations are gone, and with them the gain from crossing degeneracies. The full Fisher matrices are kept, published and added, and marginalisation comes last.

10.4.5 Changing parameters: the Jacobian sandwich

The Fisher matrix is computed in the parameters the derivatives were taken with respect to, but we may want the answer in others: H_0 instead of an angle, $\ln A_s$ instead of A_s, the pivot

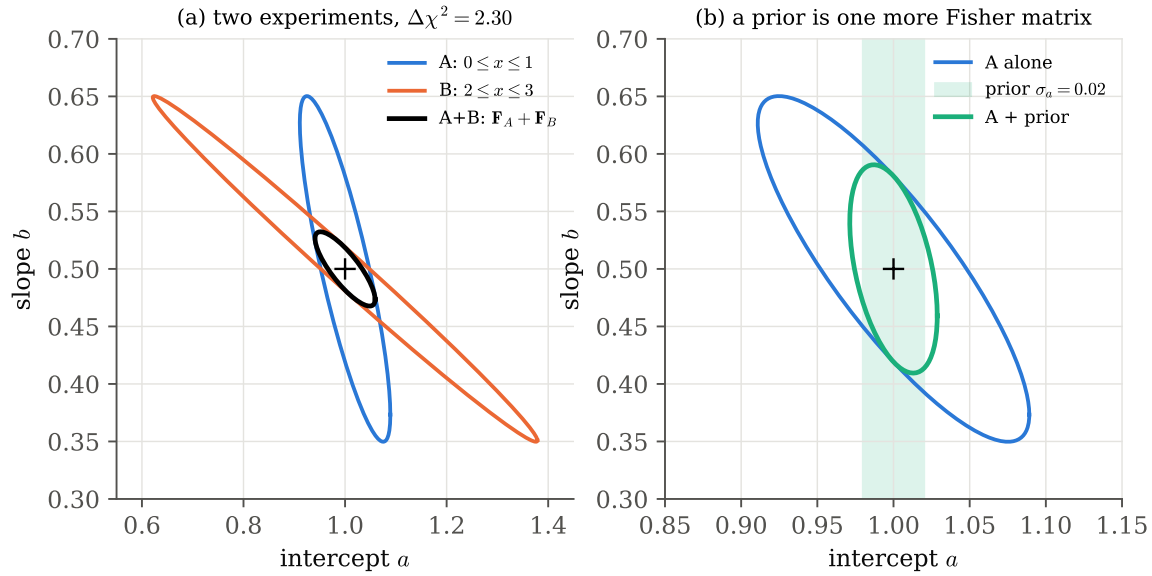

Figure 10.10: Left: two experiments measure the same line over different ranges of x; each has an elongated 68% ellipse, tilted in its own direction. The sum of their Fisher matrices gives the small black ellipse, much smaller than either. Right: a Gaussian prior on the intercept (shaded band) is one more Fisher matrix, and through the correlation it also shrinks the slope.

amplitude instead of the intercept. Let $\boldsymbol{p}$ be the new parameters and $\boldsymbol{\theta}(\boldsymbol{p})$ the old ones as functions of the new, with Jacobian $J_{ia} = \partial\theta_i/\partial p_a$. The score transforms by the chain rule, and $\mathbf{F}$ is the covariance of the score:

$$S'_a = \frac{\partial \ln \mathcal{L}}{\partial p_a} \overset{(1)}{=} \sum_i J_{ia} S_i, \qquad F'_{ab} = \mathbb{E}[S'_a S'_b] \overset{(2)}{=} \sum_{ij} J_{ia}\, \mathbb{E}[S_i S_j]\, J_{jb}, \qquad \mathbf{F}' = \boldsymbol{J}^{\mathsf{T}} \mathbf{F} \boldsymbol{J}. \tag{10.27}$$

(1) The likelihood depends on $\boldsymbol{p}$ only through $\boldsymbol{\theta}(\boldsymbol{p})$.
(2) $\boldsymbol{J}$ is not random; take it out of the expectation.

[167], eq. (18). *The covariance transforms the other way.* Inverting $\mathbf{F}' = \boldsymbol{J}^{\mathsf{T}}\mathbf{F}\boldsymbol{J}$ reverses the order of the factors: $(\mathbf{F}')^{-1} = \boldsymbol{J}^{-1}\mathbf{F}^{-1}\boldsymbol{J}^{-\mathsf{T}}$, with $\boldsymbol{J}^{-1} = \partial\boldsymbol{p}/\partial\boldsymbol{\theta}$ the Jacobian of the new parameters with respect to the old. Read as covariances,

$$\mathrm{Cov}(\boldsymbol{p}) = \frac{\partial \boldsymbol{p}}{\partial \boldsymbol{\theta}}\, \mathbf{F}^{-1} \left(\frac{\partial \boldsymbol{p}}{\partial \boldsymbol{\theta}}\right)^{\mathsf{T}},$$

which is the rule $\mathrm{Cov}(\boldsymbol{A}\boldsymbol{\theta}) = \boldsymbol{A}\,\mathrm{Cov}(\boldsymbol{\theta})\boldsymbol{A}^{\mathsf{T}}$ for a linear map, applied to the linear part of $\boldsymbol{p}(\boldsymbol{\theta})$ near $\boldsymbol{\theta}_0$. *A single derived quantity.* Now let one component of $\boldsymbol{p}$ be a quantity $g(\boldsymbol{\theta})$ that is not one of the parameters, such as H_0 or $A_s e^{-2\tau}$ (the other components can be any quantities that complete the set; they do not enter its own variance). Its row of $\partial\boldsymbol{p}/\partial\boldsymbol{\theta}$ is the gradient $\nabla g^{\mathsf{T}} = (\partial_1 g, \ldots, \partial_m g)$, and the corresponding diagonal entry of $\mathrm{Cov}(\boldsymbol{p})$ is

$$\sigma_g^2 = \nabla g^{\mathsf{T}}\, \mathbf{F}^{-1}\, \nabla g = \sum_{ij} \partial_i g\, (\mathbf{F}^{-1})_{ij}\, \partial_j g,$$

the multiparameter delta method [Wasserman p. 134, Thm. 9.28] of Section 3.13.2. A check with two parameters and $g = \theta_1 + \theta_2$: $\nabla g = (1,1)$, so $\sigma_g^2 = (\mathbf{F}^{-1})_{11} + (\mathbf{F}^{-1})_{22} + 2(\mathbf{F}^{-1})_{12}$, the familiar variance of a sum, $\mathrm{Var}\,\theta_1 + \mathrm{Var}\,\theta_2 + 2\,\mathrm{Cov}(\theta_1, \theta_2)$. Two derived quantities g and g' have covariance $\nabla g^{\mathsf{T}}\mathbf{F}^{-1}\nabla g'$, an off-diagonal entry of the same matrix.[3] The transformation is exact

[3] In Wasserman's Example 9.29 the result for $\tau = \sigma/\mu$ is printed as $\frac{1}{\sqrt{n}}\sqrt{1/\hat\mu^4 + \hat\sigma^2/2\hat\mu^2}$; the first term should be $\hat\sigma^4/\hat\mu^4$, as the product of his gradient $(-\sigma/\mu^2, 1/\mu)$ and his J_n shows.

for the Fisher matrix, which is a local quantity at $\boldsymbol{\theta}_0$; whether the transformed likelihood is still close to Gaussian is a separate question, and a nonlinear change of variables can make it better or worse (Section 9.17.6).

Example: the pivot as a change of variables. For experiment A, $a = y_p - bx_p$ and $b = b$, so $\boldsymbol{J} = \left(\begin{smallmatrix} 1 & -x_p \\ 0 & 1 \end{smallmatrix}\right)$. The new matrix $\boldsymbol{J}^{\mathsf{T}}\mathbf{F}\boldsymbol{J}$ has errors $\sigma_{y_p} = 0.032$, $\sigma_b = 0.099$ and correlation +0.000. The slope error has not changed (the slope is the same parameter), but the amplitude is now quoted where it is measured, almost twice better than the intercept at $x = 0$.

10.4.6 One number for an experiment: figures of merit

To rank designs, a single number helps. Hobson et al. list the common choices [HobsonBMC pp. 108–109]. *The determinant* $\det \mathbf{F}$ ("D-optimality"): the ellipsoid $\boldsymbol{\delta}^{\mathsf{T}}\mathbf{F}\boldsymbol{\delta} = q$ has half-axes $\sqrt{q/\lambda_a}$ along the eigenvectors of $\mathbf{F}$, so its volume is proportional to $\prod_a \lambda_a^{-1/2} = (\det \mathbf{F})^{-1/2}$, and a large determinant means a small volume. *The trace of* $\mathbf{F}^{-1}$ ("A-optimality"): the sum of the marginalised variances.

The information gain measures how much the data narrow the prior, as the Kullback–Leibler divergence (3.100) of the posterior from the prior. Take a Gaussian prior with inverse covariance $\boldsymbol{P}$, so the posterior has inverse covariance $\mathbf{F} + \boldsymbol{P}$ (Section 10.4.4), and centre both at $\boldsymbol{\theta}_0$, as a forecast does. With $\boldsymbol{\delta} = \boldsymbol{\theta} - \boldsymbol{\theta}_0$ and $\mathbb{E}$ the average over the posterior,

$$
\begin{aligned}
D(\text{post}, \text{prior}) &\overset{(1)}{=} \mathbb{E}\big[\ln p_{\text{post}}(\boldsymbol{\delta}) - \ln p_{\text{prior}}(\boldsymbol{\delta})\big] \\
&\overset{(2)}{=} \tfrac{1}{2}\ln\det(\mathbf{F}+\boldsymbol{P}) - \tfrac{1}{2}\ln\det\boldsymbol{P} - \tfrac{1}{2}\,\mathbb{E}\big[\boldsymbol{\delta}^{\mathsf{T}}(\mathbf{F}+\boldsymbol{P})\boldsymbol{\delta}\big] + \tfrac{1}{2}\,\mathbb{E}\big[\boldsymbol{\delta}^{\mathsf{T}}\boldsymbol{P}\boldsymbol{\delta}\big] \\
&\overset{(3)}{=} \tfrac{1}{2}\big[\ln\det(\mathbf{F}+\boldsymbol{P}) - \ln\det\boldsymbol{P} - \operatorname{Tr}\big(\mathbb{1} - \boldsymbol{P}(\mathbf{F}+\boldsymbol{P})^{-1}\big)\big].
\end{aligned}
$$

(1) The divergence is the average, under the first density, of the log of the ratio of the two.
(2) A Gaussian with inverse covariance $\boldsymbol{M}$ has $\ln p = \frac{1}{2}\ln\det\boldsymbol{M} - \frac{1}{2}\boldsymbol{\delta}^{\mathsf{T}}\boldsymbol{M}\boldsymbol{\delta}$ plus a constant that is the same for both and cancels.
(3) For any matrix $\boldsymbol{M}$, $\mathbb{E}[\boldsymbol{\delta}^{\mathsf{T}}\boldsymbol{M}\boldsymbol{\delta}] = \mathbb{E}\operatorname{Tr}(\boldsymbol{M}\boldsymbol{\delta}\boldsymbol{\delta}^{\mathsf{T}}) = \operatorname{Tr}(\boldsymbol{M}\boldsymbol{\Sigma})$ with the posterior covariance $\boldsymbol{\Sigma} = (\mathbf{F}+\boldsymbol{P})^{-1}$; so the third term is $-\frac{1}{2}\operatorname{Tr}\mathbb{1}$ and the fourth $+\frac{1}{2}\operatorname{Tr}(\boldsymbol{P}(\mathbf{F}+\boldsymbol{P})^{-1})$.

If the data say nothing, $\mathbf{F} = \mathbf{0}$ and every term vanishes; the more the data shrink the prior volume, the larger the gain, mostly through the first two terms, which compare the two volumes.

The dark-energy figure of merit. The equation of state of dark energy is often written $w(a) = w_0 + w_a(1-a)$ with a the scale factor (cosmology notes): w_0 is its value today and w_a how fast it changes. The figure of merit is $1/\sqrt{\det \boldsymbol{\Sigma}_{w_0 w_a}}$, with $\boldsymbol{\Sigma}_{w_0 w_a}$ the marginalised 2×2 block of $\mathbf{F}^{-1}$. By the half-axes of Section 10.4.2, the ellipse $\Delta\chi^2 = q$ has area $\pi\sqrt{q\lambda_+}\sqrt{q\lambda_-} = \pi q\sqrt{\det\boldsymbol{\Sigma}}$, so the figure of merit is inversely proportional to the area of the (w_0, w_a) ellipse: it is the determinant criterion applied to that one pair.

Each number rewards a different shape: a determinant can be large for a long thin ellipse whose long axis is useless, which is why the full matrix, not a single number, is what should be compared.

10.4.7 The recipe

Working definition 10.3 (Fisher forecast)

1. Choose the parameters and a fiducial point $\boldsymbol{\theta}_0$ (the forecast depends on both).
2. Model the data: mean $\boldsymbol{\mu}(\boldsymbol{\theta})$ and covariance $\mathbf{C}(\boldsymbol{\theta})$ of the summary the analysis will use, including the instrument (noise, beam, sky fraction).
3. Differentiate the model at $\boldsymbol{\theta}_0$ (analytically, or by finite differences checked for stability, Section 10.5).
4. Assemble $\mathbf{F}$ by (10.20), or by (10.3) for non-Gaussian data.
5. Add the Fisher matrices of priors and of independent experiments.
6. Transform to the parameters you want to report, $\mathbf{F}' = \boldsymbol{J}^{\mathsf{T}}\mathbf{F}\boldsymbol{J}$.
7. Invert. Marginalised errors are $\sqrt{(\mathbf{F}^{-1})_{ii}}$; 2×2 blocks of $\mathbf{F}^{-1}$ give ellipses at $\Delta\chi^2 = 2.30,\ 6.18$; eigenvectors give degeneracies; $\nabla g^{\mathsf{T}}\mathbf{F}^{-1}\nabla g$ gives derived parameters.
8. Check: is the predicted error small compared with the scale on which the model is nonlinear? If not, validate with simulations or a chain (Section 10.6.6).

10.5 Derivatives from a code that cannot differentiate

Equation (10.20) needs the derivative of the model with respect to each parameter. For the CMB the model is a Boltzmann code, CAMB [8]: tens of thousands of lines that integrate the coupled photon, baryon, neutrino and dark-matter perturbations from the early universe to today and return $C_\ell(\boldsymbol{\theta})$ (the physics is in the cosmology notes; Chapter T1 maps the objects). It returns numbers, not derivatives. The only practical route is a finite difference, $[C_\ell(\theta+h)-C_\ell(\theta-h)]/2h$, and the whole forecast then hangs on a number we choose by hand, the step h.

The question. How large should the step be, and how do we know the forecast does not depend on it? Two errors pull in opposite directions. With a large step, the model is no longer linear between $\theta-h$ and $\theta+h$, and the difference quotient is not the derivative: a *truncation error*. With a small step, the two spectra are nearly equal, and whatever numerical noise the code has (from its finite grids in time and wavenumber, its interpolations, its convergence tolerances) is divided by the small number $2h$: a *noise error*.

10.5.1 Truncation against noise

Expand $f(\theta\pm h) = f \pm hf' + \frac{1}{2}h^2f'' \pm \frac{1}{6}h^3f''' + \frac{1}{24}h^4f'''' \pm \frac{1}{120}h^5f^{(5)} + \dots$ (all derivatives at θ). Then the two-point and four-point central differences are

$$
\begin{aligned}
D_2(h) &\equiv \frac{f(\theta+h)-f(\theta-h)}{2h} \overset{(1)}{=} f' + \frac{h^2}{6}f''' + \frac{h^4}{120}f^{(5)} + \dots, \\
D_4(h) &\equiv \frac{4D_2(h)-D_2(2h)}{3} \overset{(2)}{=} \frac{-f(\theta+2h)+8f(\theta+h)-8f(\theta-h)+f(\theta-2h)}{12h} \\
&\overset{(3)}{=} f' - \frac{h^4}{30}f^{(5)} + \dots
\end{aligned}
\tag{10.28}
$$

(1) Subtract the two series: the even powers cancel; divide by $2h$.

(2) Write out $D_2(h)$ and $D_2(2h)$ and put everything over $12h$.

(3) From line (1), $D_2(2h) = f' + \frac{4h^2}{6} f''' + \frac{16h^4}{120} f^{(5)}$; in $4D_2(h) - D_2(2h)$ the h^2 terms cancel ($4 \cdot \frac{1}{6} - \frac{4}{6} = 0$) and the h^4 terms leave $\frac{4-16}{120} h^4 f^{(5)}$, which divided by 3 is $-h^4 f^{(5)}/30$.

The four-point rule is the two-point rule with its leading error extrapolated away (Richardson extrapolation), at the price of two more model evaluations. Chapter 9 used the two-point rule to build its emulator (Section 9.20.2).

Now add noise: suppose each evaluation of f carries an independent relative error of size ϵ, an absolute error of about $\epsilon\,|f|$. *The noise term.* In D_2 the two errors enter as a difference; being independent, they add in quadrature to about $\sqrt{2}\,\epsilon\,|f|$, and dividing by $2h$ leaves $\epsilon\,|f|\,/(\sqrt{2}\,h)$. We keep only its order, $\epsilon\,|f|\,/h$: a factor of order one changes no scaling. *The truncation term* is the first neglected term in line (1) of (10.28), $h^2\,|f'''|\,/6$. The total error is about

$$E(h) \approx \frac{\epsilon\,|f|}{h} + \frac{h^2}{6}\,|f'''|\,, \qquad h_{\rm opt} = \left(\frac{3\epsilon\,|f|}{|f'''|}\right)^{1/3}. \tag{10.29}$$

The first term falls with h and the second rises, so there is a best step in between, where the slope of E is zero:

$$\frac{\mathrm{d}E}{\mathrm{d}h} \overset{(1)}{=} -\frac{\epsilon\,|f|}{h^2} + \frac{h\,|f'''|}{3} = 0 \quad \Rightarrow \quad h^3 = \frac{3\epsilon\,|f|}{|f'''|},$$
$$\frac{\epsilon\,|f|}{h_{\rm opt}} \overset{(2)}{=} \frac{\epsilon^{2/3}\,|f|^{2/3}\,|f'''|^{1/3}}{3^{1/3}}, \qquad \frac{h_{\rm opt}^2}{6}\,|f'''| \overset{(3)}{=} \frac{3^{2/3}\epsilon^{2/3}\,|f|^{2/3}\,|f'''|^{1/3}}{6}.$$

(1) Differentiate the two terms of (10.29), set the sum to zero, and multiply by $3h^2/|f'''|$.

(2) Insert $1/h_{\rm opt} = (|f'''|\,/3\epsilon\,|f|)^{1/3}$ into the noise term.

(3) Insert $h_{\rm opt}^2 = (3\epsilon\,|f|\,/|f'''|)^{2/3}$ into the truncation term.

At the optimum both terms are of order $\epsilon^{2/3}$ (the noise term is exactly twice the truncation term): a code accurate to one part in 10^6 gives derivatives accurate to about one part in 10^4, not 10^6.

The four-point rule. Its noise term is again of order $\epsilon\,|f|\,/h$ (the weights $1, 8, 8, 1$ over $12h$ add in quadrature to $\sqrt{130}/12 \approx 0.95$ times $\epsilon\,|f|\,/h$), and its truncation term is $h^4\left|f^{(5)}\right|/30$ from line (3) of (10.28). So $E_4(h) \approx \epsilon\,|f|\,/h + h^4\left|f^{(5)}\right|/30$; setting $\mathrm{d}E_4/\mathrm{d}h = -\epsilon\,|f|\,/h^2 + \frac{4}{30}h^3\left|f^{(5)}\right| = 0$ gives $h^5 = \frac{30}{4}\,\epsilon\,|f|\,/\left|f^{(5)}\right|$, so $h_{\rm opt} \propto \epsilon^{1/5}$, and the error $\epsilon\,|f|\,/h_{\rm opt}$ is of order $\epsilon/\epsilon^{1/5} = \epsilon^{4/5}$: larger steps, and better derivatives.

Example: a function we can differentiate by hand. Take $f(x) = e^x \sin 3x$ at $x = 0.7$, whose derivative is known exactly, and give it a simulated "code noise" of relative size $\epsilon = 10^{-6}$. Figure 10.11 shows the error of the two rules against h, as the root-mean-square over 200 noise realisations. Without noise (dotted) the errors fall as h^2 and h^4 until double-precision round-off takes over near $h \sim 10^{-5}$ to 10^{-8}. With noise, the two-point error is smallest at $h = 6.1 \times 10^{-3}$, where (10.29) predicts 5.8×10^{-3} and an error of 3×10^{-4} (measured: 2×10^{-4}). The four-point rule is best at the larger step 3.3×10^{-2}, with error 4×10^{-5}. Below the optimum the error climbs as $1/h$ along the dashed line: there, making the step smaller makes the derivative worse.

10.5.2 The stability test for CAMB

For CAMB we do not know ϵ or f''', so we cannot compute $h_{\rm opt}$; we test instead. The steps h_i we use are roughly a third to a whole of the expected error of each parameter: 0.0001 in ω_b,

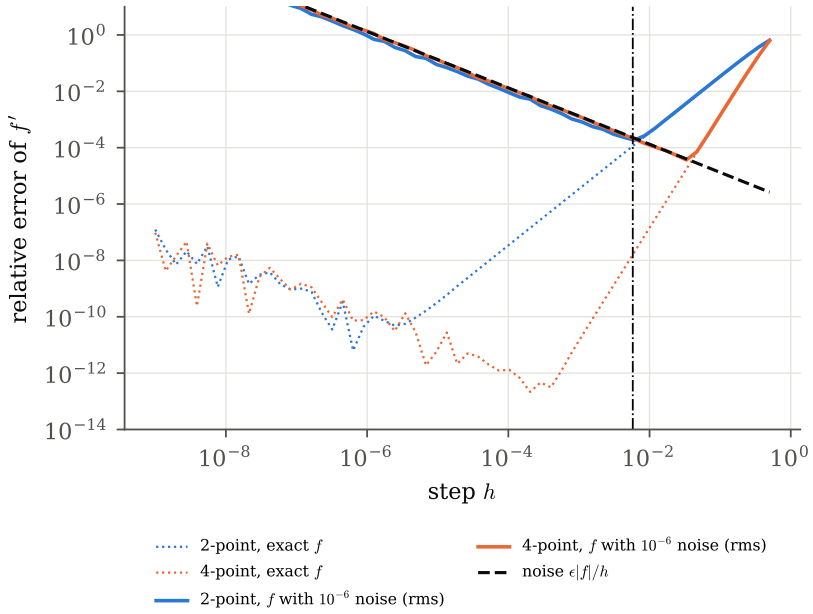

Figure 10.11: The error of a numerical derivative of $e^x \sin 3x$ against the step. Dotted: exact function values, where only truncation and double-precision round-off act. Solid: function values with a relative noise of 10^{-6}; the error is the sum of a noise term rising as $1/h$ (dashed) and a truncation term falling as h^2 (two-point) or h^4 (four-point). The vertical line is the predicted optimum of the two-point rule.

0.001 in ω_c, 0.0002 in $100\theta_{\mathrm{MC}}$, 0.005 in τ, 0.01 in $\ln(10^{10}A_s)$ and 0.004 in n_s. The reason for this scale is the truncation side of (10.29): the forecast is only meaningful over a region about one standard deviation wide, so the derivative should describe the model over that region, not over a much smaller or much larger one.

The test is to multiply every step by a factor m, recompute the derivatives with both rules, rebuild the forecast, and watch the marginalised errors. `04_derivatives.py` does this for $m = \frac{1}{64}, \frac{1}{16}, \frac{1}{4}, \frac{1}{2}, 1, 2, 4$, which takes 84 CAMB runs, cached so that every later script reuses them:

Listing 10.2: Two- and four-point derivatives of the CMB spectra, from cached CAMB runs (`code/ch10/04_derivatives.py`)

```
def derivs(m, stencil):
    out = {s: np.zeros((6, L.LMAX + 1)) for s in ("TT", "EE", "TE")}
    for i in range(6):
        h = m * L.STEPS[i]
        p1, m1 = spectra_at(i, m), spectra_at(i, -m)
        if stencil == 4:
            p2, m2 = spectra_at(i, 2 * m), spectra_at(i, -2 * m)
        for s in out:
            if stencil == 2:
                out[s][i] = (p1[s] - m1[s]) / (2 * h)
            else:
                out[s][i] = (-p2[s] + 8 * p1[s] - 8 * m1[s] + m2[s]) / (12 * h)
```

The forecast is the Planck-like temperature-and-polarization experiment of Section 10.6.3. Figure 10.12 shows the result. For $\frac{1}{4} \le m \le 4$ every marginalised error stays within 0.07% of the four-point reference, with either rule: the forecast does not care about the step. Below that, it does. At $m = \frac{1}{16}$ the largest change is 0.41%; at $m = \frac{1}{64}$ it is 2.49% (two-point) and 3.00% (four-point), and the most affected parameter is ω_c.

Why the noise makes the forecast too good. The errors at tiny steps are *smaller*, not larger. The reason is the geometric reading of Section 10.3.2, and two parameters are enough to see it. *The Fisher matrix as dot products.* By (10.31), F_{ij} is a weighted sum over multipoles of $\partial_i C_\ell \, \partial_j C_\ell$. Call the two derivative vectors $\boldsymbol{u} = (\partial_1 C_\ell)_\ell$ and $\boldsymbol{v} = (\partial_2 C_\ell)_\ell$, and write $\boldsymbol{a} \cdot \boldsymbol{b}$ for the weighted sum $\sum_\ell \frac{2\ell+1}{2} a_\ell b_\ell / (C_\ell + N_\ell)^2$. Then $F_{11} = |\boldsymbol{u}|^2$, $F_{22} = |\boldsymbol{v}|^2$, $F_{12} = \boldsymbol{u} \cdot \boldsymbol{v}$, and by the 2×2 inverse of Section 10.4.1 the correlation of the two estimates has size $|\rho| = |\boldsymbol{u} \cdot \boldsymbol{v}| \,/ (|\boldsymbol{u}|\,|\boldsymbol{v}|)$, the cosine of the angle between the two vectors. A degeneracy is two vectors pointing in nearly the same direction, $|\rho|$ close to one.

Add noise. The computed vectors are $\boldsymbol{u}' = \boldsymbol{u} + \boldsymbol{n}_1$ and $\boldsymbol{v}' = \boldsymbol{v} + \boldsymbol{n}_2$, where $\boldsymbol{n}_1$ and $\boldsymbol{n}_2$ fluctuate rapidly and randomly from one multipole to the next. A dot product of such a vector with a smooth one, or with another independent noise vector, is a sum of terms of random sign that nearly cancel; the dot product of a noise vector with itself is a sum of squares, which does not. So

$$F'_{11} \approx |\boldsymbol{u}|^2 + |\boldsymbol{n}_1|^2 , \qquad F'_{22} \approx |\boldsymbol{v}|^2 + |\boldsymbol{n}_2|^2 , \qquad F'_{12} \approx \boldsymbol{u} \cdot \boldsymbol{v} ,$$

$$|\rho'| = \frac{|\boldsymbol{u} \cdot \boldsymbol{v}|}{\sqrt{(|\boldsymbol{u}|^2 + |\boldsymbol{n}_1|^2)(|\boldsymbol{v}|^2 + |\boldsymbol{n}_2|^2)}} < \frac{|\boldsymbol{u} \cdot \boldsymbol{v}|}{|\boldsymbol{u}|\,|\boldsymbol{v}|} = |\rho| .$$

The diagonal has gained $|\boldsymbol{n}|^2$ of spurious "information" and the off-diagonal has not. Both effects lower the marginalised error $\sigma_1^{\text{marg}} = 1/\sqrt{F_{11}(1-\rho^2)}$ of (10.24): F_{11} grows and $1-\rho^2$ grows. The second effect is the strong one near a degeneracy. With $|\rho| = 0.95$ and noise carrying 1% of the power of each vector, $|\rho'| = 0.95/1.01 = 0.941$, and $1/\sqrt{1-\rho^2}$ falls from 3.20 to 2.95; together with the factor $1/\sqrt{1.01}$ the marginalised error drops by 8%, eight times the 1% by which the noise changed the vectors. So the symptom of noisy derivatives is an optimistic forecast, and it strikes first the parameters involved in the strongest degeneracy; for us that is ω_c, whose correlation with n_s is the largest in the matrix (Section 10.6.4).

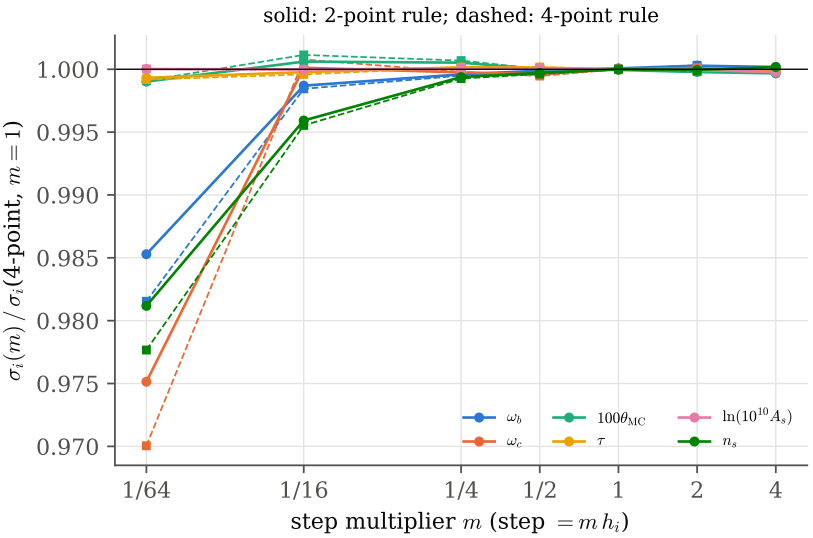

Figure 10.12: Marginalised errors of the six ΛCDM parameters for a Planck-like forecast, recomputed with every derivative step multiplied by m, relative to the four-point rule at $m = 1$. Between $m = \frac{1}{4}$ and 4 nothing moves by more than about two tenths of a per cent. At very small steps the numerical noise of CAMB enters the derivatives and the errors shrink by up to three per cent: noise looks like information.

Rules that follow. The two tests above turn into a short list of checks that every Fisher forecast should pass before its numbers are believed.

1. Choose steps of order a fraction of the expected error, not "as small as possible".
2. Halve and double the steps; quote the forecast only if it does not move.
3. Compare the two-point and four-point rules at the same step; agreement means truncation is negligible.
4. If the errors drift *downwards* as the steps shrink, the derivatives are noisy; raise the code's accuracy settings or increase the step.
5. Differentiate quantities that are nearly linear in the parameters, such as $\ln C_\ell$ in $\ln A_s$ and τ (Section 9.20.1); the truncation error is then small at any reasonable step.

10.6 A CMB forecast for ΛCDM

In 1995 the Planck satellite was a proposal. Knox [138], Jungman et al. [169] and Tegmark, Taylor and Heavens [165] used the machinery of the last five sections to tell the community what such a satellite would measure, and those forecasts helped decide its design. Twenty-three years later Planck published its final parameters [25]. We can now do what is rarely possible with a forecast: redo it, and compare it with what the experiment actually delivered.

The question. The CMB temperature and polarization are Gaussian random fields on the sphere whose statistics are set by the angular power spectra C_ℓ^{TT}, C_ℓ^{EE}, C_ℓ^{TE}, which a Boltzmann code computes from the six parameters of ΛCDM (Chapter T1; the physics is in the cosmology notes). An experiment with a given beam, noise and sky fraction will measure the $a_{\ell m}$. How well will it measure the six parameters?

10.6.1 From the $a_{\ell m}$ to the CMB Fisher matrix

The data. Expand the measured temperature map in spherical harmonics (Chapter 7). The coefficients $a_{\ell m}$ for $2 \le \ell \le \ell_{\max}$, $-\ell \le m \le \ell$, are the data vector; written as real numbers there are $2\ell+1$ of them at each ℓ. *Their mean is zero*: the parameters do not move the map, they set its variance. *Their covariance is diagonal*: statistical isotropy makes different (ℓ, m) uncorrelated, and the variance of each is the sky signal plus the instrument noise,

$$\langle a_{\ell m} a_{\ell' m'} \rangle = \big(C_\ell + N_\ell\big)\delta_{\ell\ell'}\delta_{mm'}, \qquad N_\ell = \Delta^2 e^{\ell(\ell+1)\sigma_b^2}, \quad \sigma_b = \frac{\mathrm{FWHM}}{\sqrt{8\ln 2}}. \tag{10.30}$$

Here N_ℓ is the white noise of depth Δ (in μK rad) after the Gaussian beam has been divided out of the map: the beam suppresses the signal at $\ell \gtrsim 1/\sigma_b$ but not the noise, so dividing by it makes the noise grow exponentially (Chapter 8; the cosmology notes write it as N_ℓ/W_ℓ with W_ℓ the beam window). Tegmark et al. write the same quantity as $4\pi\sigma^2/N\, e^{\theta_b^2 \ell(\ell+1)}$ for N pixels of noise σ, since $\Delta^2 = \sigma^2 \Omega_{\mathrm{pix}} = 4\pi\sigma^2/N$ [165], eq. (16).

Apply the Gaussian formula. With $\boldsymbol{\mu} = \mathbf{0}$ only the covariance channel of (10.20) survives, and $\mathbf{C}$ is diagonal, so every matrix product is a product of diagonal entries:

$$F_{ij} \overset{(1)}{=} \frac{1}{2}\,\mathrm{Tr}\big[\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}\big] \overset{(2)}{=} \frac{1}{2}\sum_{\ell=2}^{\ell_{\max}}\sum_{m=-\ell}^{\ell} \frac{\partial_i C_\ell}{C_\ell + N_\ell}\,\frac{\partial_j C_\ell}{C_\ell + N_\ell} \overset{(3)}{=} \sum_{\ell=2}^{\ell_{\max}} \frac{2\ell+1}{2}\,\frac{\partial_i C_\ell\, \partial_j C_\ell}{(C_\ell + N_\ell)^2}. \tag{10.31}$$

(1) (10.20) with $\boldsymbol{\mu}_{,i} = \mathbf{0}$.

(2) $\mathbf{C}^{-1}\mathbf{C}_{,i}$ is diagonal with entry $\partial_i C_\ell/(C_\ell + N_\ell)$ at every (ℓ, m); the noise does not depend on the cosmological parameters.
(3) Nothing depends on m, so the sum over m gives $2\ell + 1$ equal terms.

This is Tegmark, Taylor and Heavens' eq. (18) [165], the result Section 3.16.6 found for one amplitude and Section 9.20.3 found by expanding the exact likelihood. It has a plain reading: since $\mathrm{Var}\,\widehat{C}_\ell = 2(C_\ell + N_\ell)^2/(2\ell+1)$ (cosmic variance plus noise), each multipole contributes $(\partial_i C_\ell)(\partial_j C_\ell)/\mathrm{Var}\,\widehat{C}_\ell$, the squared response of the spectrum in units of its own error bar. Multipoles where the spectrum is precisely measured and responds strongly to θ_i dominate.

Part of the sky. Divide the full sky into many small patches of equal area, each carrying its own independent share of the information on the parameters. A survey that sees a fraction $f_{\rm sky}$ of the sky sees the fraction $f_{\rm sky}$ of those patches. Independent pieces of data add their Fisher matrices (Section 10.1.2), so the observed part carries $f_{\rm sky}$ times the Fisher matrix of the full sky: every term of (10.31) is multiplied by $f_{\rm sky}$, or, in the language of modes, each multipole has about $(2\ell+1)f_{\rm sky}$ independent modes instead of $2\ell+1$. The assumption is that the patches really are independent, that is, that the edge of the mask does not couple neighbouring multipoles. A mask does couple them (Chapter 8), which matters at low ℓ, where a mode is not small compared with the patch, and for sharp masks.

Temperature and polarization. At each (ℓ, m) the data are now the pair $(a^T_{\ell m}, a^E_{\ell m})$, correlated with each other but not with other (ℓ, m), with the 2×2 covariance $\mathbf{C}_\ell = \begin{pmatrix} C_\ell^{TT}+N_\ell^T & C_\ell^{TE} \\ C_\ell^{TE} & C_\ell^{EE}+N_\ell^P \end{pmatrix}$. The same three steps give

$$F_{ij} = \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2}\,\mathrm{Tr}\big[\mathbf{C}_\ell^{-1}\partial_i\mathbf{C}_\ell\,\mathbf{C}_\ell^{-1}\partial_j\mathbf{C}_\ell\big], \tag{10.32}$$

now with a 2×2 trace at each ℓ. Verde [170], eqs. (26)–(28), writes the same thing as $\sum_\ell \partial_i \boldsymbol{C}_\ell^{\mathsf T}\,\boldsymbol{\Sigma}_\ell^{-1}\,\partial_j \boldsymbol{C}_\ell$, with $\boldsymbol{C}_\ell = (C_\ell^{TT}, C_\ell^{EE}, C_\ell^{TE})$ and $\boldsymbol{\Sigma}_\ell$ the 3×3 covariance of the three estimated spectra. Our code implements both, and they agree to 4×10^{-15} in relative terms, as they must, since they are the same Gaussian likelihood seen through two different data vectors (the $a_{\ell m}$ and the spectra built from them):

Listing 10.3: The temperature-and-polarization Fisher matrix, one 2×2 trace per multipole (`code/ch10/lib_fisher10.py`)

```
163     a = C["TT"][l] + NT[l]; b = C["TE"][l]; e = C["EE"][l] + NP[l]
164     det = a * e - b * b
165     # inverse of [[a, b], [b, e]] is [[e, -b], [-b, a]] / det
166     ia, ib, ie = e / det, -b / det, a / det
167     F = np.zeros((6, 6))
168     for i in range(6):
169         Ma = ia * dC["TT"][i, l] + ib * dC["TE"][i, l]      # (Cinv dC_i), elements 11, 12,
        21, 22
170         Mb = ia * dC["TE"][i, l] + ib * dC["EE"][i, l]
171         Mc = ib * dC["TT"][i, l] + ie * dC["TE"][i, l]
172         Md = ib * dC["TE"][i, l] + ie * dC["EE"][i, l]
173         for j in range(i + 1):
174             Na = ia * dC["TT"][j, l] + ib * dC["TE"][j, l]
175             Nb = ia * dC["TE"][j, l] + ib * dC["EE"][j, l]
176             Nc = ib * dC["TT"][j, l] + ie * dC["TE"][j, l]
177             Nd = ib * dC["TE"][j, l] + ie * dC["EE"][j, l]
178             tr = Ma * Na + Mb * Nc + Mc * Nb + Md * Nd
179             F[i, j] = F[j, i] = np.sum(nu / 2 * tr)
180     return F
```

Lines 169–172 form the four entries of $\mathbf{C}_\ell^{-1}\partial_i\mathbf{C}_\ell$ for all ℓ at once, and line 178 is the trace of the product of two such 2×2 matrices.

Several frequency channels. Planck observed the CMB in several channels; each channel ν gives an independent noisy measurement of the same $a_{\ell m}$, with noise $N_{\ell,\nu}$. For the single "parameter" $a_{\ell m}$ these are independent experiments, so their Fisher informations $1/N_{\ell,\nu}$ add (Section 10.4.4): the combined noise is $1/N_\ell = \sum_\nu 1/N_{\ell,\nu}$, the inverse-variance combination.

10.6.2 Knox (1995) reproduced

His question. Inflation, the brief early epoch of accelerated expansion, predicts two kinds of primordial ripple: density fluctuations, which seed galaxies, and gravitational waves. In 1995 the anisotropy of the CMB had just been detected on large scales, and a satellite to map it on smaller scales was being argued for. Knox asked whether such a satellite could separate the three numbers that tell inflation models apart: the *amplitude* of the density fluctuations, their *tilt* (how their strength changes with scale), and the *share of gravitational waves* in the observed anisotropy [138]. If the three could not be separated, the satellite could not test inflation, however good its maps.

His method. Knox did not compute a Fisher matrix. He drew the estimated spectrum $\widehat{C}_\ell$ from its $\chi^2_{2\ell+1}$ distribution, found the maximum of the exact likelihood by simulated annealing, repeated this 100 times per experiment, and quoted the standard deviation of the maxima [Knox1995 pp. 11–14]. His Table 1 is therefore a Monte Carlo result, and a Fisher forecast should reproduce it.

His setup

The background cosmology is standard cold dark matter: a flat universe made of matter only, with no cosmological constant and no reionisation. It is held fixed; only the three primordial numbers are fitted.

The density (scalar) part. Its strength is quoted through the quadrupole it produces. Knox's Q is the root-mean-square quadrupole, defined by $Q^2 = 5C_2/4\pi$, so the scalar part alone has $C_2^S = 4\pi Q_S^2/5$. Its shape across multipoles, $s_\ell = C_\ell^S/C_2^S$, is fixed by the background cosmology and by the tilt n_S; we compute it with CAMB.

The gravitational-wave (tensor) part adds its own spectrum, with quadrupole $C_2^T = 4\pi Q_T^2/5$ and shape $t_\ell = C_\ell^T/C_2^T$. Gravitational waves decay once they come inside the horizon, so t_ℓ falls steeply above $\ell \sim 100$ and the tensor part only shows on large scales. Its strength is measured against the scalar part by the ratio of the two quadrupoles, $r = Q_T^2/Q_S^2 = C_2^T/C_2^S$. The tensor tilt n_T is held at its fiducial value.

quantity	meaning	value
h	Hubble constant/(100 km s^{-1} Mpc^{-1})	0.5
Ω	total density/critical; no Λ	1
$\Omega_b h^2$	physical baryon density	0.0125
n_S	scalar tilt (fitted)	0.94
n_T	tensor tilt (fixed)	-0.04
r	tensor/scalar quadrupole ratio (fitted)	0.28
Q_S	scalar rms quadrupole (fitted)	20 μK

These are Knox's fiducial values, from chaotic inflation [Knox1995 pp. 3–5].

His key equations, derived

The model spectrum. The two parts are independent, so their spectra add, and each is its quadrupole times its shape:

$$C_\ell \overset{(1)}{=} C_\ell^S + C_\ell^T \overset{(2)}{=} C_2^S\, s_\ell + C_2^T\, t_\ell \overset{(3)}{=} C_2^S\big[s_\ell(n_S) + r\, t_\ell\big]$$
$$\overset{(4)}{=} \frac{4\pi}{5} Q_S^2\big[s_\ell(n_S) + r\, t_\ell\big], \qquad s_\ell = \frac{C_\ell^S}{C_2^S}, \quad t_\ell = \frac{C_\ell^T}{C_2^T}. \tag{10.33}$$

(1) Uncorrelated contributions to the $a_{\ell m}$ add their variances.
(2) The definitions of the two shapes.
(3) $C_2^T = r\, C_2^S$, the definition of r.
(4) $C_2^S = 4\pi Q_S^2/5$, from $Q^2 = 5C_2/4\pi$.

The derivatives follow at once. C_ℓ is proportional to Q_S^2, so $\partial_{Q_S} C_\ell = 2C_\ell/Q_S$; it is linear in r, so $\partial_r C_\ell = \frac{4\pi}{5} Q_S^2 t_\ell$; and n_S enters only through the shape, so $\partial_{n_S} C_\ell = \frac{4\pi}{5} Q_S^2\, \partial_{n_S} s_\ell$, which we take from a cubic spline in n_S of $\ln s_\ell$ computed with CAMB on a grid of tilts. As a check of the shapes, our t_{55}/s_{55} is 0.36, against Knox's "$C_{55}^T/C_{55}^S \simeq r/3$".

His experiments. Full sky, Gaussian beams of FWHM 20′, 30′ and 40′, and noise described by a weight per solid angle w, with $w^{-1/2} = 15$ or 30 μK deg. His equation (4) gives the variance of the estimated spectrum,

$$\operatorname{Var} \widehat{C}_\ell = \frac{2}{2\ell+1}\big(C_\ell + w^{-1} e^{\ell^2 \sigma_b^2}\big)^2.$$

We derive it. At each ℓ the estimate is the average power of the $2\ell+1$ real coefficients, $\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2$, and by (10.30) each coefficient is an independent Gaussian of mean zero and variance $C_\ell + N_\ell$. Then

$$\widehat{C}_\ell \overset{(1)}{=} \frac{C_\ell + N_\ell}{2\ell+1} \sum_m \Big(\frac{a_{\ell m}}{\sqrt{C_\ell + N_\ell}}\Big)^2 \overset{(2)}{=} \frac{C_\ell + N_\ell}{2\ell+1}\, \chi^2_{2\ell+1},$$
$$\operatorname{Var} \widehat{C}_\ell \overset{(3)}{=} \frac{(C_\ell + N_\ell)^2}{(2\ell+1)^2}\, 2(2\ell+1) = \frac{2(C_\ell + N_\ell)^2}{2\ell+1}.$$

(1) Divide and multiply each term by the variance.
(2) The bracket is a standard normal, and the sum of $2\ell+1$ independent squared standard normals is $\chi^2_{2\ell+1}$ (Section 3.16.6).
(3) A χ^2_k variable has variance $2k$; a constant factor comes out squared.

This is his (4) with $N_\ell = w^{-1} e^{\ell^2 \sigma_b^2}$. Comparing with (10.30), $N_\ell = \Delta^2 e^{\ell(\ell+1)\sigma_b^2}$, his w^{-1} plays the part of our Δ^2, and he writes ℓ^2 for $\ell(\ell+1)$, which differ by less than 1% where the beam matters. The two noise levels are the same physical quantity, the pixel noise variance times the pixel solid angle, in different units. Knox quotes $w^{-1/2}$ in μK deg; we need Δ in μK rad. One degree is $\pi/180$ radians, so $w^{-1/2} = 15\,\mu$K deg is $\Delta = 15 \times \pi/180 = 0.262\,\mu$K rad and $\Delta^2 = 0.0685\,\mu\text{K}^2$ sr; with that conversion $\Delta^2 = w^{-1}$. His Fisher matrix is therefore (10.31) with $f_{\text{sky}} = 1$.

Symbol map. Knox's symbols and ours:

Knox	ours	meaning
$C_\ell, C_\ell^S, C_\ell^T$	$C_\ell, C_\ell^S, C_\ell^T$	total, scalar, tensor spectra
Q_S, Q_T	$(5C_2^S/4\pi)^{1/2}, (5C_2^T/4\pi)^{1/2}$	rms quadrupoles
w^{-1}	Δ^2	white-noise level, μK^2 sr
σ_b	$\sigma_b = \text{FWHM}/\sqrt{8\ln 2}$	beam width
$\ell_*, \bar{Q}_S$	$\ell_*, \bar{Q}_S$	pivot multipole, amplitude at the pivot

The pivot

The question. Knox's amplitude and tilt came out almost perfectly correlated, and he explained why: the spectrum is measured best around some multipole ℓ_*, and a change of tilt can be compensated by a change of amplitude that keeps the power at ℓ_* fixed. So he quoted the amplitude at the pivot, $\bar{Q}_S = Q_S(\ell_*/2)^{(n_S-0.94)/2}$, chosen so that it is uncorrelated with n_S [Knox1995 pp. 12–13]. Where does that formula come from, and which ℓ_* is it?

Why the amplitude at a pivot absorbs the tilt. A tilt n_S different from the fiducial 0.94 multiplies the primordial power at wavenumber k by $(k/k_2)^{n_S-0.94}$, where k_2 is the wavenumber the quadrupole sees and where the shape is normalised. Multipole ℓ sees mostly $k \approx \ell/D_*$ (Section 8.7.3, Step 2), so $k/k_2 \approx \ell/2$ and, to that approximation, $s_\ell(n_S) = s_\ell(0.94)\,(\ell/2)^{n_S-0.94}$. The scalar spectrum is then

$$
\begin{aligned}
C_\ell^S &\overset{(1)}{=} \frac{4\pi}{5} Q_S^2 \Big(\frac{\ell}{2}\Big)^{n_S-0.94} s_\ell(0.94) \\
&\overset{(2)}{=} \frac{4\pi}{5}\Big[Q_S^2\Big(\frac{\ell_*}{2}\Big)^{n_S-0.94}\Big]\Big(\frac{\ell}{\ell_*}\Big)^{n_S-0.94} s_\ell(0.94) \\
&\overset{(3)}{=} \frac{4\pi}{5}\,\bar{Q}_S^2\Big(\frac{\ell}{\ell_*}\Big)^{n_S-0.94} s_\ell(0.94).
\end{aligned}
$$

(1) The scalar part of (10.33) with the tilted shape.
(2) Split $(\ell/2) = (\ell_*/2)(\ell/\ell_*)$ and group the factor that does not depend on ℓ with Q_S^2.
(3) Name the bracket $\bar{Q}_S^2$; its square root is Knox's $\bar{Q}_S = Q_S(\ell_*/2)^{(n_S-0.94)/2}$.

Written this way, a change of tilt rotates the spectrum about $\ell = \ell_*$, where $(\ell/\ell_*)^{n_S-0.94} = 1$, and leaves the power there equal to $\frac{4\pi}{5}\bar{Q}_S^2 s_{\ell_*}$. So $\bar{Q}_S$ is the amplitude referred to ℓ_* instead of to the quadrupole, the move of the reference point that Section 8.7.3 made for A_s with (8.45).

Which ℓ_*. Taking logarithms, $\ln\bar{Q}_S = \ln Q_S + \tfrac{1}{2}(n_S - 0.94)\ln(\ell_*/2)$, and requiring zero covariance with n_S,

$$
\begin{aligned}
0 = \mathrm{Cov}(\ln\bar{Q}_S, n_S) &\overset{(1)}{=} \mathrm{Cov}(\ln Q_S, n_S) + \tfrac{1}{2}\ln(\ell_*/2)\,\mathrm{Var}(n_S) \;\Rightarrow\; \ln\frac{\ell_*}{2} = -\frac{2\,\mathrm{Cov}(\ln Q_S, n_S)}{\mathrm{Var}(n_S)}, \\
\mathrm{Var}(\ln\bar{Q}_S) &\overset{(2)}{=} \mathrm{Var}(\ln Q_S) - \frac{\mathrm{Cov}(\ln Q_S, n_S)^2}{\mathrm{Var}(n_S)},
\end{aligned}
\tag{10.34}
$$

(1) Covariance is linear in each argument; the term -0.94 is a constant.
(2) Expand $\mathrm{Var}(\ln Q_S + c\,n_S)$ with $c = \tfrac{1}{2}\ln(\ell_*/2)$ and insert the value of c: this is the Schur complement (10.23) once more, the variance of $\ln Q_S$ with the part explained by n_S removed.

with all variances and covariances taken from $\mathbf{F}^{-1}$. This is (8.46) in Knox's variables.

The pivot is an information-weighted mean. Leave aside the tensor part, which is small where most of the information lies, and use the tilted shape above. Then $\partial C_\ell/\partial\ln Q_S = 2C_\ell$ and $\partial C_\ell/\partial n_S = C_\ell\ln(\ell/2)$. Each multipole enters the Fisher sum (10.31) with the factor $\frac{2\ell+1}{2}(C_\ell+N_\ell)^{-2}$; call $\mathcal{I}_\ell = \frac{2\ell+1}{2}\big[C_\ell/(C_\ell+N_\ell)\big]^2$ the information of multipole ℓ and $g_\ell = \ln(\ell/2)$. Then $F_{QQ} = 4\sum\mathcal{I}_\ell$, $F_{Qn} = 2\sum\mathcal{I}_\ell g_\ell$, $F_{nn} = \sum\mathcal{I}_\ell g_\ell^2$, and

$$
\ln\frac{\ell_*}{2} \overset{(1)}{=} -\frac{2\,\mathrm{Cov}(\ln Q_S, n_S)}{\mathrm{Var}(n_S)} \overset{(2)}{=} \frac{2F_{Qn}}{F_{QQ}} \overset{(3)}{=} \frac{\sum_\ell \mathcal{I}_\ell \ln(\ell/2)}{\sum_\ell \mathcal{I}_\ell},
$$

(1) (10.34).
(2) The 2×2 inverse (10.7): $\mathrm{Cov} = -F_{Qn}/\det\mathbf{F}$, $\mathrm{Var}(n_S) = F_{QQ}/\det\mathbf{F}$; the determinant cancels.

(3) Insert the two sums; the factors $2 \cdot 2/4$ cancel.

Adding $\ln 2$ to both sides, $\ln \ell_* = \sum_\ell \mathcal{I}_\ell \ln \ell \,/\, \sum_\ell \mathcal{I}_\ell$: $\ln \ell_*$ is the mean of $\ln \ell$ over the multipoles, each weighted by the information it carries, as Section 8.7.3 found for Planck's k_*. The straight-line pivot of Section 10.4.3 is the same statement with x in place of $\ln \ell$. Our numbers below keep the tensor part and the exact shapes, so the pivots in Table 10.2 come from (10.34) with the full $\mathbf{F}^{-1}$.

What we compute, side by side, and why the numbers differ

What we compute. `05_knox1995.py` builds s_ℓ and t_ℓ with CAMB for Knox's cosmology, forms the three derivatives above, sums (10.31) with $f_{\rm sky} = 1$ and Knox's noise for each of his six experiments, inverts, and applies (10.34). To test the Fisher matrix against his own procedure, it also repeats that procedure for the first experiment with 2000 simulations instead of 100: draw $\widehat{C}_\ell$, maximise the exact likelihood, take the scatter of the maxima.

Side by side. Table 10.2 and Figure 10.13 put the numbers together. The pivot of the first experiment is at $\ell_* = 210$; Knox reports $\ell_* = 210$ for it [Knox1995 p. 13]. Our 2000 simulations give $\sigma(n_S) = 0.014$, $\sigma(r) = 0.09$, $\sigma(\bar{Q}_S)/\bar{Q}_S = 0.0028$, with pivot 212, all equal to the Fisher values within the ±1.6% simulation error, and no bias (mean $\hat{n}_S = 0.9397$, $\hat{r} = 0.283$). So for this model the Fisher matrix is an accurate description of maximum likelihood.

Why they differ: the tilt and the amplitude. Knox's numbers are standard deviations of $N = 100$ values, and a standard deviation estimated from N Gaussian values has a relative error of $1/\sqrt{2(N-1)} = 1/\sqrt{198} = 7\%$. Of the twelve tilt and amplitude entries, nine agree with ours within that 7% and the other three (the tilt of the first experiment, 0.016 against 0.014, and two amplitudes) within 14%, two sampling errors: about what twelve comparisons with 7% noise should produce. Nothing beyond sampling noise is needed to explain them.

Why they differ: the tensor ratio. Here our Fisher errors equal Knox's own analytic estimates (0.10, 0.14, 0.12, 0.19, 0.16, 0.22) but sit below his simulations by factors of 1.22 to 1.29 for five experiments and 1.83 for the last, far more than the 7% sampling error. One candidate is a constraint $r \geq 0$ on the fits. Its effect can be computed. If the fits that want $r < 0$ are set to $r = 0$, the scatter of $\hat{r}$ is that of a Gaussian cut off at zero. For a Gaussian of mean μ and unit width, the cut-off variable $Y = \max(X, 0)$ has $\mathbb{E}\,Y = \mu\Phi(\mu) + \varphi(\mu)$ and $\mathbb{E}\,Y^2 = (\mu^2+1)\Phi(\mu) + \mu\varphi(\mu)$, with Φ and φ the standard normal distribution and density (integrate y and y^2 against the Gaussian over $y > 0$). For $r/\sigma_r = \mu = 1$ this gives a standard deviation $0.87\,\sigma_r$, for $\mu = 2$ it gives $0.98\,\sigma_r$; discarding those fits instead gives 0.79 and 0.94. A constraint $r \geq 0$ therefore makes the scatter *smaller*, and cannot by itself produce an excess of 20 to 80%. The cause is not stated in Knox's paper, and we have not found it. A maximiser that sometimes stops short of the maximum would add scatter of the right sign, but that is a guess we have not tested.

Lesson. Where the likelihood is close to Gaussian, as for the tilt and the pivot amplitude, a few lines of Fisher algebra reproduce a hundred simulated annealings per experiment; where a forecast and a simulation disagree, rerunning the simulation more carefully, as our 2000 fits did, decides which one to trust.

10.6.3 A Planck-like forecast against Planck 2018

Their question. The final Planck release set out to give the definitive values of the six parameters of ΛCDM from the full mission's temperature and polarization maps [25]. Several of those numbers carried questions of their own. Whether the tilt n_s is below one, and by how much, tests inflation, which predicts a slightly red spectrum. The optical depth τ dates reionisation, and through the degeneracy described in Section 10.6.4 it limits how well the primordial

Table 10.2: Knox's Table 1 ("numerical" columns, $w^{-1/2}$ in μK deg) against the Fisher forecast for the same model and experiments, and against our own repetition of his simulation for the first experiment. ℓ_* is the pivot multipole of (10.34).

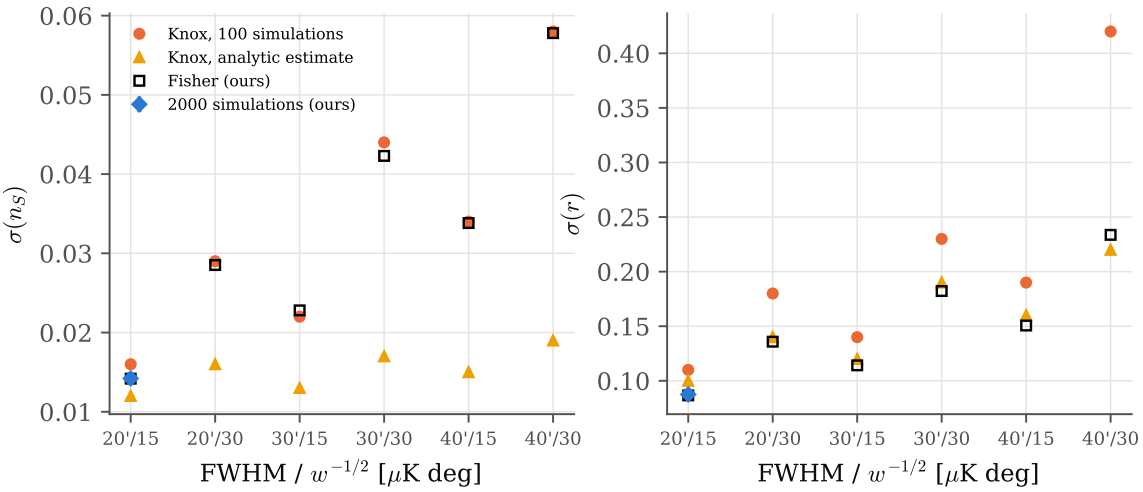

Figure 10.13: Knox's forecasts redone. Circles: Knox's 100-simulation errors; triangles: his analytic estimates; open squares: our Fisher matrix; diamond: our 2000 simulated experiments for the first configuration. The Fisher matrix reproduces his simulations for the tilt (left) and his analytic estimates for the tensor ratio (right).

amplitude is known. And the Hubble constant derived from the CMB, 67.36 ± 0.54 once the CMB lensing spectrum is added (the 0.60 of Table 10.3 is without it), is set against the 73.04 ± 1.04 of the supernova distance ladder: the Hubble tension of Section T2.12.3. Each question needs an error bar that can be trusted, which is what makes the comparison with a forecast interesting.

Their parameters, one at a time. Planck samples in a basis chosen to be close to what the spectrum measures directly, $\boldsymbol{\theta} = (\omega_b, \omega_c, 100\theta_{\rm MC}, \tau, \ln(10^{10}A_s), n_s)$. The *physical baryon density* $\omega_b = \Omega_b h^2$ sets how strongly the photon–baryon fluid is loaded, which shows as the alternating heights of odd and even acoustic peaks. The *physical cold-dark-matter density* $\omega_c = \Omega_c h^2$ sets the epoch of matter–radiation equality and so the overall heights of the first peaks. The *angle* $100\theta_{\rm MC}$ is an approximation to the angular size of the sound horizon at last scattering ($\theta_* = r_*/D_M$ in the cosmology notes); it fixes the positions of the peaks. The *optical depth* τ to reionisation suppresses all but the largest scales by $e^{-2\tau}$. The *amplitude* $\ln(10^{10}A_s)$ and the *tilt* n_s describe the primordial spectrum at the pivot $k = 0.05\,\mathrm{Mpc}^{-1}$ (Section 8.7.3): its overall height, and how its height changes from large scales to the damping tail. The fiducial model is the

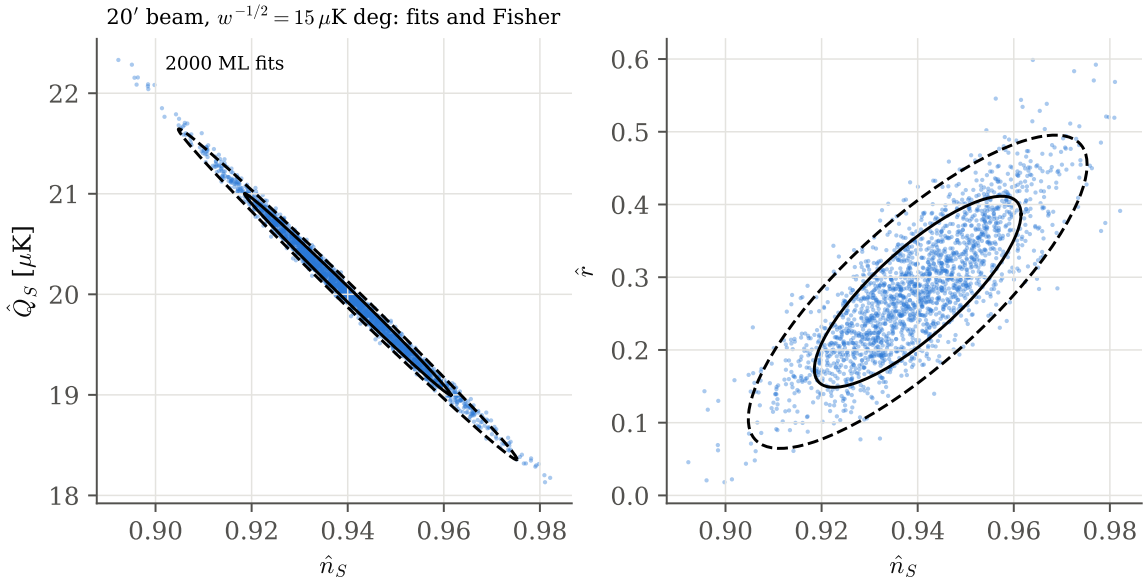

Figure 10.14: Our 2000 maximum-likelihood fits for Knox's 20′, 15 μK deg experiment, with the Fisher ellipses ($\Delta\chi^2 = 2.30$ solid, 6.18 dashed). Left: amplitude and tilt are almost perfectly anticorrelated, the lever-arm degeneracy that the pivot removes. Right: the tilt and the tensor ratio.

Planck 2018 best fit used throughout the book:

ω_b	ω_c	$100\theta_{\rm MC}$	τ	$\ln(10^{10}A_s)$	n_s	H_0 (derived)
0.02237	0.1200	≈ 1.041	0.0544	3.044	0.9649	67.36

H_0 is not in the basis; it follows from the other parameters.

Where we have met H_0 before. In Section 3.17 H_0 was fitted to mock supernovae made with $H_0 = 70$, its error was the Cramér–Rao bound from a Fisher matrix, and that matrix turned singular once the candle's absolute magnitude M was left free. The inverse ladder of Section T2.15 took the sound horizon $r_d = 147.09$ Mpc from the CMB and turned DESI's hr_d into $H_0 = 69.2 \pm 0.9$. The chain of Section 9.22 sampled H_0 directly from one simulated temperature spectrum and found 67.06 ± 0.93. What is the same here is the Fisher matrix as the error of an efficient estimator, and the experiment class of that chain: the forecast below for the chain's own one-channel experiment gives 0.93 again. What is different is that no data are fitted at all. The centre is the fiducial 67.36 by construction, and only the width is predicted; H_0 is not a parameter but a function of ω_b, ω_c and $100\theta_{\rm MC}$, its error carried by the delta method of Section 10.4.5; and the scale is set by the sound horizon at last scattering, a cousin of the r_d of the inverse ladder, not by a candle calibrated nearby. The forecast for Planck's three channels is tighter than that chain, 0.82 against 0.93, because three channels carry less noise than one, and it is tighter than Planck's own 0.92 because it leaves out the foregrounds and calibrations whose cost is traced below.

Their instrument, in our model. Planck's cosmological information at high ℓ comes from three frequency channels. We describe each by its beam and its white-noise level [159], Table 4, and combine them by inverse variance as in Section 10.6.1:

channel	beam FWHM	temperature noise	polarization noise
100 GHz	9.66′	1.29 μK deg	1.96 μK deg
143 GHz	7.22′	0.55 μK deg	1.17 μK deg
217 GHz	4.90′	0.78 μK deg	1.75 μK deg

Two forecasts are made. "PTT" uses the temperature spectrum at $2 \le \ell \le 2500$ on $f_{\rm sky} = 0.57$. "PTE" adds E-mode polarization at $30 \le \ell \le 2000$ through (10.32). Both have a Gaussian prior $\sigma_\tau = 0.0086$ standing in for Planck's low-ℓ polarization likelihood (lowE), which on its own measures τ to that precision [25]. The derivatives are the four-point ones of Section 10.5.

What Planck fitted, and how it relates to our formula. Above $\ell = 30$ Planck's likelihood is a Gaussian in the binned cross-spectra $\hat{\boldsymbol{C}}$ of the frequency maps, with a covariance $\boldsymbol{\Sigma}$ computed once for a fiducial model (Section 9.19.4):

$$-2\ln\mathcal{L} = \boldsymbol{\Delta}^{\mathsf{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{\Delta} + \text{const}, \qquad \boldsymbol{\Delta} = \hat{\boldsymbol{C}} - \boldsymbol{C}(\boldsymbol{\theta}, \boldsymbol{\nu}).$$

The model $\boldsymbol{C}(\boldsymbol{\theta}, \boldsymbol{\nu})$ is the CMB spectrum plus foregrounds and calibrations, controlled by about twenty nuisance parameters $\boldsymbol{\nu}$; below $\ell = 30$ separate likelihoods handle temperature and lowE. This is a Gaussian with fixed covariance, so only the mean channel of (10.20) survives, and its Fisher matrix is $F_{ij} = \partial_i \boldsymbol{C}^{\mathsf{T}}\boldsymbol{\Sigma}^{-1}\partial_j \boldsymbol{C}$. Leave out the nuisances, bins and cross-spectra, take $\boldsymbol{\Sigma}$ to be the Gaussian covariance of the estimated spectra, and this is Verde's form, which agrees with (10.32). So our forecast is Planck's likelihood without its nuisance parameters. Putting them back adds rows and columns to $\mathbf{F}$, and marginalising over them can only enlarge the errors (Section 10.4.1); we should expect our numbers to be optimistic, and the question is by how much.

	TT + lowE			TT,TE,EE + lowE			S4-like

Table 10.3: Marginalised 1σ errors: Planck 2018 [25], Table 2, against our Fisher forecast for the same data combination ("ratio" is ours over Planck's). The last four rows are derived parameters, computed with the delta method $\nabla g^{\mathsf{T}}\mathbf{F}^{-1}\nabla g$. The last column is the futuristic experiment of Section 10.6.5.

Side by side (Table 10.3, Figure 10.15). With temperature alone, the forecast reproduces Planck's errors on τ and $\ln A_s$ to within a few per cent, ω_c and $\theta_{\rm MC}$ to about ten per cent, and is too optimistic by about twenty per cent for ω_b and n_s. Adding polarization keeps the pattern. The correlation matrix (Figure 10.16) agrees entry by entry with that of the official Planck chains to within 0.28; the largest difference is the correlation of ω_b with n_s, +0.23 in our forecast and +0.52 in Planck's chains.

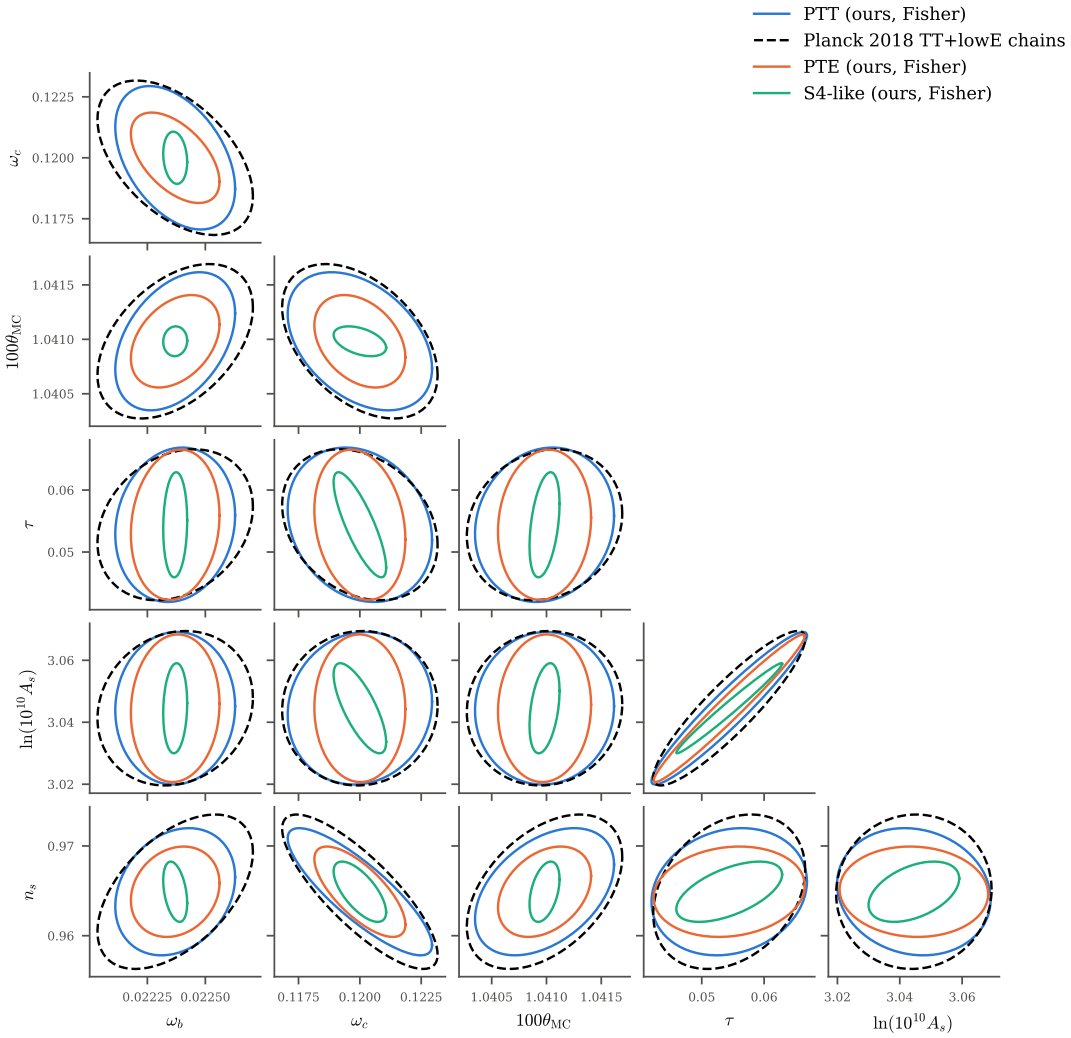

Figure 10.15: Forecast against outcome. Each panel shows the 68% ($\Delta\chi^2 = 2.30$) ellipse of a pair of ΛCDM parameters, all others marginalised, centred on the fiducial model. Black dashed: the covariance of the official Planck 2018 TT+lowE chains. Blue: our Fisher forecast for the same data. Orange: with polarization added. Green: a futuristic ground survey. The forecast reproduces the sizes and orientations of the Planck ellipses; the residual differences are in the parameters that share the high-ℓ damping tail with foregrounds.

Why the forecast is optimistic, and by how much. The idealised experiment knows its noise exactly and sees nothing but CMB. Planck's likelihood fits, in addition to the six cosmological parameters, some twenty nuisance parameters: the amplitudes of the cosmic infrared background, of unresolved point sources and of the Sunyaev–Zel'dovich effects in each frequency, Galactic dust residuals, and calibration factors (they are the extra columns of the chain covariance file). Their spectra rise towards high ℓ, where the damping tail of the CMB measures ω_b and n_s, so marginalising over them costs precision exactly in the two parameters our forecast overstates. The same mechanism explains the larger ω_b–n_s correlation in the real chains.

One nuisance can be added in a few lines, and it shows the mechanism at work. Planck compares the data with C_ℓ/y_P^2, where the overall map calibration y_P has a prior of 0.25% [25]. As a seventh parameter with $\partial C_\ell/\partial \ln y_P = -2C_\ell$ and prior Fisher element $1/0.0025^2$, it is marginalised by inverting the 7×7 matrix. The error on $10^9 A_s e^{-2\tau}$, which no other parameter can absorb, rises from 0.50% to 0.69%; Planck's TT+lowE value is 0.014/1.884 = 0.74%. The

error on $\ln A_s$ goes from 0.0162 to 0.0168. One honest nuisance parameter turns a forecast that was a third too optimistic for the best-measured amplitude into one that is within ten per cent of the published error.

Lesson. The forecast was right about everything the idealised sky contains, the sizes and the correlations, and wrong by about the amount that the missing nuisance parameters cost; adding even one of them shows where the gap comes from.

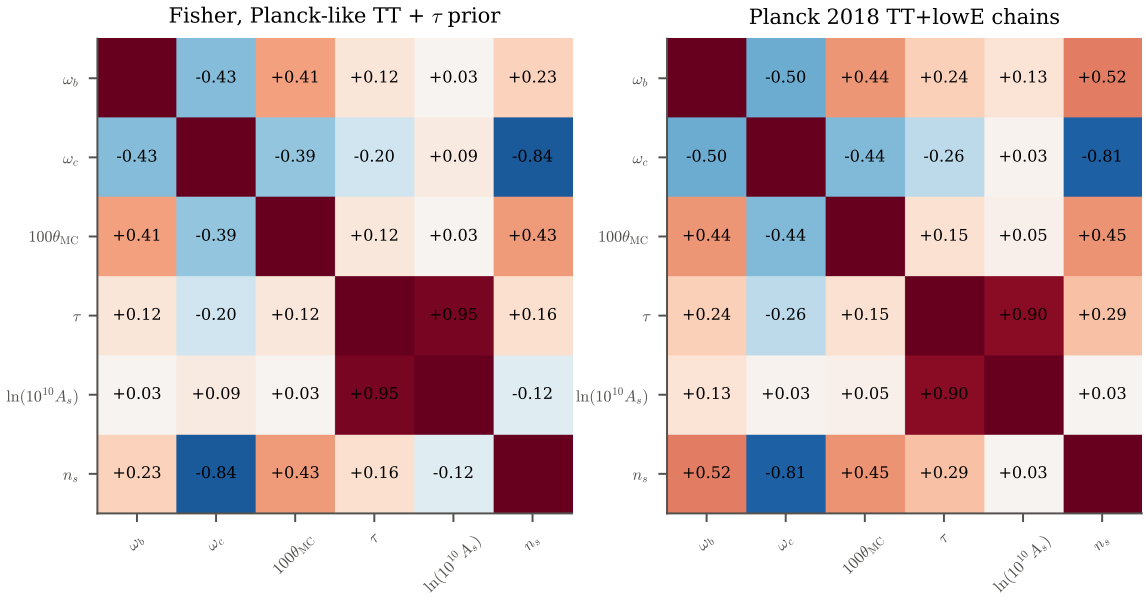

Figure 10.16: Correlation coefficients of the six parameters: our Fisher forecast for Planck-like temperature data with a τ prior (left) and the covariance of the official Planck 2018 TT+lowE chains (right). The two strongest correlations, τ with $\ln A_s$ and ω_c with n_s, are reproduced; the largest difference is ω_b with n_s.

10.6.4 The classic degeneracies

Amplitude and optical depth. Free electrons after reionisation scatter CMB photons out of the line of sight and suppress the anisotropy on all scales smaller than the horizon at reionisation by $e^{-2\tau}$, so for $\ell \gtrsim 10$ the temperature spectrum is proportional to $A_s e^{-2\tau}$ (cosmology notes). *Why this is a degeneracy.* Write that as $C_\ell \propto \exp(\ln A_s - 2\tau)$. Then

$$\frac{\partial C_\ell}{\partial \tau} = -2C_\ell, \qquad \frac{\partial C_\ell}{\partial \ln A_s} = C_\ell :$$

the two derivative vectors are parallel, both proportional to C_ℓ. In (10.31) every term of the $(\tau, \ln A_s)$ block is then C_ℓ^2 times a product of the factors -2 and 1, so the block is

$$f \begin{pmatrix} 4 & -2 \\ -2 & 1 \end{pmatrix} = f\, \boldsymbol{v}\boldsymbol{v}^{\mathsf{T}}, \qquad \boldsymbol{v} = \begin{pmatrix} -2 \\ 1 \end{pmatrix}, \qquad f = \sum_\ell \frac{2\ell+1}{2} f_{\mathrm{sky}} \left(\frac{C_\ell}{C_\ell + N_\ell} \right)^2 .$$

Its determinant is $f^2(4-4) = 0$: the matrix is singular, an exact degeneracy in the sense of Section 10.1.2. The unmeasured direction is the vector $\boldsymbol{u}$ with $\boldsymbol{v}^{\mathsf{T}}\boldsymbol{u} = 0$, $\boldsymbol{u} \propto (1, 2)$: raising τ by δ and $\ln A_s$ by 2δ leaves $\ln A_s - 2\tau$, and so the spectrum, unchanged. This is the line $\ln A_s - 2\tau = \text{const}$, of slope $\mathrm{d}\ln A_s/\mathrm{d}\tau = 2$. What the data do measure is the combination $y = \ln A_s - 2\tau$, with variance $1/f$.

What the real Fisher matrix finds. Our temperature-only Fisher matrix, *without* the τ prior, finds almost exactly this: the long axis of the $(\tau, \ln A_s)$ ellipse has slope $\mathrm{d}\ln A_s/\mathrm{d}\tau = 1.90$, the axes differ by a factor 26, the marginalised errors are $\sigma_\tau = 0.028$ and $\sigma_{\ln A_s} = 0.053$, yet the combination is measured to 0.59%. The slope is slightly below the exact null direction 2 because the lowest multipoles and the lensing of the spectrum (whose strength grows with A_s but not with τ) carry a little information on each factor separately, which turns the singular block into a merely ill-conditioned one.

Breaking it from outside. The low-ℓ polarization measures τ on its own, with error σ_τ; as a prior it adds $1/\sigma_\tau^2$ to $F_{\tau\tau}$ (Section 10.4.4). Now $\ln A_s = y + 2\tau$, with y fixed by the temperature data and τ by the prior, two independent measurements, so

$$\mathrm{Var}(\ln A_s) = \mathrm{Var}\, y + 4\,\sigma_\tau^2 \approx 4\,\sigma_\tau^2$$

whenever the combination is measured much better than $2\sigma_\tau$. That is why the amplitude error in Table 10.3 is set almost entirely by the τ prior: $\sigma_{\ln A_s} \approx 2\sigma_\tau$.

The horizon-angle degeneracy: $\Omega_m h^3$. The positions of the acoustic peaks fix the angle θ_* very precisely, and the peak heights fix the physical matter density $\omega_m = \Omega_m h^2 = \omega_b + \omega_c$ (the small neutrino contribution neglected), where $h = H_0/(100\,\mathrm{km\,s^{-1}\,Mpc^{-1}})$. The Hubble constant enters only through the distance to last scattering, so changes of h and Ω_m that keep θ_* fixed leave the spectrum nearly unchanged; Percival et al. found that this degeneracy follows $\Omega_m h^{3.4} = \text{const}$ for the data of 2002 [171], and Planck quotes $\Omega_m h^3$ as the best-measured combination [25], eq. (12). Our forecast can find the exponent itself. *The idea.* Among all the combinations $\Omega_m h^p$, the best-measured one is the one with the smallest variance: the direction in the $(\ln\Omega_m, \ln h)$ plane along which the data fix the parameters most tightly. So we write its variance as a function of p and minimise. Since $\Omega_m = \omega_m/h^2$, $\ln(\Omega_m h^p) = \ln\omega_m + (p-2)\ln h$, and its variance is

$$\begin{aligned} \mathrm{Var}\ln(\Omega_m h^p) &\overset{(1)}{=} \mathrm{Var}\ln\omega_m + 2(p-2)\,\mathrm{Cov}(\ln\omega_m, \ln h) + (p-2)^2\,\mathrm{Var}\ln h, \\ p_{\mathrm{best}} &\overset{(2)}{=} 2 - \frac{\mathrm{Cov}(\ln\omega_m, \ln h)}{\mathrm{Var}\ln h}, \end{aligned} \tag{10.35}$$

(1) $\Omega_m h^p = \omega_m h^{p-2}$; the variance of a sum.
(2) Set the derivative with respect to p to zero.

The ingredients. Both $\ln\omega_m$ and $\ln h$ are derived parameters, so their variances and covariance come from the delta method of Section 10.4.5, $\mathrm{Cov}(g, g') = \nabla g^{\mathsf{T}}\mathbf{F}^{-1}\nabla g'$. The gradient of $\ln\omega_m$ is $(1,1,0,0,0,0)/\omega_m$, nonzero only in ω_b and ω_c. The gradient of $\ln h$ is $\nabla H_0/H_0$, because $\ln h = \ln H_0 - \ln 100$ and $\mathrm{d}\ln H_0 = \mathrm{d}H_0/H_0$; CAMB's background code gives $\partial H_0/\partial(\omega_b, \omega_c, 100\theta_{\mathrm{MC}}) = (826, -350, 334)$, the other three entries being zero. The forecast gives $p_{\mathrm{best}} = 3.02$ for temperature and 2.97 with polarization: Planck's $\Omega_m h^3$, derived here from a Fisher matrix. With the much smaller errors of the futuristic survey it moves to 3.22, which is the point of Percival's different exponent: the best-measured combination depends on which multipoles carry the information. The error on $\Omega_m h^3$ itself is 0.00040 (0.42%) against Planck's 0.00046 for TT+lowE, and 0.00026 against 0.00029 with polarization.

Dark matter and tilt. The strongest correlation not broken by an external prior is ω_c with n_s, -0.84 in our forecast and -0.81 in Planck's chains. More dark matter brings matter–radiation equality earlier, which reduces the boost the first acoustic peaks receive from decaying potentials (cosmology notes); the first peaks drop relative to the damping tail, which a slightly redder tilt (smaller n_s) also does. Section 9.22.4 met the same correlation in the chain.

10.6.5 A futuristic experiment, the reach in ℓ and the sky fraction

A forecast is most useful for designing the next experiment. Take a ground-based survey with 1 μK arcmin in temperature ($\sqrt{2}$ in polarization), a 1.4′ beam, $f_{\rm sky} = 0.4$ and temperature and polarization at $30 \le \ell \le 3000$ (the atmosphere prevents a ground telescope from measuring the largest scales), plus the same τ prior. Its errors are in the last column of Table 10.3: ω_b improves by a factor 3.7 over the Planck-like experiment, $\theta_{\rm MC}$ by 3.1, ω_c by 1.7, n_s by 1.5, and even τ by 1.4, although the survey sees no multipole below 30. That last gain comes from lensing: the lensed spectra we use depend on A_s through the lensing strength but not on τ, so a precise damping tail separates the two factors. The same code with more parameters gives the larger forecasts of Jungman et al. and of Tegmark et al. (eleven parameters, [165], eqs. (19)–(20)): each new parameter costs one more derivative of the spectra and one more row and column of $\mathbf{F}$. A real forecast at this noise level must include the non-Gaussian covariance that lensing induces between multipoles, which reduces this gain (Section 10.7).

Which multipoles matter? Figure 10.17 recomputes the forecast for maximum multipoles from 500 to 3000. For the Planck-like experiment, stopping at $\ell_{\rm max} = 1000$ would multiply the error on n_s by 1.7 and on ω_b and $\theta_{\rm MC}$ by 1.5, while τ and $\ln A_s$ barely care (1.1): the third and higher peaks and the damping tail are where the densities and the tilt are measured.

How much sky? Every term of (10.31) is proportional to $f_{\rm sky}$, so the data part of $\mathbf{F}$ is too, and every error that is not dominated by a prior scales as $f_{\rm sky}^{-1/2}$. For the Planck-like experiment the error on n_s is 0.0046, 0.0033 and 0.0028 at $f_{\rm sky} = 0.3$, 0.57 and 0.8, and $0.0033\times\sqrt{0.57/0.3} \approx 0.0046$ and $0.0033 \times \sqrt{0.57/0.8} \approx 0.0028$; the error on τ, held by its prior, moves only from 0.0083 to 0.0078.

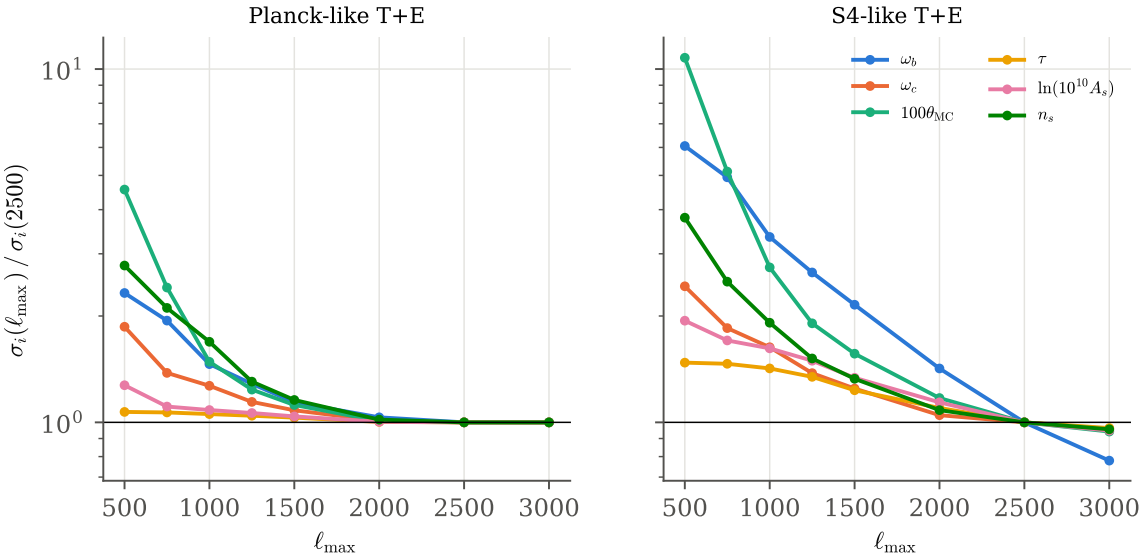

Figure 10.17: How the forecast errors depend on the highest multipole used, relative to $\ell_{\rm max} = 2500$. Left: the Planck-like experiment (polarization stops at $\ell = 2000$). Right: the futuristic survey. The densities, the angle and the tilt keep improving into the damping tail; the amplitude and τ are fixed early by the τ prior.

10.6.6 Is the forecast right? The chain and a thousand fits

A forecast is a statement about an idealised analysis of idealised data. Two independent checks are possible with tools the book already has: the Markov chain of Chapter 9, which maps the

actual posterior for one simulated data set, and a Monte Carlo of maximum-likelihood fits, which measures the actual scatter over many.

The chain. Run P6 of Section 9.22 sampled the six ΛCDM parameters from one simulated temperature spectrum: one 143 GHz-like channel (7.22′, 33 μK arcmin), $f_{\rm sky} = 0.57$, $2 \le \ell \le 2500$, the exact likelihood, and the same τ prior. It sampled in a different basis, $\boldsymbol{p} = (\ln 10^{10} A_s, n_s, H_0, \omega_b, \omega_c, \tau)$, with H_0 in place of $\theta_{\rm MC}$. Our Fisher matrix for the same experiment is computed in the Planck basis and moved to the chain's basis with the Jacobian rule (10.27). All entries of $\boldsymbol{J} = \partial\boldsymbol{\theta}/\partial\boldsymbol{p}$ are zeros and ones except the row of $100\theta_{\rm MC}$, which depends on H_0, ω_b and ω_c; CAMB's background code gives $\partial(100\theta_{\rm MC})/\partial(H_0, \omega_b, \omega_c) = (0.00299, -2.47, 1.046)$. Then:

	$\ln(10^{10}A_s)$	n_s	H_0	ω_b	ω_c	τ
Fisher, $\boldsymbol{J}^{\mathsf{T}}\mathbf{F}\boldsymbol{J}$ (CAMB derivatives)	0.0167	0.00527	0.932	0.000201	0.00215	0.00835
chain P6 (Chapter 9)	0.0166	0.00528	0.93	0.000201	0.00217	0.00833
Fisher of Chapter 9 (emulator derivatives)	0.0167	0.00529	0.936	0.000201	0.00216	0.00835
1000 maximum-likelihood fits	0.0169	0.00537	0.941	0.000204	0.00217	0.00841

The Fisher errors agree with the widths of the chain to within one per cent for every parameter, and every correlation coefficient agrees to within 0.02; the strongest, H_0 with ω_c, is -0.97 in both. Two quite different computations stand behind this: our derivatives were taken in another basis by the four-point rule and transformed with a Jacobian, chapter 9's came from an emulator of $\ln C_\ell$, and the chain never used a derivative at all.

A thousand fits. The chain describes the posterior of one data set; the Cramér–Rao reading of $\mathbf{F}^{-1}$ is about the scatter of estimates over many. `07_fisher_vs_mcmc.py` draws 1000 new spectra and τ measurements from the same experiment and finds the maximum of the likelihood of each, a thousand six-parameter maximisations. How should each be done?

One parameter first: a Newton step. Near the current guess θ_n the score, the slope of $\ln\mathcal{L}$, is nearly a straight line in θ, and its slope is minus the curvature: by (10.2), $S(\theta) \approx S(\theta_n) - \mathcal{H}\,(\theta - \theta_n)$. The maximum is where the slope of the hill vanishes, $S = 0$; solving the straight line for that point gives $\theta = \theta_n + S(\theta_n)/\mathcal{H}$, slope over curvature. If $\ln\mathcal{L}$ were an exact parabola, one step would land on its top; for a nearly parabolic hill each step lands much closer. *Many parameters.* The same expansion of the score vector is $\boldsymbol{S}(\boldsymbol{\theta}) \approx \boldsymbol{S}(\boldsymbol{\theta}_n) - \boldsymbol{\mathcal{H}}(\boldsymbol{\theta} - \boldsymbol{\theta}_n)$, and $\boldsymbol{S} = \mathbf{0}$ gives the step $\boldsymbol{\theta}_n + \boldsymbol{\mathcal{H}}^{-1}\boldsymbol{S}(\boldsymbol{\theta}_n)$. *Replace the curvature by its average.* The observed curvature $\boldsymbol{\mathcal{H}}$ of one noisy data set needs second derivatives of the model and, far from the peak, need not be positive definite, in which case the step can go downhill. Its average over data, the Fisher matrix (10.3), is known in closed form, (10.31), and is always positive definite, so the step $\mathbf{F}^{-1}\boldsymbol{S}$ always has a positive component along the uphill direction: $\boldsymbol{S}^{\mathsf{T}}\mathbf{F}^{-1}\boldsymbol{S} > 0$ whenever $\boldsymbol{S} \neq \mathbf{0}$. Near the peak the two curvatures differ only by the $1/\sqrt{n}$ fluctuation of Section 10.1.1, so little speed is lost. This iteration is called **Fisher scoring**:

$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \mathbf{F}(\boldsymbol{\theta})^{-1}\boldsymbol{S}(\boldsymbol{\theta}), \qquad S_i = \sum_\ell \frac{\nu_\ell}{2}\,\partial_i C_\ell\,\frac{\widehat{C}_\ell - C_\ell - N_\ell}{(C_\ell + N_\ell)^2}, \quad \nu_\ell = (2\ell+1) f_{\rm sky}, \tag{10.36}$$

with $\mathbf{F}(\boldsymbol{\theta})$ (10.31) evaluated at the current point.

The score of the exact likelihood. The score comes from the exact $-2\ln\mathcal{L} = \sum_\ell \nu_\ell[\widehat{C}_\ell/(C_\ell +$

$N_\ell) + \ln(C_\ell + N_\ell)]$ (Section 9.19.2). With $X_\ell = C_\ell + N_\ell$, which depends on θ_i only through C_ℓ,

$$S_i = \partial_i \ln \mathcal{L} \overset{(1)}{=} -\frac{1}{2}\sum_\ell \nu_\ell \Big[-\frac{\widehat{C}_\ell}{X_\ell^2} + \frac{1}{X_\ell}\Big]\partial_i C_\ell \overset{(2)}{=} \sum_\ell \frac{\nu_\ell}{2}\,\partial_i C_\ell\,\frac{\widehat{C}_\ell - X_\ell}{X_\ell^2},$$

$$\mathbb{E}[S_i] \overset{(3)}{=} \sum_\ell \frac{\nu_\ell}{2}\,\partial_i C_\ell\,\frac{\mathbb{E}\,\widehat{C}_\ell - X_\ell}{X_\ell^2} = 0.$$

(1) $\ln\mathcal{L}$ is $-\frac{1}{2}$ of the sum; by the chain rule $\partial_i(1/X) = -\partial_i C_\ell/X^2$ and $\partial_i \ln X = \partial_i C_\ell / X$.
(2) Put the bracket over the common denominator X_ℓ^2; this is the S_i of (10.36).
(3) The estimate is unbiased, $\mathbb{E}\,\widehat{C}_\ell = C_\ell + N_\ell = X_\ell$: the score has mean zero at the truth, as (10.4) requires.

The model spectrum is chapter 9's second-order emulator, so each step costs a fraction of a millisecond:

Listing 10.4: Fisher scoring: Newton's method with the expected curvature (`code/ch10/07_fisher_vs_mcmc.py`)

```
    for it in range(30):
        c, g = cl_and_grad(th)
        tot = c + N
        r = (chat - tot) / tot**2
        S = 0.5 * (g[:, use] * (nu * r)[use]).sum(1)            # score of the exact
    likelihood
        S[5] -= (th[5] - tau_obs) / SIG_TAU**2                  # ... plus the tau prior
        w = 0.5 * nu / tot**2
        Fk = (g[:, use] * w[use]) @ g[:, use].T                 # Fisher matrix at the
    current point
        Fk[5, 5] += 1 / SIG_TAU**2
        step = np.linalg.solve(Fk, S)
        th = th + step
        if np.max(np.abs(step) / sF) < 1e-4:
            break
```

The median fit converges in 4 iterations. The scatter of the 1000 estimates is in the last row of the table: between 1.01 and 1.02 times the Fisher errors, with a Monte Carlo uncertainty of ±2.2%; the mean offsets from the truth are a few hundredths of a standard deviation at most (-0.03 for $\ln A_s$, -0.03 for τ). The fraction of estimates inside the two-parameter 68.3% ellipse of $(\ln A_s, n_s)$ is 0.663, and inside the six-dimensional 68.3% ellipsoid ($\Delta\chi^2 \le 7.04$) it is 0.651, against 0.683 ± 0.015 (Figure 10.18). For this experiment maximum likelihood reaches the Cramér–Rao bound and the posterior has the Fisher width. The ellipses enclose close to what they claim; both fractions come out slightly low, by one to two Monte Carlo errors.

When the Fisher matrix fails. Everything above worked because the CMB spectrum is nearly linear in the parameters over a one-sigma region: the errors are tiny compared with the scale on which the spectrum bends. Vallisneri lists what goes wrong when that is not true [166], and the book has examples of each. At low signal-to-noise the likelihood is not a parabola over the scatter of the estimates (Cowan's experiment with 50 events, Section 10.2.3; the skewed decay-time posterior of Section 9.18). Near a physical boundary the Gaussian approximation puts probability where the parameter cannot go (a tensor ratio or a neutrino mass near zero). A quasi-singular Fisher matrix, with a direction the data barely constrain, makes $\mathbf{F}^{-1}$ meaningless in that direction unless a prior is added. In all three cases the Fisher matrix is still the right first calculation, and a chain on simulated data is the second.

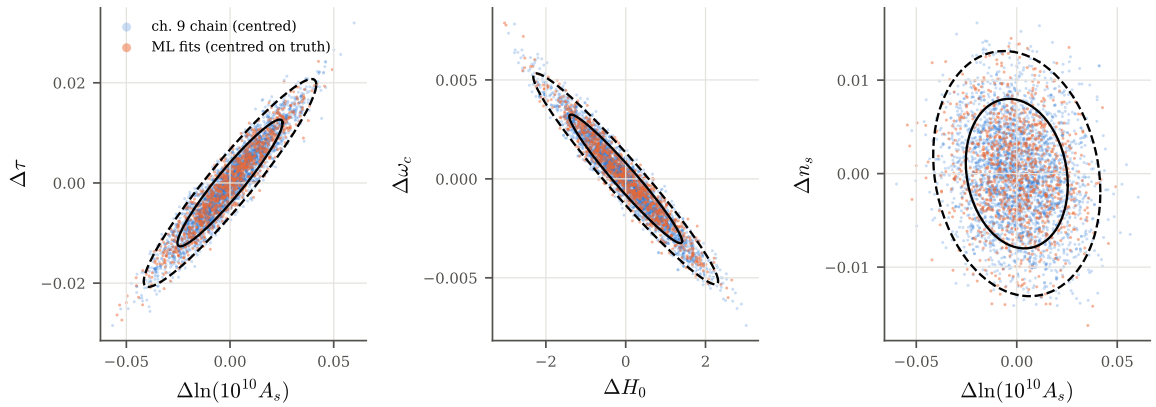

Figure 10.18: Three views of the same six-parameter problem in three planes: samples of the chapter-9 posterior for one simulated sky (blue, centred on their mean), the maximum-likelihood estimates from 1000 simulated skies (orange, centred on the truth), and the Fisher ellipses ($\Delta\chi^2 = 2.30, 6.18$) computed before any sky was simulated.

How this is used in real research: Verification and research

Here the Monte Carlo and the chain *verified* a forecast that analytic theory already gave, as the simulations of Chapter 8 verified the cosmic-variance formula. In research the roles reverse. Survey teams produce Fisher forecasts for every design option because they are instantaneous, and then run full chains on simulated data for the few designs that matter, because only the chain sees non-Gaussian posteriors, physical boundaries, nuisance parameters with non-Gaussian priors and likelihoods that are not Gaussian in the data. A forecast that survives that test is the one quoted in the proposal.

10.7 How it is done in research

A survey team writing a proposal, or a collaboration choosing between two telescope designs, runs the same calculation as Section 10.6, but every box of it is larger. A real forecast passes through those boxes in a fixed order (Figure 10.19); at each one the research version adds physics that the laptop version replaced by something simpler, and each replacement has a measurable cost.

1. Parameters, basis and fiducial. The model is ΛCDM plus the extensions the survey targets (the effective number of relativistic species $N_{\rm eff}$, which counts the light particles such as neutrinos that behaved like radiation in the early universe and is about three in the standard model; the sum of neutrino masses; the tensor ratio r), at a fiducial point taken from the best current fit. The basis is chosen close to what the data measure ($\theta_{\rm MC}$ rather than H_0, $\ln A_s$ at a pivot), so that the likelihood is nearly Gaussian in it and the finite differences behave; the quantities people quote (H_0; σ_8, the root-mean-square matter fluctuation in spheres of $8\,h^{-1}$ Mpc; $\Omega_m h^3$) are derived afterwards with the Jacobian or delta-method rule (Section 10.4.5). *Here:* the six-parameter Planck basis at the Planck 2018 best fit.

2. Theory and derivatives. A Boltzmann code such as CAMB is run at raised accuracy settings and to higher multipoles than the survey will use, producing lensed TT, TE, EE, BB spectra and the spectrum of the lensing potential $C_\ell^{\phi\phi}$ (the projected gravitational potential that deflects CMB photons on their way to us). Derivatives are taken by finite differences and checked as in

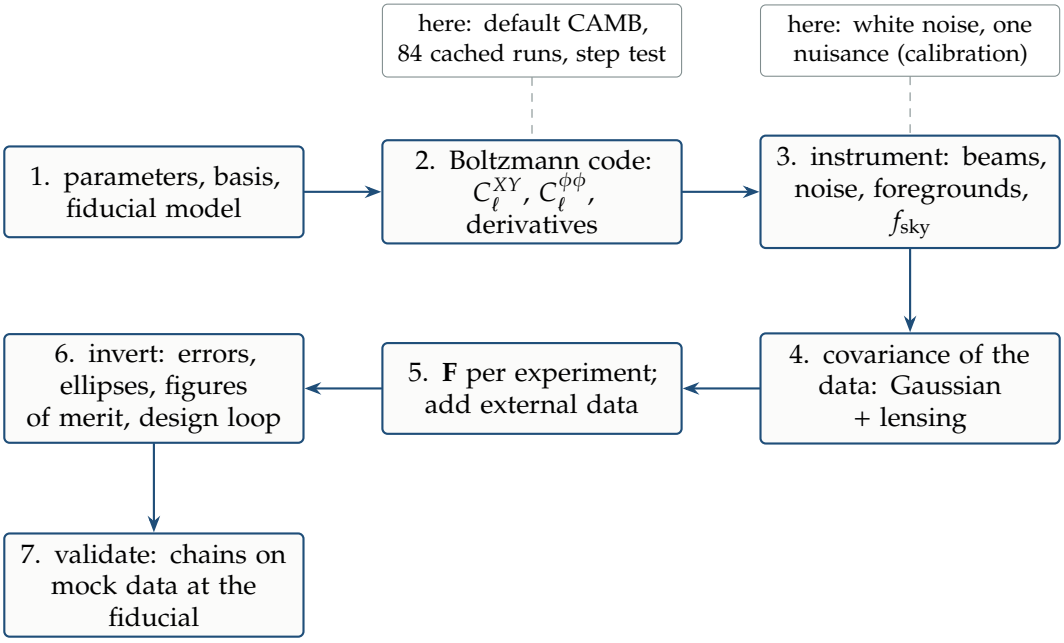

Figure 10.19: The stages of a research CMB forecast (blue boxes, in order), with two of the simplifications made by the laptop version (grey), each attached to the stage it simplifies.

Section 10.5: steps halved and doubled, two- and four-point rules compared, and the code's accuracy raised until the forecast stops moving. *Here:* default accuracy, $\ell \leq 3000$, 84 cached runs; the step test moved no error by more than a tenth of a per cent. The cost is nothing for a Planck-like experiment and possibly a few per cent for a survey that uses $\ell > 3000$.

3. The instrument. For each frequency channel: beam; white-noise depth; for a ground telescope the "$1/f$" noise, slow drifts of the atmospheric emission and of the detector gain whose power rises at low frequencies and therefore adds noise at low ℓ; the hit map, how many times each patch of sky was observed, which sets the noise of each pixel; and the sky mask. Foregrounds (Galactic dust and synchrotron, the cosmic infrared background, Sunyaev–Zel'dovich effects, point sources) are removed by a simulated component separation, which uses the several frequencies to subtract emission whose dependence on frequency differs from that of the CMB; what is left after it is added to the noise as a residual power spectrum. Lensing reconstruction, the estimate of the deflection field from the distortions it leaves in the small-scale CMB, has a noise of its own, a noise spectrum that plays for $C_\ell^{\phi\phi}$ the part N_ℓ plays for C_ℓ. *Here:* white noise, combined by inverse variance, no foregrounds, and a single nuisance parameter. The cost was measured in Section 10.6.3: errors on ω_b and n_s about twenty per cent too small for Planck, most of the gap on $A_s e^{-2\tau}$ closed by the calibration nuisance alone.

4. The covariance of the data. The Gaussian, $f_{\rm sky}$-scaled covariance (10.32) is the starting point. Research forecasts add the covariance that lensing induces between multipoles of the lensed spectra and between them and $C_\ell^{\phi\phi}$: all modes are deflected by the same large-scale field, so a fluctuation of that field moves power at many multipoles together and correlates them, which is why lensing is a non-Gaussian, mode-coupling operation. For small or irregular sky patches they add the mode coupling of the mask (cutting the sky mixes neighbouring multipoles, Chapter 8), estimated with simulations. *Here:* Gaussian covariance with $(2\ell+1)f_{\rm sky}$ modes. The cost is small for Planck-like noise and large for the futuristic survey, whose τ improvement of Section 10.6.5 comes from lensing information this approximation overstates.

5. Fisher matrices and external data. One matrix per experiment and per data product, in a common parameter basis (Jacobians where the bases differ), added together: the CMB, a τ measurement from large-scale polarization, baryon acoustic oscillations, supernovae (Section 10.4.4). Overlapping sky areas are not independent and must not simply be added; the overlap is treated as one experiment with a joint covariance. *Here:* one CMB matrix plus a τ prior.

6. Reading and design. Marginalised errors, triangle plots of ellipses, figures of merit, and the same numbers recomputed as the design changes (noise level, beam, sky fraction, observing time): a forecast is usually a curve or a grid, not a number, as in Figure 10.17. One more product is routine: the shift of the parameters that a small unmodelled systematic $\delta\boldsymbol{\mu}$ in the data would cause. *The question.* If the data have mean $\boldsymbol{\mu}(\boldsymbol{\theta}_0) + \delta\boldsymbol{\mu}$ instead of $\boldsymbol{\mu}(\boldsymbol{\theta}_0)$, where does the fit land on average? The fit lands where the score vanishes, so we ask where the *average* score vanishes. Name the vector $\boldsymbol{b}$ with components $b_i = \boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\delta\boldsymbol{\mu}$, the overlap of the systematic with the response of the data to θ_i; this is what $\left[\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\delta\boldsymbol{\mu}\right]_i$ below denotes. Then, for Gaussian data,

$$
\begin{aligned}
\mathbb{E}\big[S_i(\boldsymbol{\theta}_0)\big] &\overset{(1)}{=} \boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\,\mathbb{E}[\boldsymbol{r}] + \tfrac{1}{2}\big(\mathbb{E}[\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\boldsymbol{r}] - \operatorname{Tr}\mathbf{C}^{-1}\mathbf{C}_{,i}\big) \overset{(2)}{=} \boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\delta\boldsymbol{\mu} = b_i,\\
\mathbb{E}\big[S_i(\boldsymbol{\theta}_0+\delta\boldsymbol{\theta})\big] &\overset{(3)}{=} b_i + \sum_j \delta\theta_j\;\mathbb{E}\big[\partial_j S_i\big] \overset{(4)}{=} b_i - \sum_j F_{ij}\,\delta\theta_j,\\
\mathbf{0} = \boldsymbol{b} - \mathbf{F}\,\delta\boldsymbol{\theta} &\overset{(5)}{=} \quad\Rightarrow\quad \delta\boldsymbol{\theta} = \mathbf{F}^{-1}\left[\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\delta\boldsymbol{\mu}\right]_i,
\end{aligned}
\tag{10.37}
$$

(1) The score (10.21), with residual $\boldsymbol{r} = \boldsymbol{d} - \boldsymbol{\mu}(\boldsymbol{\theta}_0)$, averaged term by term.
(2) The residual is now $\boldsymbol{r} = \delta\boldsymbol{\mu} + \boldsymbol{n}$ with noise $\boldsymbol{n}$ of mean zero and covariance $\mathbf{C}$, so $\mathbb{E}\,\boldsymbol{r} = \delta\boldsymbol{\mu}$. In the second term, $\mathbb{E}[\boldsymbol{r}^{\mathsf{T}}\boldsymbol{M}\boldsymbol{r}] = \operatorname{Tr}(\boldsymbol{M}\mathbf{C}) + \delta\boldsymbol{\mu}^{\mathsf{T}}\boldsymbol{M}\delta\boldsymbol{\mu}$; the trace equals $\operatorname{Tr}\mathbf{C}^{-1}\mathbf{C}_{,i}$ and cancels, and the rest is second order in $\delta\boldsymbol{\mu}$, which we drop.
(3) Expand the average score to first order in the shift $\delta\boldsymbol{\theta}$.
(4) The average derivative of the score is the average second derivative of $\ln\mathcal{L}$, which is $-F_{ij}$ by (10.3) (to zeroth order in $\delta\boldsymbol{\mu}$).
(5) Set the average score to zero and solve for $\delta\boldsymbol{\theta}$.

This is the bias a systematic produces, in units that can be compared with $\mathbf{F}^{-1}$ directly. *A check with one parameter.* Let the data be a template of known shape with amplitude A, $\boldsymbol{\mu} = A\boldsymbol{s}$, so $\boldsymbol{\mu}_{,A} = \boldsymbol{s}$ and $F_{AA} = \boldsymbol{s}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{s}$ (Section 10.3.3), and let the systematic be a calibration error that scales the whole signal, $\delta\boldsymbol{\mu} = \epsilon\boldsymbol{\mu} = \epsilon A\boldsymbol{s}$. Then $b_A = \epsilon A\,\boldsymbol{s}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{s} = \epsilon A\,F_{AA}$ and $\delta A = b_A/F_{AA} = \epsilon A$: a calibration off by 1% moves the amplitude by 1%, as it must. Requirements on calibration, beam knowledge and foreground residuals are set with this formula: the systematic is acceptable if $\delta\boldsymbol{\theta}$ is small against the errors.

7. Validation. For the designs that matter, mock data are generated at the fiducial model and run through the full likelihood with a sampler (for example Cobaya, a Markov chain code of the kind built in Chapter 9), and the posterior is compared with the Fisher ellipses. This is where non-Gaussian posteriors, physical boundaries (a neutrino mass near zero, a tensor ratio near zero) and priors that are not Gaussian are found. *Here:* the chain of Chapter 9 with an emulated spectrum and 1000 maximum-likelihood fits by Fisher scoring, which agreed with the forecast to one or two per cent. For the full problem the chains take cluster hours per design; ours took seconds, because the model was an emulator and the likelihood had no nuisance parameters.

How far a forecast is from reality. Figure 10.20 condenses the comparison with Planck into one picture: the ratio of our forecast errors to the published ones. It is the realistic expectation

stage	research version	laptop version (here)	what the reduction costs
theory	high-accuracy Boltzmann runs to $\ell \sim 5000$	default CAMB, $\ell \leq 3000$, 84 cached runs	$< 0.1\%$ on the errors (step test); more for $\ell > 3000$
noise	per-channel, anisotropic, $1/f$, foreground residuals	white, inverse-variance combined	ω_b, n_s errors $\sim 20\%$ too small vs Planck
nuisances	~ 20 foreground and calibration parameters	calibration only (as a demonstration)	residual optimism in damping-tail parameters
sky	mask with mode coupling, simulated covariance	$(2\ell+1)f_{\rm sky}$ modes	a few per cent at $f_{\rm sky} \gtrsim 0.4$; worse at low ℓ
lensing	lensing reconstruction, lensing-induced covariance	lensed spectra, Gaussian covariance	futuristic τ, A_s gains overstated
low ℓ	non-Gaussian low-ℓ likelihood	Gaussian τ prior 0.0086	no skewness of τ near zero
validation	full-likelihood chains on mock data	chain of Chapter 9 (emulator), 1000 fits	none here; decisive with real complexity

Table 10.4: Each reduction made in the laptop version, what the research analysis does instead, and what the reduction costs.

for a forecast built as above: right in the parameters set by a prior or by the peak positions, optimistic by up to a quarter where unmodelled nuisances live. A research forecast closes most of the remaining gap by adding stages 3 and 4 in full.

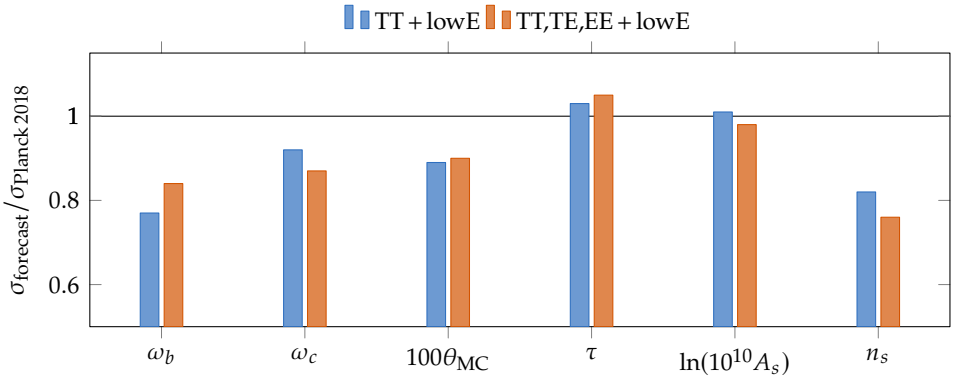

Figure 10.20: Our Fisher forecast errors divided by the published Planck 2018 errors for the same data combinations. A bar at one is a perfect forecast. The amplitude and τ are held by the τ prior and come out right; the densities, the angle and above all ω_b and n_s, which share the damping tail with foregrounds, come out too small, because the idealised experiment has no foreground nuisances to marginalise.

Recap

- The Fisher matrix $F_{ij} = -\mathbb{E}[\partial_i \partial_j \ln \mathcal{L}] = \mathbb{E}[S_i S_j]$, at a fiducial model, is the average curvature of the log-likelihood and the covariance of the score; it needs a model of the experiment, not data.
- Cramér–Rao: $\mathrm{Cov}\,\hat{\boldsymbol{\theta}} - \mathbf{F}^{-1}$ is positive semidefinite for every unbiased estimator; maximum likelihood reaches the bound for linear-Gaussian models and for informative data (Cowan's experiment from ~ 500 events on).
- Gaussian data: $F_{ij} = \boldsymbol{\mu}_{,i}^{\mathsf{T}} \mathbf{C}^{-1} \boldsymbol{\mu}_{,j} + \frac{1}{2}\,\mathrm{Tr}[\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}]$, first derivatives only; the CMB

is the covariance channel, $F_{ij} = \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2} \partial_i C_\ell \partial_j C_\ell / (C_\ell + N_\ell)^2$.

- Marginalised error $\sqrt{(\mathbf{F}^{-1})_{ii}}$ (invert, then read) versus conditional $1/\sqrt{F_{ii}}$; the difference is a Schur complement. Two-parameter ellipses at $\Delta\chi^2 = 2.30$, 6.18 hold 68.3%, 95.4%.
- Priors and independent experiments add as matrices; a change of parameters is $\boldsymbol{J}^{\mathsf{T}}\mathbf{F}\boldsymbol{J}$; derived quantities use $\nabla g^{\mathsf{T}}\mathbf{F}^{-1}\nabla g$; nuisances are marginalised by inverting.
- Finite-difference steps of a fraction of the expected error, checked by halving and doubling; noisy derivatives make forecasts too optimistic.
- Reproduced: Cowan's two-parameter errors; Knox 1995's tilt and pivot amplitude errors and pivot $\ell_* = 210$; Planck 2018 errors within $\sim 25\%$ (better with a calibration nuisance); $\Omega_m h^3$ and $A_s e^{-2\tau}$ as the degeneracy directions; the chapter-9 chain and 1000 maximum-likelihood fits within one or two per cent.

10.8 Noise alone, or a signal as well?

LISA will deliver, for years, a few numbers per second: the measured changes in the lengths of its three arms, converted into a strain $d(t)$. A strain is a fractional change of length: a passing wave of amplitude h changes an arm by $\delta L/L = h/2$ (Sections T2.1.3 and T2.3), and the detector adds its own noise (Section T2.7). Somewhere in that stream there may be a black hole of a thousand solar masses swallowing a neutron star, its wave completing millions of cycles. Or there may be nothing but the detector's own jitter. Before any parameter is estimated, and long before a dark-matter environment is discussed, there is one question that has to be answered first:

Is this data stream consistent with noise alone, or does it contain a gravitational-wave signal in addition to noise?

The answer shapes everything that follows. It fixes the likelihood we will use for the rest of the chapter, it tells us what the signal-to-noise ratio is, and its curvature is the Fisher matrix that the forecasts of Sections 10.9 and 10.11 are built on.

Why this is not the CMB problem again. In Chapters 7 and 8 the signal was a temperature map. We could look at it, see hot and cold spots, and the noise was characterised by simulating it many times with the instrument model. A gravitational wave gives us nothing like that. Its strain is far smaller than the noise at each instant (in the toy experiment below the noise is 5.314 times larger than the peak of the signal), and there is no foreground map, no picture in which the signal stands out. LISA does have something called a foreground, the confusion signal of the millions of unresolved white-dwarf binaries in our Galaxy (Section T2.7), but it is not a map either: nobody can subtract it, and it enters only statistically, as an extra term in the noise spectrum (Section 10.11.1). Worse, we never know the particular noise realisation that is in the data, only its statistics: its power spectral density, which is itself estimated. So we cannot subtract "the" noise. We have to consider *all* the noise realisations the detector could have produced, weighted by how probable each is, and ask which of them, together with a possible signal, could have produced the stream we recorded.

10.8.1 The event, and what could have produced it

We reason exactly as in the Monty Hall problem of Chapter 5.

The event. What we observed is the whole data stream, or equivalently its Fourier transform $\tilde{d}(f) = \int d(t) e^{-2\pi i f t} \mathrm{d}t$ (the book's Fourier convention, Eq. (T2.48); for a real stream the negative frequencies only repeat the positive ones, Eq. (T2.49)) at the frequencies $f_k = k/T$ of a stretch of length T. Call it $\boldsymbol{d}$.

What could have produced it? Before any number, we list the situations. The data are always the detector noise n plus whatever the sky sent:

- H_0: the sky sent nothing, so $d = n$;
- $H_1(\boldsymbol{\theta})$: a binary with parameters $\boldsymbol{\theta}$ sent a wave $h(\boldsymbol{\theta})$, so $d = n + h(\boldsymbol{\theta})$.

The thing we do not know, under either hypothesis, is the noise realisation n. This is the analogue of the unknown position of the car.

How probable is the event under each hypothesis? Take $H_1(\boldsymbol{\theta})$ first. Of all the noise realisations the detector could have produced, exactly one, $n = d - h(\boldsymbol{\theta})$, turns the prediction $h(\boldsymbol{\theta})$ into the data we hold. Every other realisation would have produced different data. So the probability of the data is the probability that the detector produced that one required realisation. In symbols, summing over all realisations with their probabilities $p_n(n)$ and keeping only the one that produces d,

$$p(\boldsymbol{d} \mid \boldsymbol{\theta}) \overset{(1)}{=} \int p_n(n)\, p(\boldsymbol{d} \mid n, \boldsymbol{\theta})\, \mathrm{d}n \overset{(2)}{=} \int p_n(n)\, \delta\big(d - h(\boldsymbol{\theta}) - n\big)\, \mathrm{d}n \overset{(3)}{=} p_n\big(d - h(\boldsymbol{\theta})\big). \tag{10.38}$$

(1) Marginalisation over the unknown noise realisation (Chapter 1): the total probability of the data is the sum, over every possible realisation, of its probability times the probability of the data given it.
(2) Given the noise and the signal, the data are fixed: $d = h(\boldsymbol{\theta}) + n$ with certainty, a delta function.
(3) The delta function picks out the single realisation $n = d - h(\boldsymbol{\theta})$.

Under H_0 the same argument with $h = 0$ gives $p(\boldsymbol{d} \mid H_0) = p_n(d)$: the data themselves must be the noise. This is the likelihood of Chapter 3, "how plausible is the fluctuation needed to turn the prediction into the data", now for a detector whose noise is a whole random function of time. Notice how little the marginalisation over the noise realisation cost: it is exact, and almost trivial, because once the data and the signal are given the noise is fixed, $n = d - h$. What we genuinely do not know is the statistics of the noise, its spectrum, and integrating over that is the marginalisation that does real work (Section 10.8.6). What remains is to know p_n.

10.8.2 The noise in the frequency domain, from its inputs

Inputs. The physical inputs are three. The noise is *stationary*: its statistical properties do not change during the stretch, so the correlation $C(\tau) = \mathbb{E}[n(t)n(t+\tau)]$ depends only on the lag τ. It has zero mean. And it is *Gaussian*: any finite set of samples has a multivariate Gaussian distribution, which is what we expect when many small independent disturbances add (Chapter 2). The mathematical inputs are two: the correlation dies off over a time τ_c much shorter than T, and the variance is finite. Everything else is derived.

Why go to Fourier space. In the time domain neighbouring samples are correlated, so p_n involves the full $N \times N$ covariance matrix $C_{jm} = C\big((j-m)\Delta t\big)$. A matrix whose entries depend only on $j - m$ is (up to the edges) a circulant matrix, and circulant matrices are diagonalised by

the discrete Fourier transform. So in Fourier space the noise modes should be uncorrelated. Let us check this and find their variance. With N samples spaced by Δt, $T = N\Delta t$, the discrete transform is $\tilde{n}_k = \Delta t \sum_j n_j e^{-2\pi i jk/N}$, an approximation to the continuous one at $f_k = k/T$. Then

$$\begin{aligned}\mathbb{E}[\tilde{n}_k \tilde{n}_l^*] &\overset{(1)}{=} \Delta t^2 \sum_j \sum_m C\big((j-m)\Delta t\big)\, e^{-2\pi i(jk-ml)/N} \\ &\overset{(2)}{=} \Delta t^2 \sum_s C(s\Delta t)\, e^{-2\pi i s l/N} \sum_j e^{-2\pi i j(k-l)/N} \\ &\overset{(3)}{=} \Delta t^2 N\, \delta_{kl} \sum_s C(s\Delta t)\, e^{-2\pi i f_l s\Delta t} \overset{(4)}{=} T\, \delta_{kl} \int C(\tau) e^{-2\pi i f_l \tau} \mathrm{d}\tau \overset{(5)}{=} \frac{T}{2} S_n(f_k)\, \delta_{kl}. \end{aligned} \tag{10.39}$$

(1) Insert the definition of $\tilde{n}_k$ twice and use $\mathbb{E}[n_j n_m] = C((j-m)\Delta t)$, stationarity.
(2) Write $m = j - s$, so $jk - ml = j(k-l) + sl$. Treating the sum over s as independent of j is exact for a periodic stretch and ignores edge terms of relative size τ_c/T, our second mathematical input.
(3) $\sum_{j=0}^{N-1} e^{-2\pi i j(k-l)/N} = N\delta_{kl}$, the orthogonality of the discrete Fourier modes; and $sl/N = f_l\, s\Delta t$ because $f_l = l/(N\Delta t)$.
(4) $N\Delta t = T$, and $\Delta t \sum_s$ becomes $\int \mathrm{d}\tau$ when $\Delta t \ll \tau_c$.
(5) The **one-sided power spectral density** is defined by $S_n(f) = 2\int C(\tau) e^{-2\pi i f\tau} \mathrm{d}\tau$ for $f > 0$ (the Wiener–Khinchin relation); the factor 2 folds the negative frequencies onto the positive ones.

The same steps with $\tilde{n}_l$ instead of $\tilde{n}_l^*$ give $\mathbb{E}[\tilde{n}_k \tilde{n}_l] = 0$ for $0 < k, l < N/2$, so the real and imaginary parts of each mode are uncorrelated and of equal variance. This is the statement $\langle \tilde{n}(f)\tilde{n}^*(f')\rangle = \frac{1}{2}\delta(f-f')S_n(f)$ of [79, eq. (35)] and [82], written for a finite stretch: $\delta(0)$ becomes T.

The density of a noise realisation. Each mode is a complex Gaussian with $\mathbb{E}\,|\tilde{n}_k|^2 = \sigma_k^2 \equiv \frac{T}{2} S_n(f_k)$; its real and imaginary parts are independent with variance $\sigma_k^2/2$ each, so its density is $\frac{1}{\pi\sigma_k^2} e^{-|\tilde{n}_k|^2/\sigma_k^2}$. Different modes are independent, so the density of the whole realisation is the product:

$$\ln p_n(n) \overset{(1)}{=} -\sum_k \frac{|\tilde{n}_k|^2}{\sigma_k^2} + \text{const} \overset{(2)}{=} -2\sum_k \Delta f\, \frac{|\tilde{n}_k|^2}{S_n(f_k)} + \text{const} \overset{(3)}{=} -\frac{1}{2}(n \mid n) + \text{const}, \tag{10.40}$$

(1) Product of independent complex Gaussians; the normalisations $1/(\pi\sigma_k^2)$ do not depend on n.
(2) $1/\sigma_k^2 = 2/(TS_n) = 2\Delta f/S_n$, since the mode spacing is $\Delta f = 1/T$.
(3) For long T the sum is an integral, $-2\int |\tilde{n}|^2/S_n\, \mathrm{d}f$, which is $-\frac{1}{2}(n \mid n)$ with the inner product defined below.

Working definition 10.4 (noise-weighted inner product and signal-to-noise ratio)

For two signals a, b and a detector with one-sided noise spectrum $S_n(f)$,

$$(a \mid b) = 4\,\mathrm{Re}\int_0^\infty \frac{\tilde{a}(f)\,\tilde{b}^*(f)}{S_n(f)}\,\mathrm{d}f$$

[a dot product in which each frequency counts in proportion to how quiet the detector is there]. The noise density is $p_n(n) \propto e^{-(n|n)/2}$, and the **optimal signal-to-noise ratio** of a signal is $\rho = \sqrt{(h \mid h)}$. *Operationally:* evaluate the integral on the frequencies where S_n is finite; for a sky-averaged detector use the sky-averaged waveform with the matching

S_n. The averages over sky position, polarisation and orbital inclination are worked out in Section T2.3, and LISA's S_n, built from its physical noise sources, in Section T2.7.

Putting (10.40) into (10.38), the likelihood of the data under $H_1(\boldsymbol{\theta})$ and under H_0 is

$$p(\boldsymbol{d}\,|\,\boldsymbol{\theta}) \propto \exp\Big[-\tfrac{1}{2}\big(d-h(\boldsymbol{\theta})\,\big|\,d-h(\boldsymbol{\theta})\big)\Big], \qquad p(\boldsymbol{d}\,|\,H_0) \propto \exp\Big[-\tfrac{1}{2}(d\,|\,d)\Big], \tag{10.41}$$

with the same constant in both [82, eq. (7)], [172]. It is the χ^2 of Chapter 3 for correlated Gaussian noise, $\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$, with the covariance diagonalised by the Fourier transform (Example 0.14 sketched it).

Key idea: The gravitational-wave likelihood

We never know the noise realisation in the data, so we weigh all of them by their probability. Under a hypothesis that predicts the signal $h(\boldsymbol{\theta})$, only the realisation $n = d - h(\boldsymbol{\theta})$ reproduces the data, and the likelihood is the probability of that realisation: $p(\boldsymbol{d}\,|\,\boldsymbol{\theta}) \propto e^{-(d-h|d-h)/2}$. The noise statistics enter only through $S_n(f)$, which weights each frequency by the inverse of its noise power.

10.8.3 The best test: the matched filter

The question in words. If the template h were known exactly, which single number computed from the data best separates "noise alone" from "noise plus h"? The Neyman–Pearson lemma of Chapter 4 answers: for two simple hypotheses the most powerful test at any false-alarm rate thresholds the likelihood ratio. From (10.41),

$$\ln\Lambda = \ln\frac{p(\boldsymbol{d}\,|\,H_1)}{p(\boldsymbol{d}\,|\,H_0)} \overset{(1)}{=} -\tfrac{1}{2}\big[(d|d) - 2(d|h) + (h|h)\big] + \tfrac{1}{2}(d|d) \overset{(2)}{=} (d\,|\,h) - \tfrac{1}{2}(h\,|\,h). \tag{10.42}$$

(1) Expand $(d-h|d-h)$ using linearity and the symmetry $(a|b) = (b|a)$ of the real inner product.
(2) The $(d|d)$ terms cancel: the data enter only through their overlap with the template.

Since $(h|h)$ is a fixed number, thresholding Λ is thresholding the **matched filter** $(d\,|\,h)$: the data correlated with the template, each frequency weighted by $1/S_n$. Its sampling distribution under each hypothesis follows from one property of the noise.

The overlap of noise with any signal. $(n|a)$ is a sum of Gaussian modes, so it is Gaussian with mean zero. Its covariance with $(n|b)$ is

$$\mathbb{E}\big[(n|a)(n|b)\big] \overset{(1)}{=} 4\Delta f^2 \sum_{k,l} \frac{\mathbb{E}\big[(\tilde n_k \tilde a_k^* + \tilde n_k^* \tilde a_k)(\tilde n_l \tilde b_l^* + \tilde n_l^* \tilde b_l)\big]}{S_n(f_k) S_n(f_l)} \overset{(2)}{=} 4\Delta f^2 \sum_k \frac{\sigma_k^2\,(\tilde a_k^* \tilde b_k + \tilde a_k \tilde b_k^*)}{S_n(f_k)^2} \overset{(3)}{=} (a\,|\,b). \tag{10.43}$$

(1) $(n|a) = 2\Delta f \sum_k (\tilde n_k \tilde a_k^* + \tilde n_k^* \tilde a_k)/S_n(f_k)$, since $2\,\mathrm{Re}\,z = z + z^*$.
(2) Only $\mathbb{E}[\tilde n_k \tilde n_l^*] = \sigma_k^2 \delta_{kl}$ survives; $\mathbb{E}[\tilde n_k \tilde n_l] = 0$.
(3) $\sigma_k^2 = \frac{T}{2} S_n$ and $T\Delta f = 1$, so $4\Delta f^2 \sigma_k^2 / S_n^2 = 2\Delta f / S_n$, and $2\Delta f \sum_k 2\,\mathrm{Re}(\tilde a_k \tilde b_k^*)/S_n$ is $(a|b)$.

So the noise-weighted inner product is exactly the covariance of the noise projections [82, eq. (8)]. With $\rho^2 = (h|h)$, the normalised statistic $z = (d|h)/\rho$ is

$$z\,|\,H_0 \sim \mathcal{N}(0,1), \qquad z\,|\,H_1 = \rho + \frac{(n|h)}{\rho} \sim \mathcal{N}(\rho, 1). \tag{10.44}$$

The two hypotheses produce two unit Gaussians a distance ρ apart. That is the meaning of the signal-to-noise ratio: the separation, in units of the noise spread, between what noise alone and noise plus the signal would give. The power of the test at false-alarm probability α follows at once: $P_D = \mathrm{P}(z > z_\alpha \mid H_1) = \Phi(\rho - z_\alpha)$, with z_α the upper-α point of $\mathcal{N}(0,1)$ and Φ the standard Gaussian cumulative distribution.

Fitting the amplitude too. So far the template had a known size. Suppose the wave is $A\,h$ with h the template of signal-to-noise ratio ρ and A an unknown strength ($A = 0$ is noise alone, $A = 1$ the template as normalised). The log-likelihood ratio of a signal of strength A against noise alone is (10.42) with $h \to Ah$, and it can be maximised over A by setting its derivative to zero:

$$\ln\Lambda(A) \overset{(1)}{=} A\,(d|h) - \tfrac{1}{2}A^2\rho^2, \qquad \frac{\partial \ln\Lambda}{\partial A} \overset{(2)}{=} (d|h) - A\rho^2 = 0 \;\Rightarrow\; \hat{A} = \frac{(d|h)}{\rho^2} = \frac{z}{\rho},$$
$$\ln\Lambda(\hat{A}) \overset{(3)}{=} \frac{(d|h)^2}{\rho^2} - \frac{(d|h)^2}{2\rho^2} \overset{(4)}{=} \frac{z^2}{2}. \tag{10.45}$$

(1) (10.42) has h in its first term and h twice in its second, and the inner product is bilinear.
(2) A parabola in A with a maximum, at $\hat{A}$.
(3) Insert $\hat{A} = (d|h)/\rho^2$ and $z = (d|h)/\rho$.
(4) Combine the two terms.

The largest log-likelihood ratio over every possible strength is $z^2/2$: the larger the filter output in either sign, the more the data prefer a signal over noise alone. (The same z^2 is the amount by which the fitted template lowers the residual, $(d|d) - (d - \hat{A}h|d - \hat{A}h) = z^2$.) By (10.44) the fitted strength has mean A and standard deviation $1/\rho$: the error on the amplitude of a known template is the inverse of the signal-to-noise ratio, the simplest example of the errors of Section 10.9. In the script, the maximum of $\ln\Lambda(A)$ over a fine grid in A equals $z^2/2$ for each of 2000 noise realisations to 1.421×10^{-14}, and $\hat{A}$ has mean 1 and scatter $0.9885/\rho$ for a signal of unit strength (`16_whiten_chi2.py`).

How far the claim of optimality reaches. The Neyman–Pearson lemma compares two *simple* hypotheses: noise alone against noise plus one exactly specified wave. For that pair the matched filter is the best possible test. It does not say that one filter is best when the wave has unknown parameters. The alternative is then a whole family $H_1(\boldsymbol{\theta})$, and no single test is the most powerful against all its members. The practical answer is the **generalised likelihood ratio**: maximise Λ over the unknown parameters, as just done for A and as Section 10.8.4 does for ϕ_c and t_0 (the unknown phase and arrival time of the wave, the coalescence constants of Section T2.4.3), and take the largest value as the statistic. Its distribution under noise alone is not the one-dimensional Gaussian of (10.44): the maximum over many possible templates is larger than any single filter (the look-elsewhere effect), and with many parameters the distribution is usually found empirically (Section 10.14). One more caveat belongs to LISA specifically. The hypothesis "noise alone" presumes a stretch of data with no signal in it, and LISA will not have one: tens of thousands of Galactic binaries and other sources overlap throughout the mission. "Noise alone" here is the idealised null of a single-source problem; the real analysis fits all the sources and the noise together.

Example: a chirp buried in coloured noise. To see all of this on data we need a stretch short enough to simulate thousands of times (script `08_detection.py`). LISA's sources last years, so for this check we use a ground-based detector: the analytic noise shape of Cutler and Flanagan [82, eq. (4)] and a $10 + 10\,M_\odot$ binary, whose whole chirp from 20 Hz to the innermost stable

circular orbit (ISCO, where the slow inspiral ends, Eq. (T2.46)) at 219.9 Hz lasts 5.959 s and fits in $T = 16$ s sampled at 1024 Hz. Every step is identical for LISA with S_n of Eq. (T2.77) and years of data. The noise is generated directly from (10.39):

Listing 10.5: Coloured Gaussian noise and the inner product (`code/ch10/08_detection.py`)

```
fs, T = 1024.0, 16.0
N = int(fs * T)
dt, df = 1 / fs, 1 / T
fk = np.fft.rfftfreq(N, dt)
band = (fk >= 15.0) & (fk <= 500.0)
Sn = np.full_like(fk, np.inf)
Sn[band] = L.Sn_cf94(fk[band])
sig2 = 0.5 * T * Sn                                   # E |n_k|^2 = (T/2) S_n(f_k)

def noise_fd(n):
    """n realisations of the noise Fourier modes (complex Gaussian, independent across k)."""
    s = np.sqrt(np.where(band, sig2, 0.0) / 2)
    return s * (rng.standard_normal((n, fk.size)) + 1j * rng.standard_normal((n, fk.size)))

def inner(a, b):
    """(a|b) = 4 Re sum a b* / S_n df  over the band."""
    return 4 * df * np.real(np.sum((a * np.conj(b))[..., band] / Sn[band], axis=-1))
```

Line 37 is (10.39): the variance of each Fourier mode. Lines 42–43 draw the real and imaginary parts independently, each with half that variance. Line 48 is the inner product of the working definition, as a sum over the band with $\mathrm{d}f \to 1/T$. The template is the stationary-phase chirp of Eq. (T2.56), the Fourier transform of the inspiral derived in Section T2.5, scaled so that $\rho = 5$.

Figure 10.21 shows one realisation. In the raw strain the chirp is invisible. Dividing each Fourier mode by $\sqrt{S_n}$ (**whitening**) makes the noise equally loud at all frequencies, and even then the chirp is a faint ripple below the noise. The Welch estimate of the spectrum, computed from this one stretch, follows the true S_n: what we can know about the noise is its spectrum, not its realisation.

Over 2000 realisations of each hypothesis (independent noise for the two), the statistic z has mean -7.002×10^{-4} and standard deviation 0.9939 under H_0, and mean 5.001 and standard deviation 0.9945 under H_1, as (10.44) predicts (Figure 10.22, left). At a false-alarm probability of 1% the threshold is $z_\alpha = 2.326$, and the detection probability is $\Phi(5 - 2.326) = 0.9962$; the simulation gives 0.9965.

10.8.4 When the arrival time and phase are unknown

The test of Section 10.8.3 was built for a template we know exactly. Imagine running it on a real detector. A binary that merged somewhere in the Universe sends us a chirp whose shape we can predict from its masses, but two of its numbers are pure accident: the moment t_0 at which it reaches the detector, and the phase ϕ_c of the wave at that moment, which depends on where the two bodies happened to be on their orbit. Neither tells us anything about the source, and neither can be known in advance. A template with the wrong arrival time lines up its oscillations against noise; a template with the wrong phase lines up its crests against the signal's troughs. In both cases the matched filter $(d|h)$ of (10.42) comes out near zero, even with a loud signal in the data.

The question, in words: *must we run a separate matched filter for every phase and every arrival time we can think of, and if we search over all of them, what does noise alone now produce?* The answer

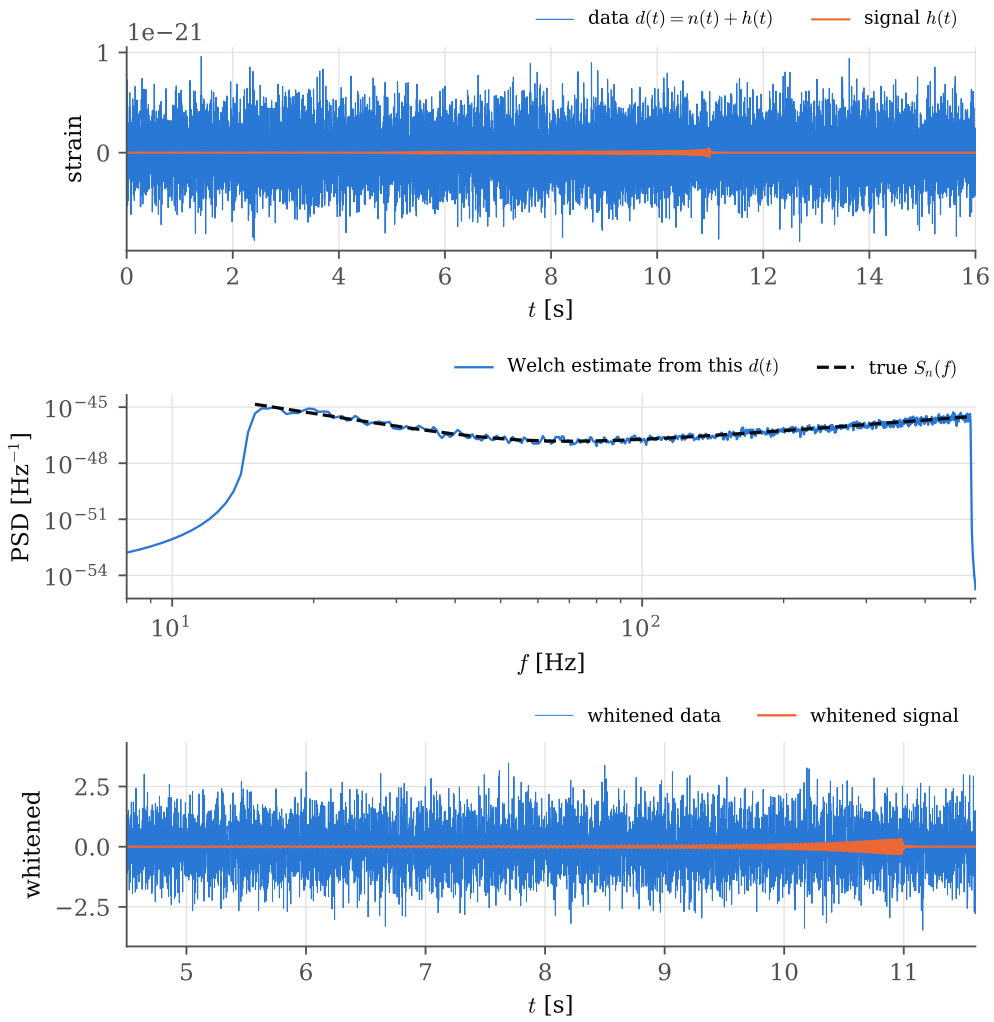

Figure 10.21: One stretch of simulated detector output with a $\rho = 5$ chirp. Top: the data and the signal; the signal is a small fraction of the noise and cannot be seen. Middle: the spectrum estimated from this stretch alone falls on the true $S_n(f)$ (dashed). Bottom: after whitening, the noise is flat and the chirp (orange) is still well below it. Only correlating with the right template brings it out.

to the first part is no. The phase costs exactly two filters instead of one, and every arrival time comes out of one Fourier transform. The answer to the second part is the price we pay for not knowing.

The phase

The simplest wave first. Take a pure tone of known amplitude A and angular frequency ω, with an unknown phase ϕ_c,

$$h(t;\phi_c) = A\cos(\omega t + \phi_c). \tag{10.46}$$

As a function of ϕ_c this looks hopeless: every value of ϕ_c is a different waveform. But the addition rule $\cos(\alpha+\beta) = \cos\alpha\cos\beta - \sin\alpha\sin\beta$, with $\alpha = \omega t$ and $\beta = \phi_c$, separates the part that depends on time from the part that depends on the phase:

$$h(t;\phi_c) \overset{(1)}{=} A\cos\omega t\,\cos\phi_c - A\sin\omega t\,\sin\phi_c \overset{(2)}{=} h_c(t)\cos\phi_c + h_s(t)\sin\phi_c, \tag{10.47}$$

with $h_c(t) \equiv A\cos\omega t$ and $h_s(t) \equiv -A\sin\omega t$.

(1) The addition rule.
(2) Give the two fixed time functions names. All of the dependence on ϕ_c is now in the two numbers $\cos\phi_c$ and $\sin\phi_c$.

So every phase is a mixture of the same two waveforms, h_c and h_s. They differ by a quarter of a cycle ($-\sin\omega t = \cos(\omega t + \pi/2)$), and are called the two **quadratures** of the signal.

The filter of a mixture is the mixture of the filters. The inner product $(a|b)$ of the working definition in Section 10.8.2 is an integral, so it is linear in each slot: $(d \mid \alpha a + \beta b) = \alpha(d|a) + \beta(d|b)$ for real numbers α, β. Applied to (10.47),

$$(d \mid h) = x_c \cos\phi_c + x_s \sin\phi_c, \qquad x_c \equiv (d \mid h_c), \quad x_s \equiv (d \mid h_s). \tag{10.48}$$

The data are correlated with each quadrature once, giving two numbers x_c and x_s; the filter for any phase is then a recombination of these two numbers, with no further reference to the data.

Which phase fits best? Treat (x_c, x_s) as a point in a plane and describe it in polar coordinates: its distance from the origin $r = \sqrt{x_c^2 + x_s^2}$ and its angle ϕ_0, so that $x_c = r\cos\phi_0$ and $x_s = r\sin\phi_0$. Then

$$(d \mid h) \overset{(1)}{=} r\cos\phi_0\cos\phi_c + r\sin\phi_0\sin\phi_c \overset{(2)}{=} r\cos(\phi_c - \phi_0). \tag{10.49}$$

(1) Substitute the polar form of x_c and x_s into (10.48).
(2) The addition rule again, read backwards: $\cos(\phi_c - \phi_0) = \cos\phi_c\cos\phi_0 + \sin\phi_c\sin\phi_0$.

A cosine is at most 1, and reaches it when its argument is zero. So the best phase is $\phi_c = \phi_0$, the angle of the point (x_c, x_s), and the filter there equals the distance r:

$$\max_{\phi_c} (d \mid h) = \sqrt{(d \mid h_c)^2 + (d \mid h_s)^2}. \tag{10.50}$$

A continuum of phases has been searched with two filters and one square root. The best-fitting phase also comes for free, as ϕ_0.

The two filters as one complex number. A point in the plane is a complex number, so define

$$x \equiv x_c + i\,x_s, \qquad |x| = \sqrt{x_c^2 + x_s^2} = \max_{\phi_c}(d \mid h), \qquad \arg x = \phi_0. \tag{10.51}$$

In the frequency domain x takes a compact form. We need the Fourier transforms of the two quadratures, in the convention of Section 10.8.2, $\tilde h(f) = \int h(t)\, e^{-2\pi i f t}\, \mathrm{d}t$. Write the two time functions as complex exponentials,

$$\cos\omega t = \tfrac{1}{2}\big(e^{i\omega t} + e^{-i\omega t}\big), \qquad -\sin\omega t = -\tfrac{1}{2i}\big(e^{i\omega t} - e^{-i\omega t}\big) = \tfrac{i}{2}\big(e^{i\omega t} - e^{-i\omega t}\big). \tag{10.52}$$

The inner product only uses positive frequencies, and there only the $e^{+i\omega t}$ term contributes. Its coefficient is $\frac{1}{2}$ for the cosine and $\frac{i}{2}$ for the sine quadrature. So, at every positive frequency,

$$\tilde h_s(f) = i\,\tilde h_c(f). \tag{10.53}$$

A quarter-cycle delay is multiplication by i. Now compute x_s from the definition of the inner product:

$$x_s = (d \mid h_s) \overset{(1)}{=} 4\,\mathrm{Re}\int_0^\infty \frac{\tilde d\,(i\tilde h_c)^*}{S_n}\,\mathrm{d}f \overset{(2)}{=} 4\,\mathrm{Re}\Big[-i\int_0^\infty \frac{\tilde d\,\tilde h_c^*}{S_n}\,\mathrm{d}f\Big] \overset{(3)}{=} 4\,\mathrm{Im}\int_0^\infty \frac{\tilde d\,\tilde h_c^*}{S_n}\,\mathrm{d}f. \tag{10.54}$$

(1) The inner product of Section 10.8.2, with (10.53).
(2) $(i\tilde h_c)^* = -i\,\tilde h_c^*$, and the constant $-i$ comes out of the integral.

(3) For any complex number $w = a + ib$, $-iw = b - ia$, so $\mathrm{Re}(-iw) = b = \mathrm{Im}\, w$.

And $x_c = 4\,\mathrm{Re}\int \tilde{d}\,\tilde{h}_c^*/S_n\,\mathrm{d}f$ by definition. Putting the two together,

$$x = x_c + i\,x_s = 4\int_0^\infty \frac{\tilde{d}(f)\,\tilde{h}_c^*(f)}{S_n(f)}\,\mathrm{d}f. \tag{10.55}$$

This is the inner product with the "Re" left out. Its real part is the cosine filter, its imaginary part the sine filter, and its modulus is the filter already maximised over the phase.

From the tone to the chirp. Nothing above used the fact that the wave was a pure tone, except to find (10.53). For the stationary-phase chirp of Eq. (T2.56), $\tilde{h}(f) = \mathcal{A} f^{-7/6} e^{-i\Psi(f)}$ with $\Psi(f) = 2\pi f t_c - \phi_c - \pi/4 + \ldots$ (Section T2.4.3), the unknown phase enters Ψ as an additive constant, so it multiplies the whole Fourier transform by one factor $e^{i\phi_c} = \cos\phi_c + i\sin\phi_c$. That is (10.47) again, with $\tilde{h}_c$ the template at $\phi_c = 0$ and $\tilde{h}_s = i\tilde{h}_c$. The complex filter (10.55) therefore searches all phases of the chirp as well. (With $-\phi_c$ inside Ψ and $e^{-i\Psi}$ outside, the factor is $e^{+i\phi_c}$; the opposite convention would only flip the sign of ϕ_0.)

The arrival time

A delay is a phase that grows with frequency. A signal arriving t_0 later is the same waveform shifted, $h(t) \to h(t - t_0)$. Its Fourier transform is

$$\int h(t - t_0)\,e^{-2\pi i f t}\,\mathrm{d}t \overset{(1)}{=} \int h(s)\,e^{-2\pi i f (s+t_0)}\,\mathrm{d}s \overset{(2)}{=} e^{-2\pi i f t_0}\,\tilde{h}(f). \tag{10.56}$$

(1) Substitute $s = t - t_0$, so $t = s + t_0$ and $\mathrm{d}t = \mathrm{d}s$.
(2) The factor $e^{-2\pi i f t_0}$ does not depend on s and comes out; what is left is $\tilde{h}(f)$.

Put the shifted template into the complex filter (10.55). The complex conjugate turns $e^{-2\pi i f t_0}$ into $e^{+2\pi i f t_0}$:

$$x(t_0) = 4\int_0^\infty \frac{\tilde{d}(f)\,\tilde{h}_c^*(f)}{S_n(f)}\,e^{+2\pi i f t_0}\,\mathrm{d}f = \int_0^\infty Q(f)\,e^{+2\pi i f t_0}\,\mathrm{d}f, \qquad Q(f) \equiv \frac{4\,\tilde{d}(f)\,\tilde{h}_c^*(f)}{S_n(f)}. \tag{10.57}$$

One transform for all arrival times. Look at what depends on what. $Q(f)$ is built from the data, the template and the noise spectrum; it does not know about t_0, so it is computed once. The arrival time appears only in $e^{+2\pi i f t_0}$, and an integral of a function of f against $e^{+2\pi i f t_0}$ is, by definition, the inverse Fourier transform of that function, evaluated at the time t_0. So

$$x(t_0) = \mathcal{F}^{-1}[Q](t_0) \quad \text{for every } t_0 \text{ at once.} \tag{10.58}$$

On a stretch of N samples there are N possible arrival times. Filtering at each one separately would take N operations per lag, N^2 in all; the fast Fourier transform delivers all N values in about $N \log_2 N$. For the 16384 lags of our example that is about a thousand times less work per template, and it is how real searches work [173]. In the script, `q` is $Q(f)$ on the frequency grid (zero outside the band), `x` is $x(t_0)$ on every lag, and the statistic maximised over both unknowns, $z_{\max} = \max_{t_0} |x(t_0)|/\rho$, is stored:

Listing 10.6: The filter at every arrival time (`code/ch10/08_detection.py`)

```
        zl.append(inner(d, h0) / norm)
        # complex filter over all lags: x(t0) = 4 sum d h* / S df e^{+2 pi i f t0}; |x| maximises over the phase
        q = np.zeros_like(d)
        q[:, band] = d[:, band] * np.conj(h0[band]) / Sn[band]
        x = 4 * df * np.fft.ifft(np.concatenate([q, np.zeros((q.shape[0], N - q.shape[1]))], axis=1), axis=1) * N
```

What noise alone now gives

Searching costs something. Every time we try another phase or another arrival time, we give the noise another chance to look like a signal. To set a threshold we need the distribution of $z_{\max}$ when the data are noise alone, $d = n$.

One arrival time. Fix t_0. Under H_0 the two filters are $x_c = (n|h_c)$ and $x_s = (n|h_s)$. By (10.43), each is Gaussian with mean zero, and their variances and covariance are inner products of the templates. These follow from (10.53):

$$(h_s \mid h_s) \overset{(1)}{=} 4\int_0^\infty \frac{|i\tilde{h}_c|^2}{S_n}\,\mathrm{d}f \overset{(2)}{=} (h_c \mid h_c) = \rho^2,$$
$$(h_c \mid h_s) \overset{(3)}{=} 4\,\mathrm{Re}\Big[-i\int_0^\infty \frac{|\tilde{h}_c|^2}{S_n}\,\mathrm{d}f\Big] \overset{(4)}{=} 0. \tag{10.59}$$

(1) The inner product of a signal with itself; the real part is not needed because $|\cdot|^2$ is real.
(2) $|i| = 1$; and $(h_c|h_c) = \rho^2$ is the optimal signal-to-noise ratio of the working definition.
(3) The same manipulation as for x_s above, with $\tilde{d}$ replaced by $\tilde{h}_c$.
(4) The integral is a real number, so $-i$ times it is purely imaginary, and its real part vanishes.

So x_c/ρ and x_s/ρ are Gaussians with mean zero, variance one and covariance zero. For jointly Gaussian variables zero covariance means independence, so they are two independent $\mathcal{N}(0,1)$ variables, and

$$\frac{|x|^2}{\rho^2} = \left(\frac{x_c}{\rho}\right)^2 + \left(\frac{x_s}{\rho}\right)^2 \sim \chi^2_2 \tag{10.60}$$

is the sum of the squares of two independent unit Gaussians, a χ^2 with two degrees of freedom (Section 2.13.2). With $p = 2$ the χ^2_p density (2.92) becomes simply $\frac{1}{2}e^{-v/2}$, an exponential, so its tail is $\mathrm{P}(\chi^2_2 > v) = \int_v^\infty \frac{1}{2}e^{-v'/2}\mathrm{d}v' = e^{-v/2}$. With $v = u^2$,

$$\mathrm{P}\Big(\frac{|x|}{\rho} > u \,\Big|\, H_0\Big) = e^{-u^2/2}. \tag{10.61}$$

Compare the known-phase test: there $\mathrm{P}(z > u)$ was a one-sided Gaussian tail, about $e^{-u^2/2}/(u\sqrt{2\pi})$ for large u. Searching over the phase has raised the false-alarm probability by a factor of about $u\sqrt{2\pi}$, roughly 6 at $u = 2.5$: the price of one unknown angle.

All arrival times. Now we take the largest $|x(t_0)|/\rho$ over all $N = 16384$ lags. If the lags were independent, the largest would stay below u only if every one did:

$$\mathrm{P}(z_{\max} > u \mid H_0) = 1 - \big(1 - e^{-u^2/2}\big)^N \approx N\,e^{-u^2/2} \quad \text{while this is small.} \tag{10.62}$$

This is the look-elsewhere effect of Chapter 4: the largest of many noise peaks is larger than a typical one, and a threshold that was safe for one trial is not safe for N. The simulation shows how large the effect is. Under H_0 the median of $z_{\max}$ is 4.226, the 1% threshold rises from $z_\alpha = 2.326$ to 5.123, and for the same $\rho = 5$ the detection probability falls from 0.9965 to 0.54 (Figure 10.22, middle and right).

How many trials, really? The lags are not independent: the filter output is smooth over a time about the inverse of the bandwidth, so neighbouring lags see nearly the same noise. We can measure how many independent trials the search is worth by solving (10.62) for N at the measured threshold, $N_{\mathrm{eff}}e^{-u^2/2} = 0.01$. This gives $N_{\mathrm{eff}} \approx 5000$, fewer than the 16384 lags. It is a rough number: the 1% threshold rests on the twenty largest of the 2000 noise-only values, and N_{eff} grows as $e^{u^2/2}$, so a small error in u becomes a large one in N_{eff}.

The lesson, in one line: not knowing when and in what phase a signal arrives costs nothing in computation (two filters and one Fourier transform) but a great deal in significance, because noise alone now gets thousands of chances. This is why ground-based searches demand $\rho \gtrsim 8$ before claiming a detection, and why LISA forecasts assume a threshold near $\rho \approx 15$ for these long signals [84].

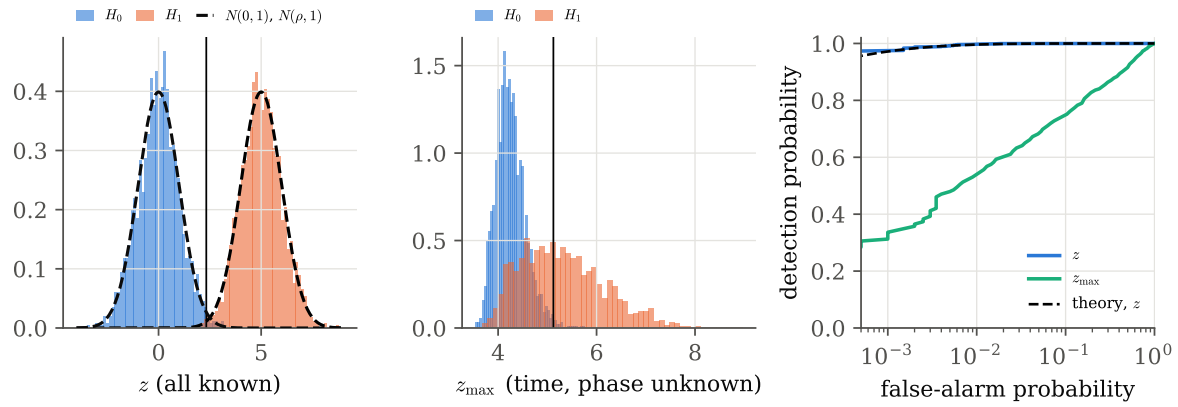

Figure 10.22: Sampling distributions of the detection statistic over 2000 noise realisations, $\rho = 5$. Left: with the template, time and phase known, z is $\mathcal{N}(0,1)$ under H_0 and $\mathcal{N}(\rho,1)$ under H_1 (dashed); the vertical line is the 1% false-alarm threshold. Middle: maximising over arrival time and phase pushes the noise-only distribution up, and the threshold with it. Right: detection probability against false-alarm probability (receiver operating characteristic); the price of not knowing t_0 and ϕ_c is the gap between the two curves.

10.8.5 Whitening, and what one stretch can tell us about the spectrum

Everything above rests on the claim that each Fourier mode of the noise is a complex Gaussian of variance $\sigma_k^2 = \frac{T}{2} S_n(f_k)$ (Eq. (10.39)). Two practical questions follow at once. How do we look at the data so that this claim can be checked? And if the spectrum is not known, what does one stretch of data say about it?

Whitening. Divide each mode by its own standard deviation, $w_k = \tilde{n}_k/\sigma_k$. Then $\mathbb{E}\,|w_k|^2 = 1$ in every bin, however steep the spectrum: the noise has become equally loud at all frequencies, **white**. The same division turns the noise-weighted inner product into an ordinary dot product. For two signals with whitened modes $a_k = \tilde{a}_k/\sigma_k$, $b_k = \tilde{b}_k/\sigma_k$,

$$(a \mid b) = 4\Delta f \sum_k \frac{\operatorname{Re} \tilde{a}_k \tilde{b}_k^*}{S_n(f_k)} \overset{(1)}{=} 2 \sum_k \operatorname{Re}\left(a_k b_k^*\right), \tag{10.63}$$

(1) $\sigma_k^2 = T S_n(f_k)/2$ and $\Delta f = 1/T$, so $\operatorname{Re}(\tilde{a}_k \tilde{b}_k^*)/\sigma_k^2 = 2\Delta f \operatorname{Re}(\tilde{a}_k \tilde{b}_k^*)/S_n(f_k)$.

so in whitened data the filter $(d|h)$ is a plain correlation between the whitened data and the whitened template, and $(n|n) = 2\sum_k |w_k|^2$ is the sum of squares of independent unit-variance numbers, as in (10.40). This is what the bottom panel of Figure 10.21 shows.

What one stretch says about the spectrum. The natural estimate of σ_k^2 from one stretch is the **periodogram** of that bin, $|\tilde{n}_k|^2$. Its distribution follows from (10.39): the real and imaginary parts of $\tilde{n}_k$ are independent Gaussians of variance $\sigma_k^2/2$, so with a and b two independent $\mathcal{N}(0,1)$ variables,

$$\frac{|\tilde{n}_k|^2}{\sigma_k^2} = \frac{a^2 + b^2}{2} = \tfrac{1}{2}\chi_2^2, \qquad \text{density } e^{-v}, \quad v \geq 0, \tag{10.64}$$

the exponential distribution (the χ^2_2 density is $\frac{1}{2}e^{-v/2}$, as used for (10.61)). An exponential has its standard deviation equal to its mean. So a single-bin periodogram is right on average but is wrong by 100% in any one realisation, and a longer stretch does not help: it only supplies more bins, each as noisy as before. The way to a good estimate is to average. Cut the data into M segments, compute the periodogram of each and average the M values in each bin (Welch's method). The sum of M independent exponentials is a gamma variable of mean M and variance M, so the average has mean one and variance $1/M$: the fractional error falls as $1/\sqrt{M}$. This sum is exactly the quantity Q of the next subsection.

Cutting the data into segments has a price. Each segment is the product of the signal with a rectangular window, and in the Fourier domain a product is a convolution: the loud low-frequency part of the spectrum leaks, through the slowly decaying wings of the window's transform, into frequency bins where the true noise is orders of magnitude lower. For detector noise that spans many decades the leakage can dominate the estimate. Segments are therefore multiplied by a smooth taper that falls to zero at the ends (for example a Tukey or Hann window), which suppresses the wings, and overlapping segments recover the information the taper discards. In the script, the periodograms of 400 simulated noise realisations in the band have mean 0.9998 and variance 0.9996 in units of σ_k^2, as (10.64) requires; a Kolmogorov–Smirnov test against the exponential gives $p = 0.08844$; and the real parts of the whitened modes have standard deviation 0.9999 and excess kurtosis -0.002005, as for a Gaussian of variance one half per component after the factor $\sqrt{2}$ (`16_whiten_chi2.py`). On real data the same two checks, an exponential periodogram and Gaussian whitened modes, are what tells us the Gaussian stationary noise model is adequate, or that glitches and drifts are present.

10.8.6 When the noise spectrum is itself estimated

The likelihood (10.41) assumed S_n known. It never is: it is estimated from data near the event, for instance by averaging $|\tilde{n}_k|^2$ over M stretches without a signal. Plugging the estimate $\hat{S}_n$ into the Gaussian likelihood treats a noisy number as exact. What should we do instead?

The question in words. What is the probability of the on-source residual in one frequency bin, regardless of the true noise level in that bin, given what the off-source stretches told us about that level? It is a marginal: the true variance is a nuisance, and we integrate it out, exactly as V was integrated out to obtain Student's t in Chapter 2.

Ingredients. In bin k write $s = \mathbb{E}\,|\tilde{n}_k|^2$ for the unknown true variance, $r = \tilde{d}_k - \tilde{h}_k$ for the on-source residual, and $x_1, \dots, x_M$ for the same bin in M off-source stretches. Each is a complex Gaussian of variance s. With the prior $p(s) \propto 1/s$ (scale-free, Chapter 5), the off-source data give the posterior

$$p(s \mid x) \overset{(1)}{=} \frac{\prod_m \frac{1}{\pi s} e^{-|x_m|^2/s} \cdot \frac{1}{s}}{\int (\cdots) \mathrm{d}s} \overset{(2)}{=} \frac{Q^M}{\Gamma(M)}\, s^{-M-1} e^{-Q/s}, \qquad Q \equiv \sum_{m=1}^{M} |x_m|^2 \equiv M\hat{s}. \tag{10.65}$$

(1) Bayes' theorem with the complex-Gaussian density of each stretch and the prior $1/s$.

(2) Collect $s^{-M} \cdot s^{-1}$ and $e^{-\sum |x_m|^2/s}$; the normalisation is the gamma integral $\int_0^\infty s^{-a-1} e^{-Q/s} \mathrm{d}s = \Gamma(a)/Q^a$ (substitute $y = Q/s$), with $a = M$. $\hat{s}$ is the averaged estimate of the variance.

Marginalise. The density of the on-source residual, regardless of s, is

$$\begin{aligned} p(r \mid x) &\overset{(1)}{=} \int_0^\infty \frac{1}{\pi s} e^{-|r|^2/s}\, p(s \mid x)\, \mathrm{d}s \overset{(2)}{=} \frac{Q^M}{\pi \Gamma(M)} \int_0^\infty s^{-M-2} e^{-(Q+|r|^2)/s} \mathrm{d}s \\ &\overset{(3)}{=} \frac{Q^M}{\pi \Gamma(M)} \frac{\Gamma(M+1)}{(Q+|r|^2)^{M+1}} \overset{(4)}{=} \frac{1}{\pi \hat{s}} \left(1 + \frac{|r|^2}{M\hat{s}}\right)^{-(M+1)}. \end{aligned} \tag{10.66}$$

(1) Marginalisation over the nuisance s.
(2) Insert (10.65) and collect the powers of s: $s^{-1}s^{-M-1} = s^{-M-2}$.
(3) The same gamma integral with $a = M + 1$ and $Q \to Q + |r|^2$.
(4) $\Gamma(M+1)/\Gamma(M) = M$; divide numerator and denominator by Q^{M+1} and use $Q = M\hat{s}$.

This is a two-dimensional Student-t (with $\nu = 2M$ and $t^2 = 2|r|^2/\hat{s}$ it reads $(1 + t^2/\nu)^{-(\nu+2)/2}$) [174]. As $M \to \infty$, $(1 + x/M)^{-(M+1)} \to e^{-x}$ with $x = |r|^2/\hat{s}$: the Gaussian likelihood with the estimate is recovered, because the estimate has become exact. For finite M the tails are heavier. A residual that is large compared with $\hat{s}$ is no longer catastrophic, because it may mean that the noise in that bin was underestimated.

Example: what the plug-in costs. The script estimates the amplitude of the known chirp ($\rho = 5$, true amplitude one) in 2000 experiments, each with its own M off-source stretches, in two ways: the Gaussian likelihood with $\hat{S}_n$ plugged in (maximum-likelihood estimate and its curvature error) and the Student-t likelihood (10.66) summed over bins (posterior on a grid). The amplitude is in units of the true one, so the ideal error is $1/\rho$; we quote widths and scatters times ρ.

	Gaussian, $\hat{S}_n$ plugged in			Student-t, S_n marginalised		
M	claimed width	actual scatter	coverage	claimed width	actual scatter	coverage
2	0.709	2.367	27.2%	1.001	1.226	58.65%
4	0.8662	1.253	49.95%	1.001	1.122	62.25%
8	0.9356	1.087	60.3%	1.001	1.065	64.8%
16	0.9682	1.043	64.4%	1.001	1.036	66.4%
32	0.9843	1.028	66.4%	1.001	1.026	67.35%

Read the plug-in columns first. The claimed width is too small, by a factor close to $\sqrt{(M-1)/M}$ (0.707 for $M = 2$). The reason is Jensen's inequality: $\hat{s}$ is unbiased, but $\mathbb{E}[1/\hat{s}] = \frac{M}{M-1}\frac{1}{s}$ is not, so $(h|h)$ computed with $\hat{S}_n$ is too large on average. Worse, the actual scatter of the estimate is larger than the ideal one, because a bin whose noise was underestimated by chance receives too much weight. Both effects push the coverage of the nominal 68.3% interval down to 27.2% for $M = 2$. The Student-t likelihood gives a more robust estimate (its scatter is half as large at $M = 2$) and an interval closer to honest. What it cannot do is recover information that was never measured: with only two off-source stretches per bin, thousands of separately uncertain noise levels still cost coverage (the Monte Carlo error of each coverage is ±1.043%). Both methods converge for $M \gtrsim 16$ (Figure 10.23). Research analyses therefore estimate the spectrum from long stretches, or describe it by a smooth model with few parameters fitted together with the signal [175, 176].

Watch out: A plugged-in spectrum is an overconfident spectrum

An unbiased estimate of S_n gives a biased estimate of $1/S_n$, the quantity the likelihood actually uses. With few averages the plug-in Gaussian likelihood claims error bars too small by $\sqrt{(M-1)/M}$ and lets badly estimated bins dominate. Either average many stretches, or marginalise the spectrum.

10.8.7 A signal must have the right shape: the χ^2 consistency test

A large filter output does not prove a gravitational wave. A short burst of instrumental noise (a glitch) can also correlate with the template and give a large z. What a glitch lacks is the

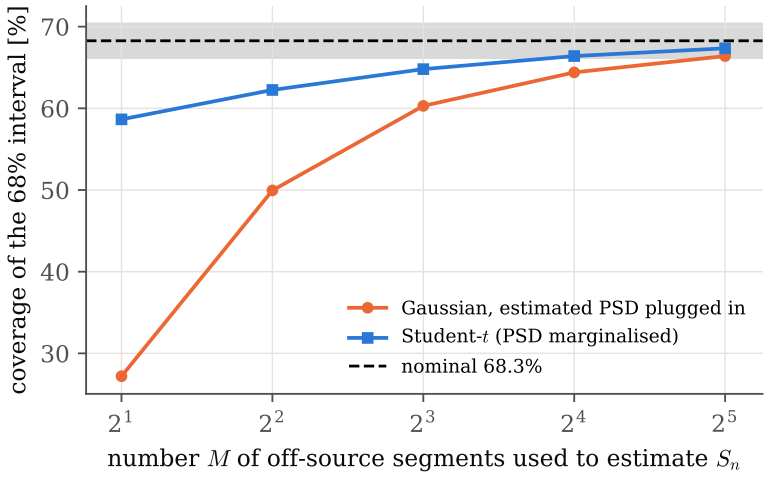

Figure 10.23: Coverage of the nominal 68.3% interval on the signal amplitude when S_n is estimated from M off-source stretches, over 2000 experiments (grey band: ±2 Monte Carlo standard errors). Plugging the estimate into the Gaussian likelihood is overconfident for small M; marginalising the unknown spectrum (Student-t) recovers most of the gap.

shape of the chirp: the template predicts how the signal-to-noise ratio should be shared among frequency bands, and a burst puts its power somewhere else. That prediction is a test with a known distribution.

The question in words. Having found a peak of the filter $x(t_0)$ at some lag, is the way x was built up across frequency what the template predicts, up to noise? Split the band into p pieces with edges chosen so that each carries the same share of the signal-to-noise ratio, $\rho_i^2 = \rho^2/p$ (possible because $4|\tilde{h}|^2/S_n$ is positive). Let x_i be the complex filter (10.55) restricted to piece i, so $\sum_i x_i = x$. For the true signal and noise,

$$\mathbb{E}\, x_i = \frac{\rho^2}{p}\, e^{i\phi_0} = \frac{\mathbb{E}\, x}{p}, \tag{10.67}$$

because the signal's filter output accumulates ρ_i^2 in piece i. So the residuals $r_i = x_i/\rho - x/(p\rho)$ have zero mean when the data contain the template (or only noise). Their noise is Gaussian: by (10.43) the real and imaginary parts of x_i/ρ each have variance $\rho_i^2/\rho^2 = 1/p$. The $2p$ real numbers $\mathrm{Re}\, r_i$, $\mathrm{Im}\, r_i$ therefore have variance $1/p$ each, and two linear constraints, $\sum_i \mathrm{Re}\, r_i = 0$ and $\sum_i \mathrm{Im}\, r_i = 0$ (the sum of the residuals is zero by construction), so

$$\chi^2 \equiv p \sum_{i=1}^{p} |r_i|^2 \sim \chi^2_{2p-2}. \tag{10.68}$$

A sum of squares of $2p$ unit Gaussians would be χ^2_{2p}; each linear constraint removes one degree of freedom (the same count as the $n-1$ of the sample variance in Chapter 2). A glitch correlates with the template mainly in the band where it has power, so one x_i is far from x/p and χ^2 is large.

What the simulation shows. The script (`16_whiten_chi2.py`) divides the chirp band into $p = 8$ pieces ($2p - 2 = 14$ degrees of freedom), finds the lag of the largest $|x|$ and evaluates (10.68) there. For noise alone the mean is 12.89, a little below 14 because the lag was chosen to be the one where the pieces happen to line up; for a true chirp of $\rho = 10$ it is 13.51 and the fraction below the 0.1% threshold 36.12 is 100%. Now take a short burst at 60 Hz, placed at the moment the chirp passes that frequency, and scaled to the same optimal signal-to-noise

ratio as the chirp, $\rho = 10$. The template matches it only in part: the median $|x|/\rho$ is 5.119, well above the 4.222 of noise alone but below the 9.983 of the chirp. Many such bursts would pass a threshold on the filter output alone. Its median χ^2 is 62.65, and only 15.83% of the bursts fall below the threshold (Figure 10.24, left). The test does not make the matched filter better; it rejects the large values of z that come from something other than the template, and detection pipelines weight their statistic by it.

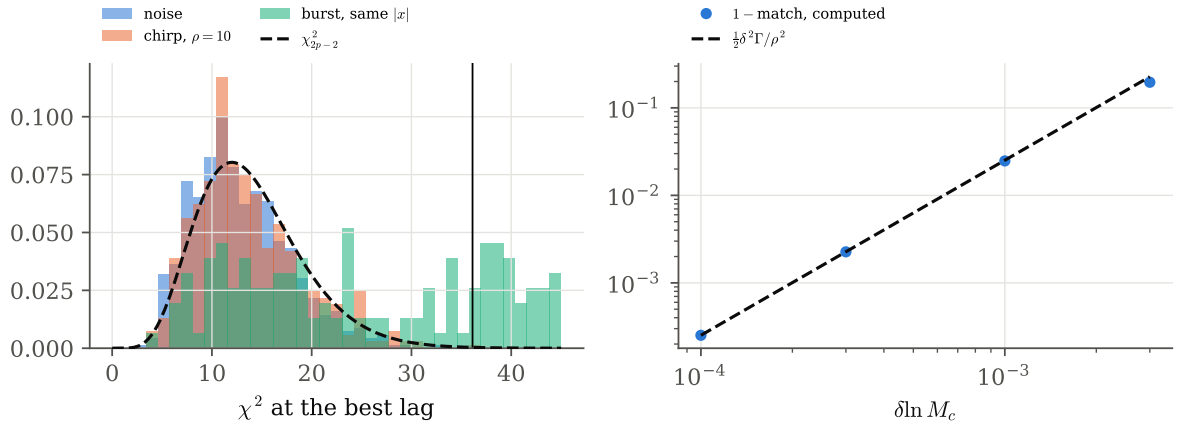

Figure 10.24: Left: the χ^2 statistic of (10.68) at the best lag, for noise alone, for a chirp of $\rho = 10$ (both follow χ^2_{14}, dashed) and for a narrow-band burst with a similar filter output, which does not. The vertical line is the 0.1% threshold. Right: one minus the match between two chirps whose chirp masses (the mass combination of Eq. (T2.42) that sets the sweep) differ by $\delta \ln M_c$, against the Fisher expansion of Section 10.9.5.

What this buys the rest of the chapter. Once a signal is detected, the same likelihood (10.41), now read as a function of $\boldsymbol{\theta}$, is what parameter estimation explores. Its peak is the best fit and its width is the error. The expected curvature of its logarithm at the true parameters is the Fisher matrix of Section 10.1, and for this likelihood it takes a particularly transparent form.

10.9 The Fisher matrix of a chirp

Suppose LISA has detected the inspiral. The likelihood (10.41) of Section 10.8, $p(\boldsymbol{d}\,|\,\boldsymbol{\theta}) \propto e^{-(d-h(\boldsymbol{\theta})|d-h(\boldsymbol{\theta}))/2}$, now becomes a function on parameter space, and its peak sits close to the true masses, arrival time and phase (the chirp mass, the coalescence time t_c and the coalescence phase ϕ_c of the chirp, Sections T2.4 and T2.4.3). How sharp will that peak be? That is what a mission designer, or a theorist asking whether a dark-matter spike could ever be seen, needs before the data exist. In Section 10.1 the answer was the Fisher matrix, the expected curvature of $-\ln\mathcal{L}$ at the true parameters. For the gravitational-wave likelihood it turns into a short, transparent formula, and that formula explains in one picture why some parameters are measured to a part in ten million and others to tens of per cent.

10.9.1 From the likelihood to $\Gamma_{ij} = (\partial_i h|\partial_j h)$

The question in words. If the data were generated by the true parameters $\boldsymbol{\theta}_0$ with a typical noise realisation, how quickly would $\ln\mathcal{L}$ fall as we move away from $\boldsymbol{\theta}_0$? Differentiate $\ln\mathcal{L} = -\frac{1}{2}(d-h|d-h)$ twice, using that the inner product is bilinear and symmetric, and write

$\partial_i \equiv \partial/\partial\theta_i$:

$$-\partial_i\partial_j \ln\mathcal{L} \overset{(1)}{=} -\partial_j\big(d-h\,\big|\,\partial_i h\big) \overset{(2)}{=} \big(\partial_j h\,\big|\,\partial_i h\big) - \big(d-h\,\big|\,\partial_i\partial_j h\big),$$
$$\Gamma_{ij} \equiv \mathbb{E}\left[-\partial_i\partial_j \ln\mathcal{L}\right]_{\boldsymbol{\theta}_0} \overset{(3)}{=} \big(\partial_i h\,\big|\,\partial_j h\big) - \mathbb{E}\,\big(n\,\big|\,\partial_i\partial_j h\big) \overset{(4)}{=} \big(\partial_i h\,\big|\,\partial_j h\big). \tag{10.69}$$

(1) $\partial_i(d-h|d-h) = -2(d-h|\partial_i h)$, because only h depends on $\boldsymbol{\theta}$.
(2) Product rule: the derivative hits either $d-h$ (giving $-\partial_j h$) or $\partial_i h$.
(3) At the true parameters $d - h(\boldsymbol{\theta}_0) = n$, the noise.
(4) $(n|a)$ has mean zero for any fixed signal a (10.43).

This is the **Fisher information matrix** of gravitational-wave astronomy, $\Gamma_{ij} = (\partial h/\partial\theta_i \,|\, \partial h/\partial\theta_j)$ [82, eq. (10)], [79, eq. (41)], written Γ by tradition where Section 10.1 wrote $\mathbf{F}$. Its other face, the covariance of the score, gives the same: the score is $S_i = \partial_i \ln\mathcal{L} = (n|\partial_i h)$ at the truth, and by (10.43) $\mathbb{E}[S_i S_j] = (\partial_i h|\partial_j h)$.

It is also the Gaussian formula (10.20) of Section 10.3 in disguise. Take as data vector the real and imaginary parts of all Fourier modes. Their means are $\mathrm{Re}\,\tilde h_k$ and $\mathrm{Im}\,\tilde h_k$, their covariance is diagonal with entries $\sigma_k^2/2 = \frac{T}{4}S_n(f_k)$ (10.39), with S_n the detector's noise spectrum (for LISA Eq. (T2.77)), and the covariance does not depend on $\boldsymbol{\theta}$. So the trace term vanishes and the mean term is $\sum_k[\mathrm{Re}\,\partial_i\tilde h_k\,\mathrm{Re}\,\partial_j\tilde h_k + \mathrm{Im}\,\partial_i\tilde h_k\,\mathrm{Im}\,\partial_j\tilde h_k]/(\sigma_k^2/2) = 4\Delta f\,\sum_k \mathrm{Re}(\partial_i\tilde h_k\,\partial_j\tilde h_k^*)/S_n(f_k)$, which is $(\partial_i h|\partial_j h)$. All information sits in the mean channel, because the detector noise does not care what the source is. Then, exactly as before, $\boldsymbol{\Sigma} = \Gamma^{-1}$ is the forecast covariance and $\sqrt{\Sigma_{ii}}$ the marginalised error of θ_i [82, eq. (11)].

10.9.2 The signal model and its derivatives

The waveform is the stationary-phase chirp derived in Section T2.5, $\tilde h(f) = \mathcal{A} f^{-7/6} e^{-i\Psi(f)}$: the Fourier transform of the inspiral, in which each frequency is built by the short stretch of the chirp that passes through it, with amplitude $\mathcal{A}$ (T2.56) and phase Ψ. We carry the phase to the order at which the mass ratio first appears. Cutler and Flanagan's restricted post-Newtonian (PN) phase (an expansion in powers of $(v/c)^2$, with v the orbital speed, Section T2.6) [82, eq. (42)] is, in our sign convention (the footnote to Eq. (T2.51) explains why theirs has $e^{+i\Psi}$),

$$\Psi(f) = 2\pi f t_c - \phi_c - \frac{\pi}{4} + \frac{3}{128}\,u^{-5/3}\left[1 + \frac{20}{9}\left(\frac{743}{336} + \frac{11}{4}\eta\right)x - 16\pi x^{3/2}\right],$$
$$u = \frac{\pi G\mathcal{M} f}{c^3}, \qquad x = u^{2/3}\eta^{-2/5}. \tag{10.70}$$

The Newtonian term is Eq. (T2.54): t_c and ϕ_c are the time and phase at which the binary would coalesce (Section T2.4.3), and $\mathcal{M}$ is the chirp mass, the one combination of the two masses that sets the Newtonian sweep (T2.42). The bracket adds the first and the 1.5PN corrections, derived term by term in Section T2.6 as (T2.67), with u the reduced frequency of (T2.58). Here $x = (\pi GMf/c^3)^{2/3}$ is $(v/c)^2$ with the total mass $M = \mathcal{M}\eta^{-3/5}$, and $\eta = m_1m_2/M^2$ is the symmetric mass ratio ([$\eta = 1/4$ for equal masses, $\eta \approx m_2/m_1$ when one is much lighter]). The parameters are $\boldsymbol{\theta} = (\ln\mathcal{M}, \ln\eta, t_c, \phi_c, \ln\mathcal{A})$; logarithms make the errors fractional.

The derivatives are short because every parameter but one sits in the phase. With $\tilde h = \mathcal{A} f^{-7/6} e^{-i\Psi}$,

$$\frac{\partial\tilde h}{\partial\ln\mathcal{A}} = \tilde h, \qquad \frac{\partial\tilde h}{\partial\theta} = -i\,\frac{\partial\Psi}{\partial\theta}\,\tilde h \quad \text{for } \theta \in \{\ln\mathcal{M}, \ln\eta, t_c, \phi_c\}, \tag{10.71}$$

with $\partial\Psi/\partial t_c = 2\pi f$, $\partial\Psi/\partial\phi_c = -1$, and the mass derivatives obtained term by term from (10.70): a term $u^{-5/3}x^k$ scales as $\mathcal{M}^{-5/3+2k/3}\eta^{-2k/5}$, so its logarithmic derivatives are $(-\frac{5}{3} + \frac{2k}{3})$

and $-\frac{2k}{5}$ times itself, and the explicit η in the 1PN coefficient adds $\frac{20}{9}\frac{11}{4}\eta\,x$. The library does exactly this:

Listing 10.7: Fisher matrix from the logarithmic derivatives of $\tilde h$ (`code/ch10/lib_gw10.py`)

```
169 def fisher_from_dlogh(f, amp2, Sn, D):
170     """D: array (P, Nf) of d ln h / d theta_i (complex). Returns the P x P Fisher matrix."""
171     w = 4.0 * amp2 / Sn
172     P = D.shape[0]
173     F = np.empty((P, P))
174     for i in range(P):
175         for j in range(i, P):
176             F[i, j] = F[j, i] = integ(f, w * np.real(D[i] * np.conj(D[j])))
177     return F
178
179
180 def phase_derivs(f, Mc, eta, b=None, order=1.5):
181     """d ln h/d theta for theta = (ln Mc, ln eta, tc, phic, ln A [, beta]) at beta = 0:
182     d ln h = -i dPsi for phase parameters and 1 for ln A; beta enters Psi as beta u^b."""
183     dM, de = dpsi_pn(f, Mc, eta, order)
184     rows = [-1j * dM, -1j * de, -1j * 2 * np.pi * f, -1j * (-1.0) + 0 * f, 1.0 + 0j * f]
185     if b is not None:
186         rows.append(-1j * u_of(f, Mc) ** b)
187     return np.array(rows)
```

Line 176 is (10.69) written with $D_i = \partial_i \ln\tilde h$: $(\partial_i h|\partial_j h) = 4\,\mathrm{Re}\int |\tilde h|^2 D_i D_j^*/S_n\,\mathrm{d}f$. Lines 183–187 are (10.71); the optional last row is the environmental term of Section 10.10. The integrals use a logarithmic frequency grid, $\int g\,\mathrm{d}f = \int gf\,\mathrm{d}\ln f$, because the integrand varies as a power of f.

10.9.3 Amplitude and phase separate; the phase block is a weighted average

Insert (10.71) into (10.69). Three things happen.

$$\Gamma_{\ln\mathcal{A}\,\ln\mathcal{A}} \overset{(1)}{=} (h|h) = \rho^2,$$
$$\Gamma_{\ln\mathcal{A}\,\theta} \overset{(2)}{=} 4\,\mathrm{Re}\int \frac{\tilde h\,\big(-i\partial_\theta\Psi\,\tilde h\big)^*}{S_n}\mathrm{d}f = 4\,\mathrm{Re}\Big[\,i\int \frac{|\tilde h|^2\partial_\theta\Psi}{S_n}\mathrm{d}f\Big] \overset{(3)}{=} 0,$$
$$\Gamma_{\theta\varphi} \overset{(4)}{=} 4\int \frac{|\tilde h|^2}{S_n}\,\partial_\theta\Psi\,\partial_\varphi\Psi\,\mathrm{d}f \overset{(5)}{=} \rho^2\,\big\langle \partial_\theta\Psi\,\partial_\varphi\Psi\big\rangle_w, \qquad w(f) \equiv \frac{4|\tilde h(f)|^2}{\rho^2 S_n(f)}. \tag{10.72}$$

(1) Definition of the signal-to-noise ratio.
(2) $\partial\tilde h/\partial\ln\mathcal{A} = \tilde h$, and $(-i)^* = i$.
(3) The integral is real, so i times it is purely imaginary, and its real part is zero.
(4) $(-i)(-i)^* = 1$: the phases cancel and only $|\tilde h|^2$ remains.
(5) $w(f)$ is positive and $\int w\,\mathrm{d}f = 1$, so $\langle g\rangle_w = \int wg\,\mathrm{d}f$ is an average over frequency, weighted by where the signal-to-noise ratio accumulates.

So the amplitude decouples from everything in the phase: $\Delta\mathcal{A}/\mathcal{A} = 1/\rho$ whatever else is unknown, the result Cutler and Flanagan state below their eq. (43). The distance is measured with an error of order $1/\rho$, a few per cent at best. The phase parameters are a different matter: their Fisher matrix is ρ^2 times the matrix of weighted averages of products of the phase derivatives. This is the formula to keep in mind.

What the marginalised error is. Single out one phase parameter β with $g(f) = \partial\Psi/\partial\beta$, and collect the derivatives with respect to the others into a vector $\boldsymbol{e}(f)$. By the Schur complement of

Section 10.4.1, the marginalised variance of β is

$$\frac{1}{\Sigma_{\beta\beta}} \overset{(1)}{=} \Gamma_{\beta\beta} - \Gamma_{\beta e}\Gamma_{ee}^{-1}\Gamma_{e\beta} \overset{(2)}{=} \rho^2\Big[\langle g^2\rangle_w - \langle g\boldsymbol{e}\rangle_w^{\mathsf{T}}\langle \boldsymbol{e}\boldsymbol{e}^{\mathsf{T}}\rangle_w^{-1}\langle \boldsymbol{e} g\rangle_w\Big] \overset{(3)}{=} \rho^2 \min_{\boldsymbol{c}} \big\langle (g - \boldsymbol{c}\cdot\boldsymbol{e})^2\big\rangle_w. \tag{10.73}$$

(1) The inverse of the $\beta\beta$ entry of Γ^{-1} is the Schur complement of the other parameters (Eq. (10.23)).
(2) Each block is ρ^2 times a weighted average, by (10.72).
(3) Minimise $Q(\boldsymbol{c}) = \langle (g - \boldsymbol{c}\cdot\boldsymbol{e})^2\rangle_w$: setting $\partial Q/\partial \boldsymbol{c} = 0$ gives the normal equations $\langle \boldsymbol{e}\boldsymbol{e}^{\mathsf{T}}\rangle \boldsymbol{c} = \langle \boldsymbol{e} g\rangle$ of weighted least squares (Chapter 3), and putting that $\boldsymbol{c}$ back gives $\langle g^2\rangle - \langle g\boldsymbol{e}\rangle^{\mathsf{T}}\langle \boldsymbol{e}\boldsymbol{e}^{\mathsf{T}}\rangle^{-1}\langle \boldsymbol{e} g\rangle$.

In words: fit the phase signature $g(f)$ of β by the best weighted combination of the other parameters' signatures. Whatever cannot be fitted, the residual $g_\perp = g - \boldsymbol{c}\cdot\boldsymbol{e}$, is what measures β, and

$$\sigma_\beta = \frac{1}{\rho\sqrt{\langle g_\perp^2\rangle_w}}. \tag{10.74}$$

A shift of β by σ_β therefore changes the phase, after the other parameters have absorbed all they can, by a weighted root-mean-square of exactly $1/\rho$ radians. Figure 10.25 draws this.

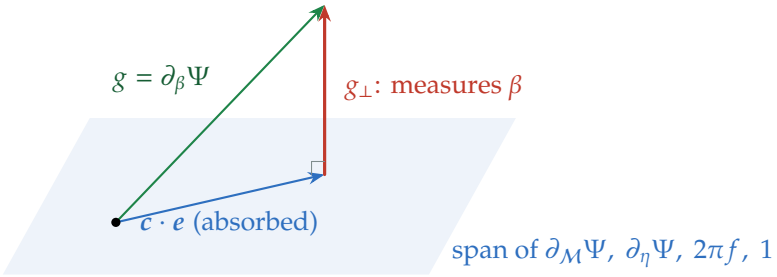

Figure 10.25: The marginalised error as a projection. Functions of frequency form a vector space with the weighted inner product $\langle a\, b\rangle_w$. The phase signature g of a parameter is split into the part that the other parameters can imitate (its projection on their span) and the residual $g_\perp$. Only $g_\perp$ carries information about β: $\sigma_\beta = 1/(\rho\,\|g_\perp\|_w)$. A signature nearly inside the plane is almost unmeasurable, however large it is.

Key idea: What makes a phase parameter measurable

For a chirp in Gaussian noise, $\Gamma_{\theta\varphi} = \rho^2\langle \partial_\theta\Psi\,\partial_\varphi\Psi\rangle_w$ with the weight $w = 4|\tilde h|^2/(\rho^2 S_n)$, and the amplitude decouples. A parameter is measured to $\sigma = 1/(\rho\|g_\perp\|_w)$, where $g_\perp$ is the part of its phase signature that no combination of the other parameters can imitate over the band where the signal-to-noise ratio accumulates.

10.9.4 Examples: timing, bandwidth, and a classic table

Example: the arrival time alone. If only t_c were unknown, $g = 2\pi f$ and nothing absorbs it, so $\sigma_{t_c} = 1/(2\pi\rho\sqrt{\langle f^2\rangle_w})$: the timing error is the period at the root-mean-square frequency of the signal, divided by $2\pi\rho$. For a $1.4 + 1.4\,M_\odot$ binary in the noise of [82, eq. (4)] between 10 Hz and the ISCO (the end of the inspiral, Eq. (T2.46)), the script `09_cf94.py` finds the weight of Figure 10.26, peaked near 55.35 Hz, with $\langle f\rangle_w = 64.26$ Hz and spread $\sigma_f = 44.14$ Hz. At $\rho = 10$, $\sigma_{t_c} = 0.2041$ ms.

Example: arrival time and phase. Now let ϕ_c be unknown too. Its signature is the constant -1, and the best constant fit to $2\pi f$ is $2\pi\langle f\rangle_w$, so $g_\perp = 2\pi(f - \langle f\rangle_w)$ and

$$\sigma_{t_c} = \frac{1}{2\pi\rho\,\sigma_f}, \qquad \sigma_f^2 = \langle f^2\rangle_w - \langle f\rangle_w^2. \tag{10.75}$$

A constant phase offset can imitate the mean frequency of a time shift, but not its spread, so what is left to measure the arrival time is the spread of frequencies in the signal, the **effective bandwidth** σ_f. This is the familiar radar result that timing needs bandwidth. The numbers give 0.3605 ms, and the 2×2 Fisher block gives 0.3605 ms, the same. With the two masses free as well, part of $2\pi f$ is absorbed by the mass terms, and the full matrix gives 0.713 ms (below). Each new nuisance parameter can only remove more of the signature, never add to it.

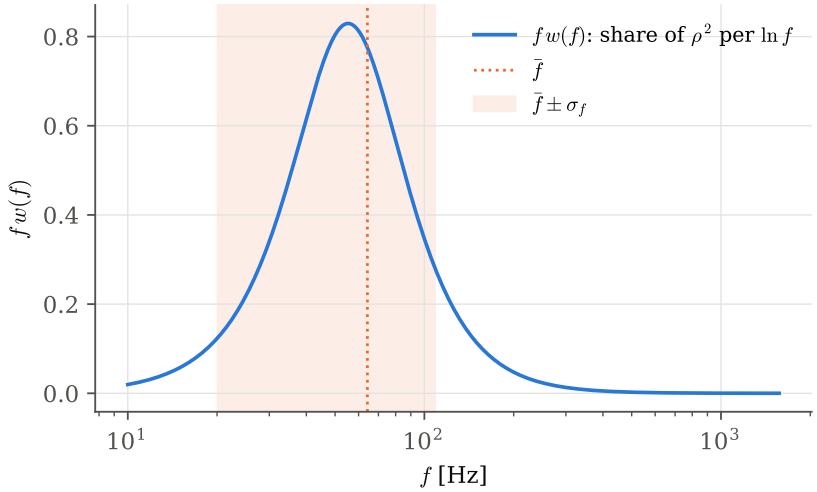

Figure 10.26: Where a $1.4 + 1.4\,M_\odot$ inspiral accumulates its signal-to-noise ratio in the advanced-detector noise of Cutler and Flanagan: $f\,w(f)$ is the share of ρ^2 per unit $\ln f$. The weight is a few tens of hertz wide; its mean (dotted) and spread (band) set the timing errors with and without an unknown phase.

Example: Cutler and Flanagan's Table I. The full five-parameter matrix is a test of the whole machinery, because Cutler and Flanagan published its result for five mass pairs [82, Table I], normalised to $\rho = 10$. They quote the chirp mass and the reduced mass $\mu = \eta M = \mathcal{M}\eta^{2/5}$, so we convert our $(\ln\mathcal{M}, \ln\eta)$ covariance with the Jacobian of $\ln\mu = \ln\mathcal{M} + \frac{2}{5}\ln\eta$ (Section 10.4.5). The comparison:

$m_1 + m_2$ [$M_\odot$]	$\Delta\phi_c$	Δt_c [ms]	$\Delta\mathcal{M}/\mathcal{M}$ [%]	$\Delta\mu/\mu$ [%]	$c_{\mathcal{M}\mu}$
2.0 + 1.0 paper / ours	1.31 / 1.306	0.721 / 0.7212	0.0038 / 0.003859	0.39 / 0.3951	0.899 / 0.899
1.4 + 1.4	1.28 / 1.282	0.713 / 0.7128	0.0040 / 0.004	0.41 / 0.4083	0.906 / 0.906
10 + 1.4	1.63 / 1.635	1.01 / 1.013	0.020 / 0.02036	0.54 / 0.5434	0.927 / 0.927
15 + 5	2.02 / 2.019	1.44 / 1.441	0.113 / 0.1137	1.5 / 1.519	0.954 / 0.9545
10 + 10	1.98 / 1.986	1.43 / 1.43	0.16 / 0.1566	1.9 / 1.944	0.958 / 0.9583

Every entry agrees to within 2.33%, which is the rounding of the published table and of their crude ISCO cut-off. Three features are the projection picture at work. The chirp mass is measured a hundred times better than the reduced mass, because $u^{-5/3}$ dominates the phase at low frequency while the mass ratio enters only through the smaller 1PN and 1.5PN terms. The two mass errors are strongly correlated ($c_{\mathcal{M}\mu} > 0.9$), because the 1PN signature of η is partly

imitated by the Newtonian signature of $\mathcal{M}$. And all errors grow with the total mass, because a heavier binary leaves the band at a lower ISCO frequency and spends fewer cycles in it.

Cutler and Flanagan state the noise density $p(n) \propto e^{-(n|n)/2}$, the Fisher matrix and its inverse in three equations [82, Sec. II B]. Between them lie the variance of a Fourier mode (Eq. (10.39)), the density of one realisation (Eq. (10.40)), the expected curvature of the log-likelihood (Eq. (10.69)) and the weighted-average form (Eq. (10.72)), which turns their table into a statement about projections of phase signatures.

Watch out: Normalised tables hide the distance

Forecast tables are often quoted at a fixed ρ (here 10; Eda et al. use 10, Barack and Cutler 30 [79]). Every Fisher error scales as $1/\rho$, so a table at $\rho = 10$ says nothing about whether a given source reaches $\rho = 10$. Always compute ρ for the source at its distance first, then rescale.

10.9.5 The Fisher matrix as a distance between waveforms

There is a second way to read Γ_{ij}, and it explains how searches are built. If the true wave has parameters $\boldsymbol{\theta}$ and the template has $\boldsymbol{\theta} + \Delta\boldsymbol{\theta}$, how much of the signal-to-noise ratio does the template recover? The **match** M is the normalised overlap

$$\mathsf{M}(h, h') = \frac{(h|h')}{\sqrt{(h|h)(h'|h')}} \le 1, \tag{10.76}$$

the cosine of the angle between the two waveforms in the space with inner product $(\cdot|\cdot)$; the bound is the Cauchy–Schwarz inequality, with equality when $h' \propto h$. A filter built with h' and run on a signal h has mean $\mathsf{M}\rho$ instead of ρ (by (10.44)), so $1 - \mathsf{M}$ is the fractional loss of signal-to-noise ratio. For a small change write the unit-norm waveform $\hat{h} = h/\rho$, so that $\mathsf{M} = (\hat{h}|\hat{h}')$. For two unit vectors $(\hat{h} - \hat{h}'|\hat{h} - \hat{h}') = 2 - 2\mathsf{M}$, and for phase parameters (which leave ρ unchanged, Eq. (10.72)) $\hat{h}' - \hat{h} \simeq \Delta\theta^i\, \partial_i h/\rho$. Therefore

$$1 - \mathsf{M} \overset{(1)}{=} \tfrac{1}{2}\big(\hat{h}' - \hat{h}\,\big|\,\hat{h}' - \hat{h}\big) \overset{(2)}{=} \frac{1}{2\rho^2}\,\Delta\theta^i \Delta\theta^j\,(\partial_i h|\partial_j h) \overset{(3)}{=} \frac{\Delta\boldsymbol{\theta}^{\mathsf{T}}\Gamma\,\Delta\boldsymbol{\theta}}{2\rho^2}. \tag{10.77}$$

(1) Expand the square with $(\hat{h}|\hat{h}) = (\hat{h}'|\hat{h}') = 1$.
(2) Insert $\hat{h}' - \hat{h} \simeq \Delta\theta^i \partial_i h/\rho$ and use bilinearity.
(3) The definition (10.69).

So Γ_{ij}/ρ^2 is the *metric* that measures how different two waveforms are, and the Fisher 1σ ellipsoid $\Delta\boldsymbol{\theta}^{\mathsf{T}}\Gamma\Delta\boldsymbol{\theta} = 1$ is the set of waveforms with $\rho^2(1 - \mathsf{M}) = \frac{1}{2}$: the template loses exactly the amount of log-likelihood that defines one standard deviation. A search bank is laid out by the same metric: the templates are spaced so that the worst match to any possible signal stays above a chosen value (typically 0.97), which is why high-ρ errors and bank densities are both set by Γ. The script (`16_whiten_chi2.py`) checks the expansion for a change of the chirp mass alone: for $\delta \ln \mathcal{M} = 10^{-4}, 3\times10^{-4}, 10^{-3}, 3\times10^{-3}$ the computed $1 - \mathsf{M}$ is 2.518×10^{-4}, 0.002262, 0.02475, 0.1961, against 2.519×10^{-4}, 0.002267, 0.02519 and 0.2267 from (10.77) with $\Gamma_{\ln\mathcal{M}\ln\mathcal{M}} = 1.259\times10^{6}$ (right panel of Figure 10.24). The two agree to a part in 10^3 for the smallest changes and separate once the phase has moved by a radian (where the surface of waveforms has curved away from its tangent plane, the content of Section 10.13.1).

10.10 Environments as power laws in the phase

A binary in vacuum loses energy only to gravitational waves. A binary inside a dark-matter spike, an accretion disc or a gas cloud loses some more: to the wake that drags behind the companion, to the matter it swallows, to the torque of the disc. Each of these makes the binary sweep through frequency a little faster, and by Eq. (T2.53) anything that changes the sweep rate changes the Fourier phase. The projection picture of Figure 10.25 tells us that whether LISA can see such a change depends on one thing only: the shape of the phase change as a function of frequency, and how well the vacuum parameters can imitate it. So the question is:

what shape does an environmental energy loss give to the phase, and how does the shape differ from one environment to the next?

The answer, derived in Section T2.10 for dynamical friction and in general form in Section T2.6, is that at leading order every smooth environment adds a single power of frequency, with an exponent fixed by its physics. That is what turns many separate dark-matter and astrophysics problems into one statistical problem with a single parameter, the exponent.

10.10.1 From an extra power to a power law in the phase

What the physics supplies. The derivation belongs to the theory and is done in Section T2.10; here we recall its result in the form the forecast needs. The orbit is quasi-circular and shrinks slowly (Section T2.4); the environment removes a power $P_{\rm env}$ on top of the gravitational-wave power $P_{\rm GW}$, with a small ratio that varies as a power of the radius, $\epsilon \equiv P_{\rm env}/P_{\rm GW} \propto r^p \ll 1$. Energy balance with the vacuum binding energy $E(f)$ of Eq. (T2.41) then speeds up the sweep by the factor $1+\epsilon$ (Eq. (T2.91)), and Kepler's law $r \propto f^{-2/3}$ turns the power of r into a power of f:

$$\dot f = \dot f_{\rm V}\,(1+\epsilon), \qquad \epsilon = c_f\, f^{-n}, \quad n = \frac{2p}{3}, \tag{10.78}$$

where $\dot f_{\rm V} = K f^{11/3}$, $K = \frac{96}{5}\pi^{8/3}(G\mathcal{M}/c^3)^{5/3}$, is the vacuum chirp rate (T2.43) and $\mathcal{M}$ the chirp mass. Because the curvature of the Fourier phase is $2\pi/\dot f$ (Eq. (T2.53): the slope of Ψ is the arrival time of each frequency, so a faster sweep bends it), integrating the change of curvature twice gives the environmental part of the phase (Eq. (T2.94)):

$$\delta\Psi(f) = -\frac{2\pi c_f}{K}\,\frac{f^{-n-5/3}}{(n+\frac{8}{3})(n+\frac{5}{3})} \overset{(1)}{=} -\frac{2\pi f^2}{\dot f_{\rm V}(f)}\,\frac{\epsilon(f)}{(n+\frac{8}{3})(n+\frac{5}{3})} \overset{(2)}{=} \beta\, u^b, \qquad b = -\frac{5}{3} - n. \tag{10.79}$$

(1) Rewrite $c_f f^{-n-5/3}/K = f^2\epsilon(f)/\dot f_{\rm V}(f)$.

(2) With the reduced frequency $u = \pi G\mathcal{M} f/c^3$ of (T2.58), every power of f is a power of u; the constants are collected in β. The two integration constants, $a_0 + a_1 f$, are a shift of ϕ_c and t_c and are absorbed by those parameters.

The middle form is the one the analysis uses: it gives the phase shift at any frequency directly from the ratio ϵ there. The factor $2\pi f^2/\dot f_{\rm V}$ is 2π times the number of cycles the binary spends near f (per unit $\ln f$), so in words the phase shift is "the fractional speed-up times the number of radians spent there, divided by a number of order ten". The last form is the **parametrised post-Einsteinian** (ppE) phase correction of Yunes and Pretorius [86, eq. (1)]: β carries the strength of the effect and b its physics (Eq. (T2.69), where the same rule is derived for any correction that scales as a power of the orbital speed). In post-Newtonian language, the expansion in powers of $(v/c)^2$ of Section T2.6, a relative correction $\epsilon \propto f^{-n} = (v/c)^{-3n}$ enters at order $-\frac{3}{2}n$ PN.

10.10.2 The exponents of the common environments

Each exponent follows from how $P_{\rm env}/P_{\rm GW}$ scales with r, and $P_{\rm GW} = \frac{32}{5}G^4M^3\mu^2/(c^5r^5)$ (the quadrupole power of a circular binary, Eq. (T2.27)) falls as r^{-5}, steeper than almost anything an environment does. That is why environments matter at large radius, at the low-frequency start of the band.

Dynamical friction in a spike. Chandrasekhar's drag in a density $\rho \propto r^{-\gamma}$ removes $P_{\rm DF} = 4\pi G^2 m_2^2 \rho \ln\Lambda/v$ with $v = \sqrt{GM/r}$ (Eq. (T2.87)). Divided by $P_{\rm GW} \propto r^{-5}$ this is $\propto \rho\, r^{11/2} \propto r^{11/2-\gamma}$, with the constants worked out in Eq. (T2.92) [77, eq. (16)], [83, eq. (16)]. So

$$p = \tfrac{11}{2} - \gamma, \qquad n = \tfrac{11-2\gamma}{3}, \qquad b = \tfrac{2\gamma-16}{3}.$$

For the adiabatic spike $\gamma = 7/3$ this is $b = -34/9 \approx -3.78$, a -3.2PN effect.

Gas accretion onto the central black hole. Suppose the heavy hole grows at a fraction $f_{\rm Edd}$ of the Eddington rate, $\dot M/M = f_{\rm Edd}/t_{\rm S}$ with the Salpeter time $t_{\rm S} \approx 4.5\times10^7$ yr. The companion feels a slowly growing central mass. Its specific angular momentum $\sqrt{GMr}$ is conserved (the force is still central), so $r \propto 1/M$, and Kepler's law $\omega^2 = GM/r^3$ gives $\omega \propto M^2$, hence $\dot f/f = 2\dot M/M$ in addition to the radiative sweep. The fractional speed-up is

$$\epsilon = \frac{2f\,\dot M/M}{\dot f_{\rm V}} \propto \frac{f}{f^{11/3}} = f^{-8/3}, \qquad n = \tfrac{8}{3}, \quad b = -\tfrac{13}{3},$$

a -4PN effect, as for the mass changes discussed by Barausse et al. [87, Sec. XII].

Migration in a thin disc. A companion embedded in a thin accretion disc exchanges angular momentum with it. For type-I migration far from the inner edge, Barausse et al. find $\dot L_{\rm migr}/\dot L_{\rm GW} = 10^{-5} f_{\rm Edd}^{2/5} (M/10^6 M_\odot)^{7/5} (\alpha/0.1)^{-3/5} \tilde r^{7/2}$, with $\tilde r = rc^2/(GM)$ and α the disc viscosity parameter [87, eq. (108)]. On a circular orbit $\dot E = \omega \dot L$ for both torques, so the energy ratio is the same and $p = 7/2$, $n = 7/3$, $b = -4$.

effect	$\epsilon = P_{\rm env}/P_{\rm GW} \propto$	$b = -\frac{5}{3} - n$	PN order
friction, spike $\rho \propto r^{-\gamma}$ [77, 84]	$r^{11/2-\gamma}$	$\frac{2\gamma-16}{3}$ (-3.78 at $\frac{7}{3}$)	$\gamma - \frac{11}{2}$
friction, uniform medium	$r^{11/2}$	$-\frac{16}{3}$	-5.5
collisionless accretion, spike [87]	$r^{9/2-\gamma}$	$\frac{2\gamma-14}{3}$	$\gamma - \frac{9}{2}$
enclosed dark-matter mass (no loss) [77, 83]	$r^{3-\gamma}$	$\frac{2\gamma-11}{3}$	$\gamma - 3$
Eddington accretion onto m_1	$f^{-8/3}$	$-\frac{13}{3}$	-4
type-I migration, thin disc [87]	$r^{7/2}$	-4	-3.5
dipole radiation (Brans–Dicke) [86]	r	$-\frac{7}{3}$	-1
massive graviton (propagation) [86]	—	-1	$+1$
GR: chirp mass, 1PN, 1.5PN, ϕ_c, t_c	—	$-\frac{5}{3}$, -1, $-\frac{2}{3}$, 0, 1	
vector ultralight dark matter [95]	a step at a resonance: not a power law		

Table 10.5: Leading-order exponents of environmental and beyond-GR phase corrections $\delta\Psi = \beta u^b$. The PN order of a relative correction $\epsilon \propto f^{-n}$ is $-\frac{3}{2}n$. The GR exponents in the last block are the signatures every environmental term must be distinguished from.

Table 10.5 collects these. All the dissipative environments sit at $b \lesssim -3$, well below the chirp-mass exponent $-5/3$; the propagation and dipole corrections of modified gravity sit

between $-7/3$ and -1, in the middle of the GR terms. Figure 10.27 shows what that means on the frequency axis.

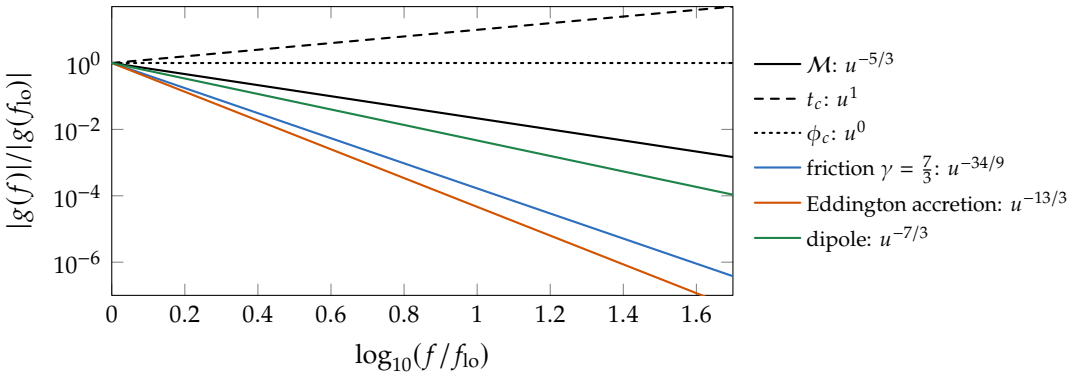

Figure 10.27: Phase signatures over the LISA band of the benchmark binary (a factor 50 in frequency), normalised at the start frequency f_{lo}. On these axes each is a straight line of slope b. The environmental signatures fall far more steeply than the chirp-mass one and are concentrated in the first fraction of a decade; a dipole term lies close to the chirp-mass line and is easily imitated by it.

10.10.3 Example: how large is each effect for one source?

Take the benchmark of Section T2.4 that recurs below: a $10^3 + 1.4\,M_\odot$ intermediate mass-ratio inspiral observed for the last five years before its ISCO (the innermost stable circular orbit, where the inspiral ends, Eq. (T2.46)), from $f_{lo} = 19.96\,\mathrm{mHz}$ up to 1 Hz (its ISCO is at 4.391 Hz, above the LISA band), chirp mass $19.39\,M_\odot$. The script `10_env_phases.py` evaluates $\epsilon(f)$ for each effect with the parameters of the literature (the spike density $\rho_6 = 5.45 \times 10^{15} M_\odot\,\mathrm{pc}^{-3}$ at 10^{-6} pc of Coogan et al. [84], $\xi = 0.58$, $\ln\Lambda = \ln\sqrt{m_1/m_2}$; $f_{\rm Edd} = 1$ for gas accretion; $f_{\rm Edd} = 0.1$, $\alpha = 0.1$ for the disc) and converts it to $\delta\Psi$ with (10.79). At the start of the band:

effect	b	$\epsilon(f_{lo})$	$\lvert\delta\Psi(f_{lo})\rvert$ [rad]
friction, spike $\gamma = 7/3$	-3.778	0.6913	2.021×10^6
friction, spike $\gamma = 3/2$	-4.333	0.01549	35351
collisionless accretion, $\gamma = 7/3$	-3.111	0.006635	27371
enclosed mass, $\gamma = 7/3$ (order of magnitude)	-2.111	4.911×10^{-6}	39.45
Eddington gas accretion onto m_1	-4.333	5.926×10^{-7}	1.353
type-I migration, thin disc	-4	0.03892	1.027×10^5

A tiny ϵ can still give a large phase shift, because $2\pi f^2/\dot f_{\rm V}$ is enormous for a binary that spends years near f_{lo}: an Eddington-limited growth that changes the sweep rate by six parts in ten million still shifts the phase by more than a radian. Before trusting the closed form, the script compares it with the exact double integral of $2\pi/\dot f - 2\pi/\dot f_{\rm V}$ for a weak spike; after removing the $a_0 + a_1 f$ that t_c and ϕ_c absorb, they differ by 2.285×10^{-6} of the shift.

Figure 10.28 shows the whole band. One number in the table is a warning: for the static $7/3$ spike, $\epsilon(f_{lo}) = 0.6913$, because friction equals radiation at $f_{\rm eq} = 16.75\,\mathrm{mHz}$, just below the band (Section T2.10). There the expansion in ϵ is not valid, and the full dephasing Eq. (T2.96) must be used. The power law is a statement about weak environments, which are precisely the ones whose detectability is in question.

The hidden assumption, and a counterexample. "An environment is a power law in the phase" contains an assumption: that the environment changes smoothly and monotonically

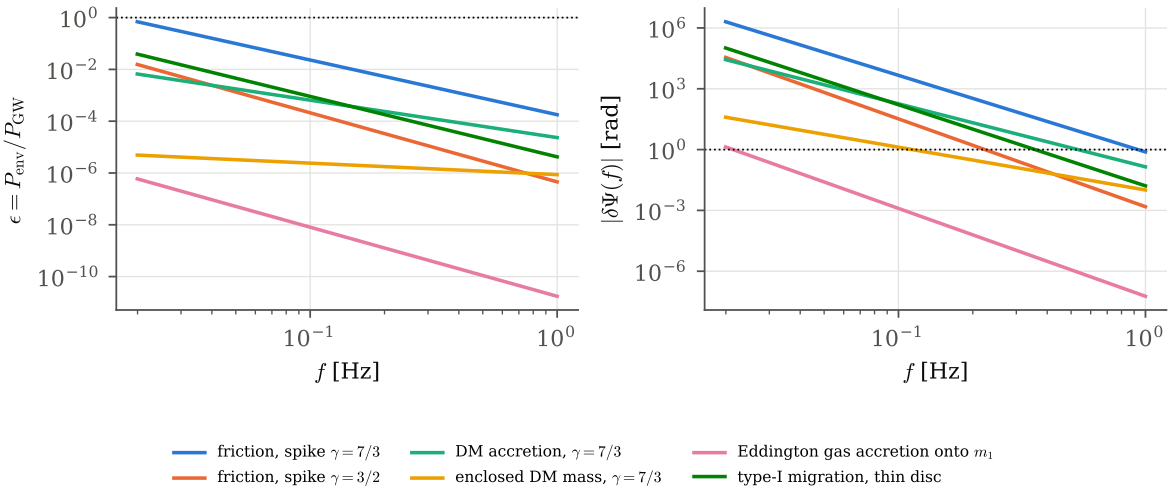

Figure 10.28: The six effects for the $10^3 + 1.4\,M_\odot$ binary over its last five years in the LISA band. Left: the ratio ϵ of environmental to gravitational-wave power; each is a power law falling towards high frequency. Right: the resulting Fourier-phase shift (10.79); the dotted line marks one radian. All shifts are largest at the start of the band.

with radius, so a single power of r describes it across the band. A vector ultralight dark-matter field breaks it. Its oscillating potential does nothing on average until the orbital frequency crosses a resonance with the field, and then shifts the orbit within a narrow band [95]. Chase, López Nacir and Yunes find that the resulting phase correction is a step, and that below the threshold it is partly degenerate with t_c and ϕ_c. In the projection picture this is no surprise: a correction of the form $a_0 + a_1 f$ lies entirely in the span of the ϕ_c and t_c signatures, $g_\perp = 0$, and it is invisible however large it is. Only the sudden switch-on, which no smooth GR term can imitate, can be measured. So the lesson in one line: *a phase correction is measured by its shape, not its size*.

10.11 One forecast for every environment

The two previous sections give us all the pieces. Section 10.9 says that a phase parameter is measured by the part of its signature that the vacuum parameters cannot imitate, and Section 10.10 says that the signature of any smooth environment is a single power, $\delta\Psi = \beta u^b$, with an exponent set by its physics: the ppE form of Eq. (T2.69), with $u = \pi G\mathcal{M}f/c^3$ the reduced frequency, β the strength and b the exponent. So instead of writing one forecast for dark-matter friction, another for accretion and another for a gas disc, we can ask a single question for a given source:

for each exponent b, what is the smallest amplitude β that LISA would detect?

One Fisher matrix per value of b answers it, and the answer is one curve. Every environment then becomes a point, above or below the curve. We build that curve for the benchmark intermediate mass-ratio inspiral and read it.

10.11.1 The noise curve, checked against its source

The forecast weights each frequency by $1/S_n(f)$, the one-sided noise spectrum of Section 10.8.2, so the noise model comes first. We use the sky-averaged LISA sensitivity of Robson, Cornish

and Liu [80, eqs. (10)–(14)]: optical metrology and test-mass acceleration noise, divided by the sky-averaged response of two Michelson channels (the factor $\frac{3}{10}$ of Eq. (T2.37): how strongly a source at a random place on the sky registers), plus the Galactic confusion noise for a four-year mission. Its pieces are derived and explained in Section T2.7; the formula is Eq. (T2.77). The script `11_lisa_robson.py` implements it independently of chapter T2 (the two agree to 4.441×10^{-16}) and checks it against what the paper itself shows and computes.

Their figure. The script renders page 6 of the paper, finds the frame of Figure 4, calibrates its axes and reads the curve of $\sqrt{S_n}$ from the colour of its pixels. Figure 10.29 overlays the digitised points on our curve. Below 30 mHz they agree to within 8.594%, the precision of reading a plotted line; at $f = 1$, 10 and 100 mHz the ratios ours/theirs are $2.880 \times 10^{-19}/2.894 \times 10^{-19}$, $1.201 \times 10^{-20}/1.173 \times 10^{-20}$ and $4.615 \times 10^{-20}/4.019 \times 10^{-20}$. The last is 15% high: above the transfer frequency $f_* = c/(2\pi L) = 19.09$ mHz (their 19.09 mHz), where the wave's phase advances by a radian while light crosses one arm, so the arm starts to average the wave away (Eq. (T2.38)), their plot uses the exact numerical response, which oscillates, while the formula uses the smooth fit $R(f) = \frac{3}{10}/[1 + 0.6(f/f_*)^2]$ of their eq. (9). The wiggles are visible in the digitised points; the fit runs through their average.

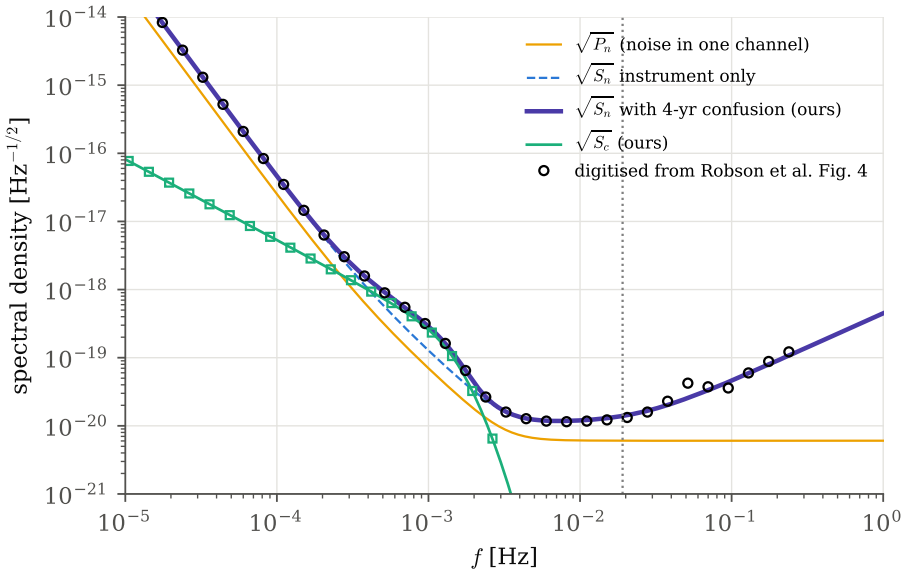

Figure 10.29: The LISA sensitivity used in all forecasts, against Figure 4 of Robson, Cornish and Liu digitised from the published PDF (open circles: $\sqrt{S_n}$; open squares: the Galactic confusion noise $\sqrt{S_c}$). The thick curve includes four years of confusion noise; the thin dashed one is the instrument alone. Above the transfer frequency (dotted) the published curve shows the oscillations of the exact detector response, which the fit smooths.

Their worked numbers. Robson et al. quote three numbers that test both the curve and the signal normalisation.

- *A verification binary.* SDSS J0651+2844 ($0.5 + 0.25\,M_\odot$, $D_L \approx 1$ kpc, $f = 2.6$ mHz) barely changes frequency in four years, so its signal-to-noise integral collapses to one frequency. With the stationary-phase amplitude $|\tilde h| = \frac{1}{2}A_t \dot f^{-1/2}$ (Eq. (T2.51)) and the band $\Delta f = \dot f T$ swept in a time T,

$$\rho^2 \overset{(1)}{=} \frac{16}{5}\int \frac{|\tilde h|^2}{S_n}\mathrm{d}f \overset{(2)}{=} \frac{16}{5}\,\frac{A_t^2 T}{4S_n(f)} \overset{(3)}{=} \frac{h_{\mathrm{GB}}^2}{S_n(f)}, \qquad h_{\mathrm{GB}} = \frac{8\,T^{1/2}(G\mathcal{M}/c^3)^{5/3}\pi^{2/3}f^{2/3}}{5^{1/2}D_L/c},$$

(1) Sky-, polarisation- and inclination-averaged signal-to-noise ratio (Eq. (T2.80)); the $\frac{4}{5}$ in $\frac{16}{5} = 4 \cdot \frac{4}{5}$ is the inclination average (T2.36)), with $|\tilde{h}|$ the face-on stationary-phase amplitude.
(2) $\int |\tilde{h}|^2 \mathrm{d}f = \frac{1}{4} A_t^2 \int \mathrm{d}f/\dot{f} = \frac{1}{4} A_t^2 T$, the amplitude and S_n being constant over the tiny band.
(3) $A_t = 4(G\mathcal{M})^{5/3}(\pi f)^{2/3}/(c^4 D_L)$, so $\frac{16}{5} \cdot \frac{16}{4} = \frac{64}{5}$ and $\sqrt{64/5} = 8/\sqrt{5}$: their eq. (27).

We obtain $\rho = 139.8$; they quote 140. (Without the confusion noise it would be 147.6: at 2.6 mHz the unresolved Galaxy matters.) Our $h_{\mathrm{GB}} = 3.107 \times 10^{-18}\,\mathrm{Hz}^{-1/2}$ is 10% above the 2.8×10^{-18} they print, although the signal-to-noise ratios agree; the printed amplitude is inconsistent with their own $\rho = 140$ and is presumably rounded from slightly different inputs.

- *A GW150914-like binary* five years before merger sweeps from 16 to 29 mHz during four years; we find 15.83 and 28.94 mHz (Section T2.4 derives it by hand).
- *An equal-mass* $10^6 M_\odot$ *binary at* $z = 3$ radiates at 2.93×10^{-5} Hz one year before merger when the detector-frame mass $(1+z)M$ is used; we find 2.927×10^{-5} Hz.

10.11.2 The benchmark source and its vacuum errors

The source is the $10^3 + 1.4\,M_\odot$ binary of Section 10.10.3 at $D_L = 76$ Mpc, the distance of the astrophysical benchmark of Coogan et al. [84]. LISA observes its last five years before the ISCO (Eq. (T2.46)), from $f_{\mathrm{lo}} = 19.96$ mHz to the 1 Hz edge of the band, and the sky-averaged signal-to-noise ratio is $\rho = 13.25$. The parameters are those of Section 10.9.2 (chirp mass, mass ratio, coalescence time t_c and phase ϕ_c, amplitude; their physical meaning is listed in Table T2.1) plus the environmental amplitude,

$$\boldsymbol{\theta} = (\ln \mathcal{M},\ \ln \eta,\ t_c,\ \phi_c,\ \ln \mathcal{A},\ \beta), \qquad \Psi = \Psi_{1.5\mathrm{PN}} + \beta u^b, \tag{10.80}$$

with $\Psi_{1.5\mathrm{PN}}$ the phase (10.70) through 1.5 post-Newtonian order (Section T2.6), evaluated at the vacuum, $\beta = 0$: the question is whether the data could tell an environment apart from no environment. Without the environmental term, the five-parameter errors are $\sigma_{\ln\mathcal{M}} = 2.622\times10^{-7}$, $\sigma_{\ln\eta} = 2.700 \times 10^{-4}$, $\sigma_{t_c} = 2.904$ s, $\sigma_{\phi_c} = 6.778$ rad and $\sigma_{\ln\mathcal{A}} = 0.07545 = 1/\rho$. The chirp mass is fixed to a few parts in ten million because the binary completes about a million cycles in the band; this is the reservoir of precision an environment can draw on.

10.11.3 The error on β as a function of the exponent

The script `12_ppe_scan.py` computes the six-parameter Fisher matrix for 815 values of b between -6.5 and 1.6:

Listing 10.8: One Fisher matrix per exponent (`code/ch10/12_ppe_scan.py`)

```
for b in bs:
    F = L.ppe_fisher(f, Mc, eta, DL, Sn, b)
    C = L.inv_scaled(F)
    s = np.sqrt(np.diag(C))
    sig.append(s[5]); sigc.append(1 / np.sqrt(F[5, 5]))
    Dlo.append(3 * s[5] * u_lo**b)
    R = C / np.outer(s, s)
    cMc.append(R[5, 0]); ceta.append(R[5, 1]); ctc.append(R[5, 2]); cphi.append(R[5, 3])
    keep = [0, 2, 3, 4, 5]                          # the same with eta known
    cMc4.append(L.corr(F[np.ix_(keep, keep)])[4, 0])
```

Line 49 is (10.69) with the extra row $\partial \ln \tilde{h}/\partial\beta = -iu^b$. Line 52 records both the marginalised error and the error with all other parameters known, $1/\sqrt{\Gamma_{\beta\beta}}$. Line 53 turns σ_β into a phase: a 3σ shift at the start of the band. The lines that follow redo the calculation in the projection form (10.74), fitting u^b with the vacuum signatures by weighted least squares; the two agree to 2.809×10^{-9}.

Because β multiplies a different power of u for each b, its value is not comparable across b. A physical measure is the phase shift it produces where it is largest, $\sigma_\beta u_{\rm lo}^b$ at $f_{\rm lo}$. Figure 10.30 shows it.

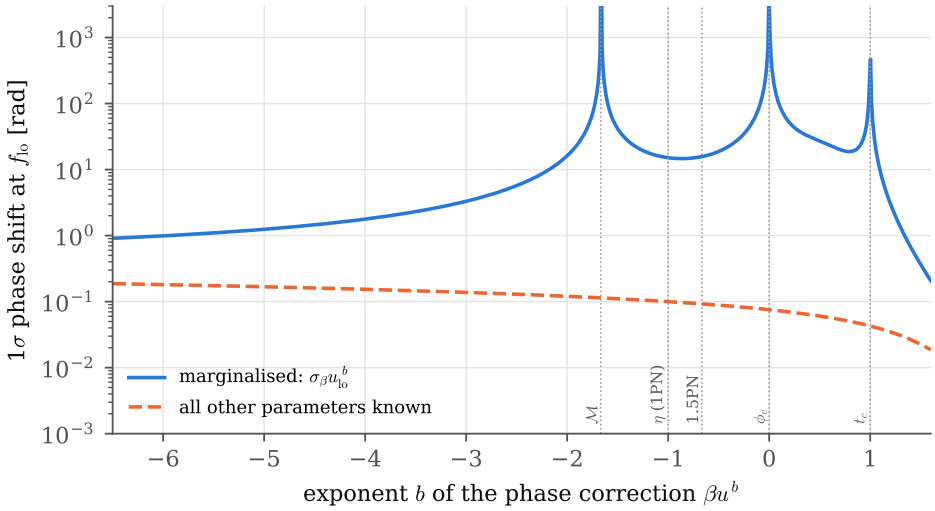

Figure 10.30: The 1σ error of a power-law phase correction, expressed as the phase shift it allows at the start of the band, for the benchmark binary ($\rho = 13.25$). Solid: marginalised over $\ln\mathcal{M}$, $\ln\eta$, t_c, ϕ_c and $\ln\mathcal{A}$. Dashed: with all of them known. The marginalised error diverges where u^b coincides with a vacuum signature: the chirp mass ($b = -5/3$), the phase ($b = 0$) and the arrival time ($b = 1$).

Three things are visible. First, the error diverges at $b = -5/3$, 0 and 1, where u^b is exactly the signature of $\ln\mathcal{M}$, ϕ_c or t_c: there $g_\perp = 0$ and the correction is simply reabsorbed into a wrong chirp mass, phase or arrival time. Second, near the 1PN and 1.5PN exponents (-1, $-2/3$) the error is large but finite: those terms are tied to η with fixed coefficients, so η can imitate only one combination of them. Third, the marginalised error is far larger than the conditional one even away from the singular points: by a factor 11.55 at $b = -4$, 58.43 at the dipole exponent $-7/3$ and 150.8 at the massive-graviton exponent -1. A forecast that holds the masses fixed would be wrong by these factors.

10.11.4 Correlations: why low-frequency effects separate from the chirp mass

The correlation coefficient between two parameters is, in the projection picture, the cosine of the angle between their signatures (after removing the others). For β and $\ln\mathcal{M}$ alone it is $\langle u^b u^{-5/3}\rangle_w / \sqrt{\langle u^{2b}\rangle_w \langle u^{-10/3}\rangle_w}$, and the Cauchy–Schwarz inequality says this is one only if the two functions are proportional over the band. Two decreasing powers look more and more alike as their exponents approach each other, and more and more different as they separate. An effect with $b \ll -5/3$ is concentrated in the first fraction of a decade above $f_{\rm lo}$ (Figure 10.27), while the chirp-mass signature is spread over the whole band. That is why low-frequency effects decorrelate from the chirp mass.

The script shows it directly (Figure 10.31). With η known, the correlation of β with $\ln\mathcal{M}$ is 0.9988 at $b = -2$, 0.9635 at $b = -4$ and 0.8648 at $b = -8$. With η free, the picture changes in an instructive way: η is now the parameter whose signature is closest to the environmental one

(its correlation with β is 0.7417 at $b = -4$), and the correlation with the chirp mass drops to -0.5391. The arrival time, whose signature $2\pi f$ grows with frequency, is the least similar of all, with a correlation near 0.5091 for every steep effect. Across the singular points the correlations jump between ± 1: on one side u^b is slightly steeper than $u^{-5/3}$, on the other slightly flatter, and the sign of the compensating chirp-mass error flips.

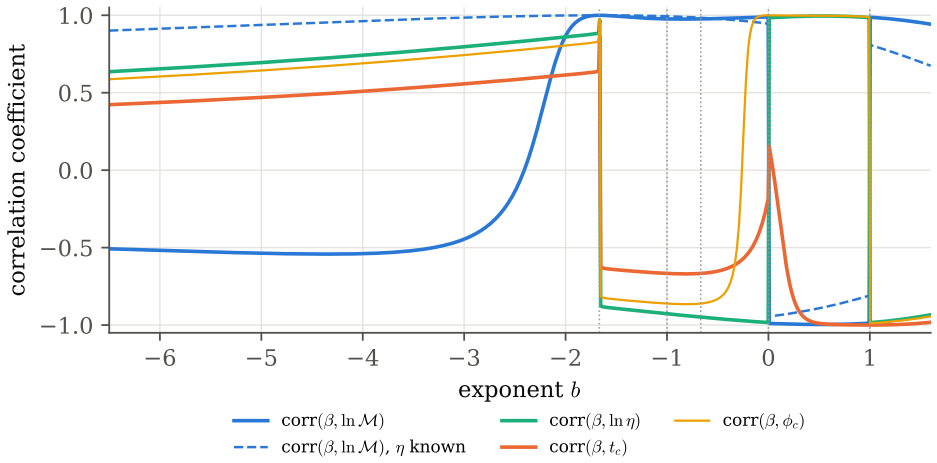

Figure 10.31: Correlation of the environmental amplitude β with the vacuum parameters as a function of the exponent. Dashed: with $\ln \mathcal{M}$ when η is known, which falls steadily as b moves below $-5/3$. Solid: all parameters free; η then takes over part of the chirp-mass role. Dotted verticals mark the GR exponents.

10.11.5 The detectability map

Now the single curve. An environment with exponent b and amplitude β is detected at 3σ if $|\beta| > 3\sigma_\beta(b)$, that is if the phase shift it produces at the start of the band exceeds

$$\delta\Psi_{\rm det}(b) = 3\,\sigma_\beta(b)\,u_{\rm lo}^{b}. \tag{10.81}$$

The predicted shift of each physical effect at $f_{\rm lo}$ is the last column of the table in Section 10.10.3. Figure 10.32 puts them together.

Reading the map, in units of the forecast error σ_β for each predicted amplitude:

- friction in a static $\gamma = 7/3$ spike: $1.023 \times 10^6\,\sigma$; in a $\gamma = 3/2$ spike: $22864\,\sigma$;
- collisionless accretion in the 7/3 spike: $9074\,\sigma$;
- type-I migration in a thin disc: $57840\,\sigma$;
- the pull of the enclosed dark matter: $3.36\,\sigma$, marginal;
- Eddington-limited gas accretion onto the heavy hole: $0.875\,\sigma$, not detected.

The dissipative dark-matter and disc effects are not just detectable, they dominate the phase; the problem for them is modelling, not detection (Section 10.12 shows how much the model matters). The two weak effects sit near the curve, where the forecast decides.

The same curve in physical units. For friction, β is proportional to the spike density as long as $\epsilon \ll 1$, so the curve converts into a smallest detectable density. Figure 10.33 shows it as a function of distance (the threshold grows in proportion to D_L, because $\rho \propto 1/D_L$). At 76 Mpc

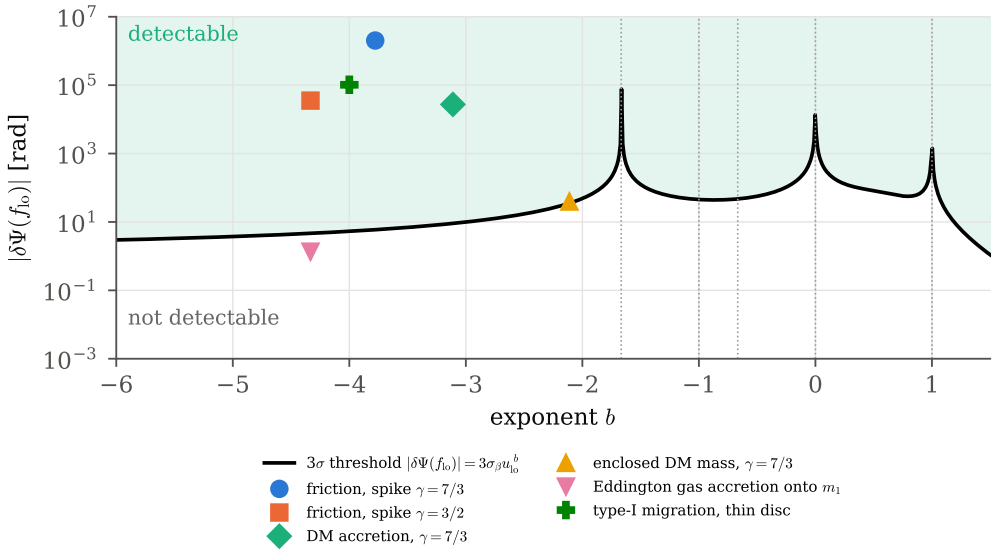

Figure 10.32: Detectability map for the $10^3 + 1.4\,M_\odot$ binary at 76 Mpc ($\rho = 13.25$). The black curve is the phase shift at the start of the band that LISA would detect at 3σ, for every exponent b; the shaded region above it is detectable. Points are the effects of Section 10.10.3 at their exponents. Everything above the curve is seen; the curve moves down in proportion to $1/\rho$ for closer sources.

LISA would see friction from a $\gamma = 7/3$ spike with ρ_6 as low as $1.597 \times 10^{10}\,M_\odot\,\mathrm{pc}^{-3}$ at 10^{-6} pc, five orders of magnitude below the static benchmark; for $\gamma = 2$ and $3/2$ the thresholds are 7.270×10^{10} and 7.148×10^{11}. Above the dotted lines, friction exceeds radiation already at $f_{\rm lo}$ ($\rho_6 > 7.881 \times 10^{15}$ for $\gamma = 7/3$) and the power-law forecast is not applicable; the benchmark density sits just below that line.

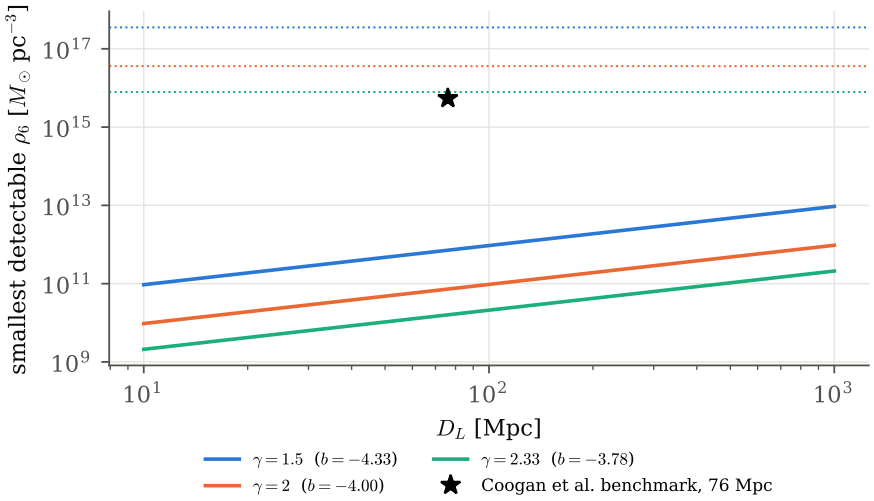

Figure 10.33: Smallest spike density at 10^{-6} pc whose dynamical friction LISA would detect at 3σ in this binary, against luminosity distance, for three spike slopes. Dotted: the density at which friction equals radiation at the start of the band, above which the small-ϵ expansion fails. The star is the astrophysical benchmark of Coogan et al.

Key idea: When is an environment detectable?

Write the environment as $\delta\Psi = \beta u^b$. Fit it with the vacuum parameters by weighted least squares over the band, weight $w \propto |\tilde{h}|^2/S_n$. It is detected at $k\sigma$ when the weighted root-mean-square of the residual phase exceeds k/ρ radians. The rule "a dephasing of more than a radian is detectable" [83] keeps the radian but forgets both the $1/\rho$ and the part that the masses, arrival time and phase can absorb.

How the error scales with the signal strength. In the Fisher approximation every error scales exactly as $1/\rho$: double the distance and the curve rises by two. Whether that scaling holds at the signal-to-noise ratios of real sources is a separate question, answered in Section 10.13 by comparing with a Markov chain.

10.12 Reproducing the published forecasts

A forecast printed in a paper is a claim: "with this source, this detector and this model, the spike slope would be measured to a part in a million". We can trust such a claim only if we can make it again ourselves, with our own code, and land on the same number, or explain why we do not. Two of the claims already passed: the LISA noise curve and its worked examples (Section 10.11.1) and Cutler and Flanagan's table of errors (Section 10.9.4). Here are the two dark-matter forecasts on which most of the later literature builds. Eda, Itoh, Kuroyanagi and Silk [77] put an intermediate-mass black hole inside a static dark-matter spike and asked how well an eLISA-like detector would measure the spike. Kim, Lenoci, Stomberg and Xue [81] repeated the question for wave-like (ultralight) dark matter, with LISA, a halo that loses its inner modes to the black hole, and a full Bayesian posterior.

The procedure is the same for both. First derive the quantity the paper plots, from what is already established. Then rebuild the paper's model, ingredient by ingredient, and compute the same quantity. Then compare, number by number, and when the two disagree, ask what could have produced the disagreement before deciding.

10.12.1 The two phases that papers plot

Both papers summarise the effect of the dark matter by a "phase difference" accumulated between a frequency f and the end of the inspiral. They do not mean the same phase. One is the phase of the Fourier transform, the quantity that enters the likelihood. The other is the phase of the wave in time, which counts cycles. Both follow from the stationary-phase formula of Section T2.5, so we derive both once.

Inputs. The Fourier phase is $\Psi(f) = 2\pi f t(f) - \phi(t(f)) - \pi/4$ (Eq. (T2.51); in words, the Fourier component at f is built by the short stretch of the chirp that passes through f), where $t(f)$ is the time at which the chirp passes through frequency f and $\phi(t)$ is the phase of the wave in time, with $\mathrm{d}\phi/\mathrm{d}t = 2\pi f$. The sweep rate $\dot{f}(f)$ is whatever the physics gives: vacuum (Eq. (T2.43), set by the chirp mass $\mathcal{M}$), or vacuum plus friction (Eq. (T2.91)). Let the signal end at f_I (the ISCO, Eq. (T2.46)) at the time t_c with the phase ϕ_c (the coalescence constants of Section T2.4.3). Then

$$t(f) \overset{(1)}{=} t_c - \int_f^{f_I} \frac{\mathrm{d}f'}{\dot{f}(f')}, \qquad \phi(t(f)) \overset{(2)}{=} \phi_c - 2\pi \int_f^{f_I} \frac{f'\,\mathrm{d}f'}{\dot{f}(f')},$$

$$\Psi(f) \overset{(3)}{=} 2\pi f t_c - \phi_c - \frac{\pi}{4} + 2\pi \int_f^{f_I} \frac{f'-f}{\dot{f}(f')}\,\mathrm{d}f' \equiv 2\pi f t_c - \phi_c - \frac{\pi}{4} + \tilde{\Phi}(f). \tag{10.82}$$

(1) The time it takes to sweep from f to f_I is the sum of $\mathrm{d}t = \mathrm{d}f'/\dot{f}$ over the frequencies in between.
(2) The phase accumulated over the same interval is $\int 2\pi f' \mathrm{d}t = 2\pi \int f' \mathrm{d}f'/\dot{f}$.
(3) Insert both into Ψ and collect the two integrals under one sign: $2\pi f \int \mathrm{d}f'/\dot{f}$ and $2\pi \int f' \mathrm{d}f'/\dot{f}$ combine into $2\pi \int (f' - f)\mathrm{d}f'/\dot{f}$.

The integral $\tilde{\Phi}(f)$ is Eda et al.'s eq. (28c), with their $L(f) = 1 + \epsilon(f)$ in $\dot{f} = \dot{f}_{\mathrm{V}} L$; multiplying out their prefactor $\frac{10}{3}(8\pi G\mathcal{M}/c^3)^{-5/3}$ gives exactly $2\pi/(\dot{f}_{\mathrm{V}} f^{-11/3})$. (With their opposite Fourier sign it enters Ψ with the opposite sign, as the footnote to Eq. (T2.51) explains; the function is the same.) The quantity in their Figure 1 is the difference with and without dark matter, $\Delta\tilde{\Phi} = \tilde{\Phi} - \tilde{\Phi}_{\mathrm{V}}$ [77, eq. (29)].

The time-domain phase still to come is the second integral alone, $\Phi(f) = 2\pi \int_f^{f_I} f' \mathrm{d}f'/\dot{f}$, and its difference with and without dark matter,

$$\Delta\Phi(f) = 2\pi \int_f^{f_I} \left[\frac{f'}{\dot{f}(f')} - \frac{f'}{\dot{f}_{\mathrm{V}}(f')} \right] \mathrm{d}f', \tag{10.83}$$

is Kim et al.'s eq. (49), plotted in their Figure 3; Eq. (T2.95) evaluated it for a power-law ϵ. The two differ by $\Delta\tilde{\Phi} = \Delta\Phi - 2\pi f\, \Delta t(f)$, where Δt is the change in the time left before the ISCO: the Fourier phase does not count the cycles that a shift of the arrival time would explain. Both are "accumulated between f and the ISCO", both are dominated by the low-frequency end, and for a power-law ϵ they have the same exponent, $-\frac{5}{3} - n$ (Section T2.10). In the script `13_eda2015.py` the integral (10.82) is two cumulative trapezoid sums run from the ISCO downwards:

Listing 10.9: The Fourier phase accumulated between f and the ISCO (`code/ch10/13_eda2015.py`)

```
45 def phit(f, fdot):
46     """Phi~(f) = 2 pi int_f^{f_ISCO} (f' - f)/fdot df' on the (increasing) grid f, which
       ends at f_ISCO."""
47     A = -cumulative_trapezoid((f / fdot)[::-1], f[::-1], initial=0)[::-1]
48     B = -cumulative_trapezoid((1 / fdot)[::-1], f[::-1], initial=0)[::-1]
49     return 2 * np.pi * (A - f * B)
```

Line 47 is $\int_f^{f_I} f' \mathrm{d}f'/\dot{f}$ and line 48 is $\int_f^{f_I} \mathrm{d}f'/\dot{f}$, both accumulated from the top of the grid (the reversed arrays); line 49 combines them as in step (3).

10.12.2 Eda et al. 2015: a static spike and an eLISA forecast

The model. A black hole of $M_{\mathrm{BH}} = 10^3 M_\odot$ sits in a spike $\rho = \rho_{\mathrm{sp}}(r_{\mathrm{sp}}/r)^\alpha$ with $\rho_{\mathrm{sp}} = 226\, M_\odot\,\mathrm{pc}^{-3}$ and $r_{\mathrm{sp}} = 0.54\,\mathrm{pc}$, the values Eda et al. derive for an NFW minihalo grown adiabatically around the hole [77, Table I]; the slope is $\alpha = 7/3$ for that history and is left free otherwise. A companion of $\mu = 1\, M_\odot$ circles it (they call the companion's mass μ). Friction removes $P_{\mathrm{DF}} = 4\pi G^2\mu^2\rho \ln\Lambda/v$ [77, eq. (16)], radiation removes the quadrupole power of a circular binary (Eq. (T2.27)), and Kepler's law uses M_{BH}. The ratio is the friction-to-radiation ratio of Eq. (T2.92) with $m_1 \to M_{\mathrm{BH}}$, $M \to M_{\mathrm{BH}}$ and $\xi = 1$:

$$\begin{aligned} \epsilon(f) = \frac{P_{\mathrm{DF}}}{P_{\mathrm{GW}}} &= \frac{4\pi G^2\mu^2\rho \ln\Lambda\, R^{1/2}(GM_{\mathrm{BH}})^{-1/2}}{\frac{32}{5} G^4\mu^2 M_{\mathrm{BH}}^3/(c^5 R^5)} \\ &= \frac{5\pi}{8} \frac{c^5 \ln\Lambda}{G^{5/2} M_{\mathrm{BH}}^{7/2}} \rho(R)\, R^{11/2}, \qquad R = \left(\frac{GM_{\mathrm{BH}}}{\pi^2 f^2}\right)^{1/3}. \end{aligned} \tag{10.84}$$

The companion's mass cancels, and $\epsilon \propto R^{11/2-\alpha}$. With $\dot{f} = \dot{f}_V(1+\epsilon)$ and $\mathcal{M} = \mu^{3/5}M_{\rm BH}^{2/5} = 15.85\,M_\odot$, (10.82) gives $\Delta\tilde{\Phi}(f)$ for each α, without any expansion in ϵ. The ISCO is at $f_I = 4.397$ Hz.

Example: the dephasing curves. The script renders page 8 of the paper, calibrates the axes of Figure 1 on its tick marks and reads the three curves from the dark pixels; Figure 10.34 overlays them on ours.

The event. With the Coulomb logarithm the text gives, $\ln\Lambda \simeq 3$, our three curves (dashed) run parallel to the published ones and sit below them by the same amount everywhere: the median of $\log_{10}$(ours/theirs) is -0.3672, -0.3674 and -0.355 for $\alpha = 1.5$, 2 and 7/3, across two decades of frequency and fourteen decades of phase.

What could produce a constant factor? We go through the candidates.

- *A misread figure.* Digitisation errors scatter from point to point and do not depend on which curve is read. A common offset of 0.36 in $\log_{10}$ on three separately read curves is not a reading error; the scatter about the offset, 0.02097 to 0.1027 dex, is.
- *Different masses.* A different $M_{\rm BH}$ or μ changes f_I, the vacuum rate and the radius at a given frequency, each with a different power of f. It would tilt the curves, not shift them.
- *A different normalisation of ϵ.* Over the range where $\epsilon \ll 1$, the dephasing is proportional to ϵ (Eq. (T2.95)), and $\epsilon \propto \rho_{\rm sp}\ln\Lambda$. A different value of the product $\rho_{\rm sp}\ln\Lambda$ shifts all curves by the same factor. This fits.

How large is the factor? $10^{0.367} = 2.33$, which is $\ln 10 = 2.303$ to within the scatter. The natural reading is that the authors meant $\log_{10}\Lambda = 3$, a Coulomb logarithm of $\ln 10^3 = 6.908$, and the text abbreviated it as "$\ln\Lambda \simeq 3$". With $\ln\Lambda = 6.908$ (solid curves) the median offsets fall to -0.00495, -0.005213 and -0.009118 dex. The figure cannot separate $\ln\Lambda$ from $\rho_{\rm sp}$, since only their product enters; the Fisher numbers below confirm the reading independently.

The curves also show how large the effect is. At 0.01 Hz the $\alpha = 7/3$ spike has $\epsilon = 10.62$ (friction is ten times stronger than radiation there) and $\Delta\tilde{\Phi} = 3.062\times10^7$ rad; the paper's caption reads this as "a factor of 10^7 more GW cycles". For $\alpha = 1.5$ the same number is 58.96 rad, and at 1 Hz only 1.262×10^{-7} rad: a shallow spike leaves its mark only at the low-frequency end of the band.

The forecast. Eda et al. compute a Fisher matrix for six parameters, $\ln\mathcal{A}$, t_c, Φ_c, $\ln\mathcal{M}$, $\ln\alpha$ and $\ln c_\epsilon$, where c_ϵ is the strength of the friction [77, eqs. (37)–(38)]. Their detector is the eLISA design of the time, with arm length 10^9 m and the noise of their eq. (32a), which `lib_gw10.py` implements as `Sn_elisa`. The band runs from the frequency five years before the ISCO, $f_{\rm ini}(\alpha)$, to f_I [77, eq. (40)]: friction speeds up the early inspiral, so a steeper spike starts the five years at a lower frequency. We find $f_{\rm ini} = 0.02264$ Hz for $\alpha \to 0$ (the vacuum), 0.01481 Hz for $\alpha = 7/3$ and 7.586×10^{-4} Hz for $\alpha = 2.5$: a plateau and then a steep fall above $\alpha \approx 2.3$, the shape of their Figure 2 (Figure 10.35, left). The errors are normalised to $S/N = 10$ by scaling the matrix so that $\Gamma_{\ln\mathcal{A}\ln\mathcal{A}} = \rho^2 = 100$ (Eq. (10.72)). The derivatives with respect to $\ln\alpha$ and $\ln c$ are central differences of the complete waveform, amplitude factor $L^{-1/2}$ included, as in the paper.

The comparison at $\alpha = 7/3$, $S/N = 10$, with their eqs. (41a)–(41f):

	$\Delta\mathcal{A}/\mathcal{A}$	Δt_c [s]	$\Delta\Phi_c$ [rad]	$\Delta\mathcal{M}/\mathcal{M}$	$\Delta\alpha/\alpha$	$\Delta c/c$
Eda et al. (41)	0.1	1	1.3	3.100×10^{-7}	1.200×10^{-6}	5.900×10^{-5}
ours, $\ln\Lambda = 3$	0.1	1.273	1.42	3.280×10^{-7}	3.211×10^{-6}	see text
ours, $\ln\Lambda = 6.9$	0.1	1.213	1.366	3.224×10^{-7}	1.254×10^{-6}	see text

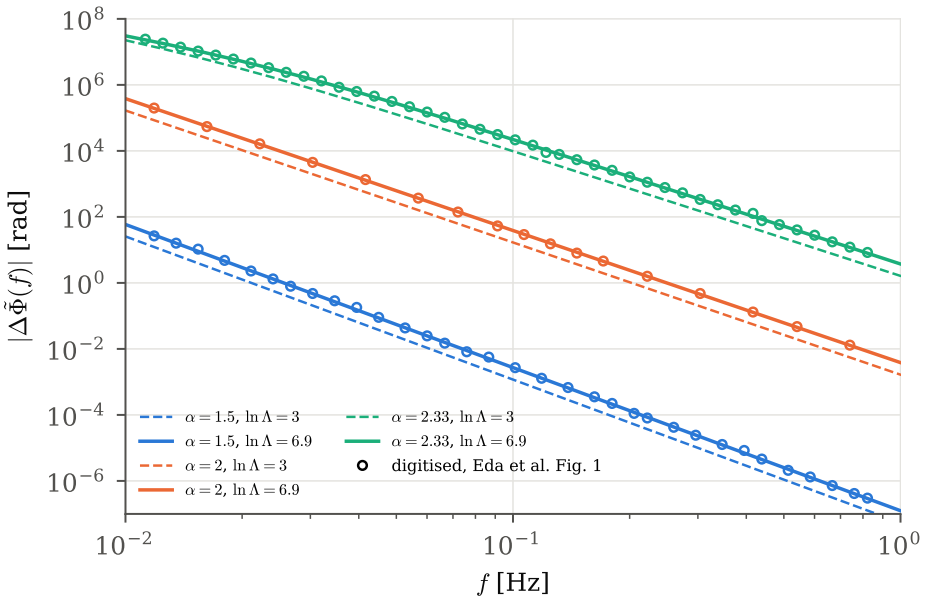

Figure 10.34: The Fourier-phase difference between an inspiral in a dark-matter spike and in vacuum, accumulated between f and the ISCO, for three spike slopes. Open circles: Figure 1 of Eda et al., digitised from the published PDF. Dashed: our calculation with the Coulomb logarithm stated in their text, $\ln\Lambda = 3$; it is low by the same factor 2.3 on every curve. Solid: with $\ln\Lambda = \ln 10^3 = 6.9$, which reproduces the figure.

The amplitude error is $1/\rho$ by construction. The chirp mass agrees to 4%, the phase to 5%, the arrival time to 20%; these three depend on the shape of the noise curve and on where the band starts, which we rebuilt from the paper's description, not from its code. The slope settles the Coulomb logarithm: with $\ln\Lambda = 3$ we get $\Delta\alpha/\alpha = 3.211\times10^{-6}$, almost three times the published value; with $\ln\Lambda = 6.9$ we get 1.254×10^{-6}, within 5% of it. A stronger friction measures the slope better, because the signature it leaves is larger compared with the noise, and the figure and the forecast now agree on the same strength.[4]

Example: why the amplitude's error depends on where it is defined. Our $\Delta c/c$ is 2.200×10^{-6}, twenty-seven times smaller than their 5.900×10^{-5}. The event is a disagreement in one parameter only, the amplitude of the friction, while the slope in the same matrix agrees. What could make the error of an amplitude differ while everything else agrees? The amplitude is not a single number until we say at which frequency it is the amplitude. Our c is ϵ at the pivot $f_p = 0.05\,\mathrm{Hz}$, inside the band: $\epsilon(f) = c\,(f/f_p)^{-n}$, with $n = (11-2\alpha)/3$ from (10.84). The same law, written with the amplitude c' at another pivot f_q, has $c' = c\,(f_q/f_p)^{-n}$. Then

$$\ln c' \overset{(1)}{=} \ln c - n\ln\frac{f_q}{f_p},$$

$$\delta\ln c' \overset{(2)}{=} \delta\ln c + \frac{2}{3}\,\alpha\ln\frac{f_q}{f_p}\,\delta\ln\alpha,$$

$$\sigma^2_{\ln c'} \overset{(3)}{=} \sigma^2_{\ln c} + 2\lambda\,\mathrm{Cov}(\ln c,\ln\alpha) + \lambda^2\sigma^2_{\ln\alpha}, \qquad \lambda \equiv \frac{2}{3}\,\alpha\ln\frac{f_q}{f_p}. \tag{10.85}$$

(1) Take the logarithm of $c' = c\,(f_q/f_p)^{-n}$.

[4] The conclusion of Eda et al. quotes $\pm5\times10^{-6}$ for the 1σ error on α; eq. (41e), which we reproduce, corresponds to $\Delta\alpha = 2.8\times10^{-6}$.

(2) Vary both sides; n depends on α through $\mathrm{d}n = -\frac{2}{3}\mathrm{d}\alpha = -\frac{2}{3}\alpha\,\mathrm{d}\ln\alpha$.
(3) The variance of a linear combination $\delta\ln c + \lambda\,\delta\ln\alpha$ (the propagation rule of Section 10.4.5).

The error of the amplitude grows quadratically with the lever arm λ, the logarithmic distance between the two pivots. Where is Eda et al.'s pivot? Their c_ϵ multiplies $x^{(11-2\alpha)/2}$, where x is the orbital radius in units of R_*, the radius at which the spike, extrapolated inwards, would enclose a mass equal to the black hole's [77, eqs. (10b), (17), (18), (28d)–(28f)]. For their halo $R_* = 0.9829\,\mathrm{pc}$. The orbit in the band has a radius of about $10^{-8}\,\mathrm{pc}$, so their amplitude is defined eight decades in radius, and twelve in frequency ($f_* = 2.195\times10^{-14}\,\mathrm{Hz}$; Eda et al.'s pivot, not LISA's transfer frequency), away from the data. The script evaluates (10.85) at f_*:

Listing 10.10: The amplitude error at another pivot (`code/ch10/13_eda2015.py`)

```
179     C = L.inv_scaled(F)
180     a73 = 7 / 3
181     Rstar = (MBH * L.MSUN * (3 - a73) / (4 * np.pi * RHOSP * L.MSUN / L.PC**3 * RSP**a73))
        ** (1 / (3 - a73))
182     fstar = np.sqrt(L.G * MBH * L.MSUN / Rstar**3) / np.pi
183     def dlnc_at(fq):
184         lev = 2 / 3 * a73 * np.log(fq / 0.05)
185         return np.sqrt(C[5, 5] + lev**2 * C[4, 4] + 2 * lev * C[4, 5])
186     fq = np.geomspace(1e-16, 1.0, 4000)
187     dq = np.array([dlnc_at(x) for x in fq])
188     nums.update({f"TenBedaRstar{tag}": Rstar / L.PC, f"TenBedaFstar{tag}": fstar,
189                  f"TenBedaCstar{tag}": dlnc_at(fstar), f"TenBedaFbest{tag}":
        fq[np.argmin(dq)],
190                  f"TenBedaCbest{tag}": dq.min(), f"TenBedaCorrAC{tag}": C[4, 5] /
        np.sqrt(C[4, 4] * C[5, 5])})
```

Line 181 is R_*, from $4\pi\rho_{\rm sp}r_{\rm sp}^{\alpha}R_*^{3-\alpha}/(3-\alpha) = M_{\rm BH}$; line 182 is Kepler's law at R_*; lines 183–185 are (10.85). At f_* the error is 5.336×10^{-5}, against their 5.900×10^{-5}: the factor of twenty-seven has become ten per cent. In the other direction, the pivot at which c and α decorrelate, $f_q = 0.01658\,\mathrm{Hz}$, gives the smallest possible error, 4.133×10^{-7}. The decorrelation pivot sits where the signal-to-noise ratio accumulates, for the same reason that Knox's tilt and amplitude decorrelate at $\ell_* \approx 210$ in Section 10.6.2: an amplitude measured where the data are is not dragged by the uncertainty of the slope. At our $f_p = 0.05\,\mathrm{Hz}$ the correlation between $\ln c$ and $\ln\alpha$ is already 0.9822; at f_* it is essentially one.

Watch out: An amplitude without a pivot has no error bar

When a power law has a free exponent, the error of its amplitude depends on the frequency (or scale) at which the amplitude is defined, and grows with the logarithmic distance from the data. Quote amplitudes at a pivot inside the band, ideally the decorrelation pivot, or quote the pivot with the error.

Example: how shallow a spike can be measured. Repeating the forecast for every slope gives $\Delta\alpha/\alpha$ as a function of α at $S/N = 10$ (Figure 10.35, right). The error falls by many orders of magnitude between $\alpha = 1.4$ and 2.4, because $\epsilon \propto \rho_{\rm sp}(r_{\rm sp}/R)^{\alpha}$ grows rapidly with α at the tiny radii of the band, and turns up near $\alpha \approx 2.5$ where the band start drops and the binary spends its five years with friction in charge. Eda et al. state that the slope is measured to 10% down to $\alpha \approx 1.7$ [77, Sec. IV D]. We find $\alpha = 1.738$ (and 1.783 with $\ln\Lambda = 3$).

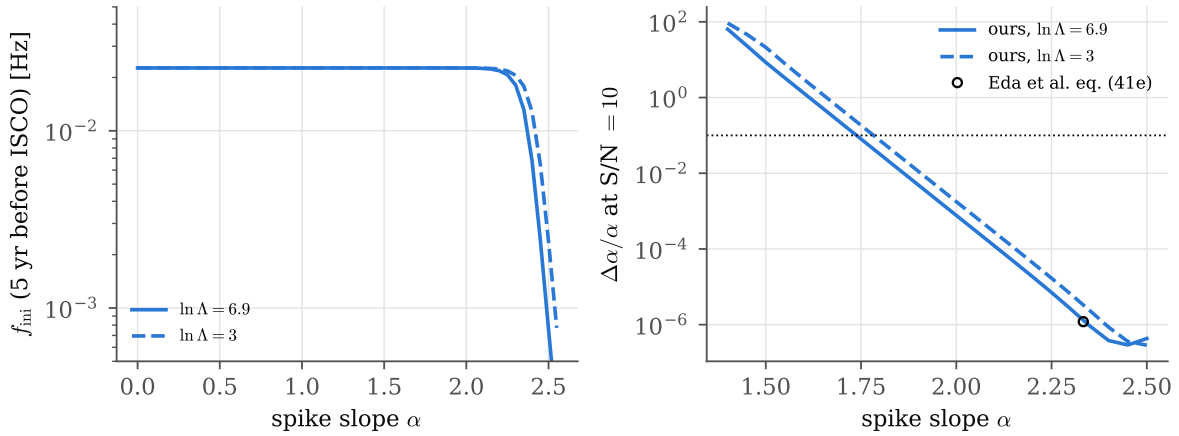

Figure 10.35: Left: the frequency at which the last five years before the ISCO begin, against the spike slope; friction makes steep spikes start lower. Right: the forecast relative error on the slope at $S/N = 10$ with the eLISA noise of Eda et al., for the two Coulomb logarithms; the circle is their eq. (41e) and the dotted line the 10% level, crossed near $\alpha = 1.7$ as they state.

10.12.3 Kim et al. 2023: a wave-like halo, LISA, and a posterior

The model. The benchmark of Kim et al. [81, Table I] is a $m_1 = 10^4 M_\odot$ black hole with a $m_2 = 1\,M_\odot$ companion ($\mathcal{M} = 39.8\,M_\odot$, $q = m_2/m_1 = 10^{-4}$) at $D_L = 203\,\mathrm{Mpc}$, in a spike of slope $\gamma_{\rm sp} = 7/3$ with density $\rho_6 = 25\times10^{15} M_\odot\,\mathrm{pc}^{-3}$ at $r_6 = 10^{-6}\,\mathrm{pc}$. The dark matter is a wave with gravitational Bohr radius $a = 10^{-11}\,\mathrm{pc}$. Each ingredient of their model has a short physical reason, and each is a line of `14_kim2023.py`.

- *Energy balance.* $\mathrm{d}E_o/\mathrm{d}t = -(P_{\rm GW} + \dot{E}_f)$ with the vacuum orbital energy [81, eq. (36)], so $\dot{f} = \dot{f}_{\rm V}(1+\epsilon)$ with $\epsilon = \dot{E}_f/P_{\rm GW}$, exactly Eq. (T2.91).
- *Friction.* $\dot{E}_f = 4\pi(Gm_2)^2\rho(<v)\,C/v$, with $\rho(<v) \approx 0.6\rho$ the density of the slower particles [81, eq. (39)]: Chandrasekhar's formula (Eq. (T2.87)) with $\xi = 0.6$ and the Coulomb logarithm replaced by a factor C. For particles, $C_p = \frac{1+\Lambda}{\Lambda}\ln\left[1+\Lambda+\sqrt{\Lambda(2+\Lambda)}\right] - \sqrt{1+2/\Lambda}$ with $\Lambda = v^2 r/(Gm_2)$, which tends to $\ln 2\Lambda - 1$ for $\Lambda \gg 1$ [81, eq. (41)]. For a wave, $C_w(kr) = \mathrm{Cin}(2kr) - 1 + \sin(2kr)/2kr$ [81, eq. (42)], whose limits Section T2.10 derives: friction is suppressed as $(kr)^2/3$ when the de Broglie wavelength exceeds the orbit.
- *The density.* For particles the spike is cut off at twice the Schwarzschild radius, $\rho_6(r_6/r)^\gamma(1-2R_S/r)^\gamma$. For a wave, the modes of low angular momentum fall into the hole: a mode (n,ℓ) decays at a rate $\Gamma_{n\ell}$ that grows steeply as ℓ falls [81, eq. (31)], and the modes with $2\Gamma_{n\ell}t_{\rm halo} > 1$ are gone after the halo's age. The lowest surviving angular momentum ℓ_c sets an inner radius $R_c = a\,\ell_c(\ell_c+1)$ and the profile $\rho_6(r_6/r)^\gamma(1-R_c/2r)^\gamma$ [81, eq. (40)]. We solve $2\max_n \Gamma_{n\ell}t_{\rm halo} = 1$ for continuous ℓ with $t_{\rm halo} = 13.6\,\mathrm{Gyr}$ (a halo formed at $z \approx 20$) and find $\ell_c = 24.03$, 10.22 and 5.16 for $a = 10^{-11}$, 10^{-10} and $10^{-9}\,\mathrm{pc}$, that is particle masses $mc^2 = 9.245\times10^{-14}$, 2.924×10^{-14} and $9.245\times10^{-15}\,\mathrm{eV}$ (their figure labels: 9×10^{-14}, 3×10^{-14}, $9\times10^{-15}\,\mathrm{eV}$).
- *Backreaction.* The friction cannot dissipate more energy than the halo can absorb. Kim et al. cap it by the rate at which the companion sweeps through the binding energy of the shells it crosses: $\dot{E}_f \to (1/\dot{E}_f + 2/\dot{U})^{-1}$, a smooth minimum of the two [81, eq. (43)].

The cap needs one more step, because $\dot{U}$ depends on how fast the orbit shrinks, which depends on the capped friction itself. Write x for the capped friction power. A shell of thickness Δr at r

has binding energy $\Delta U = G[m_1 + m_{\rm enc}(r)]\,4\pi r^2\rho\,\Delta r/r$, and the orbit crosses shells at the rate $|\dot r|$:

$$\dot U \overset{(1)}{=} \frac{G(m_1+m_{\rm enc})\,4\pi r^2\rho}{r}\,|\dot r| \overset{(2)}{=} \frac{G(m_1+m_{\rm enc})\,4\pi r\rho\cdot 2r^2}{Gm_1m_2}\,(P_{\rm GW}+x) \equiv \kappa\,(P_{\rm GW}+x),$$
$$\frac{1}{x} \overset{(3)}{=} \frac{1}{\dot E_f} + \frac{2}{\kappa(P_{\rm GW}+x)} \quad\Longrightarrow\quad \kappa x^2 - \left[\kappa(\dot E_f - P_{\rm GW}) - 2\dot E_f\right]x - \kappa \dot E_f P_{\rm GW} \overset{(4)}{=} 0. \tag{10.86}$$

(1) The binding energy per unit radius times the radial speed.
(2) $E_o = -Gm_1m_2/2r$ gives $|\dot r| = |\dot E_o|/(\mathrm{d}E_o/\mathrm{d}r) = (P_{\rm GW}+x)\,2r^2/(Gm_1m_2)$; G cancels.
(3) Kim et al.'s eq. (43) with $\dot U$ from step (2).
(4) Multiply by $x\,\dot E_f\,\kappa(P_{\rm GW}+x)$ and collect powers of x; the positive root is the capped friction.

Kim et al. do not say how they evaluate $\dot U$; taking the radial speed from the total power, as here, is the self-consistent choice, and the quadratic (10.86) is lines 108–110 of the script.

Example: the dephasing curves. Figure 10.36 compares $|\Delta\Phi|$ of (10.83) with Figure 3 (top) of Kim et al., digitised by colour. For the particle halo the median of $\log_{10}$(ours/theirs) is 0.005896 and the largest deviation 0.01903 dex; for the wave halo with $a = 10^{-11}$ pc, −0.005077 and 0.0699; for $a = 10^{-10}$ pc, 0.01456 and 0.1264. For $a = 10^{-9}$ pc the median deviation is 0.2712 dex: there the inner cut-off R_c lies inside the band, the curve plunges where the companion reaches $R_c/2$, and a small change in ℓ_c moves the plunge enough to change the phase there by large factors; in Figure 10.36 our green curve plunges slightly earlier than theirs. The comparison is therefore a test of the decay rates as much as of the friction. At 10 mHz the particle halo has dephased the signal by 4.387×10^5 rad and the wave halo with $a = 10^{-11}$ pc by 2.983×10^5 rad. Everything in the figure depends on ϵ only through (10.83), so this agreement confirms the whole chain from the decay rates to the backreaction cap.

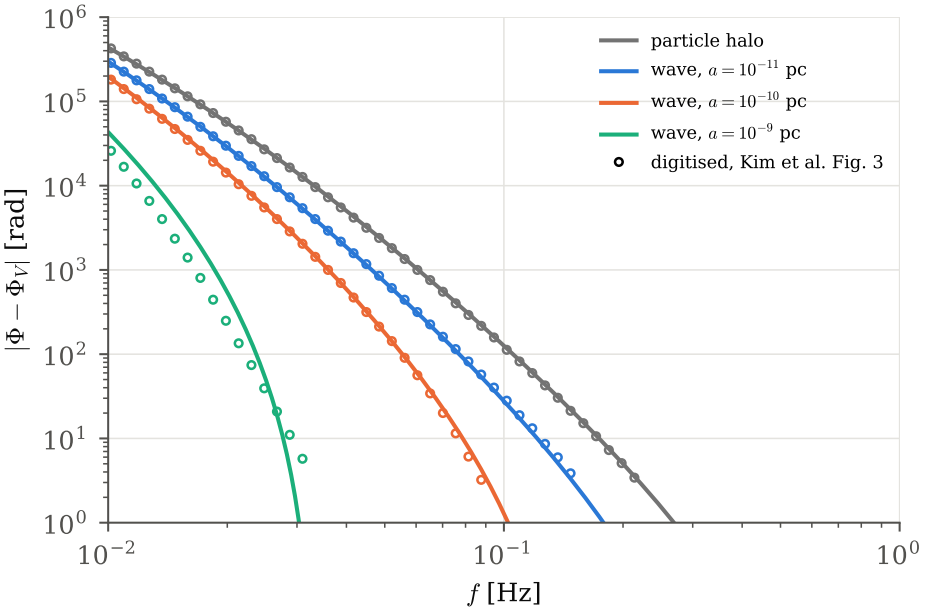

Figure 10.36: The time-domain phase lost between f and the ISCO by the $10^4 + 1\,M_\odot$ inspiral in a particle halo (grey) and in wave halos of three Bohr radii, against the published Figure 3 of Kim et al. (open circles, digitised). The larger the Bohr radius, the more inner modes the black hole has swallowed and the earlier the friction switches off.

Example: the signal-to-noise ratio. With the sky-averaged amplitude $\sqrt{4/5}\,A(f)$ [81, eqs. (44)–(45)] (the $4/5$ is the average over the orbit's inclination, (T2.36); the sky and polarisation average sits in the noise curve, Section T2.3), the Robson et al. noise with four-year Galactic confusion (Sections T2.7 and 10.11.1), and the band from five years before the ISCO, $f_{5\mathrm{yr}} = 0.01269\,\mathrm{Hz}$, to $\min(1\,\mathrm{Hz}, f_I) = 0.4398\,\mathrm{Hz}$, we find $\rho = 15.05$. They state $\rho \simeq 15$.

Example: the forecast against their posterior. Kim et al. do not compute a Fisher matrix. They inject the benchmark signal without noise, $d = h(\boldsymbol{\theta}_{\mathrm{true}})$ (the "median experiment" of Section 10.13), and sample the posterior of $(\mathcal{M}, \log_{10} q, \rho_6, \gamma_{\mathrm{sp}}, \log_{10} a)$ with a nested sampler, maximising the likelihood over the arrival time and the phase and fixing the distance at its best value [81, eqs. (50)–(53), Fig. 4]. Their Figure 4 quotes the 2.5% and 97.5% quantiles of each marginal. We turn each 95% interval into a Gaussian-equivalent width by dividing it by 3.92, and compare with the Fisher matrix of eight parameters, the five plus $(\ln \mathcal{A}, t_c, \phi_c)$, with the derivatives taken by central differences of the complete waveform (amplitude factor $(1+\epsilon)^{-1/2}$ included):

Listing 10.11: The waveform whose derivatives make the Fisher matrix (`code/ch10/14_kim2023.py`)

```
212 Sn = L.Sn_robson(ff, "4yr")
213 nums.update(TenBkimfFive=f5, TenBkimfUp=fup)
214
215
216 def lnh(x, wave=True):
217     """ln h(f) up to the overall amplitude: -(1/2) ln(1+eps) - i Psi, Psi = 2 pi f t(f) -
        Phi(f) (ISCO reference)."""
218     Mc, lq, rho6, gam, la = x
219     eps = eps_kim(ff, Mc, 10**lq, rho6, gam, 10**la if wave else None)
220     fdv = L.fdot_vac(ff, Mc)
221     g = 1 / (fdv * (1 + eps)) - 1 / fdv
```

Line 217 is the integrand of (10.83) divided by f', and line 219 builds the dark-matter part of $\tilde{\Phi}$ from it as in (10.82); line 221 returns $\ln \tilde{h}$ up to a constant, whose real part is the slower-sweep amplitude and whose imaginary part is the phase. Halving and doubling the steps changes no error by more than 3.524×10^{-5}. At the Gaussian level, maximising over $(t_c, \phi_c, \ln \mathcal{A})$ and marginalising over them give the same widths (both are the Schur complement of Section 10.4.1), so the comparison is fair. The result (Figure 10.37):

	$\mathcal{M}\,[M_\odot]$	$\log_{10} q$	$\rho_6\,[10^{15} M_\odot \mathrm{pc}^{-3}]$	γ_{sp}	$\log_{10} a$
posterior (Kim et al.)	4.538×10^{-4}	0.03513	11.53	0.1319	0.1003
Fisher (ours)	8.232×10^{-5}	0.01884	6.978	0.09143	0.06318
ratio	0.1814	0.5364	0.6052	0.6932	0.6302

The order of magnitude is right for every parameter, and the Fisher matrix finds the same structure as the posterior: a correlation of -0.9999 between ρ_6 and γ_{sp} and of 0.9912 between ρ_6 and $\log_{10} q$, the two degeneracies Kim et al. point out in their Figure 4. But every Fisher width is smaller, by a factor 1.4 to 5.5. The matrix is nearly singular (the ratio of its largest to smallest eigenvalue, after scaling to unit diagonal, is 4.160×10^{10}), and along its long axis a 1σ step moves ρ_6 by a quarter of its value and γ_{sp} by 0.09, far beyond the region where the waveform is linear in the parameters. Section 10.13 quantifies this and shows that it, not the code, is the cause. For a particle halo of the same density the four common errors would be $3.211 \times 10^{-5}\,M_\odot$, 0.002314, 0.5984 and 0.007009: the dense inner spike that the wave halo has lost carries most of the information.

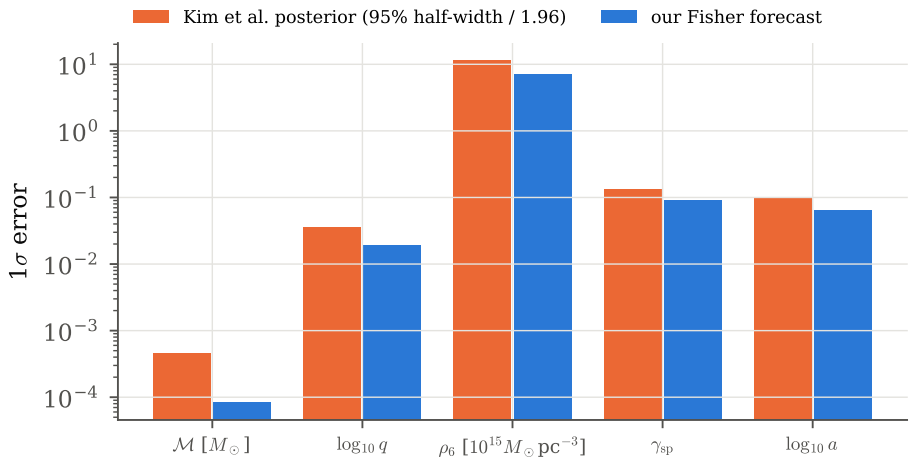

Figure 10.37: The 1σ widths of the five halo and binary parameters for the benchmark of Kim et al. ($\rho \approx 15$): their nested-sampling posterior (Figure 4, 95% half-width divided by 1.96) and our Fisher forecast. The forecast is right to within a factor of a few and too optimistic everywhere, most for the chirp mass, whose posterior is skewed by its correlation with the mass ratio and the density.

10.12.4 Paper against ours

Table 10.6 collects every published gravitational-wave number we have reproduced. Where we agree to better than the precision of reading a plotted line, the paper's model has been rebuilt correctly. Where we disagree, the disagreement has been traced to a cause: a fitted response function (Robson et al. above the transfer frequency f_*, Eq. (T2.38)), a rounded amplitude (the printed $h_{\rm GB}$), an abbreviated Coulomb logarithm and a pivot far outside the band (Eda et al.), or the breakdown of the Gaussian approximation (Kim et al.).

10.13 When the Fisher ellipse lies

The benchmark of Kim et al. ended on an uncomfortable note (Section 10.12.3): the Fisher matrix found the right parameters to worry about and the right correlations, but every width came out too small, by factors up to five compared with the posterior that a sampler drew from the same model. A forecast that is optimistic by a factor of five can turn "LISA will measure the dark-matter density" into "LISA will see that there is something there". So before any detectability map is believed, the question in words is:

for this source, at this signal-to-noise ratio, does the Fisher ellipse describe the posterior we would actually obtain, and if not, where does it fail?

Of Vallisneri's three readings of Γ^{-1} (Section 10.2.3) [166], the one a forecast relies on is the third: the covariance of the posterior from one experiment. The posterior is something we can compute exactly, by sampling, so the question has an answer that does not depend on approximations.

10.13.1 The linearised signal

The median experiment. To compare a forecast with a posterior we need data. Papers, Kim et al. and Coogan et al. among them [81, 84], use the data with the noise set to zero, $d = h(\boldsymbol{\theta}_0)$, and we do the same. This is not a claim that there is no noise. A noise realisation moves the peak of the posterior away from $\boldsymbol{\theta}_0$, by a random amount whose covariance (at high signal-to-noise ratio) is Γ^{-1} itself, but it leaves the shape of the posterior almost unchanged. Setting $n = 0$ removes the random shift and keeps the shape, the quantity a forecast is about. The noise-free data stand for the typical, or median, experiment.

When is the likelihood exactly the Fisher Gaussian? With $d = h_0 \equiv h(\boldsymbol{\theta}_0)$ the likelihood (10.41) is $\ln \mathcal{L}(\boldsymbol{\theta}) = -\frac{1}{2}(\Delta h|\Delta h)$, with $\Delta h \equiv h(\boldsymbol{\theta}) - h_0$. Expand the signal around the truth, $\Delta h = \Delta\theta^i \partial_i h + R$, where the first term is the tangent (linear) part, the sum over i is implied, and R is everything of second order and higher. Then

$$\begin{aligned} -2\ln\mathcal{L}(\boldsymbol{\theta}) &\overset{(1)}{=} \left(\Delta\theta^i\partial_i h + R \,\middle|\, \Delta\theta^j\partial_j h + R\right) \\ &\overset{(2)}{=} \Delta\theta^i\Delta\theta^j\,(\partial_i h|\partial_j h) + 2\,\Delta\theta^i(\partial_i h|R) + (R|R) \\ &\overset{(3)}{=} \Delta\boldsymbol{\theta}^{\mathsf{T}}\Gamma\,\Delta\boldsymbol{\theta} + 2\,\Delta\theta^i(\partial_i h|R) + (R|R). \end{aligned} \tag{10.87}$$

(1) Insert the expansion of Δh into $-2\ln\mathcal{L} = (\Delta h|\Delta h)$.
(2) The inner product is bilinear and symmetric.
(3) $(\partial_i h|\partial_j h) = \Gamma_{ij}$, (10.69).

If the signal were exactly linear in the parameters, $R = 0$, the log-likelihood would be exactly the quadratic $-\frac{1}{2}\Delta\boldsymbol{\theta}^{\mathsf{T}}\Gamma\Delta\boldsymbol{\theta}$, and with a flat prior the posterior would be exactly the Gaussian of covariance Γ^{-1}, at any signal-to-noise ratio. This is the **linearised-signal approximation** (LSA): it is the whole content of a Fisher forecast. Everything that makes the forecast wrong is in R.

Geometrically (Figure 10.38), as $\boldsymbol{\theta}$ varies the waveforms $h(\boldsymbol{\theta})$ trace out a curved surface in the space of all possible data, and the noise is a cloud of radius about one around the true signal, in the units of the inner product (Eq. (10.43)). The Fisher matrix replaces the surface by its tangent plane. That is harmless if the surface is flat across the cloud and fatal if it bends within it.

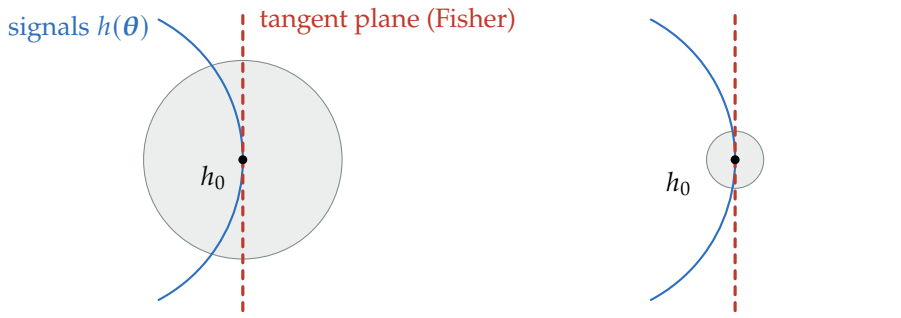

Figure 10.38: The linearised-signal approximation in the space of data. The blue arc is the family of signals $h(\boldsymbol{\theta})$ as one parameter varies, the dashed red line its tangent at the true signal h_0, and the grey disc the region of radius one that the noise fills. When the signal is weak compared with the noise, the true family departs from its tangent inside the disc and the Fisher Gaussian is wrong; when it is strong, the disc is small and the tangent is all that matters.

A test of the approximation. How large may R be? The Fisher 1σ ellipsoid is the surface $\Delta\boldsymbol{\theta}^{\mathsf{T}}\Gamma\Delta\boldsymbol{\theta} = 1$, where the forecast says the log-likelihood has fallen by $\frac{1}{2}$. Vallisneri proposes to walk over that surface and compute there the noise-weighted size of the nonlinear part,

$$|\log r| = \tfrac{1}{2}\,(R \mid R), \qquad R = h(\boldsymbol{\theta}) - h_0 - \Delta\theta^i \partial_i h, \tag{10.88}$$

and to accept the forecast if $|\log r| \lesssim 0.1$ everywhere on it [166, eq. (47)]. He shows that this is the logarithm of the ratio of the exact and the linearised likelihood, averaged over the noise realisations that would put the best fit on that surface. In words: on the boundary that the forecast calls "one sigma", the true signals must differ from their tangent-plane stand-ins by much less than the noise. Since the 1σ surface shrinks as $1/\rho$ and R is quadratic in $\Delta\boldsymbol{\theta}$, R shrinks as $\rho \cdot \rho^{-2}$ and $|\log r|$ falls as $1/\rho^2$: every forecast becomes right at high enough signal-to-noise ratio, and the test says how high is high enough.

Key idea: When to trust a Fisher forecast

A Fisher forecast is the posterior of the linearised signal. Check it on its own 1σ surface: the part of the signal change that is not linear in the parameters must have noise-weighted size $\frac{1}{2}(R|R) \lesssim 0.1$ there. Where it fails, sample the posterior.

Example: the benchmark of Kim et al. The script `14_kim2023.py` draws 300 random points on the 1σ surface of its eight-parameter Fisher matrix and evaluates (10.88) with the complete waveform. The median is $|\log r| = 219.5$ (the largest 246.2), and every point fails the test: not by a little, but by three orders of magnitude. The reason is the near-degeneracy of ρ_6 and γ_{sp} (their Fisher correlation is -0.9999): along it the 1σ surface stretches to changes of the density by a quarter and of the slope by a tenth, and there the dephasing, a strongly nonlinear function of both, is nothing like its tangent. Repeating the test with the surface scaled down, as it would be for a louder source, the median falls to 15.07 at a hundred times the signal-to-noise ratio and reaches 0.1 only near $\rho \approx 20000$. For this benchmark the honest forecast is the posterior; the Fisher matrix is a guide to which parameters are degenerate, not to how large the errors are.

10.13.2 A chain against the ellipse

The criterion says whether to trust the forecast; it does not say how wrong it is. For that we sample the posterior with the Metropolis–Hastings chain of Chapter 9 and compare. To keep

the chain small, the problem is reduced to the four parameters that matter for an environment.

The set-up. The source is the $10^3 + 1.4\,M_\odot$ binary of Section 10.11.2, observed by LISA over its last five years from $f_{\rm lo} = 19.96\,$mHz. Its phase is the 1.5PN phase (10.70) (the vacuum template through 1.5 post-Newtonian order, Section T2.6, with chirp mass $\mathcal{M}$ and the coalescence time and phase t_c, ϕ_c of Section T2.4.3) plus a power-law environment (the ppE term of Eq. (T2.69)) written through its size at the start of the band,

$$\Psi(f) = \Psi_{1.5\rm PN}(f; \mathcal{M}, \eta, t_c, \phi_c) + A\left(\frac{u}{u_{\rm lo}}\right)^b, \qquad A = \delta\Psi(f_{\rm lo}), \tag{10.89}$$

with $u = \pi G\mathcal{M}f/c^3$ as in Section 10.10 and $u_{\rm lo}$ its value at $f_{\rm lo}$. Writing the amplitude as the phase shift at $f_{\rm lo}$, rather than as β, keeps it of order radians for every b. The free parameters are $(\ln\mathcal{M}, t_c, A, b)$; η is held at its true value, the amplitude $\ln\mathcal{A}$ decouples (Section 10.9.3) and is held too, and ϕ_c is integrated out analytically. The truth is a friction-like effect with $b = -4$ and $A = -19.87\,$rad, three times the Fisher error $\sigma_A = 6.624\,$rad at $\rho = 10$. Then the source is moved closer, $\rho = 10, 20, 40, 80$, with the same A.

Integrating out the phase. The phase ϕ_c is a nuisance with a flat prior on $[0, 2\pi)$, and it can be removed exactly. The question in words: what is the probability of the data regardless of ϕ_c? With $\tilde h(\boldsymbol\theta, \phi_c) = \tilde h(\boldsymbol\theta)e^{i\phi_c}$ (the phase enters Ψ as $-\phi_c$), noise-free data $d = h_0$, equal amplitudes $(h|h) = (h_0|h_0) = \rho^2$, and the weight w of (10.72),

$$\begin{aligned}
(d-h\,|\,d-h) &\overset{(1)}{=} (h_0|h_0) + (h|h) - 2(h_0|h) \overset{(2)}{=} 2\rho^2 - 2\rho^2\,\mathrm{Re}\big[Z\,e^{-i\phi_c}\big],\\
Z(\boldsymbol\theta) &\equiv \int w(f)\,e^{i[\Psi(f;\boldsymbol\theta)-\Psi_0(f)]}\,\mathrm{d}f,\\
\mathcal{L}(\boldsymbol\theta) &\overset{(3)}{=} \frac{1}{2\pi}\int_0^{2\pi} e^{-\rho^2+\rho^2|Z|\cos(\phi_c - \arg Z)}\,\mathrm{d}\phi_c \overset{(4)}{=} e^{-\rho^2}\,I_0\big(\rho^2|Z(\boldsymbol\theta)|\big).
\end{aligned} \tag{10.90}$$

(1) Expand the inner product; it is symmetric.
(2) $(h_0|h) = 4\,\mathrm{Re}\int \tilde h_0\tilde h^*/S_n\,\mathrm{d}f$ with $\tilde h_0\tilde h^* = |\tilde h|^2 e^{i(\Psi-\Psi_0)}e^{-i\phi_c}$, and $4|\tilde h|^2/S_n = \rho^2 w$.
(3) Marginalise $e^{-(d-h|d-h)/2}$ over ϕ_c with the flat prior $1/2\pi$; write $Z = |Z|e^{i\arg Z}$.
(4) $\frac{1}{2\pi}\int_0^{2\pi} e^{x\cos\varphi}\mathrm{d}\varphi = I_0(x)$, the modified Bessel function; the shift by $\arg Z$ does not change an integral over a full period.

$|Z| \le 1$ is the overlap of the trial phase with the true one, averaged with the signal-to-noise weight: it is one when the phases agree up to a constant and falls as they drift apart. For large argument $\ln I_0(x) \approx x - \frac12\ln 2\pi x$, so $\ln\mathcal{L} \approx -\rho^2(1-|Z|)$: the likelihood penalises the lost overlap times ρ^2, the same structure as the phase-maximised likelihood of Kim et al. [81, eq. (53)]. The script `15_fisher_vs_mh.py` implements it in three lines:

Listing 10.12: The likelihood with the phase integrated out (`code/ch10/15_fisher_vs_mh.py`)

```
53 def Z(th, psi_true):
54     y = fw * np.exp(1j * (psi(th) - psi_true))
55     return np.sum(0.5 * (y[1:] + y[:-1]) * dlf)
56
57
58 def loglike(th, psi_true, rho):
59     x = rho**2 * np.abs(Z(th, psi_true))
60     return np.log(i0e(x)) + x - rho**2
```

Line 54 is the integrand of Z on the logarithmic grid (`fw` is $f\,w(f)$), line 55 the trapezoid sum, and line 60 is $\ln\mathcal{L} = \ln I_0(x) - \rho^2$, computed as $\ln(e^{-x}I_0(x)) + x$ because $I_0(x)$ itself overflows

for $x = \rho^2 \sim 6400$. The Fisher matrix to compare with is the 5×5 matrix of $(\ln \mathcal{M}, t_c, A, b, \phi_c)$ with ϕ_c removed by its Schur complement, the Gaussian version of the same marginalisation. The chain is the sampler of Chapter 9, with a proposal covariance tuned in three short runs and then 40 000 steps per signal-to-noise ratio; acceptance rates are 0.08865 to 0.3004, and the whole script runs in 156.3 s.

Example: the banana at $\rho = 10$. Figure 10.39 shows the chain against the Fisher ellipses. At $\rho = 10$ the posterior is curved: larger amplitudes $|A|$ pair with flatter exponents b, because a flatter power law must be larger at f_{lo} to produce the same phase drift where the signal-to-noise ratio accumulates. The tail reaches $A \approx -60$ rad and $b \approx -2.5$, far outside the 95% ellipse, and on the other side it runs into the region of steep exponents where the effect is confined to the first few millihertz. Only 28.43% of the samples fall inside the Fisher 68.3% ellipse in the (A, b) plane. The marginal standard deviations from the chain exceed the Fisher errors by factors of 2.163 for A, 1.305 for b, 2.154 for $\ln \mathcal{M}$ and 3.564 for t_c. The chirp mass and the arrival time are dragged along the banana, because each point on it is a different combination of environment and vacuum parameters that fits the same data.

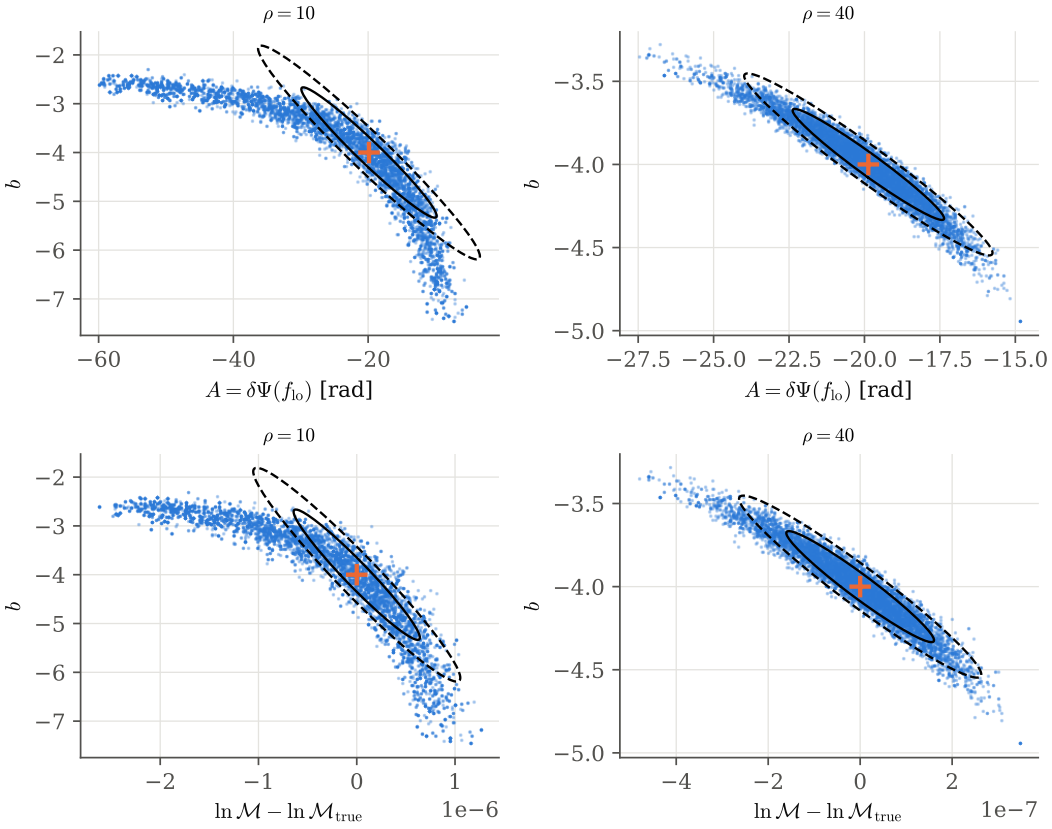

Figure 10.39: Posterior samples from the Metropolis–Hastings chain (dots) against the Fisher 68.3% and 95.4% ellipses (solid, dashed) for a power-law environment with exponent b and phase shift A at the start of the band. Left: at $\rho = 10$ the posterior is a curved banana that the ellipse cannot follow. Right: at $\rho = 40$ it has become an ellipse. Top: environment amplitude against exponent; bottom: chirp mass against exponent. The cross marks the truth.

Example: the approach to the Fisher limit. As ρ grows (Figure 10.40), the ratio of chain to Fisher widths falls towards one: for A it is 2.163, 1.565, 1.172, 1.103 at $\rho = 10, 20, 40, 80$, and for t_c, the worst, 3.564, 1.995, 1.329, 1.117. The fraction of samples inside the 68.3% ellipse climbs

to 50.8, 60.5 and 65.46%. The analogue of Vallisneri's test for this experiment, the difference between the actual fall of $\ln \mathcal{L}$ on the Fisher 1σ surface and the $\frac{1}{2}$ the forecast predicts (median over 200 points), is 0.1471, 0.06673, 0.03061 and 0.01137: it crosses 0.1 between $\rho = 10$ and 20. Here it falls roughly as $1/\rho$, not $1/\rho^2$, because the noise-free drop contains the cross term $\Delta\theta^i(\partial_i h|R)$ of (10.87), which is first order in R.

Notice what the numbers say together. At $\rho = 20$ the median test is already passed, yet the marginal widths are still 20 to 100% larger than the forecast. The median over the 1σ surface hides the directions where the surface bends most, and the marginal widths are set by the tails. This is why Vallisneri asks for the criterion to hold *everywhere* on the surface, not on average, and why he calls it a consistency check rather than a guarantee [166, Sec. VI]. For environmental effects at the signal-to-noise ratios LISA expects for these sources, a signal-to-noise ratio of ten to a few tens, the Fisher error is optimistic by factors of up to two to four, and most so for the vacuum parameters it is correlated with.

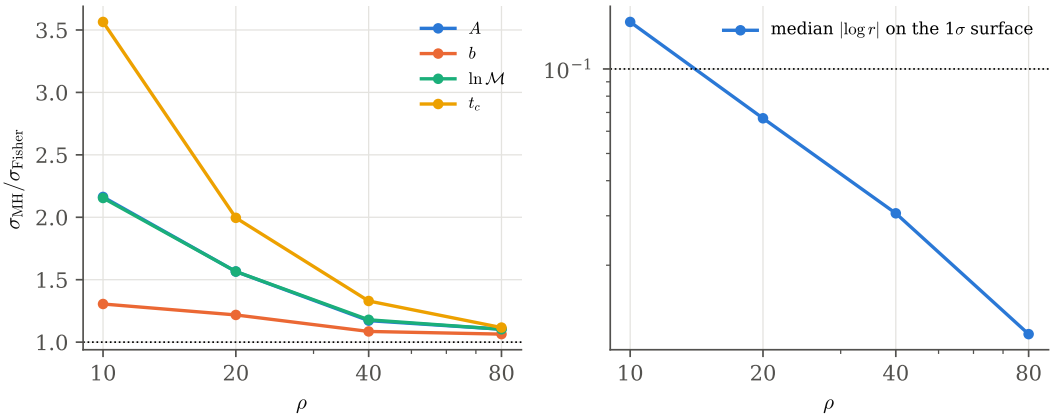

Figure 10.40: Left: marginal standard deviation from the chain divided by the Fisher error, for the four parameters, as the same source is moved closer. All ratios fall towards one, slowest for the arrival time. Right: the median mismatch between the exact and the Fisher log-likelihood on the Fisher 1σ surface; the dotted line is Vallisneri's threshold of 0.1.

Example: a one-sided effect on a vacuum signal. Friction, accretion and migration all take energy from the orbit; none gives it back. Their phase shift therefore has a known sign ($A \le 0$ in our convention), and the right prior is one-sided. Suppose the source is in vacuum, $A = 0$, at the benchmark distance ($\rho = 13.25$), with $b = -4$ known. The Fisher matrix says $\sigma_A = 1.191$ rad, a symmetric Gaussian centred on zero. The posterior cannot be: half of that Gaussian lies at $A > 0$, which the prior forbids. A chain with the prior $A \le 0$ finds a one-sided posterior piled against the boundary, with mean $|A| = 1.168$ rad and a 95% upper limit $|A| < 2.952$ rad, that is $2.479\,\sigma_A$. A half-Gaussian of the Fisher width would give $1.96\,\sigma_A$; most of the excess is the nonlinearity of the previous example at $\rho \approx 13$. The forecast question for a non-detection is "what upper limit would we set?", and the Fisher error answers it only after the prior boundary and the nonlinearity have been put in by hand.

Watch out: A Fisher ellipse knows nothing about boundaries

The Fisher matrix is computed from derivatives at one point and assumes every direction is open. A parameter with a physical boundary (a density that cannot be negative, a dissipative effect of fixed sign, a slope confined to a range by the formation history) has a posterior that the ellipse cannot represent near the boundary, and the published posteriors of Kim et al. show such skewed marginals, with long one-sided tails, for ρ_6 and $\log_{10} a$.

Where the Fisher forecast fails, in one list. The examples above and those of Section 10.12.3 show four distinct mechanisms. Low signal-to-noise ratio makes the signal surface bend within the noise (the banana). Near-degenerate parameters stretch the 1σ ellipsoid into the nonlinear region even at moderate ρ (Kim's ρ_6–$\gamma_{\rm sp}$). Prior boundaries cut the posterior (one-sided effects). And separate parameter regions that fit equally well, which a single expansion point cannot see, give multimodal posteriors; none appeared here, but they are common when the environment can mimic a change of masses. Each is visible to a sampler and invisible to the matrix.

How this is used in real research: Verification here, the instrument in research

Above, the chain verifies the forecast on a four-parameter problem where both can be computed in a minute. In a research analysis the roles reverse: the posterior is computed directly, by nested sampling (Kim et al. use `dynesty` [177]) or by parallel-tempered ensemble samplers built for LISA such as `Eryn` [178], with the full set of 15 or more source parameters, and the Fisher matrix is used before that, to design the proposal distributions, to choose parameters that are nearly uncorrelated, and to locate the degeneracies a sampler will have to cross. The full version of this experiment runs a few million likelihood calls per source on a cluster, with the noise realisation drawn rather than set to zero; ours runs about 3×10^5 calls in under a minute and therefore shows only the median experiment.

10.14 How it is done in research

A collaboration asking "will LISA see the dark-matter spike around this kind of binary?" runs the same chain of reasoning as we did: a likelihood for data that are signal plus Gaussian noise, a detection statistic, a Fisher matrix for a first answer, a sampler for the real one. Every box is larger. The stages, in the order a real analysis passes through them, are drawn in Figure 10.41; at each one the laptop version made a reduction, and each reduction has a cost that can be named.

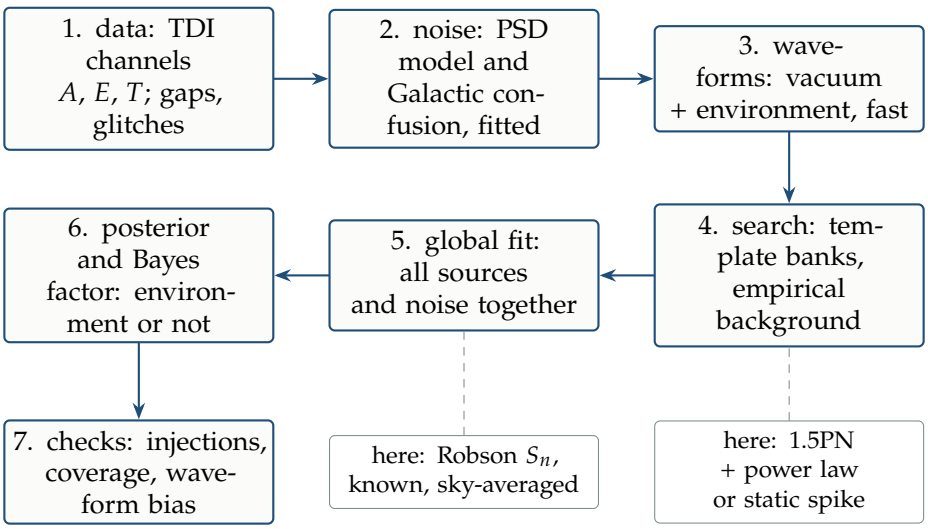

Figure 10.41: The stages of a research analysis of an environmental effect in a LISA source (blue boxes, in order), and the two places where the laptop version cuts most deeply (grey). In a real analysis stages 2 to 5 are not separate: the noise, the resolved sources and the search are iterated inside one global fit.

1. The data. LISA does not record a strain (the fractional change of arm length that a wave causes, Section T2.3). Each spacecraft measures the phase of the laser light arriving from the other two, and the raw measurements are dominated by laser frequency noise many orders of magnitude above any gravitational wave. Time-delay interferometry combines the measurements, delayed by the light travel times along the arms, into channels in which the laser noise cancels [179]; the usual choice is three channels A, E, T whose noises are nearly uncorrelated, with T almost blind to gravitational waves at low frequency. The data come with gaps (antenna repointing, maintenance) and glitches. The community prepares for this with simulated data sets of increasing realism, the LISA Data Challenges [180]. *Here:* a single sky-averaged strain channel in the frequency domain, without gaps. The full analysis keeps the detector response, the antenna patterns F_+, $F_\times$ of (T2.34) that weight the two polarisations h_+, $h_\times$, which carries the sky position and orientation; the reduction loses those parameters and replaces the source-dependent response by its average (Eqs. (T2.36) and (T2.37)), which can be off by tens of per cent for an individual source.

2. The noise. The noise spectrum is not known in advance. It is described by a model with a few parameters for each instrumental component, and fitted together with the signals; with few independent averages the unknown spectrum is integrated out, which turns the Gaussian likelihood into a Student-t [174] as in Section 10.8.6, and glitches are modelled rather than cut [175]. The Galactic confusion noise is the part of the white-dwarf population that cannot be resolved (Section T2.7); it changes during the mission as more binaries are resolved, and it is modulated through the year as the constellation's orientation changes, so the noise is not stationary. *Here:* the Robson et al. spectrum with its four-year confusion fit, known exactly and stationary. A forecast loses nothing by this if the real spectrum matches the fit; an analysis of real data with a fixed spectrum would quote errors that are too small, as Figure 10.23 measured for few averages.

3. The waveforms. The vacuum waveform of an intermediate- or extreme-mass-ratio inspiral is computed from black-hole perturbation theory, not from a 1.5PN expansion (Section T2.6), because the companion completes 10^5 to 10^6 cycles in the band and every small phase error accumulates; fast surrogate codes make this affordable inside a sampler [181]. The environment is then added either as a physical model, such as a dark-matter spike that is heated and thinned by the energy friction deposits in it [84, 182], or agnostically as the ppE power law of Section 10.10 (Eq. (T2.69)). *Here:* the 1.5PN restricted waveform, a static spike, and the power law. The full analysis must also ask whether the model is accurate enough: a waveform error δh shifts the best fit by

$$\delta\theta^i = (\Gamma^{-1})^{ij}\,(\partial_j h \,|\, \delta h), \tag{10.91}$$

the bias formula (10.37) of Section 10.7 with $\mathbf{C} = S_n$ [183]. A model is good enough when this bias is small compared with the statistical error, which requires roughly $(\delta h|\delta h) \lesssim 1$: the waveform error must be below the noise, not merely small. The static spike fails this test by a wide margin for the binaries of Section 10.12, since the heated spike dephases far less [84, 182]; the cost of the reduction is that our environmental amplitudes are those of an idealised model, while the detectability map of Section 10.11.5, which is stated in terms of β and b, is unaffected.

4. The search. The matched filter of Section 10.8.3 is the most powerful test only for a known template, by the Neyman–Pearson lemma. With unknown parameters, a search maximises the filter over a bank of templates: this is a generalised likelihood ratio, and its distribution under noise alone is not a textbook distribution. Real searches therefore measure it empirically; ground-based detectors build the background by shifting the data of one detector in time

against another by more than the light travel time, which destroys any real coincidence and keeps the noise [78, 184]. The phase and the arrival time are handled exactly as in Section 10.8.4, by two quadratures and one fast Fourier transform [173]. *Here:* a single template with known masses, and a look-elsewhere factor measured from 2000 simulations. The full search costs many templates and an empirical background; the reduction overstates the significance of a weak signal found by searching.

5. The global fit. LISA never records a stretch of data without signals: tens of thousands of resolvable Galactic binaries, massive black-hole mergers and extreme-mass-ratio inspirals overlap in time and frequency throughout the mission. "Noise alone" is therefore the idealised null hypothesis of a single-source problem. The research analysis fits all the sources and the noise jointly, with the number of sources itself a parameter, and iterates as the data grow [176]. *Here:* one source in Gaussian noise. The cost is that confusion between sources, and the extra uncertainty it adds to each, is absent from all our errors.

6. The posterior and the decision. Parameters are estimated by sampling the full likelihood, with the detector response and the noise parameters, using nested sampling [177] or tempered ensemble samplers [178] through general frameworks such as `bilby` [185]; the likelihood is made cheap enough by expanding it around a reference waveform (relative binning, [186]). Whether an environment is present is a model comparison: the evidence of the vacuum model against that of the environmental one [84], or of particle against wave dark matter [81]. *Here:* a four-parameter Metropolis–Hastings chain on noise-free data; the posterior width is right for that reduced problem but the model comparison is not done.

7. Checks. Signals are injected into many simulated noise realisations and recovered; the fraction of injections whose true parameters fall inside the nominal $x\%$ credible region must be $x\%$ (a coverage test, as in Section 10.8.6). The bias (10.91) is evaluated for the known approximations of the waveform. And the Fisher matrix is checked against the posterior with Vallisneri's criterion before any forecast is quoted (Section 10.13). *Here:* the comparison of the chain with the ellipse at four signal-to-noise ratios.

Recap

- Detection is inference between $H_0 : d = n$ and $H_1 : d = n + h(\boldsymbol{\theta})$. Only one noise realisation, $n = d - h$, turns a prediction into the data, so $p(\boldsymbol{d} \mid \boldsymbol{\theta}) = p_n(d - h)$; for stationary Gaussian noise $\ln p_n(n) = -\frac{1}{2}(n|n) + \text{const}$ with $(a|b) = 4\,\mathrm{Re}\int \tilde{a}\tilde{b}^*/S_n \,\mathrm{d}f$.
- The likelihood ratio is $(d|h) - \frac{1}{2}(h|h)$: the matched filter. Under the two hypotheses $z = (d|h)/\rho$ is $\mathcal{N}(0,1)$ and $\mathcal{N}(\rho,1)$, $\rho^2 = (h|h)$. An unknown phase costs a second quadrature, an unknown time one FFT, and both raise the threshold (look-elsewhere). An unknown spectrum, integrated out, gives a Student-t.
- $\Gamma_{ij} = (\partial_i h|\partial_j h)$ is the Gaussian Fisher formula with $\mathbf{C} = S_n$. The amplitude decouples ($\sigma_{\ln \mathcal{A}} = 1/\rho$); the phase block is $\rho^2\langle \partial_i\Psi\, \partial_j\Psi\rangle_w$; a parameter is measured by the part $g_\perp$ of its phase signature that the others cannot imitate, $\sigma = 1/(\rho\|g_\perp\|_w)$.
- Any environment with $P_{\mathrm{env}}/P_{\mathrm{GW}} \propto f^{-n}$ adds $\delta\Psi = \beta u^b$, $b = -\frac{5}{3} - n$; friction in a spike $\rho \propto r^{-\gamma}$ has $b = (2\gamma - 16)/3$. One Fisher matrix per b gives a detectability map; the error diverges where u^b is a vacuum signature ($b = -\frac{5}{3}, 0, 1$), and low-frequency effects separate from the chirp mass.
- Reproduced: the Robson et al. LISA curve and its worked numbers, Cutler and Flanagan's

stage	research version	laptop version (here)	what the reduction costs
data	TDI A, E, T time series, response, gaps	one sky-averaged channel, frequency domain	no sky parameters; per-source response off by tens of per cent
noise	fitted PSD, evolving confusion, glitches	Robson S_n, four-year confusion, known	errors too small if the spectrum is not known (Figure 10.23)
waveform	perturbation-theory inspirals, heated spikes	1.5PN, static spike, ppE power law	absolute dephasing overstated; detectability in (b, β) unaffected
search	template banks, empirical background	one template, simulated look-elsewhere	significance of searched signals overstated
sources	global fit of all sources and noise	one source	no source confusion in the errors
inference	full-likelihood sampling, Bayes factors	Fisher matrix; MH on 4 parameters, ~ 40 s	widths right for the reduced problem only; no evidence
checks	injections over noise realisations	noise-free (median) experiment	no scatter of the best fit, no coverage test of the full chain

Table 10.7: Each reduction made in the laptop version of the gravitational-wave forecast, what a research analysis does instead, and what the reduction costs.

Table I (within 2.33%), Eda et al.'s dephasing and errors (with $\ln \Lambda = \ln 10^3$, and their amplitude at its own pivot), Kim et al.'s dephasing, signal-to-noise ratio and, within a factor 1.4 to 5.5, their posterior widths.

- The Fisher matrix is the posterior of the linearised signal. Trust it where $\frac{1}{2}(R|R) \lesssim 0.1$ on its own 1σ surface; otherwise sample. At $\rho = 10$ the chain is up to 3.564 times wider than the ellipse, at $\rho = 80$ within about 10%; degeneracies and one-sided priors break it at any ρ.

10.15 How small a twist can the sky reveal?

Section 10.6 forecast the six numbers of ΛCDM from the temperature and E-mode spectra of a Planck-like experiment, and the forecast came close to what Planck delivered. Every parameter there did the same kind of thing: it changed the size of a spectrum that is already large, C_ℓ^{TT}, C_ℓ^{TE} or C_ℓ^{EE}, and the Fisher matrix weighed that change against the scatter of the measured spectrum. The birefringence part of Chapter T1 then introduced a parameter of a different kind. Light from the last-scattering surface may have its plane of polarization turned by a small angle β on the way to us. Picture the polarization at each point of the sky as a short headless stick. The ordinary sky makes the sticks line up in spoke-and-ring patterns (E) and almost never in swirls (B); a uniform twist turns every stick by β, so a little of every spoke pattern becomes a swirl, and that new swirl remembers the spoke it came from. In the spectra this shows up as a correlation between E and B, and between T and B, which the untwisted sky does not have at all (Section T1.10.2).

That is where the earlier forecast stops being enough. At $\beta = 0$ the twist changes none of the spectra the ΛCDM forecast used, to first order: EE and BB move by an amount proportional to β^2, and TT does not move at all. Its whole first-order effect sits in two spectra, EB and TB, whose expected value in the fiducial model is exactly zero. A spectrum that is zero on average

still scatters from sky to sky, and how much it scatters is not obvious: it is not set by its own size, which is zero, but by the sizes of the other spectra. The forecast must therefore be built from the full covariance of the three fields T, E, B together.

A fence knocked off true. A surveyor wants to know whether a long straight fence has been knocked a tiny angle off its line. Measuring the angle at the near end is hopeless; the angle is far too small for her protractor. Instead she walks to the far end and measures how far the last post sits to the side of the true line. The sideways shift is the length of the fence times the angle, so a longer fence turns the same small angle into a larger shift. What limits her is not the length but the sideways wobble: the posts were never perfectly in line, and her tape shakes in the wind. The angle she can detect is roughly the wobble divided by the length, and every extra post she checks gives her one more independent reading. One thing she should not do is look at how much the posts wobble in total: a small knock adds only (length $\times$ angle)^2 to the wobble's square, which is lost among the posts' own irregularities long before the shift itself is.

The polarized sky is that fence. The bright E pattern is its length. The twist moves a fraction 2β of E into the sideways direction, B. The wobble is whatever B was there anyway: the swirls made by gravitational lensing (Section T1.10.4) and the noise of the instrument. Each mode of the sky, each (ℓ, m), is one post. In one sentence: *the information on a small twist is the E power divided by the B wobble, per mode, added up over all the modes we can measure.*

The fence in symbols. Take one mode with a large E of variance C_E, a pre-existing B of variance C_B, and noise of variance N in each. After a small twist β (in radians),

$$E^{\rm o} = E + n_E, \qquad B^{\rm o} = 2\beta E + B + n_B, \tag{10.92}$$

from the rotation rule $B' = \sin 2\beta\, E + \cos 2\beta\, B \approx 2\beta E + B$ of Eq. (T1.37). The dials are the lever C_E, the wobble $C_B + N$, and the number n of modes. The naive choice is to look at the B power. Its average is $\mathbb{E}\,|B^{\rm o}|^2 = 4\beta^2 C_E + C_B + N$, so the twist adds only $4\beta^2 C_E$ to it, and the derivative of this with respect to β vanishes at $\beta = 0$: a measurement of B power contains no information on β to first order. The good choice is the product $E^{\rm o}B^{\rm o}$. Its average is $\mathbb{E}[E^{\rm o}B^{\rm o}] = 2\beta C_E$, linear in β, because E, B, n_E, n_B are independent with mean zero and only the term $2\beta E \cdot E$ survives. Its variance at $\beta = 0$ is $\mathbb{E}[(E+n_E)^2(B+n_B)^2] = (C_E+N)(C_B+N)$, the product of two independent variances. So one mode measures β with variance $(C_E+N)(C_B+N)/(4C_E^2)$, and n independent modes divide that by n:

$$\sigma^2(\beta) \overset{(1)}{=} \frac{(C_E+N)(C_B+N)}{4\,n\,C_E^2} \overset{(2)}{=} \frac{C_B+N}{4\,n\,C_E} \quad (N \ll C_E). \tag{10.93}$$

(1) The estimate $\hat\beta = \overline{E^{\rm o}B^{\rm o}}/(2C_E)$ is the average product over n modes divided by its slope $2C_E$; dividing a quantity by a constant divides its variance by the square of the constant.

(2) When E is measured much better than its noise, $C_E + N \approx C_E$ and one factor of C_E cancels.

The second form is the surveyor's rule: wobble over length, divided by the number of posts. Put numbers in. Let the wobble be one hundredth of the lever, $C_B + N = 0.01\,C_E$, and let there be $n = 1000$ modes. Then $\sigma(\beta) = \sqrt{0.01/4000} = 1.6\times10^{-3}$ rad, or $0.09°$, so a twist of $0.35°$ (6.1×10^{-3} rad) stands out at about 3.9σ. The B power of the same modes would grow by $4\beta^2 C_E = 1.5\times10^{-4}\,C_E$, while the average of n squared Gaussian values has a relative scatter of $\sqrt{2/n}$ (Chapter 7), so the measured B power itself scatters by $\sqrt{2/1000}\times 0.01\,C_E = 4.5\times10^{-4}\,C_E$: the twist would appear in the power at a third of a standard deviation. Lesson: the twist is measured in the cross product, with an error set by the ratio of what is in B anyway to what is in E; its square in the B power is useless at small angles.

A picture: fitting a line through the origin. Section T1.10 drew every mode as a point with its E across and its B up: a thin horizontal cigar, which a twist tilts, and that tilt is why the correlation, not the power, identifies a twist. The same picture also says how well the tilt can be measured. By (10.92) the points scatter around the straight line $B = 2\beta E$ through the origin, so measuring β is fitting the slope of that line, and $\hat{\beta} = \sum E^{\mathrm{o}}B^{\mathrm{o}}/(2\sum(E^{\mathrm{o}})^2)$ is exactly least squares through the origin (Section 3.10.2). Everyone who has fitted a line knows the two dials: the vertical scatter of the points, which is the wobble $C_B + N$, and how far the points spread along the horizontal axis, which is the lever $\sum E^2 \approx nC_E$. A slope is pinned when the points reach far out and sit close to the line.

One idea, many names. Measuring a tiny turn of a bright quantity by looking in the direction at right angles to it is the principle of quadrature readout: a gravitational-wave interferometer runs close to a dark fringe so that a small change of arm length appears as light in an output that is otherwise nearly empty, and the noise that matters is the noise of that empty port, not the brightness of the beam. In statistics it is a slope estimated by regression through the origin, and in the language of the Fisher matrix it is the information about a rotation, which we now compute for the real T, E, B sky. The computation answers three questions: which multipoles carry the information, how the error depends on the noise, the beam, the multipole range and the sky fraction, and how close a Planck-like experiment comes to the errors that were actually published.

10.15.1 The information on an angle, from the covariance of T, E and B

The data. At each multipole ℓ and each m the experiment measures three harmonic coefficients, $T_{\ell m}$, $E_{\ell m}$, $B_{\ell m}$ (Eq. (T1.26)), each the sky plus white noise with the beam divided out. They are Gaussian with mean zero, and different (ℓ, m) are independent, exactly as the temperature $a_{\ell m}$ were in Section 10.6.1. What is new is that at one (ℓ, m) we now have three correlated numbers instead of one or two. Their covariance is the 3×3 matrix of rotated spectra of Section T1.10.2, plus the noise N_ℓ^T in temperature and N_ℓ^P in each of E and B:

$$\mathbf{C}_\ell(\beta) = \begin{pmatrix} C_\ell^{TT} + N_\ell^T & \cos 2\beta\, C_\ell^{TE} & \sin 2\beta\, C_\ell^{TE} \\ \cos 2\beta\, C_\ell^{TE} & c^2 C_\ell^{EE} + s^2 C_\ell^{BB} + N_\ell^P & \tfrac{1}{2}\sin 4\beta\, \Delta_\ell \\ \sin 2\beta\, C_\ell^{TE} & \tfrac{1}{2}\sin 4\beta\, \Delta_\ell & s^2 C_\ell^{EE} + c^2 C_\ell^{BB} + N_\ell^P \end{pmatrix}, \tag{10.94}$$

with $c = \cos 2\beta$, $s = \sin 2\beta$ and $\Delta_\ell \equiv C_\ell^{EE} - C_\ell^{BB}$; the spectra on the right are those of the untwisted sky, which has no EB and no TB. The noise enters E and B with the same N_ℓ^P because white noise in Q and U has no preferred orientation, so it is not twisted by anything.

The formula to use. Equation (10.32) is the Fisher matrix for exactly this situation, a zero-mean Gaussian vector at each (ℓ, m) with an ℓ-dependent covariance; it was written there for the pair (T, E), but nothing in its derivation used the size of the matrix. With one parameter,

$$F_{\beta\beta} = \sum_\ell \frac{(2\ell+1) f_{\mathrm{sky}}}{2} \operatorname{Tr}\left[\mathbf{C}_\ell^{-1}\partial_\beta \mathbf{C}_\ell\, \mathbf{C}_\ell^{-1}\partial_\beta \mathbf{C}_\ell\right], \tag{10.95}$$

where $(2\ell+1)f_{\mathrm{sky}}$ counts the independent m-modes of a sky fraction f_{sky} (the argument of Section 10.6.1).

The derivative at $\beta = 0$. Differentiate each entry of (10.94) and set $\beta = 0$. The diagonal entries contain $\cos^2 2\beta$ and $\sin^2 2\beta$, whose derivatives $\mp 2\sin 4\beta$ vanish there; the TE entry contains $\cos 2\beta$, whose derivative $-2\sin 2\beta$ also vanishes. Only the two entries that were zero survive: $\partial_\beta \sin 2\beta = 2\cos 2\beta \to 2$ and $\partial_\beta \tfrac{1}{2}\sin 4\beta = 2\cos 4\beta \to 2$. Write $b_\ell \equiv 2C_\ell^{TE}$ and $e_\ell \equiv 2\Delta_\ell$, gather the (T, E) block of the covariance at $\beta = 0$ into a 2×2 matrix $\boldsymbol{A}_\ell$ and the B entry into one number

$\tilde{B}_\ell \equiv C_\ell^{BB} + N_\ell^P$:

$$\mathbf{C}_\ell(0) = \begin{pmatrix} \boldsymbol{A}_\ell & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & \tilde{B}_\ell \end{pmatrix}, \quad \boldsymbol{A}_\ell = \begin{pmatrix} C_\ell^{TT} + N_\ell^T & C_\ell^{TE} \\ C_\ell^{TE} & C_\ell^{EE} + N_\ell^P \end{pmatrix}, \quad \partial_\beta \mathbf{C}_\ell = \begin{pmatrix} \mathbf{0} & \boldsymbol{v}_\ell \\ \boldsymbol{v}_\ell^\mathsf{T} & 0 \end{pmatrix}, \quad \boldsymbol{v}_\ell = \begin{pmatrix} b_\ell \\ e_\ell \end{pmatrix}. \tag{10.96}$$

The trace. The covariance is block diagonal, so its inverse is too, with $\boldsymbol{A}_\ell^{-1}$ and $1/\tilde{B}_\ell$ on the diagonal. Then

$$\begin{aligned} \mathbf{C}_\ell^{-1}\partial_\beta \mathbf{C}_\ell &\overset{(1)}{=} \begin{pmatrix} \boldsymbol{A}_\ell^{-1} & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & \tilde{B}_\ell^{-1} \end{pmatrix} \begin{pmatrix} \mathbf{0} & \boldsymbol{v}_\ell \\ \boldsymbol{v}_\ell^\mathsf{T} & 0 \end{pmatrix} = \begin{pmatrix} \mathbf{0} & \boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell \\ \boldsymbol{v}_\ell^\mathsf{T}/\tilde{B}_\ell & 0 \end{pmatrix}, \\ \left(\mathbf{C}_\ell^{-1}\partial_\beta \mathbf{C}_\ell\right)^2 &\overset{(2)}{=} \begin{pmatrix} \boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell\boldsymbol{v}_\ell^\mathsf{T}/\tilde{B}_\ell & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & \boldsymbol{v}_\ell^\mathsf{T}\boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell/\tilde{B}_\ell \end{pmatrix}, \\ \mathrm{Tr}\left[\left(\mathbf{C}_\ell^{-1}\partial_\beta \mathbf{C}_\ell\right)^2\right] &\overset{(3)}{=} \frac{\mathrm{Tr}(\boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell\boldsymbol{v}_\ell^\mathsf{T}) + \boldsymbol{v}_\ell^\mathsf{T}\boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell}{\tilde{B}_\ell} \overset{(4)}{=} \frac{2\,\boldsymbol{v}_\ell^\mathsf{T}\boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell}{\tilde{B}_\ell}. \end{aligned} \tag{10.97}$$

(1) Multiply the blocks: the top-left block of $\mathbf{C}^{-1}$ meets the top-right block $\boldsymbol{v}_\ell$ of the derivative, the bottom-right number meets the bottom-left row $\boldsymbol{v}_\ell^\mathsf{T}$.
(2) Square the result block by block: (top-right)(bottom-left) gives a 2×2 matrix, (bottom-left)(top-right) a single number; the off-diagonal blocks of the square are products with a zero block.
(3) The trace of a block-diagonal matrix is the sum of the traces of its blocks.
(4) The cyclic property, $\mathrm{Tr}(\boldsymbol{A}^{-1}\boldsymbol{v}\boldsymbol{v}^\mathsf{T}) = \mathrm{Tr}(\boldsymbol{v}^\mathsf{T}\boldsymbol{A}^{-1}\boldsymbol{v}) = \boldsymbol{v}^\mathsf{T}\boldsymbol{A}^{-1}\boldsymbol{v}$, since the last expression is a single number.

Insert this into (10.95): the factor $\frac{1}{2}$ cancels the 2, and

$$\boxed{F_{\beta\beta} = \sum_\ell (2\ell+1) f_{\rm sky}\, \frac{\boldsymbol{v}_\ell^\mathsf{T}\boldsymbol{A}_\ell^{-1}\boldsymbol{v}_\ell}{C_\ell^{BB} + N_\ell^P} = \sum_\ell (2\ell+1) f_{\rm sky}\, \frac{b_\ell^2\tilde{E}_\ell - 2b_\ell e_\ell C_\ell^{TE} + e_\ell^2\tilde{T}_\ell}{(\tilde{T}_\ell\tilde{E}_\ell - (C_\ell^{TE})^2)\,\tilde{B}_\ell}} \tag{10.98}$$

with $\tilde{T}_\ell = C_\ell^{TT} + N_\ell^T$, $\tilde{E}_\ell = C_\ell^{EE} + N_\ell^P$, and the second form written out with the inverse of a 2×2 matrix, $\boldsymbol{A}^{-1} = \begin{pmatrix} \tilde{E} & -C_\ell^{TE} \\ -C_\ell^{TE} & \tilde{T} \end{pmatrix}/\det \boldsymbol{A}$. The error on the angle is $\sigma(\beta) = F_{\beta\beta}^{-1/2}$. The script `code/ch10/17_biref_fisher.py` also evaluates (10.95) numerically, differentiating the full matrix (10.94) by central differences; the two agree to 4.9×10^{-8} in relative terms.

Example: EB alone, and the variance of a cross-spectrum. Drop the temperature: the data at each (ℓ, m) are only (E, B), $\boldsymbol{A}_\ell$ shrinks to the number $\tilde{E}_\ell$ and $\boldsymbol{v}_\ell$ to e_ℓ, and

$$F_{\beta\beta}^{EB} = \sum_\ell (2\ell+1) f_{\rm sky}\, \frac{4\Delta_\ell^2}{\tilde{E}_\ell\tilde{B}_\ell} = \sum_\ell \frac{\left(\partial_\beta C_\ell^{EB}\right)^2}{\mathrm{Var}\,\widehat{C}_\ell^{EB}}, \qquad \mathrm{Var}\,\widehat{C}_\ell^{EB} = \frac{\tilde{E}_\ell\tilde{B}_\ell}{(2\ell+1) f_{\rm sky}}. \tag{10.99}$$

The second form reads the same number as "squared response over variance" of the measured spectrum, the reading of Section 10.6.1, and it identifies the variance of a measured EB when the true EB vanishes. That variance follows directly. On the full sky $\widehat{C}_\ell^{EB}$ is an average over $2\ell+1$ real modes of the product $E\,B$ (Eq. (T1.26)), and for each mode E and B are independent with variances $\tilde{E}_\ell$ and $\tilde{B}_\ell$, so the product has variance $\tilde{E}_\ell\tilde{B}_\ell$; an average of $2\ell+1$ independent copies divides it by $2\ell+1$. In general, for Gaussian fields, the covariance of two measured spectra is $\mathrm{Cov}(\widehat{C}_\ell^{XY}, \widehat{C}_\ell^{ZW}) = (\tilde{C}_\ell^{XZ}\tilde{C}_\ell^{YW} + \tilde{C}_\ell^{XW}\tilde{C}_\ell^{YZ})/(2\ell+1)$, by Isserlis' theorem for the four-point average (Section 7.2.1); this is the formula of [71], Appendix A, and of [75], eq. (21), and with $X = Z = E$, $Y = W = B$ and $\tilde{C}^{EB} = 0$ it gives (10.99). The one-channel forecast of Section T1.12.3 used this variance as an input; here it is a consequence of the Gaussian likelihood.

Example: when does TB help? With only (T, B), the same steps give the information $F_\ell^{TB} = (2\ell+1) f_{\rm sky}\, 4(C_\ell^{TE})^2/(\tilde{T}_\ell \tilde{B}_\ell)$ from one multipole. Divide it by the EB information of the same multipole:

$$\frac{F_\ell^{TB}}{F_\ell^{EB}} \overset{(1)}{=} \frac{(C_\ell^{TE})^2\, \tilde{E}_\ell}{\tilde{T}_\ell\, \Delta_\ell^2} \overset{(2)}{=} \rho_\ell^2\, \frac{\tilde{E}_\ell}{C_\ell^{EE}} \quad (N_\ell^T \ll C_\ell^{TT},\ C_\ell^{BB} \ll C_\ell^{EE}), \qquad \rho_\ell \equiv \frac{C_\ell^{TE}}{\sqrt{C_\ell^{TT} C_\ell^{EE}}}. \tag{10.100}$$

(1) The common factors $(2\ell+1) f_{\rm sky} \cdot 4$ and $\tilde{B}_\ell$ cancel.
(2) Neglect the temperature noise and the B power next to the E power, and multiply and divide by C_ℓ^{EE}.

The correlation coefficient ρ_ℓ between temperature and E is never larger than one in size, and on the acoustic scales its square is well below one. So TB beats EB only at multipoles where the E measurement is swamped by its own noise, $\tilde{E}_\ell/C_\ell^{EE} > 1/\rho_\ell^2$: there the temperature, measured almost without noise, serves as a cleaner copy of the E pattern through their correlation. In the opposite limit, with no noise at all, (10.98) collapses to the EB answer. Set $N = 0$ and $C_\ell^{BB} \ll C_\ell^{EE}$ in the numerator: $b^2\tilde{E} - 2be\, C_\ell^{TE} + e^2\tilde{T} = 4(C_\ell^{TE})^2 C_\ell^{EE} - 8(C_\ell^{TE})^2 C_\ell^{EE} + 4(C_\ell^{EE})^2 C_\ell^{TT} = 4C_\ell^{EE}\big(C_\ell^{TT} C_\ell^{EE} - (C_\ell^{TE})^2\big)$, and the bracket cancels the determinant, leaving $F_\ell = (2\ell+1) f_{\rm sky}\, 4C_\ell^{EE}/\tilde{B}_\ell$, exactly F_ℓ^{EB} in the same limit. A perfectly measured E already contains everything the temperature knows about it.

Example: what EE and BB add. At $\beta = 0$ they add nothing, because their derivatives vanish. At $\beta \neq 0$ they respond, $\partial_\beta C^{EE\prime} = -2 \sin 4\beta\, \Delta$, and one might expect a little extra information. There is none, for a reason worth knowing. Write $\boldsymbol{R}$ for the matrix that turns (E, B) by 2β and leaves T alone. By Eq. (T1.37) the twisted coefficients are $\boldsymbol{R}$ times the untwisted ones, and the noise is unchanged by $\boldsymbol{R}$ in distribution, so $\mathbf{C}_\ell(\beta) = \boldsymbol{R}\, \mathbf{C}_\ell(0)\, \boldsymbol{R}^{\mathsf{T}}$. Then $\partial_\beta \mathbf{C}_\ell(\beta) = \boldsymbol{R}\left[\boldsymbol{J}\mathbf{C}_\ell(0) + \mathbf{C}_\ell(0)\boldsymbol{J}^{\mathsf{T}}\right]\boldsymbol{R}^{\mathsf{T}}$ with $\boldsymbol{J} = \boldsymbol{R}^{\mathsf{T}}\partial_\beta \boldsymbol{R}$ a fixed matrix, and $\boldsymbol{R}^{\mathsf{T}} = \boldsymbol{R}^{-1}$, so in $\mathrm{Tr}[\mathbf{C}^{-1}\partial\mathbf{C}\,\mathbf{C}^{-1}\partial\mathbf{C}]$ every $\boldsymbol{R}$ meets an $\boldsymbol{R}^{-1}$ and cancels. The information is the same at every angle. Turning all the sticks by a known amount changes nothing about how well a further turn can be measured, so as β grows the information moves out of EB and TB into EE and BB, and the total stays fixed. The script finds the total at $\beta = 0.35°$ equal to that at $\beta = 0$ to 4.8×10^{-8}, with the share carried by EE and BB alone at that angle only 9.4×10^{-4}. For any angle of interest, EB and TB are where the information is.

Key idea: The information on a twist

Each (ℓ, m) mode contributes $\boldsymbol{v}^{\mathsf{T}}\boldsymbol{A}^{-1}\boldsymbol{v}/\tilde{B}$ to the Fisher information on β, with $\boldsymbol{v} = (2C^{TE}, 2(C^{EE} - C^{BB}))$ the response of TB and EB, $\boldsymbol{A}$ the (T, E) covariance and $\tilde{B} = C^{BB} + N^P$ the B power already present. For a well-measured E this is $4C^{EE}/\tilde{B}$: the E power is the lever, the B power and noise are the floor, and the B power itself carries no information at small angles.

10.15.2 Which multipoles carry the information

Read (10.98) one multipole at a time, in its well-measured-E form, $F_\ell \approx (2\ell+1) f_{\rm sky}\, 4C_\ell^{EE}/(C_\ell^{BB} + N_\ell^P)$. Three factors compete: the number of modes $2\ell+1$, which grows with ℓ; the lever C_ℓ^{EE}, which falls with ℓ apart from its acoustic peaks; and the floor $C_\ell^{BB} + N_\ell^P$, which is the lensing B power where the noise is low and the noise where it is high. The noise after the beam has been divided out is $N_\ell^P = \Delta_P^2 e^{\ell(\ell+1)\sigma_b^2}$ (Eq. (10.30)), with Δ_P the depth of the polarization map

and $\sigma_b = \mathrm{FWHM}/\sqrt{8\ln 2}$ the width of the beam; it is flat until the beam scale and then grows exponentially.

Figure 10.42 shows the ingredients and the result for two experiments. The Planck-like one combines the three Planck HFI channels used for the CMB, 100, 143 and 217 GHz, with the noise levels and beams of [159], Table 4, by inverse-variance weighting at each ℓ (as in Section 10.6.3); its polarization depth is 52.3 μK-arcmin on large scales. Its noise lies above the lensing BB at every multipole, so the floor is pure noise and the information follows $(2\ell+1)C_\ell^{EE}$ until the beam cuts it: it peaks at $\ell \approx 373$, half of it comes from multipoles below 457, and only 5.1% from $\ell < 200$. The deep experiment, 2 μK-arcmin with a 3′ beam, has noise below the lensing floor out to $\ell \approx 2000$. Its information then traces the acoustic peaks of C_ℓ^{EE} divided by the smooth lensing BB, and it peaks near $\ell \approx 992$.

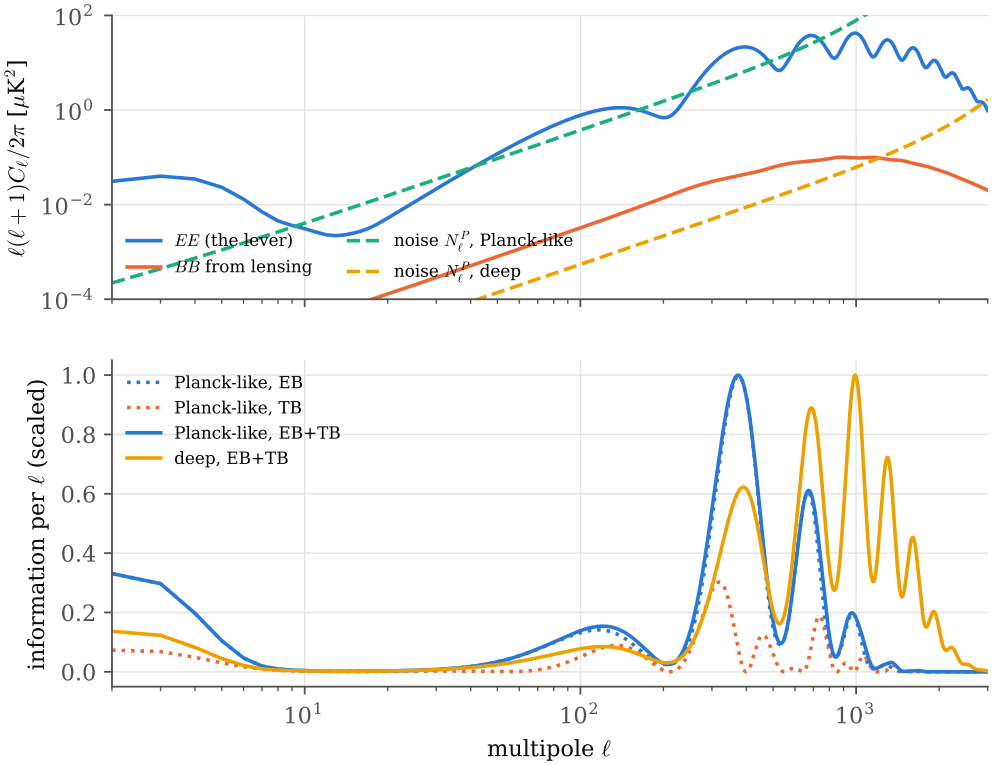

Figure 10.42: Where the information on a twist comes from. Top: the lever and the floor. The E-mode spectrum (blue) is what the twist turns into B; the lensing B modes (orange) and the noise (dashed: Planck-like and deep) are the B that is there anyway. Bottom: the Fisher information on β per multipole, (10.98), scaled to the peak of each experiment's combined EB+TB curve. For the Planck-like experiment the noise is the floor and the information follows the E power out to the beam; TB (dotted orange) adds little because the temperature is a good copy of E only where E is noisy. For the deep experiment the lensing B is the floor and the information follows the acoustic peaks of EE to $\ell \approx 2000$. The large-scale bump at $\ell < 10$ is the reionization peak of EE.

This answers the question of which spectra matter. EE is large and it is the lever: the twist borrows its pattern, so the brighter E is at some multipole, the more B the twist makes there. BB is small and it is the floor: it enters only the denominator, as part of the wobble against which the borrowed B is seen. A brighter EE helps; a brighter BB hurts. Both are needed in the forecast, but only through the covariance, never through a derivative.

Watch out: The reionization bump

The information per multipole at $\ell < 10$ is large, because C_ℓ^{EE} has its reionization peak there while the lensing B is smallest. The published analyses nevertheless start at $\ell = 51$ [57]: on the largest scales the polarization maps are dominated by foreground residuals and instrumental systematics, whose EB is not that of a twist. A forecast that keeps $\ell < 50$ promises information that the real analysis throws away. The forecast numbers for both experiments therefore use $51 \le \ell \le \ell_{\rm max}$.

10.15.3 The dials: depth, beam, multipole range and sky fraction

The sky fraction. Every term of (10.98) carries one factor $f_{\rm sky}$, so $\sigma(\beta) \propto f_{\rm sky}^{-1/2}$ exactly. For the Planck-like experiment the forecast is 0.0415° at $f_{\rm sky} = 0.7$ and 0.0366° at $f_{\rm sky} = 0.9$, in the ratio $\sqrt{0.7/0.9} = 0.88$. With a tapered mask the $f_{\rm sky}$ to use is not the plain fraction of sky kept but $f_{\rm sky} = w_2^2/w_4$, with w_i the average of the i-th power of the mask over the sphere [75], eq. (22). It is the number of independent modes a tapered window leaves, derived in Eq. (8.72): a mode in a region where the mask has weight W has its variance multiplied by W^2, and the modes count fully only where $W = 1$.

The depth. Fix the beam at 5′ and vary Δ_P, with the temperature depth $\Delta_P/\sqrt{2}$ as for detectors that measure both. Equation (10.98) predicts three regimes, which we read off the well-measured-E form $F_\ell \propto C_\ell^{EE}/(C_\ell^{BB} + N_\ell)$ and its noisy-E version $F_\ell \propto (C_\ell^{EE})^2/[(C_\ell^{EE} + N_\ell)(C_\ell^{BB} + N_\ell)]$.

1. *Noise above the E signal* ($N_\ell \gg C_\ell^{EE}$): $F_\ell \propto (C_\ell^{EE})^2/N_\ell^2$, and $N_\ell \propto \Delta_P^2$, so $\sigma(\beta) \propto \Delta_P^2$. Halving the noise improves the error four times.
2. *Noise between the two* ($C_\ell^{BB} \ll N_\ell \ll C_\ell^{EE}$): $F_\ell \propto C_\ell^{EE}/N_\ell$, so $\sigma(\beta) \propto \Delta_P$.
3. *Noise below the lensing B* ($N_\ell \ll C_\ell^{BB}$): $F_\ell \propto C_\ell^{EE}/C_\ell^{BB}$, independent of the noise. The error stops improving: lensing is the floor.

Figure 10.43(a) shows all three. A real experiment mixes regimes across multipoles, so the local slope $\mathrm{d}\ln\sigma/\mathrm{d}\ln\Delta_P$ lies between them: 1.36 at 60 μK-arcmin, where the noise is above the E signal at high ℓ and below it at low ℓ, and 0.54 at 3 μK-arcmin, close to the lensing floor. The floor itself, with $\ell \le 3000$, is $9.8 \times 10^{-4^\circ}$ at 0.1 μK-arcmin; with the lensing B removed it would be $5.2 \times 10^{-5^\circ}$, almost twenty times smaller, which is why a future experiment measuring very small angles would want to remove the lensing B modes first (delensing, Section T1.10.4).

The beam. At fixed depth a wider beam pushes N_ℓ up at lower ℓ and removes the multipoles where most modes live: at 60 μK-arcmin, $\sigma(\beta)$ grows from 0.045° with a 5′ beam to 0.16° with 30′ (Figure 10.43(b)).

The multipole range. Raising $\ell_{\rm max}$ helps only while the new multipoles have $N_\ell \lesssim C_\ell^{EE}$. At 60 μK-arcmin and 5′ the error is 0.065° for $\ell_{\rm max} = 500$, 0.047° for 1000, 0.045° for 1500, and 0.045° for 3000: beyond $\ell \approx 1000$ the noise has won. A deeper map keeps gaining to much higher ℓ (Figure 10.43(c)), because its noise stays below the E signal there.

10.15.4 A Planck-like forecast against the published errors

Their question. The Planck team [187] and later [57] measured the angle by which the CMB polarization appears turned, from the EB (and TB) spectra of the HFI maps over $51 \le \ell \le 1500$. With the detector angles held at their ground calibration, $\alpha_\nu = 0$, the measured angle is the sum $\alpha + \beta$ of Section T1.10.6, and the statistical error is what our forecast predicts. The Planck team

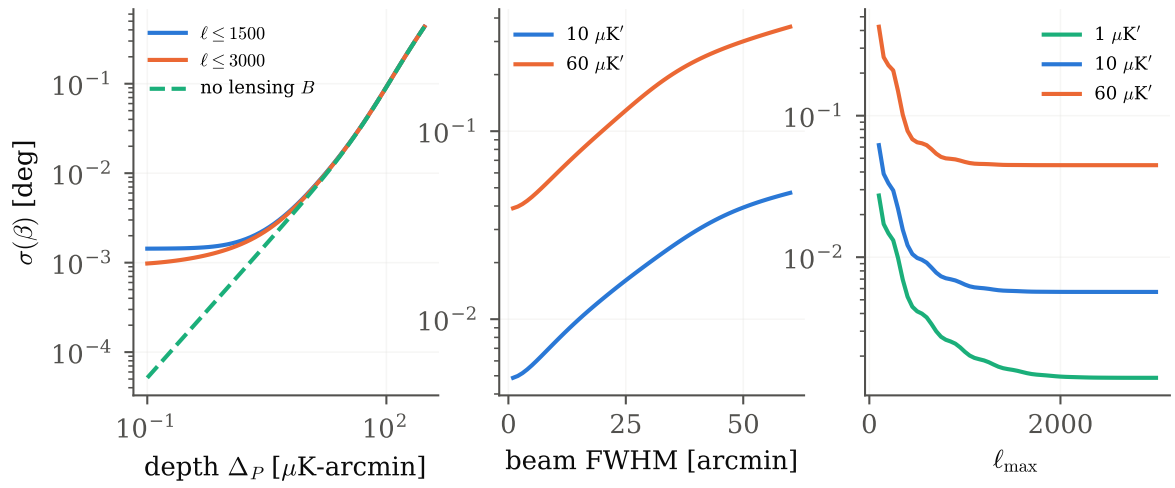

Figure 10.43: The dials of a birefringence forecast, from (10.98) with EB and TB and $f_{\rm sky} = 0.7$. (a) Error against polarization depth with a 5′ beam: steeper than linear for noisy maps, linear in between, and flat below a few μK-arcmin, where the lensing B modes become the floor; without them (dashed) the error would keep falling. (b) Error against beam width at two depths. (c) Error against the largest multipole used: it stops improving where the noise overtakes the E signal, earlier for a noisier map.

found 0.29° ± 0.05° (statistical), Minami and Komatsu 0.289° ± 0.048° with the same data, and Eskilt and Komatsu, from the reprocessed maps (PR4) with more detector splits, 0.288° ± 0.032° [75].

Our forecast. The Planck-like experiment of Section 10.15.2, $51 \le \ell \le 1500$, gives

$$\sigma(\beta) = 0.0428^\circ\ (EB), \qquad 0.0879^\circ\ (TB), \qquad 0.0415^\circ\ (EB + TB) \qquad (f_{\rm sky} = 0.7), \tag{10.101}$$

and 0.0366° for $f_{\rm sky} = 0.9$. TB alone is about twice worse than EB and adds only a few per cent when combined, as (10.100) predicts for an experiment whose E is measured above its noise over most of the range.

Side by side, and why they differ. The published statistical errors, 0.048° to 0.05° for the PR3 maps, are about a third larger than our 0.0366° at a similar sky fraction (their apodized masks keep $f_{\rm sky} = 0.77$–0.97 depending on the map, [57]). Three causes push the real error up. The published analyses use cross-spectra between half-mission maps, each of which has $\sqrt{2}$ times the noise of the full map; this removes the noise bias but loses information wherever the noise matters. Their covariance is built from the observed spectra, which contain the residual Galactic emission, so the floor $\tilde{B}_\ell$ is higher than our CMB-plus-noise model. And the real noise is not white: it rises towards large scales and varies over the sky. The PR4 error is smaller because the reprocessing lowered the noise by 10–30% [74] and because more independent detector splits were used. Lesson: a Fisher forecast with white noise and an ideal sky fraction lands within about a third of the measured error; the remaining gap is a list of known losses, each of which can be put back into the covariance.

10.16 Two angles and one sum

Everything in Section 10.15 assumed that the experiment knows which way its own detectors point. It does not, exactly. Each detector measures polarization along an axis whose orientation on the sky is calibrated on the ground, and if that axis is off by an angle α, every stick the detector sees appears twisted by α (Section T1.10.6). The CMB light then arrives twisted by β

on its journey and by α in the instrument, and its spectra depend only on the sum $\alpha + \beta$. For Planck the ground calibration of α is uncertain by 0.28° [57], almost seven times the statistical error of the forecast (10.101). Section T1.12 described the way out with a door frame next to a crooked painting: the polarized light of our own Galaxy passes through the same detectors but travels too short a distance to be twisted by β, so it carries α alone [71]. A single-channel forecast there showed that the dust in one map can close the degeneracy, at a price. A real experiment has several frequency channels, each with its own detector angle α_ν, and dust that is faint in some and bright in others. How well is β then measured, and what sets the answer?

Four scales, each with its own zero. A post office has four kitchen scales, and each one reads a little off: scale i shows its true load plus an unknown zero error α_i. A parcel of unknown weight β is put on every scale in turn. Each reading is $\alpha_i + \beta$, so the parcel alone can never tell the clerk whether the parcel is heavy or the scales read high: shifting every zero up by a gram and the parcel down by a gram changes no reading at all. The clerk needs a second measurement that involves the zeros but not the parcel. She looks at each scale with its pan empty. That reading is α_i itself, though on some scales the display flickers so much that the empty reading is poor. Now each scale gives its own estimate of the parcel, the loaded reading minus the empty one, and the error of that estimate is set mostly by the worse of the two readings. A scale whose empty reading is useless contributes nothing to the parcel's weight; it only measures its own zero.

The four scales are the four frequency channels of the Planck HFI, 100, 143, 217 and 353 GHz. The parcel is β, which only the CMB carries. The empty pan is the Galactic dust, which sees each channel's α_ν and not β. The flicker is the dust's faintness: at 100 GHz the dust is barely there, at 353 GHz it is bright.

The scales in symbols. Suppose each channel's sum $\alpha_i + \beta$ is measured with error σ_s and its zero α_i with an independent error σ_i. Then $\hat{\beta}_i = \widehat{(\alpha_i + \beta)} - \hat{\alpha}_i$ has variance $\sigma_s^2 + \sigma_i^2$. The dials are σ_s, the σ_i and the number of channels. The naive choice fixes every α_i at its nominal zero and quotes $\hat{\beta}$ with error σ_s: it is precise, and wrong by whatever the true α_i are. The good choice fits the zeros too. With $\sigma_s = 0.05^\circ$, roughly the Planck-like sum of (10.101), and zeros known to $\sigma_i = 0.5^\circ$ from the dust, each channel gives β to $\sqrt{0.05^2 + 0.5^2} = 0.50^\circ$: the sum hardly matters. Four such channels would average to 0.25° if their errors were independent. The CMB part is not independent between channels, because all of them see the same CMB sky, but that part is small here; the dust part, which differs from channel to channel through its noise, is what averages. Lesson: once the detector angles are free, the error on β is set by how well the dust measures the α_ν, not by how well the CMB measures the sum [71].

A picture. In the plane of (α, β) for one channel, the CMB alone allows a band along the line $\alpha + \beta = \text{const}$, infinitely long. The dust adds a band along $\alpha = \text{const}$, a vertical strip. The two cross in a parallelogram, long and thin along the CMB band when the dust strip is wide, and that parallelogram (Figure 10.44) is what the Fisher ellipse in (α, β) looks like. Its long axis is tilted at 45° downwards, so α and β are anti-correlated: a fit that pushes α up pushes β down by the same amount.

One idea, many names. Separating a common offset from individual offsets by adding a measurement that sees only the individual ones is the logic of every calibration network: the zero points of several telescopes from stars that all of them see, the gains of an interferometer's antennas from a calibrator source, the alignment of tracking detectors from cosmic rays that cross them all. In the Fisher matrix it appears as a null direction, $(\delta\alpha_1, \ldots, \delta\alpha_N, \delta\beta) \propto (1, \ldots, 1, -1)$, that the second kind of data lifts. We now build the covariance of several channels, show that without dust it is exactly singular, and compute what the dust buys, channel by channel and for all four channels at once.

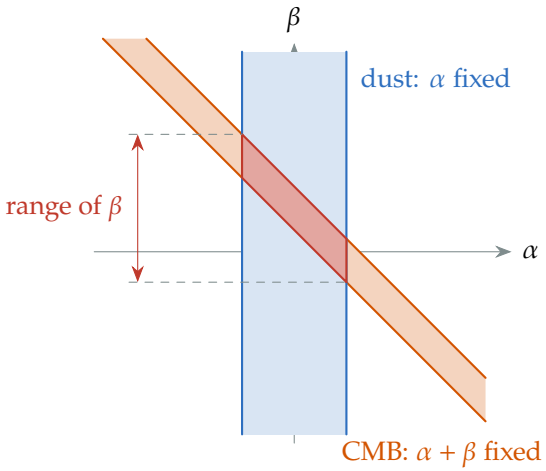

Figure 10.44: Why the dust sets the error on β. The CMB of one channel allows a band of constant $\alpha+\beta$ (orange); the dust allows a strip of α values (blue). They cross in a tilted parallelogram (red) whose height, the error on β, is set by the width of the dust strip once the CMB band is narrow, and whose tilt makes α and β anti-correlated.

10.16.1 The covariance of several channels

The maps. Channel ν sees the CMB, twisted by $\alpha_\nu+\beta$, the dust, twisted by α_ν, and its own noise. By Eq. (T1.61), mode by mode,

$$E_\nu + iB_\nu = e^{2i\alpha_\nu}\, a_\nu \big(E_\mathrm{d} + iB_\mathrm{d}\big) + e^{2i(\alpha_\nu+\beta)}\big(E_\mathrm{c} + iB_\mathrm{c}\big) + n_\nu^E + in_\nu^B, \tag{10.102}$$

where $(E_\mathrm{c}, B_\mathrm{c})$ are the CMB coefficients, $(E_\mathrm{d}, B_\mathrm{d})$ those of one fixed dust pattern, and a_ν the brightness of the dust in channel ν in CMB temperature units. Writing the dust as one pattern times a number per channel assumes that its emission law is the same in every direction of the sky. It is the simplest model, and it makes the dust in different channels perfectly correlated; a dust whose emission law changes across the sky would decorrelate the channels a little and weaken the calibration.

The covariance. The data at one (ℓ, m) are the $2N$ numbers $(E_1, B_1, \ldots, E_N, B_N)$. Write $\boldsymbol{R}(\theta)$ for the 2×2 matrix that turns (E,B) by 2θ, $\boldsymbol{S}_\mathrm{c} = \mathrm{diag}(C_\ell^{EE}, C_\ell^{BB})$ for the CMB and $\boldsymbol{S}_\mathrm{d} = \mathrm{diag}(C_{\ell,\mathrm{d}}^{EE}, C_{\ell,\mathrm{d}}^{BB})$ for the dust pattern. Since the three pieces of (10.102) are independent with mean zero, the 2×2 block between channels μ and ν is the sum of three covariances:

$$\mathbf{C}_{\mu\nu} = \boldsymbol{R}(\alpha_\mu+\beta)\,\boldsymbol{S}_\mathrm{c}\,\boldsymbol{R}(\alpha_\nu+\beta)^\mathsf{T} + a_\mu a_\nu\,\boldsymbol{R}(\alpha_\mu)\,\boldsymbol{S}_\mathrm{d}\,\boldsymbol{R}(\alpha_\nu)^\mathsf{T} + \delta_{\mu\nu}N_{\ell,\nu}^P\mathbb{1}. \tag{10.103}$$

Each term is the rule "if $\boldsymbol{x} = \boldsymbol{R}\boldsymbol{y}$ then $\mathrm{Cov}\,\boldsymbol{x} = \boldsymbol{R}\,\mathrm{Cov}(\boldsymbol{y})\boldsymbol{R}^\mathsf{T}$" applied to one component in two channels; the noise is independent between channels and isotropic in (E,B). The dust model is the one of Section T1.12.3: Planck's power-law fit over 71% of the sky at 353 GHz, $C_\mathrm{d}^{BB} = 0.53\,C_\mathrm{d}^{EE}$, scaled to other frequencies by a modified black body [66]. The Fisher matrix in the $N+1$ parameters $(\alpha_1,\ldots,\alpha_N,\beta)$ is (10.95) with the $2N\times 2N$ trace, and the script computes the derivatives of (10.103) by central differences (Section 10.5).

Without dust the matrix is singular, exactly. Set $a_\nu = 0$. Every entry of (10.103) depends on the angles only through the sums $\alpha_\nu+\beta$. Change every α_ν by $+\delta$ and β by $-\delta$: no sum changes, so the covariance is unchanged, so the likelihood is unchanged, so the curvature of $-\ln\mathcal{L}$ along the direction $\boldsymbol{u} = (1,\ldots,1,-1)$ is zero, $\boldsymbol{u}^\mathsf{T}\mathbf{F}\boldsymbol{u} = 0$. A Fisher matrix with a zero-curvature direction has a zero eigenvalue and no inverse (Section 10.4.3). For the four Planck channels the script finds the ratio of the smallest to the largest eigenvalue to be 5×10^{-17}, zero to round-off. With the dust, the dust terms depend on α_ν alone, the shift $\boldsymbol{u}$ changes them, and the eigenvalue is lifted.

10.16.2 One channel at a time

Take one Planck channel with its noise and beam, the CMB and the dust, $f_{\rm sky} = 0.7$ and $51 \le \ell \le 1500$, and compute the 2×2 Fisher matrix in (α, β). Table 10.8 lists the marginal errors (the square roots of the diagonal of $\mathbf{F}^{-1}$, Section 10.4.1).

channel	$\sigma(\alpha)$ [deg]	$\sigma(\beta)$ [deg]	$\sigma(\alpha+\beta)$ [deg]	$\rho(\alpha,\beta)$
100 GHz	7	7	0.18	−1.000
143 GHz	1.1	1.2	0.07	−0.998
217 GHz	0.49	0.54	0.12	−0.976
353 GHz	0.3	2.4	2.2	−0.596

Table 10.8: Fisher forecast for the detector angle α and the birefringence angle β from the E and B modes of one Planck HFI channel at a time, with CMB, dust and noise, $f_{\rm sky} = 0.7$, $51 \le \ell \le 1500$. The sum is always measured better than either angle, and the two angles are almost perfectly anti-correlated except at 353 GHz.

Reading the table across frequency. At 100 and 143 GHz the dust is faint. The CMB fixes the sum well (0.07° at 143 GHz, close to the CMB-only value 0.066°), but the dust pins α so weakly that $\beta = (\alpha+\beta) - \alpha$ inherits the large error of α, and the two are anti-correlated with $\rho \approx -1$: the ellipse is the CMB band, cut off far away. At 217 GHz the dust is brighter and $\sigma(\beta)$ drops to 0.54°. At 353 GHz the dust is so bright that it measures α to 0.3°, but it also fills $\tilde{E}_\ell$ and $\tilde{B}_\ell$ with its own power, which is the floor against which the CMB's EB is read (Section 10.15.1). The sum is now known only to 2.2°, and β to 2.4°. Too little dust cannot calibrate, too much blurs the CMB.

Figure 10.45(a) turns this into a curve. For one channel with the same depth at every frequency, the error on β is large at both ends and has a minimum in between, near 280 GHz in our dust model, where the dust and CMB polarization are of comparable size on the scales that carry the information. A lower noise moves the whole curve down and widens the useful range, but hardly moves the minimum. Minami et al. found the same shape for the channels of the planned LiteBIRD satellite, with the best single-channel error, 11′ (0.18°), at 195 GHz [71], Table 2. Their minimum sits at a lower frequency for a reason the curve itself suggests: the minimum is where dust and CMB balance on the scales that carry the information. LiteBIRD's beams are tens of arcminutes wide, so its information comes from ℓ of a few hundred and below, where the E power of the CMB is much smaller and the dust, whose power falls with ℓ, relatively brighter; the balance is then struck at a lower frequency, where the dust is fainter.

10.16.3 All four channels, each with its own angle

Now fit all four channels at once, with five parameters $(\alpha_{100}, \alpha_{143}, \alpha_{217}, \alpha_{353}, \beta)$ and the full 8×8 covariance (10.103). The channels help each other in two ways. The bright dust at 353 GHz is the same dust pattern that is faint at 143 GHz, so it tells the fit what that faint dust looks like; and the CMB, the same in every channel, ties all the sums together. The forecast is

$$\sigma(\beta) = 0.25^\circ \quad (\alpha_\nu \text{ free}), \qquad \sigma(\beta) = 0.044^\circ \quad (\alpha_\nu \text{ known}), \tag{10.104}$$

with each $\sigma(\alpha_\nu)$ between 0.23° and 0.27° and each correlation $\rho(\alpha_\nu, \beta)$ between −0.98 and −0.9. Not knowing the detector angles costs a factor of about six. All four α_ν end up with nearly the same error as β: the scales of the story, whose loaded readings are nearly perfect, so that each zero is known as well as the parcel and no better.

The dials. Shrinking the sky to $f_{\rm sky} = 0.5$ gives 0.3°; enlarging it to 0.9, 0.22°, the $f_{\rm sky}^{-1/2}$ scaling. Lowering every channel's noise by a factor of three gives 0.15°, by ten 0.1°; raising it

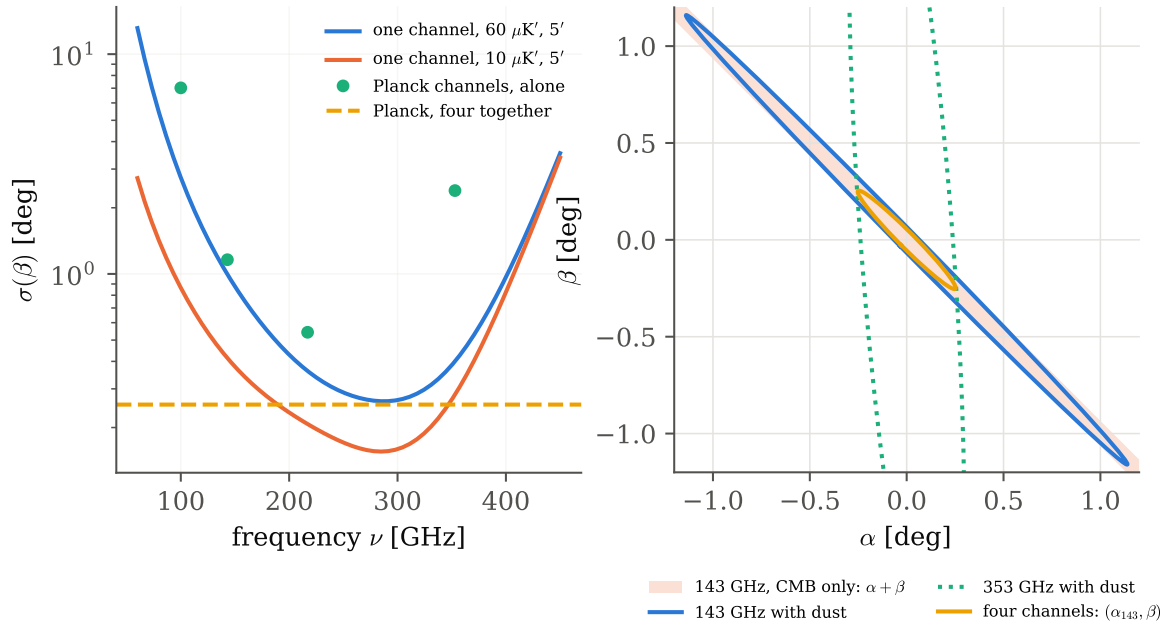

Figure 10.45: Breaking the degeneracy with dust. (a) Error on β from a single channel against its frequency, for a channel of fixed depth (two depths shown) and 5′ beam, with the detector angle free: poor where the dust is too faint to calibrate (low ν) and where it is so bright that it blurs the CMB (high ν). Dots: the four Planck HFI channels, each alone; dashed line: all four together, each with its own α_ν. (b) The 1σ regions in (α, β): the CMB alone at 143 GHz allows a band of constant $\alpha + \beta$ (shaded); the faint 143 GHz dust closes it far away (blue), the bright 353 GHz dust pins α but leaves β loose (dotted green); the four channels together (orange, shown in the plane of α_{143} and β) give the smallest region.

threefold gives 0.42°. Making the dust three times fainter in power gives 0.42°, three times brighter 0.17°. Both the noise and the dust brightness matter, because the dust calibrates α_ν only where it stands above the noise.

Side by side with the measurement. [57] fitted the same five parameters to the Planck 2018 maps and found $\beta = 0.35° \pm 0.14°$, an error about half of our 0.25°. Their setup differs from ours in the direction that helps them. Their masks keep 77–97% of the sky, including regions close to the Galactic plane, where the dust is several times brighter than in the 71% region our dust model describes; our forecast with three times brighter dust gives 0.17°, and with $f_{\rm sky} = 0.9$ on top of that the error would fall further. They did not model the dust spectra at all: the relation Eq. (T1.64) uses the observed $EE - BB$ of each map as the dust template, so the brightest regions contribute fully. And they used every cross-spectrum between half-mission maps of different channels. Lesson: with the detector angles free, the error on β is a statement about the polarized Galaxy, its brightness and the area over which it is used, more than about the CMB.

Watch out: A brighter Galaxy is also a less certain reference

Using more of the bright Galactic plane shrinks $\sigma(\beta)$ in the forecast, but the method assumes that the dust itself has no EB. Any intrinsic dust EB appears as an extra twist γ of the dust and shifts the result to $\beta - \gamma$ (Eq. (T1.65)). The PR4 analysis found β falling as the Galactic mask grows [74], which is what a dust EB concentrated near the plane would do. The Fisher error does not see this bias; only a model of the dust EB, or a calibration that does not rely on the dust, can.

10.17 Simulating the measurement

A forecast is a promise made with a clean model of the data. Twice already the book has checked such a promise by building many skies on the computer and measuring them. In Section 10.6.2 Knox's error bars for a beamed, noisy map were set against a hundred simulated skies per experiment, and they matched. In Section 10.6.6 a Markov chain run on the full likelihood found the Fisher ellipses of ΛCDM where the forecast had put them, except along degeneracies. And in Chapter 8 the simulations showed what a mask does to a temperature spectrum: it couples neighbouring multipoles and changes the scatter, and the MASTER method undoes the first effect on average. The forecast of Section 10.15 made its promise for clean, full-sky T, E, B coefficients with a sky fraction put in by hand. A real polarization map has a hole where the Galaxy is, and that hole does something to polarization that it does not do to temperature.

Think of a field of wheat stalks combed in neat rows by the wind, all leaning east along the rows. Photograph it through a window frame. Inside the frame the rows are perfect. But cut the photograph along the edge of the frame, and ask someone who has only the cut photograph to describe the pattern by its waves. A wave that ends abruptly at the frame is no longer a single wave; it is a bundle of waves pointing in slightly different directions, and for those other directions the same stalks no longer lean along the wave but at an angle to it. Part of a pure "along the rows" pattern is now described as "across", and nothing in the field has changed. The leakage is an artefact of cutting.

On the sky the combed rows are E, the "across" description is B, and the window frame is the Galactic mask. A mask turns some E into B by itself. For a measurement of β this is the dangerous direction: the twist is read as B that remembers E, and the floor against which it is read is the B already present. Leaked B raises that floor. Does it also fake a twist? Does the estimator stay unbiased? And if the covariance used to weight the data and quote the error ignores the leaked B, are the quoted error bars still honest? Those are questions about the whole distribution of the estimate over many skies, and the simulations answer them.

The leak in symbols. On a flat patch, take one pure-E plane wave along the first axis, so that its sticks lie along or across the wavevector: $Q(\boldsymbol{\theta}) = A\cos(k\theta_1)$, $U = 0$ (Eq. (T1.23) with $\varphi_{\boldsymbol{\ell}} = 0$). Multiply it by a window $W(\theta_2)$ that depends only on the other coordinate, a straight edge parallel to the wave's direction of travel. The masked Q is a product, so its Fourier transform is a product of a delta function in ℓ_1 and the transform $\widetilde{W}(\ell_2)$ in ℓ_2; U stays zero. At a wavevector $\boldsymbol{\ell} = (k, \ell_2)$ whose angle is φ, with $\tan\varphi = \ell_2/k$,

$$B(\boldsymbol{\ell}) \overset{(1)}{=} -\sin 2\varphi\; Q(\boldsymbol{\ell}) + \cos 2\varphi\; U(\boldsymbol{\ell}) \overset{(2)}{=} -\sin 2\varphi\; \tfrac{A}{2}\,\widetilde{W}(\ell_2) \overset{(3)}{=} -\frac{2k\ell_2}{k^2+\ell_2^2}\,\tfrac{A}{2}\,\widetilde{W}(\ell_2),$$

$$E(\boldsymbol{\ell}) \overset{(4)}{=} \frac{k^2-\ell_2^2}{k^2+\ell_2^2}\,\tfrac{A}{2}\,\widetilde{W}(\ell_2). \tag{10.105}$$

(1) The definition of B for one wave, Eq. (T1.23).
(2) $U = 0$; the masked Q at (k, ℓ_2) is $\frac{A}{2}\widetilde{W}(\ell_2)$ (the cos splits into two delta functions at $\ell_1 = \pm k$, and we keep the one at $+k$).
(3) $\sin 2\varphi = 2\tan\varphi/(1+\tan^2\varphi)$ with $\tan\varphi = \ell_2/k$.
(4) The same for E, with $\cos 2\varphi = (1-\tan^2\varphi)/(1+\tan^2\varphi)$.

The mask spreads the single wave over a range of ℓ_2 as wide as $\widetilde{W}$, and at every $\ell_2 \neq 0$ a part $\propto \ell_2/k$ of it is read as B. How much in total? Parseval's theorem, $\int |\widetilde{W}(\ell_2)|^2\,\mathrm{d}\ell_2/2\pi = \int W(\theta_2)^2\,\mathrm{d}\theta_2$, turns the question into one about the window on the sky. Let the window keep a strip of width L, many wavelengths wide. The masked wave then carries the power $(A/2)^2\int W^2\mathrm{d}\theta_2 \approx (A/2)^2 L$ in the component at $+k$, and its B part carries $P_B = (A/2)^2\int \sin^2 2\varphi\,|\widetilde{W}|^2\,\mathrm{d}\ell_2/2\pi$. The dials are

the wavenumber k and the shape of the edge. Take the two edges in turn.

$$\begin{aligned}
\text{sharp edges:}\quad & \frac{P_B}{(A/2)^2} \overset{(1)}{=} \int \frac{4k^2\ell_2^2}{(k^2+\ell_2^2)^2}\,\frac{2}{\ell_2^2}\,\frac{\mathrm{d}\ell_2}{2\pi} \overset{(2)}{=} \frac{8k^2}{2\pi}\,\frac{\pi}{2k^3} = \frac{2}{k},\\
\text{tapered edges:}\quad & \frac{P_B}{(A/2)^2} \overset{(3)}{=} \frac{4}{k^2}\int \ell_2^2\,|\widetilde{W}|^2\,\frac{\mathrm{d}\ell_2}{2\pi} \overset{(4)}{=} \frac{4}{k^2}\int W'(\theta_2)^2\,\mathrm{d}\theta_2 \overset{(5)}{=} \frac{\pi^2}{k^2\theta_{\rm apo}}.
\end{aligned} \tag{10.106}$$

(1) $\sin^2 2\varphi$ from (10.105). The strip $|\theta_2| < L/2$ has $\widetilde{W} = 2\sin(\ell_2 L/2)/\ell_2$, whose square oscillates quickly and averages to $2/\ell_2^2$, since $\sin^2$ averages to $\frac{1}{2}$.

(2) The integral $\int \mathrm{d}x/(k^2+x^2)^2 = \pi/(2k^3)$, found by substituting $x = k\tan u$, which turns it into $k^{-3}\int \cos^2 u\,\mathrm{d}u$ over $(-\pi/2, \pi/2)$.

(3) A taper of width $\theta_{\rm apo} \gg 1/k$ confines $\widetilde{W}$ to $|\ell_2| \lesssim 1/\theta_{\rm apo} \ll k$, where $\sin 2\varphi \approx 2\ell_2/k$.

(4) Parseval's theorem again, for the derivative: the transform of W' is $i\ell_2\widetilde{W}$.

(5) A cosine taper rises as $W = \frac{1}{2}[1-\cos(\pi x/\theta_{\rm apo})]$ over $0 < x < \theta_{\rm apo}$, so $W' = \frac{\pi}{2\theta_{\rm apo}}\sin(\pi x/\theta_{\rm apo})$ and $\int W'^2\mathrm{d}x = \pi^2/(8\theta_{\rm apo})$; the strip has two edges.

Divide by the power $(A/2)^2 L$ of the wave. A sharp edge leaks the fraction $2/(kL)$: it is as if a strip about one wavelength wide along each cut were read as B, so the leaked fraction falls only like $1/\ell$. A taper leaks $\pi^2/(k^2\theta_{\rm apo}L)$, falling like ℓ^{-2}, and the ratio of the two,

$$\frac{\text{taper}}{\text{sharp}} = \frac{\pi^2}{2k\theta_{\rm apo}}, \tag{10.107}$$

does not depend on the size of the kept region. For a 5° taper, $\theta_{\rm apo} = 0.087$ rad, it is 0.2 at $\ell \approx 290$: the taper cuts the leak fivefold there. At $\ell \approx 60$ the formula gives 0.9, but there $k\theta_{\rm apo} \approx 5$ and the assumption behind step 3 is only roughly met; the taper helps little on the largest scales either way. The good choice, tapering, costs sky: the tapered part of the mask counts only partly. Lesson: a sharp edge leaks a fraction of E into B that falls like $1/\ell$, a smooth one a fraction that falls like ℓ^{-2}.

Does the leaked B correlate with E and so look like a twist? In (10.105) the product $E(\boldsymbol{\ell})B^*(\boldsymbol{\ell}) \propto -(k^2-\ell_2^2)\,2k\ell_2\,|\widetilde{W}(\ell_2)|^2$ is odd in ℓ_2, while the window of a straight edge has $|\widetilde{W}(\ell_2)| = |\widetilde{W}(-\ell_2)|$. The leaks at $+\ell_2$ and $-\ell_2$ have opposite signs and cancel in a spectrum, which sums over directions: the mask makes B power without a hand. The same holds for any mask on the sphere, because the pseudo-EB spectrum of a masked sky is fed by the true EB only and not by EE or BB [142]. A leak adds wobble to the floor; it does not fake the twist.

One idea, many names. Spreading a pure tone into neighbouring frequencies by cutting it off is spectral leakage, met for the temperature in Chapter 8 and for gravitational-wave data in Section 10.8.5; here the neighbours differ in direction, and direction is what separates E from B. The research tools built on this are the pseudo-C_ℓ estimators of polarization: MASTER generalised to spin-2 fields [140, 142], which undoes the leak in the mean spectra, and "pure" B-mode estimators, which build the B map so that it never receives E in the first place [188]. We use neither: the twist passes through the mask untouched, as Section 10.17.1 shows, so the angle can be measured from the raw masked spectra; the leak then matters only for the error bar.

10.17.1 The simulated skies

The script `code/ch10/18_biref_mc.py` draws 1000 independent skies, each a Gaussian realisation of the lensed fiducial T, E, B spectra with $EB = TB = 0$, on a HEALPix grid of $N_{\rm side} = 256$

(pixels of 13.7′). The lensing B modes are drawn as a Gaussian field with the lensed BB spectrum; real lensing B is not Gaussian (Section T1.10.4), which matters for the scatter of BB itself but very little for EB. Each sky is smoothed with a 7.22′ Gaussian beam, that of the 143 GHz channel [159], and the pixel window. Two noise levels are added, white in each pixel:

- *Planck-like*: 52.3 μK-arcmin in Q and U and 25.5 μK-arcmin in T, the depths of the combined HFI channels of Section 10.15.2;
- *deep*: 3 μK-arcmin in Q, U and $3/\sqrt{2}$ in T, below the lensing floor.

Two Galactic-like masks remove $|b| < 17.5°$: one with a sharp edge, one with a 5° cosine taper eating into the kept region, with effective sky fractions $w_2^2/w_4 = 0.699$ and 0.656 (Section 10.15.3). The analysis uses $51 \le \ell \le 600$ in 22 bins of 25 multipoles. The full research version (Section 10.18) works at $N_{\rm side} = 2048$ to $\ell = 1500$ with the real noise of each map; the smaller grid keeps a thousand skies under half an hour on four cores. It costs the information above $\ell = 600$: by Section 10.15.3, a 60 μK-arcmin map measures β to 0.065° with $\ell \le 500$ and to 0.045° with $\ell \le 1500$. Every Fisher number set against the simulations is computed for exactly the simulated set-up, so the comparison is fair.

Two choices make the simulation cheap and the leakage visible. The E part of each sky (with its correlated T) and the B part are turned into maps separately, masked, and transformed back. Because the transform is linear, their sum is the masked sky, and the B coefficients of the masked E part are exactly the leaked B. The noise is drawn once per sky at unit depth and scaled to each noise level, again by linearity.

The twist passes through the mask. The twist is applied after masking, to the coefficients of the masked sky. That is legitimate because the two operations commute. Masking multiplies $Q + iU$ at each pixel by the real number W; twisting multiplies it by the constant $e^{2i\beta}$; at each pixel $W\, e^{2i\beta}(Q+iU) = e^{2i\beta}\, W(Q+iU)$, so the masked twisted sky is the twisted masked sky. Its spin-2 coefficients are then the twisted ones of Eq. (T1.36), and the pseudo-E and pseudo-B of the masked sky turn into each other by exactly the rule Eq. (T1.37). On one sky, twisting the Q, U maps before the mask and twisting the masked coefficients after it agree to 2×10^{-16} of the largest coefficient, round-off. The consequence is the relation of Section T1.10.5, now on the masked sky: for each sky, the measured pseudo-spectra obey $\widetilde{C}_\ell^{EB\prime} = \frac{1}{2}\sin 4\beta\,(\widetilde{C}_\ell^{EE} - \widetilde{C}_\ell^{BB}) + \cos 4\beta\,\widetilde{C}_\ell^{EB}$, whatever the mask has done to them. No mode-coupling matrix is needed to measure the angle.

10.17.2 The estimator

The model. Divide every measured pseudo-spectrum by w_2, the average of W^2, so that it estimates the full-sky spectrum on average, and bin it. For a small twist the relation above becomes, bin by bin,

$$e_b = 2\beta\, D_b + n_b, \qquad e_b \equiv \widetilde{C}_b^{EB}, \quad D_b \equiv \widetilde{C}_b^{EE} - \widetilde{C}_b^{BB}, \tag{10.108}$$

where n_b is the chance EB the sky and the noise would have shown without a twist, and $\sin 4\beta = 4\beta$ to a relative accuracy of $(4\beta)^2/6 \approx 10^{-4}$. The template D_b is measured on the same sky; its noise bias cancels in the difference, because white noise puts the same power into EE and BB. For the joint fit we add $t_b = \widetilde{C}_b^{TB} = 2\beta\, G_b + \dots$ with $G_b = \widetilde{C}_b^{TE}$.

The estimate. With the data vector $\boldsymbol{e}$, the template $\boldsymbol{D}$ and a covariance $\boldsymbol{V}$ for $\boldsymbol{n}$, the least-squares fit of the slope 2β minimises $(\boldsymbol{e} - 2\beta\boldsymbol{D})^{\mathsf{T}}\boldsymbol{V}^{-1}(\boldsymbol{e} - 2\beta\boldsymbol{D})$ (Section 3.10.5). Setting the derivative with respect to β to zero,

$$\hat\beta \overset{(1)}{=} \frac{\boldsymbol{D}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{e}}{2\,\boldsymbol{D}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{D}}, \qquad \hat\sigma(\hat\beta) \overset{(2)}{=} \frac{1}{2\sqrt{\boldsymbol{D}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{D}}}. \tag{10.109}$$

(1) ∂_β of the quadratic form is $-4\boldsymbol{D}^{\mathsf{T}}\boldsymbol{V}^{-1}(\boldsymbol{e} - 2\beta\boldsymbol{D})$; set it to zero and solve.
(2) $\hat{\beta}$ is linear in $\boldsymbol{e}$ with coefficient vector $\boldsymbol{c} = \boldsymbol{V}^{-1}\boldsymbol{D}/(2\boldsymbol{D}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{D})$, so its variance is $\boldsymbol{c}^{\mathsf{T}}\boldsymbol{V}\boldsymbol{c} = 1/(4\boldsymbol{D}^{\mathsf{T}}\boldsymbol{V}^{-1}\boldsymbol{D})$ when $\boldsymbol{V}$ is the true covariance of $\boldsymbol{e}$.

The quoted error is honest only if $\boldsymbol{V}$ is the true covariance. We try three.

(a) *The model covariance, which ignores the leak.* $V_b = \tilde{E}_b\tilde{B}_b/\nu_b$ from (10.99), with the full-sky signal-plus-noise spectra and $\nu_b = f_{\rm sky}\sum_{\ell\in b}(2\ell+1)$ modes. This is what the forecast assumed.

(b) *The measured spectra.* The same formula with each sky's own measured $\widetilde{C}_b^{EE}$ and $\widetilde{C}_b^{BB}$ in place of the model, as the published analyses do [57, 75]. The measured BB contains the leaked B, so this covariance knows about the leak without being told.

(c) *The simulations.* The covariance of the bandpowers over the other half of the skies (even skies for odd, odd for even), with the Hartlap correction of Section 8.13.2 for the noise in its inverse. It contains everything the simulations contain, bin-to-bin correlations included.

For the joint fit each V_b becomes the 2×2 covariance of (e_b, t_b) from the general Gaussian formula of Section 10.15.1, $\mathrm{Cov}(EB, TB) = C_\ell^{TE}\tilde{B}_\ell/\nu$. The angle put into every sky is $\beta_{\rm in} = 0.35°$.

10.17.3 What a thousand skies say

The leak. Figure 10.46(a) shows the B power of the masked E part of the skies, averaged over the 1000 skies: pure leakage, since those skies had no B at all. In the lowest bin, $51 \le \ell < 76$, it is 0.8% of the E power for the tapered mask and 1.3% for the sharp one, which is 1.5 and 2.5 times the lensing B there. In the bin centred on $\ell = 288$ the sharp edge still leaks 0.24% of the E power, 0.59 of the lensing B, while the taper has cut it to 0.048% of E, 0.12 of the lensing B. Both behave as the cut wave predicts. At the sharp edge the leaked fraction falls by about the factor by which ℓ grows, the $1/\ell$ of (10.106). The ratio of taper to sharp edge is 0.20 at $\ell = 288$, where (10.107) gives 0.2, and 0.60 at $\ell = 63$, where the formula's assumption $k\theta_{\rm apo} \gg 1$ fails. (The slight rise of the tapered curve above $\ell \approx 500$ comes from the pixel grid, which also mixes E and B near its resolution limit.) The Planck-like noise lies well over an order of magnitude above the leak at every multipole, so for it none of this matters. For the deep noise the leak is the largest part of the floor on large scales. Panel (b) shows the other half of the promise: the average measured EB of the twisted skies follows $\frac{1}{2}\sin 4\beta(C^{EE} - C^{BB})$ at every multipole, with no extra EB from the mask.

The bias. With the simulation covariance and both EB and TB, the average of $\hat{\beta} - \beta_{\rm in}$ over the skies is $0.0034° \pm 0.002°$ for the Planck-like noise and $0.00029° \pm 0.0002°$ for the deep noise, tapered mask, and similar for the sharp one (the error is the Monte Carlo error of an average of 1000 values, the scatter divided by $\sqrt{1000}$). Is an offset this size, or a larger one, something we would reasonably expect from an unbiased estimator? An unbiased average lands more than one Monte Carlo error from the truth a third of the time and more than two errors away one time in twenty. Over all eight set-ups (two noise levels, two masks, EB alone or with TB) the largest offset is 2.0 Monte Carlo errors, which is 0.06 of the scatter of a single measurement. The eight are not eight independent checks, though. They are measured on the same thousand skies, with the noise of each sky scaled from one draw, so a chance lean of the particular skies drawn shows up in all of them together, and the eight offsets move as one rather than averaging out. What the skies establish is an upper limit: a bias as large as three Monte Carlo errors, 0.09 of the scatter of a single measurement, would have been seen, and none was. That is what the commutation argument predicts, since it says the estimator needs no mask correction at all; a smaller bias than a tenth of the scatter could only be tested with many more skies.

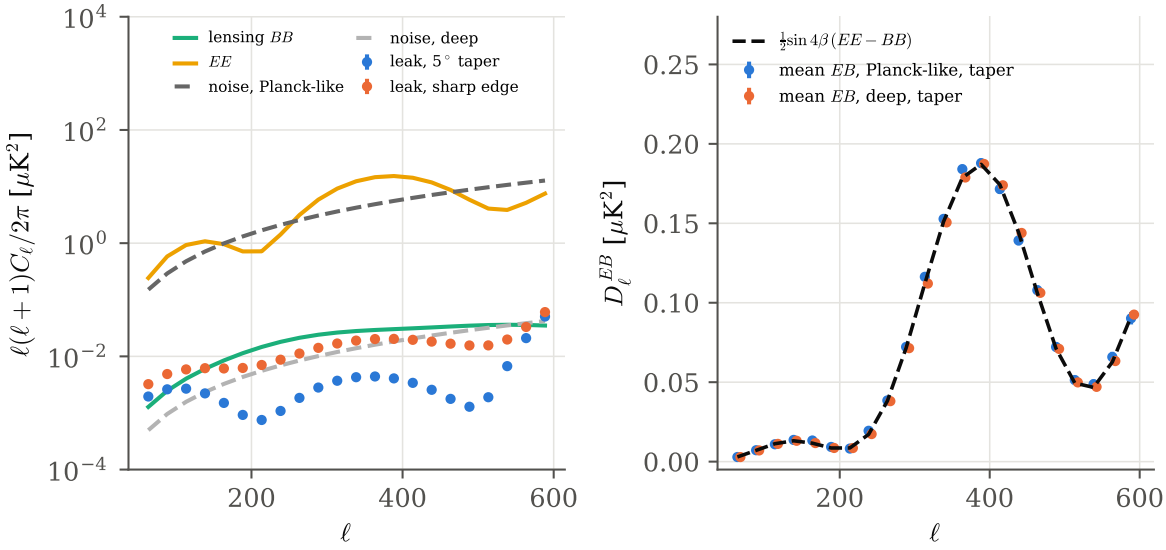

Figure 10.46: (a) E-to-B leakage of the two masks, measured as the B power of skies that contain only E (dots, with the error of the average over 1000 skies), against the lensing B, the E power and the two noise levels, all with the beam. Relative to E, the sharp edge leaks a fraction that falls roughly like $1/\ell$, the tapered mask one that falls faster, so the taper gains most at high ℓ. (b) The average EB of the skies twisted by 0.35°, tapered mask, Planck-like and deep noise (shifted slightly in ℓ for visibility), against the prediction of Eq. (T1.40): the mask adds no EB.

The scatter against the forecast. Table 10.9 sets the standard deviation of $\hat{\beta}$ over the skies against two Fisher errors for exactly the simulated set-up: the forecast of (10.98) with the sky fraction w_2^2/w_4, and the same with the measured leak added to the floor $\tilde{B}_\ell$. For the Planck-like noise the estimator reaches the forecast: the scatter is 1.034 times the Fisher error with the taper and 1.038 with the sharp edge, where the scatter itself is known to 0.001° from the finite number of skies, and adding the leak to the floor changes the forecast by less than one per cent. For the deep noise the scatter is 1.079 and 1.102 times the plain forecast. With the taper, the forecast that includes the leak, 0.00514°, accounts for most of the difference. With the sharp edge, the scatter lies between the two forecasts: counting the leak as extra noise independent of everything else overstates its harm, and the weights built from the simulations, which know how the leaked B is correlated across bins, recover part of the loss.

noise	mask	Fisher	Fisher, leak in floor	scatter of $\hat{\beta}$	ratio	bias
Planck-like	taper	0.0638	0.0639	0.066 ± 0.001	1.034	0.0034 ± 0.002
Planck-like	sharp	0.0618	0.0621	0.0641 ± 0.001	1.038	0.0025 ± 0.002
deep	taper	0.00486	0.00514	0.00524 ± 0.0001	1.079	0.00029 ± 0.0002
deep	sharp	0.0047	0.00563	0.00518 ± 0.0001	1.102	0.00033 ± 0.0002

Table 10.9: The estimator of β on 1000 simulated skies twisted by $\beta_{\rm in} = 0.35°$, EB and TB together, simulation covariance, $51 \le \ell \le 600$; all angles in degrees. "Ratio" is the scatter over the Fisher error. The Planck-like forecast is reached within a few per cent; for the deep noise the leak raises the floor and the scatter.

The error bars. A $\pm1\sigma$ interval should contain the true angle in 68.3% of the skies; with 1000 skies the fraction we measure carries a Monte Carlo error of ±1.5 percentage points (the binomial standard deviation $\sqrt{0.683 \times 0.317/1000}$). Figure 10.47(b) shows the coverage for the three covariances.

- *Planck-like noise:* model, measured spectra and simulations give 68%, 67.9% and 67.5% with

the taper, 69.3%, 69.3% and 67.9% with the sharp edge, all consistent with 68.3% given the Monte Carlo error. When the noise dominates the floor, ignoring the leak costs nothing.

- *Deep noise, model covariance (leak ignored):* 64.8% with the taper and 64.7% with the sharp edge, about 2.4 and 2.4 Monte Carlo errors short of 68.3%. The coverage does not stand alone: the quoted error, 0.00473° for the sharp mask, is smaller than the measured scatter of that estimator, 0.00504°, by about 3 times the Monte Carlo error of the scatter, and the Fisher error with the leak in the floor says why it must be. The error bars are too short, and an analysis that used them would claim more significance than its data hold.
- *Deep noise, measured spectra:* 69% with the taper, correct, but 74.5% with the sharp edge, too high. The measured BB contains the leak, and the formula treats it as independent noise, so the quoted error, 0.00569°, is larger than the scatter, 0.00502°: safe, but wasteful.
- *Deep noise, simulations:* 67.9% and 67%, correct within the Monte Carlo error, as they must be: this covariance contains everything the skies contain.

Figure 10.47(a) shows the shape behind these numbers. The distribution of $(\hat{\beta} - \beta_{\rm in})/\sigma_{\rm Fisher}$ over the skies is a Gaussian of nearly unit width, for both noise levels; a linear estimator of many nearly Gaussian bandpowers is itself nearly Gaussian.

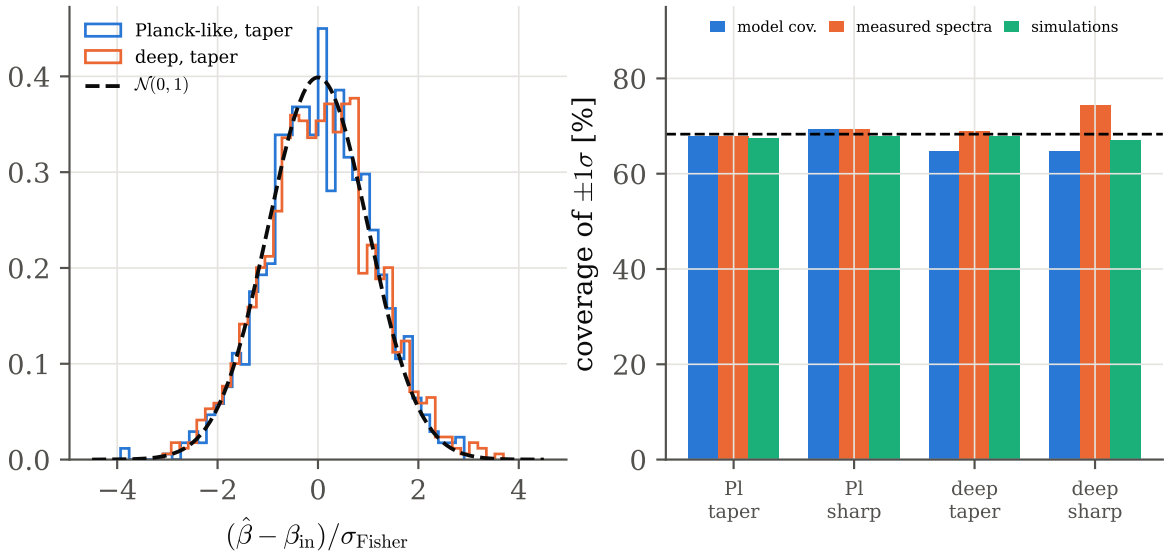

Figure 10.47: (a) The distribution of the estimated angle over 1000 skies, in units of the Fisher error of each set-up (tapered mask, EB and TB, simulation covariance): close to a unit Gaussian, as the forecast promised, slightly wider for the deep noise, where the leak raises the floor (Table 10.9). (b) The fraction of skies whose $\pm1\sigma$ interval contains $\beta_{\rm in}$, for the three covariances (model, which ignores the leak; measured spectra; simulations) and four set-ups; the dashed line is 68.3%, and the Monte Carlo error of each bar is ±1.5 points. Only the deep noise separates the covariances: ignoring the leak gives too short error bars, the measured spectra too long ones at a sharp edge.

The answer. Is the forecast reached on a sky with a hole, noise and a beam? For a Planck-like map it is, within a few per cent, by an estimator on raw masked spectra with no bias the skies can detect, with honest error bars from any of the three covariances. For a map deep enough to see below the lensing floor the mask's leak becomes part of the floor; the estimator still shows no bias, its scatter grows to 1.079–1.102 times the plain forecast, and the error bars are honest only if the covariance knows about the leak. A tapered mask keeps the loss small, and simulations make the error bars right. Every one of these statements is an average over 1000

skies with its Monte Carlo error attached, and a different set of random skies would move each number only within that error.

Watch out: A covariance from the model is only as good as the model

The forecast covariance knows the CMB, the noise and the sky fraction, and nothing else. Whatever the analysis does to the sky that the forecast did not, a mask, a filter, a beam asymmetry, enters the true scatter but not the quoted error. The test is the one done here: simulate the whole analysis on skies with a known answer and count how often the error bars cover it.

10.18 How a birefringence measurement is made in research

The published measurements of Sections 10.15.4 and 10.16.3 follow the same three steps, forecast, simulate, measure, at full scale and with every known imperfection of the instrument put in.

The data. Not one map per channel but two or more independent splits (half-missions, detector sets), so that only cross-spectra between splits are used and the noise bias never appears [57]. For four Planck channels in two splits this gives sixteen maps and many cross-spectra, each with its own detector angle in the model. The masks remove the Galactic plane, carbon-monoxide regions and bright point sources and are tapered by half a degree to a degree [57, 74], close to the masks of the Planck likelihood [70].

The spectra. Pseudo-spectra corrected for the mask with the spin-2 version of MASTER, in the codes NaMaster or PolSpice [142], and corrected for the leakage of temperature into polarization caused by the beams. Section 10.17.1 showed that the angle itself does not need the mask correction; the real analyses apply it anyway because the dust template and the CMB template of Eq. (T1.64) must be compared at the same multipoles.

The likelihood. The relation Eq. (T1.64), written for every pair of maps, is turned into a Gaussian likelihood for (α_ν, β) whose covariance is built from the observed spectra with the formula of (10.99), divided by an effective sky fraction [75], eqs. (21)–(22); it is sampled with an MCMC (Chapter 9). This is choice (b) of Section 10.17.2, which the simulations of Section 10.17.3 found honest with a tapered mask, and safe but wasteful at a sharp edge on a map deep enough for the leak to matter.

The simulations. End-to-end simulations of the instrument, with no twist: ten FFP10 skies for the PR3 analysis gave $\beta = 0.010^\circ \pm 0.030^\circ$ [57], six hundred NPIPE skies for PR4 [74]. Here the simulations are the research instrument, not a check: they contain the scanning, the beams, the noise correlations and the detector systematics, for which no closed form exists, and the published pipeline is trusted only because it returns zero on skies that have no twist. Ten skies whose estimates scatter by 0.030° pin their mean to $0.030^\circ/\sqrt{10} \approx 0.01^\circ$, a third of the scatter of one sky; excluding a bias of a tenth of the scatter, as Section 10.17.3 did, takes hundreds.

How this is used in real research: Simulations that check, simulations that measure

In Section 10.17 the simulations *verify*: the Fisher error and the coverage have analytic predictions, and a thousand Gaussian skies test them. In a real analysis the same machinery *is* the measurement of everything that has no analytic answer: the covariance of spectra from an inhomogeneous noise and a complicated mask, the bias from beam systematics, the distribution of $\hat{\beta}$ under the null hypothesis. Chapter 13 measures the sum $\alpha + \beta$ on the Planck SMICA maps with the estimator of Section 10.17.2, calibrated by simulations of exactly this kind.

	research analysis	here
maps	$N_{\rm side} = 2048$, four channels, split maps, real noise	$N_{\rm side} = 256$, one effective channel, white noise
multipoles	$51 \le \ell \le 1500$	$51 \le \ell \le 600$
foregrounds	real Galaxy, dust as the reference for α_ν	none in the simulations; Gaussian dust in the forecast
spectra	spin-2 MASTER, beam leakage corrected	raw masked pseudo-spectra (the angle commutes with the mask)
covariance	from the observed spectra	three options compared over 1000 skies
validation	FFP10 (10 skies), NPIPE (600 skies)	1000 Gaussian skies with a known twist

Table 10.10: The research version of a birefringence measurement and the laptop-scale version used for the forecast and the simulations.

One chain of reasoning leads from the twist to its measurement. A twist moves a little of the bright E pattern into B, so its information is the E power measured against the B already there; the instrument's own angle hides it until a component that sees only the instrument, the Galaxy, is added; and on a real sky the mask adds to the B already there without faking a twist, so the forecast survives, provided the error bars are built from a covariance that has seen the mask.

Recap

- A twist β enters the T, E, B covariance only through EB and TB at first order. The Fisher information per mode is $\boldsymbol{v}^{\mathsf{T}}\boldsymbol{A}^{-1}\boldsymbol{v}/\tilde{B}$, with $\boldsymbol{v} = (2C^{TE}, 2(C^{EE} - C^{BB}))$; for a well-measured E it is $4C^{EE}/(C^{BB} + N^P)$: E is the lever, the B already present the floor. B power carries no information at small angles; the information on a rotation is the same at every angle.
- TB adds to EB only where E is noise-dominated by more than $1/\rho^2$. A Planck-like experiment measures the sum $\alpha + \beta$ to 0.0415° ($f_{\rm sky} = 0.7$, $51 \le \ell \le 1500$), within about a third of the published statistical errors; the error scales as $f_{\rm sky}^{-1/2}$, as Δ_P^2 to Δ_P with depth, and flattens at the lensing floor.
- With one detector angle per channel the CMB-only Fisher matrix is exactly singular. The dust lifts the null direction; four Planck-like channels give $\sigma(\beta) = 0.25^\circ$, about six times the error with known angles, and the error is set by the brightness of the dust and the noise, not by the CMB.
- A mask turns E into B (a fraction falling like $1/\ell$ at a sharp edge, like ℓ^{-2} with a taper) but makes no EB on average. The twist commutes with the mask, so the template estimator on raw pseudo-spectra needs no mask correction.
- Over 1000 simulated skies the estimator shows no bias; a bias of a tenth of its scatter would have been seen. With Planck-like noise it reaches the Fisher error within a few per cent and every covariance gives honest error bars. Below the lensing floor the leak raises the scatter to 1.079–1.102 times the plain forecast; a model covariance that ignores it covers only 64.8% (taper) and 64.7% (sharp edge), the measured spectra over-cover at a sharp edge, and the simulation covariance covers correctly.

Reading the literature

- **The Fisher matrix and the Cramér–Rao bound, textbook level.** Wasserman, *All of Statistics*, Chapter 9 on the Fisher information matrix and the asymptotic normality of maximum likelihood [Wasserman pp. 133–134]; Cowan, *Statistical Data Analysis*, Chapters 6 and 9 on the in-

formation inequality, the variance of maximum-likelihood estimators and confidence regions [Cowan §§6.6–6.8, Ch. 9]; Casella and Berger, *Statistical Inference*, Section 7.3 [CasellaBerger §7.3]; Sivia, *Data Analysis*, Chapter 3 on the Gaussian approximation to a posterior [Sivia Ch. 3]; Hobson et al., *Bayesian Methods in Cosmology*, Chapter 5 on Fisher forecasts [HobsonBMC Ch. 5].

- **Fisher forecasts in cosmology.** Tegmark, Taylor and Heavens on the Gaussian formula and its use [165]; Knox on the CMB [138]; Jungman et al. on cosmological parameters from the CMB [169]; Coe on reading Fisher matrices [167]; Heavens and Verde on statistical methods and forecasting in cosmology [168, 170]; Planck 2018 for the instrument and the parameters [25, 159].
- **Gravitational-wave data analysis.** Finn on detection as hypothesis testing [172]; Cutler and Flanagan on the inner product and the Fisher matrix of an inspiral [82]; Barack and Cutler on LISA forecasts [79]; Vallisneri on the uses and abuses of the Fisher matrix [166]; Cutler and Vallisneri on waveform systematics [183]; Allen et al. on the matched-filter search [173]; Röver, Meyer and Christensen on an unknown noise spectrum [174]; Cornish and Littenberg on noise and glitch modelling [175]; the LIGO–Virgo guide to detector noise [78]; Usman et al. on a search and its background [184]; Zackay, Dai and Venumadhav on relative binning [186]; Speagle, Ashton et al. and Karnesis et al. on samplers [177, 178, 185].
- **LISA.** The mission proposal [189]; Robson, Cornish and Liu on the sensitivity curve [80]; Tinto and Dhurandhar on time-delay interferometry [179]; Katz et al. on fast inspiral waveforms [181]; Littenberg and Cornish on the global fit [176]; the LISA Data Challenges [180].

- **Cosmic birefringence and polarization on a cut sky.** Minami et al. on determining the detector angles and the birefringence angle together [71]; Minami and Komatsu, Diego-Palazuelos et al. and Eskilt and Komatsu on the measurements from Planck and WMAP [57, 74, 75]; the Planck team's measurement with the angles fixed [187]; Hivon et al. and Alonso et al. on pseudo-spectra and their spin-2 version [140, 142]; Smith on B modes that receive no E [188]; the Planck likelihood paper for the masks and multipole ranges of a real analysis [70].

Chapter summary

Before an experiment exists, we can still ask how sharp its likelihood will be. A model of the signal, a model of the noise and a guess for the truth say what the data would look like on average; the average curvature of $-\ln\mathcal{L}$ at the truth is the Fisher matrix, and its inverse is the covariance the experiment will deliver. It equals the covariance of the score, no unbiased estimator beats it, and maximum likelihood reaches it when the data are informative. For Gaussian data it has a closed form with a mean part and a covariance part. The CMB lives in the covariance part and reproduces Knox's and Planck's numbers; a gravitational wave lives in the mean part, where the formula becomes $(\partial_i h|\partial_j h)$ and says that a phase parameter is measured by the part of its signature the others cannot imitate. That one sentence turns many separate dark-matter and astrophysics questions into one: an environment is a power law in the phase, and its detectability is a single curve in the exponent. Every forecast was then reproduced against the papers that published it, and every one was tested against a Markov chain, which showed where the Gaussian picture breaks: at low signal-to-noise ratio, along degeneracies

and at prior boundaries. A twist of the CMB polarization showed the covariance part at work on a parameter whose signal sits in spectra that are zero on average: the information on the angle is the E power over the B already present, the instrument's own angle makes the problem singular until the Galaxy is added as a reference, and a thousand simulated masked skies showed the estimator free of any detectable bias, the forecast reached for a Planck-like map, and the error bars honest once the covariance knows what the mask does to B. In the pipeline

$$\text{physical model} \to \text{field or data} \to \text{summary } S \to \boxed{P(S \mid \theta) \to \text{infer physics}},$$

the Fisher matrix works the last two arrows before the data exist. Chapter 12 uses it, with Monte Carlo derivatives, to forecast $f_{\rm NL}$ from topological summaries, Chapter 11 to forecast distance measurements, and Chapter 14 collects the ways in which a forecast and a posterior part company.

The Fisher matrix

concept	operational meaning	used later in
Fisher matrix	$F_{ij} = -\mathbb{E}[\partial_i \partial_j \ln \mathcal{L}] = \mathbb{E}[S_i S_j]$ at a fiducial $\boldsymbol{\theta}_0$; needs a model, not data	Chapters 11, 12 and 14
Cramér–Rao bound	$\mathrm{Cov}\,\hat{\boldsymbol{\theta}} - \mathbf{F}^{-1} \geq 0$ for unbiased estimators; reached by linear-Gaussian models	Chapter 14
Gaussian Fisher formula	$\boldsymbol{\mu}_{,i}^{\mathsf{T}} \mathbf{C}^{-1} \boldsymbol{\mu}_{,j} + \frac{1}{2}\,\mathrm{Tr}[\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}]$	Chapters 11 and 12
CMB Fisher matrix	$\sum_\ell \frac{(2\ell+1) f_{\rm sky}}{2} \partial_i C_\ell \partial_j C_\ell / (C_\ell + N_\ell)^2$	Chapter 13
marginal vs conditional	$\sqrt{(\mathbf{F}^{-1})_{ii}}$ vs $1/\sqrt{F_{ii}}$; the gap is a Schur complement	Chapters 11 to 13
ellipses	$\Delta\chi^2 = 2.30, 6.18$ for 68.3%, 95.4% in two parameters	Chapters 11 and 13
priors, experiments, Jacobians	add matrices; $\boldsymbol{J}^{\mathsf{T}}\mathbf{F}\boldsymbol{J}$; $\nabla g^{\mathsf{T}} \mathbf{F}^{-1} \nabla g$	Chapter 11
pivot	the scale where amplitude and slope decorrelate; amplitude errors grow away from it	Chapters 11 and 13
numerical derivatives	steps a fraction of the expected error; halve and double	Chapters 12 and 13
bias of a systematic	$\delta\boldsymbol{\theta} = \mathbf{F}^{-1}[\boldsymbol{\mu}_{,i}^{\mathsf{T}} \mathbf{C}^{-1} \delta\boldsymbol{\mu}]_i$	Chapters 11 and 13

Gravitational waves

concept	operational meaning	used later in
noise-weighted inner product	$(a\|b) = 4\,\mathrm{Re}\int \tilde{a}\tilde{b}^*/S_n\,\mathrm{d}f$; covariance of noise projections	Chapter 14
GW likelihood	$p(\boldsymbol{d} \mid \boldsymbol{\theta}) = p_n(d-h) \propto e^{-(d-h\|d-h)/2}$	Chapter 14
matched filter, SNR	$(d\|h)$; $z \sim \mathcal{N}(0,1)$ vs $\mathcal{N}(\rho,1)$, $\rho^2 = (h\|h)$	Chapter 14
unknown phase, time, PSD	two quadratures; one FFT over lags; Student-t after integrating out S_n	Chapter 14
GW Fisher matrix	$\Gamma_{ij} = (\partial_i h \| \partial_j h)$; $\sigma = 1/(\rho \|g_\perp\|_w)$; $\sigma_{\ln \mathcal{A}} = 1/\rho$	Chapter 14
ppE environment	$\delta\Psi = \beta u^b$, $b = -\frac{5}{3} - n$; friction $b = (2\gamma - 16)/3$	Chapter 14
detectability map	$3\sigma_\beta(b) u_{\rm lo}^b$ against each effect's predicted shift	Chapter 14
linearised signal	Fisher = posterior of $h \approx h_0 + \Delta\theta^i \partial_i h$; check $\frac{1}{2}(R\|R) \lesssim 0.1$ on the 1σ surface	Chapter 14
median experiment	noise-free data $d = h(\boldsymbol{\theta}_0)$: the shape of a typical posterior without its random shift	Chapter 14
waveform bias	$\delta\theta^i = (\Gamma^{-1})^{ij}(\partial_j h \| \delta h)$; model good enough if $(\delta h \| \delta h) \lesssim 1$	Chapter 14

A twist of the CMB polarization

concept	operational meaning	used later in
information on a twist	$F_{\beta\beta} = \sum_\ell (2\ell+1) f_{\rm sky}\, \boldsymbol{v}^{\mathsf{T}} A^{-1} \boldsymbol{v}/\tilde{B}$, $\boldsymbol{v} = (2C^{TE}, 2(C^{EE} - C^{BB}))$; $\approx 4C^{EE}/\tilde{B}$ per mode	Chapter 13
EB versus TB	$F^{TB}/F^{EB} = \rho^2 \tilde{E}/C^{EE}$: TB helps only where E is noisy	Chapter 13
rotation invariance	$F(\beta) = F(0)$; at $\beta \neq 0$ information moves from EB, TB into EE, BB	
depth regimes	$\sigma \propto \Delta^2$, $\propto \Delta$, then the lensing floor	Chapter 13
α–β degeneracy	null direction $(1, \ldots, 1, -1)$ without dust; dust sets $\sigma(\beta)$ when the α_ν are free	Chapter 13
$E \to B$ leakage	a cut wave is read partly as B; fraction $\propto 1/\ell$ at a sharp edge, $\propto \ell^{-2}$ with a taper; no EB on average	Chapter 13
twist through a mask	$We^{2i\beta}(Q+iU) = e^{2i\beta} W(Q+iU)$: pseudo-$E$, B rotate exactly; no MASTER needed for the angle	Chapter 13
honest error bars	weights and errors from a covariance that contains the leak: measured spectra or simulations	Chapter 13

Chapter 11

Large-Scale Structure as Data

Where this chapter is going

A galaxy redshift survey hands us a table. Each row is one galaxy: two angles on the sky and a redshift. Turned into distances with a fiducial cosmology, the table becomes a cloud of a few hundred thousand, or a few million, points in a box of space several billion light years across. No theory predicts where any one of those points should be. What a cosmological model predicts is how the points *cluster*: how much more often than chance two galaxies sit $100\,h^{-1}$Mpc apart, how much the clustering depends on direction relative to our line of sight, and how both change with redshift. Every cosmological number that comes out of a galaxy survey is extracted from that clustering pattern.

Getting from the table to the numbers is a statistics problem from start to finish. The points are a random sample of an underlying continuous density field, so the first question is what sampling does to the statistics: it adds a noise term, the shot noise, whose size we can derive exactly from Poisson's law. The survey sees only part of the sky and is thinner at large distance, so the second question is how to estimate the correlation function $\xi(r)$ and the power spectrum $P(k)$ without letting the survey's edges and its varying depth leak into the answer. The answers are pair-count estimators built from a random catalogue (the Landy–Szalay estimator) and a weighted Fourier estimator (the FKP estimator); in both cases the best combination follows from writing out the first-order fluctuations and choosing the combination in which they cancel, or the weights that minimise the variance. With a good estimate of the clustering in hand, two features carry most of the cosmology. The baryon acoustic peak is a ruler of known length, so its apparent size measures distance. The squashing of the clustering along the line of sight, caused by galaxies' own motions, measures how fast structure grows. Each becomes a parameter fit, and each parameter error can be forecast with the Fisher matrix of Chapter 10 and checked with mock surveys.

The same catalogue holds more than its two-point function. Galaxies live in dark matter haloes and the cosmic web has large empty regions; the halo model and void statistics describe what these structures add. Closest to us, the galaxies' velocities are measured directly, and the local expansion rate, the flows towards nearby superclusters and the ages of passively evolving galaxies give a second, independent route to H_0. Figure 11.1 shows how the pieces connect. In the pipeline that runs through the book (physical model, field, summary, sampling distribution, inference) galaxy clustering lives in the middle three boxes: the summaries of a point process are built and their sampling distributions derived, so that Chapters 9 and 10 can turn them into parameter constraints, and the same catalogues hand Chapter 12 the cosmic web as a field whose shape the two-point function does not see.

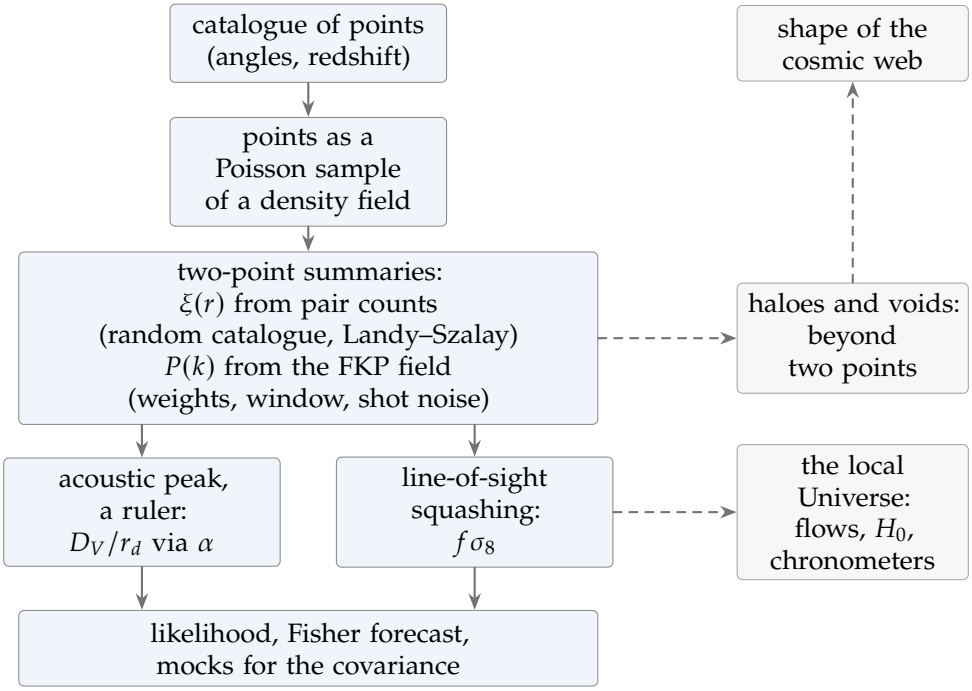

Figure 11.1: The route from a galaxy catalogue to cosmology. The main column is the two-point route: the points are treated as a random sample of a density field, their clustering is summarised by $\xi(r)$ or $P(k)$, and two features of that summary, the acoustic peak and the anisotropy caused by galaxy motions, become parameters. The grey boxes on the right are the other routes through the same data: the structures that two-point statistics miss (haloes, voids, and the shape of the web), and the local Universe, where velocities are measured directly.

11.1 Galaxies as a random sample of a smooth density field

Picture the Sloan luminous red galaxies of 2005: 46,748 points spread through $0.72\,(h^{-1}\mathrm{Gpc})^3$ [42]. That is about one galaxy per cube of $25\,h^{-1}$Mpc on a side, a very sparse sprinkling. The theory of structure formation does not talk about points at all. It talks about a smooth density contrast $\delta(\boldsymbol{x})$, the matter density divided by its mean, minus one, whose two-point function $\xi(r)$ and power spectrum $P(k)$ it predicts (Chapters T1 and 7). Between the two sits one step that every galaxy analysis takes, usually in a single sentence: the galaxies are assumed to be a random sample of the smooth field, more of them where the field is high and fewer where it is low.

That single sentence determines the noise of every clustering measurement in the chapter. If we know exactly what "random sample" means, we can say how the statistics of the points differ from the statistics of the field: how much extra scatter the counts in a cell have, why the power spectrum of the points sits above the power spectrum of the field by a constant, and when that constant swamps the signal. So the question, in words, is:

> *If galaxies are scattered at random with a probability that follows a fluctuating density, how are the pair statistics of the galaxies related to the pair statistics of the density?*

This is a question in the *predictive* direction. We start from a hypothesis, a particular density field, and ask what catalogues it can produce and how often. The measurements of the later sections run the other way. The Universe has produced one catalogue, and we ask which fields, and behind them which cosmological parameters, could have produced it. To answer that we need, for every candidate, the probability of the catalogue we actually observed, and that probability is exactly what the predictive question supplies. So the Poisson sampling worked

out here is the part of the chain that every estimator, error bar and likelihood of the chapter rests on.

11.1.1 The inputs, and the counts they imply

Cut space into small cells of volume ΔV, labelled by i, and let N_i be the number of galaxies in cell i. Write $\bar{n}$ for the mean number of galaxies per unit volume, and $\delta_g(\boldsymbol{x})$ for the density contrast of the smooth field that the galaxies follow. (On large scales δ_g is the matter contrast times a bias factor, $\delta_g = b\,\delta$; see the cosmology notes. None of the sampling results depends on that relation.) The cells are small enough that δ_g is constant across each one; call its value in cell i δ_i. We now state what we assume, separating physics from mathematics, as for the Poisson process of Section 2.5.1.

Physical inputs, all of them statements *given the field*, that is, with the whole map of δ_g held fixed:

(G1) *Rate set by the local density.* The expected number of galaxies per unit volume at $\boldsymbol{x}$ is $\bar{n}\,[1 + \delta_g(\boldsymbol{x})]$. Inside one cell this rate is constant.

(G2) *No memory between places.* The counts in non-overlapping volumes are independent. A galaxy here does not make another galaxy nearby more or less likely, beyond what the field already does.

(G3) *One at a time.* Galaxies are points; two never sit at exactly the same position.

Mathematical inputs: δ_g is smooth on the scale of a cell, and $1 + \delta_g \geq 0$ everywhere, because a rate cannot be negative.

Inside one cell, with the field held fixed, (G1)–(G3) are exactly the three inputs of Section 2.5.1, with volume in place of time: no memory, a constant rate, and events one at a time. The derivation there needed nothing else, so it applies word for word and gives

$$N_i \mid \delta_g \;\sim\; \text{Poisson}(\lambda_i), \qquad \lambda_i = \bar{n}\,\Delta V\,(1 + \delta_i), \tag{11.1}$$

with different cells independent of one another given the field (G2). The field itself is random, drawn once by the Universe. A point process built this way, a Poisson process whose rate is itself a random field, is called a **Cox process** or doubly stochastic Poisson process. Cosmologists call the same assumption the **local Poisson model** [Bernardeau2002 §6.3, p. 135].

Working definition 11.1 (Cox process for galaxies)

Galaxies form a **Cox process** with mean density $\bar{n}$ and contrast δ_g if, given the field $\delta_g(\boldsymbol{x})$ [one realisation of the smooth density, held fixed], the count in any small cell is Poisson with mean $\bar{n}\,\Delta V\,(1 + \delta_g)$ and counts in disjoint cells are independent. *Operationally:* draw a field, then draw a Poisson count in every cell with that cell's mean; repeating both steps generates the ensemble of possible catalogues.

11.1.2 From the inputs to counts in cells and pair counts

Two layers of randomness now act on every count: the Universe chose the field, and then the sampling chose the galaxies. To find the mean and variance of N_i we take them one layer at a time. The tool is the **law of total variance** [the spread of N is the average spread at fixed field plus the spread of the field's own prediction]: $\text{Var}(N) = \mathbb{E}[\text{Var}(N \mid \delta_g)] + \text{Var}(\mathbb{E}[N \mid \delta_g])$, and its two-variable version $\text{Cov}(N_i, N_j) = \mathbb{E}[\text{Cov}(N_i, N_j \mid \delta_g)] + \text{Cov}(\mathbb{E}[N_i \mid \delta_g], \mathbb{E}[N_j \mid \delta_g])$. Both

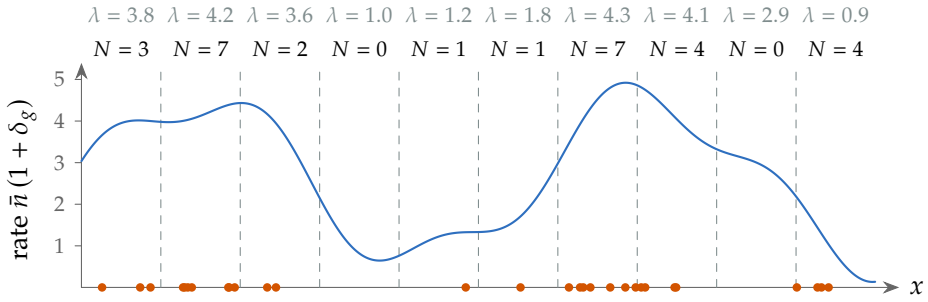

Figure 11.2: A Cox process in one dimension. The blue curve is one realisation of the smooth rate $\bar{n}(1+\delta_g)$; the orange dots are the galaxies drawn from it. Each cell (dashed lines) has an expected count λ (grey, the area under the curve in that cell) and an actual count N (black), which is a Poisson draw with that mean. Cells where the curve is high get many points, but the counts still scatter: the last cell, with $\lambda = 0.9$, happens to hold four galaxies, and the one before it, with $\lambda = 2.9$, holds none.

follow from writing $N - \mathbb{E}\,N = (N - \mathbb{E}[N \mid \delta_g]) + (\mathbb{E}[N \mid \delta_g] - \mathbb{E}\,N)$ and noticing that the cross term averages to zero, because the first bracket has zero mean at every fixed field. We also need the statistics of the field: $\mathbb{E}[\delta_i] = 0$, $\mathbb{E}[\delta_i^2] = \sigma^2$ (the variance of the field in one cell) and $\mathbb{E}[\delta_i \delta_j] = \xi(r_{ij})$, the two-point function at the separation of the two cells (Section 7.1.2).

For one cell:

$$\mathbb{E}[N_i] \overset{(1)}{=} \mathbb{E}\big[\mathbb{E}[N_i \mid \delta_g]\big] \overset{(2)}{=} \mathbb{E}\big[\bar{n}\Delta V(1+\delta_i)\big] \overset{(3)}{=} \bar{n}\Delta V, \tag{11.2}$$

$$\begin{aligned}\mathrm{Var}(N_i) &\overset{(4)}{=} \mathbb{E}\big[\mathrm{Var}(N_i \mid \delta_g)\big] + \mathrm{Var}\big(\mathbb{E}[N_i \mid \delta_g]\big) \overset{(5)}{=} \mathbb{E}\big[\bar{n}\Delta V(1+\delta_i)\big] + \mathrm{Var}\big(\bar{n}\Delta V \delta_i\big) \\ &\overset{(6)}{=} \bar{n}\Delta V + (\bar{n}\Delta V)^2 \sigma^2. \end{aligned} \tag{11.3}$$

(1) Average first over the galaxies at fixed field, then over fields (the law of iterated expectations).
(2) (11.1): the conditional mean of a Poisson count is its rate.
(3) δ_i has zero mean.
(4) The law of total variance.
(5) A Poisson variable has variance equal to its mean; the constant $\bar{n}\Delta V$ in the conditional mean does not vary and drops out of the second variance.
(6) $\mathbb{E}[\delta_i] = 0$ and $\mathrm{Var}(\delta_i) = \sigma^2$.

The variance of a count has two parts. The first, $\bar{n}\Delta V$, is what a perfectly uniform field would give: pure Poisson scatter, the shot noise. The second grows as the square of the mean count and is the clustering. Their ratio is $\bar{n}\Delta V \sigma^2$, the mean count times the field variance. In a sparse survey or a small cell, shot noise wins; in a dense survey or a big cell, clustering wins.

For two different cells $i \neq j$ the same steps give

$$\begin{aligned}\mathrm{Cov}(N_i, N_j) &\overset{(1)}{=} \mathbb{E}\big[\mathrm{Cov}(N_i, N_j \mid \delta_g)\big] + \mathrm{Cov}\big(\mathbb{E}[N_i \mid \delta_g], \mathbb{E}[N_j \mid \delta_g]\big) \\ &\overset{(2)}{=} 0 + (\bar{n}\Delta V)^2\, \mathbb{E}[\delta_i \delta_j] \overset{(3)}{=} (\bar{n}\Delta V)^2\, \xi(r_{ij}), \end{aligned} \tag{11.4}$$

$$\mathbb{E}[N_i N_j] \overset{(4)}{=} \mathrm{Cov}(N_i, N_j) + \mathbb{E}[N_i]\,\mathbb{E}[N_j] = (\bar{n}\Delta V)^2 \big[1 + \xi(r_{ij})\big]. \tag{11.5}$$

(1) The two-variable law of total variance.
(2) (G2): at fixed field the two counts are independent, so their conditional covariance is zero. The conditional means are $\bar{n}\Delta V(1+\delta_i)$ and $\bar{n}\Delta V(1+\delta_j)$, whose covariance is $(\bar{n}\Delta V)^2\,\mathrm{Cov}(\delta_i, \delta_j)$.
(3) The covariance of the field at two points a distance r_{ij} apart is the two-point function.

(4) Definition of covariance, and (11.2).

Read (11.5) with cells so small that each holds at most one galaxy. Then $N_i N_j$ is 1 when both cells hold a galaxy and 0 otherwise, so $\mathbb{E}[N_i N_j]$ is the probability of finding a galaxy in each of two volume elements a distance r apart:

$$\mathrm{d}\,\mathrm{P}_{\mathrm{pair}} = \bar{n}^2 \left[1 + \xi(r)\right] \mathrm{d}V_1\, \mathrm{d}V_2. \tag{11.6}$$

This is the classical definition of the galaxy correlation function [190]: $\xi(r)$ is the excess probability, over a random distribution, of finding a pair at separation r. Put as a question, $\xi(r)$ asks how strongly the density at one place is tied to the density at another place a distance r away. Under (G1)–(G3) it is not a separate definition. The pair excess of the *points* is the two-point function of the *field*, exactly, with no shot-noise correction, as long as the two volume elements are distinct. Shot noise lives only at zero separation. That one fact explains the designs of all the estimators of Sections 11.2 and 11.3.

Example: counts in cells. Take a cubic cell of side R, so that $\bar{N} = \bar{n}R^3$, and let σ_R^2 be the variance of the field averaged over that cube. Summing (11.3) and (11.4) over all the small cells inside the cube,

$$\mathrm{Var}(N) \overset{(1)}{=} \sum_i \mathrm{Var}(N_i) + \sum_{i \neq j} \mathrm{Cov}(N_i, N_j) \overset{(2)}{=} \bar{N} + (\bar{n}\Delta V)^2 \sum_{i,j} \xi(r_{ij}) \overset{(3)}{=} \bar{N} + \bar{N}^2 \sigma_R^2, \tag{11.7}$$

(1) The variance of a sum is the sum of all variances and covariances.

(2) (11.3) and (11.4); the diagonal σ^2 terms join the off-diagonal ξ terms because $\xi(0) = \sigma^2$, and the $\bar{n}\Delta V$ terms add up to $\bar{N}$.

(3) The variance of the cube average, $\sigma_R^2 = \mathrm{Var}\big(\frac{1}{n_c}\sum_i \delta_i\big) = \frac{1}{n_c^2}\sum_{i,j}\xi(r_{ij})$ with n_c cells in the cube, and $(\bar{n}\Delta V)^2 n_c^2 = \bar{N}^2$.

So the ratio of variance to mean, the Fano factor, is $1 + \bar{N}\sigma_R^2$. A cube of side $6.25\,h^{-1}$Mpc in a survey with $\bar{n} = 10^{-3}\,h^3\mathrm{Mpc}^{-3}$ holds on average $\bar{N} = 0.244$ galaxies. For the field of our simulation below, the predicted Fano factor there is 2.173: the clustering term is only a little larger than the shot noise. A cube of side $50\,h^{-1}$Mpc holds 125.1 galaxies on average, and the predicted ratio is 19.62: the clustering term is about twenty times the shot noise. The same field looks Poisson-dominated in small cells and clustering-dominated in big ones. In contrast form, with $\delta_N = N/\bar{N} - 1$, (11.7) reads $\mathrm{Var}(\delta_N) = 1/\bar{N} + \sigma_R^2$ [Bernardeau2002 eq. (374)].

11.1.3 The power spectrum of points: the shot-noise term

The same reasoning in Fourier space gives the most used formula in galaxy clustering. We work on the periodic grid of Section 7.4.1: a box of volume V cut into cells of volume ΔV, Fourier modes $\delta_{\boldsymbol{k}} = \Delta V \sum_{\boldsymbol{x}} \delta(\boldsymbol{x}) e^{-i\boldsymbol{k}\cdot\boldsymbol{x}}$, and the convention $\mathbb{E}\big[\delta_{\boldsymbol{k}}\delta^*_{\boldsymbol{k}'}\big] = VP(k)$ when $\boldsymbol{k} = \boldsymbol{k}'$ and zero otherwise. The density contrast of the galaxies in cell $\boldsymbol{x}$ is $\delta_n(\boldsymbol{x}) = N(\boldsymbol{x})/(\bar{n}\Delta V) - 1$. Dividing (11.3) and (11.4) by $(\bar{n}\Delta V)^2$, its covariance between cells $\boldsymbol{x}$ and $\boldsymbol{y}$ is $\xi(\boldsymbol{x}-\boldsymbol{y}) + \delta^K_{\boldsymbol{xy}}/(\bar{n}\Delta V)$, where the Kronecker δ^K is 1 for the same cell and 0 otherwise. Then

$$\begin{aligned}\mathbb{E}\big[|\delta_{n,\boldsymbol{k}}|^2\big] &\overset{(1)}{=} \Delta V^2 \sum_{\boldsymbol{x},\boldsymbol{y}} \left[\xi(\boldsymbol{x}-\boldsymbol{y}) + \frac{\delta^K_{\boldsymbol{xy}}}{\bar{n}\Delta V}\right] e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})} \\ &\overset{(2)}{=} \Delta V^2 \frac{V}{\Delta V} \sum_{\boldsymbol{r}} \left[\xi(\boldsymbol{r}) + \frac{\delta^K_{\boldsymbol{r0}}}{\bar{n}\Delta V}\right] e^{-i\boldsymbol{k}\cdot\boldsymbol{r}} \overset{(3)}{=} V\left[P(k) + \frac{1}{\bar{n}}\right].\end{aligned} \tag{11.8}$$

(1) Insert the definition of $\delta_{n,\boldsymbol{k}}$ twice and take the expectation inside the double sum ($\boldsymbol{k} \neq \boldsymbol{0}$, so the mean of δ_n drops out).
(2) Statistical homogeneity: the bracket depends only on $\boldsymbol{r} = \boldsymbol{x} - \boldsymbol{y}$, so the sum over $\boldsymbol{y}$ at fixed $\boldsymbol{r}$ gives the number of cells, $V/\Delta V$.
(3) $\Delta V \sum_{\boldsymbol{r}} \xi(\boldsymbol{r}) e^{-i\boldsymbol{k}\cdot\boldsymbol{r}} = P(k)$ is the grid Wiener–Khinchin relation (Section 7.3.2); the Kronecker term picks out $\boldsymbol{r} = \boldsymbol{0}$ and leaves $\Delta V \cdot 1/(\bar{n}\Delta V) = 1/\bar{n}$.

Key idea: Shot noise

For galaxies that are a Cox sample of a field with spectrum $P(k)$, the power spectrum of the galaxy density contrast is

$$P_{\rm gal}(k) = P(k) + \frac{1}{\bar{n}}.$$

The added constant is the power spectrum of pure randomness: it comes entirely from each galaxy being paired with itself, and it is the same at every k.

Why is the shot noise flat? In real space it lives at a single point, the zero separation of a galaxy with itself, and the Fourier transform of a spike is a constant. The size of the spike, $1/\bar{n}$, is the volume per galaxy: the sparser the sample, the larger the noise. The quantity that decides whether a survey measures the field or the noise at wavenumber k is therefore $\bar{n}P(k)$, the signal-to-noise per mode. It recurs in every formula of Sections 11.3 and 11.4.

Example: a field with no structure. If $\delta_g = 0$ everywhere, the catalogue is a homogeneous Poisson process and (11.8) gives $P_{\rm gal} = 1/\bar{n}$ at every k. With $\bar{n} = 10^{-3}\,h^3\mathrm{Mpc}^{-3}$ that is $1000\,h^{-3}\mathrm{Mpc}^3$. A uniform random catalogue is not "unclustered" in its measured power spectrum: it has exactly this flat power.

Example: how sparse is too sparse? Eisenstein and collaborators chose luminous red galaxies at $\bar{n} \approx 10^{-4}\,h^3\mathrm{Mpc}^{-3}$, so $1/\bar{n} = 10^4\,h^{-3}\mathrm{Mpc}^3$. They quote the galaxy power as $10^4\,h^{-3}\mathrm{Mpc}^3$ at $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ and 4×10^4 at $k \approx 0.05$ [Eisenstein2005 §2]. So $\bar{n}P \approx 1$ at the smallest scales of the acoustic feature and $\bar{n}P \approx 4$ on the larger scales. A survey ten times denser would gain little on large scales, where the error is already dominated by the finite number of Fourier modes in the volume, and a survey ten times sparser would lose most of its signal to noise. Sparse, luminous, and spread over a huge volume is the right design for large-scale clustering, which is what Section 11.3 will make precise with the effective volume.

11.1.4 Simulating a Cox process: lognormal fields

To test (11.8) we need a field to sample. A Gaussian field from Section 7.4 will not do. Galaxy fields on the scale of a few Mpc have variance of order one, so a Gaussian δ_g dips below -1 in a sizeable fraction of cells, and the input $1 + \delta_g \geq 0$ fails: a Poisson count cannot have a negative mean. The standard fix is the **lognormal field** [55]. Take a Gaussian field G with zero mean, variance σ_G^2 and two-point function $\xi_G(r)$, and define

$$1 + \delta_g(\boldsymbol{x}) = \exp\!\left[G(\boldsymbol{x}) - \tfrac{1}{2}\sigma_G^2\right], \tag{11.9}$$

which is positive by construction. What two-point function does δ_g have? For two points with $G_1 = G(\boldsymbol{x}_1)$, $G_2 = G(\boldsymbol{x}_2)$,

$$\mathbb{E}\big[(1+\delta_1)(1+\delta_2)\big] \overset{(1)}{=} e^{-\sigma_G^2}\,\mathbb{E}\big[e^{G_1+G_2}\big] \overset{(2)}{=} e^{-\sigma_G^2}\,e^{\frac{1}{2}\mathrm{Var}(G_1+G_2)} \overset{(3)}{=} e^{-\sigma_G^2}\,e^{\sigma_G^2+\xi_G(r)} = e^{\xi_G(r)},$$
$$\xi(r) \overset{(4)}{=} \mathbb{E}\big[(1+\delta_1)(1+\delta_2)\big] - 1 = e^{\xi_G(r)} - 1. \tag{11.10}$$

(1) Multiply out the two exponentials of (11.9).
(2) $G_1 + G_2$ is Gaussian with zero mean, and for a Gaussian Y with zero mean, $\mathbb{E}[e^Y] = e^{\mathrm{Var}(Y)/2}$ (the moment generating function of Chapter 2 at $t = 1$).
(3) $\mathrm{Var}(G_1 + G_2) = \sigma_G^2 + \sigma_G^2 + 2\xi_G(r)$.
(4) $\mathbb{E}[\delta_1] = \mathbb{E}[\delta_2] = 0$ (set $\boldsymbol{x}_1 = \boldsymbol{x}_2$ in the first line with one factor: $\mathbb{E}[1 + \delta] = e^{-\sigma_G^2/2} e^{\sigma_G^2/2} = 1$), so the cross terms vanish.

So to make a lognormal field with a target $\xi(r)$, we build the Gaussian field with $\xi_G = \ln(1 + \xi)$ [Xavier2016 eq. (7)], compute its spectrum P_G by a Fourier transform on the grid, and draw it as in Section 7.4.2. When the target is a realistic galaxy spectrum, the transformed P_G can be slightly negative at a few high wavenumbers (no Gaussian field has exactly the required ξ_G); we set those to zero. For the fields below this touches 1.78% of the modes. The lognormal is not the true distribution of galaxies, but it has the right two-point function, it is positive, and it is skewed in the same direction as the real density, which is all a test of (11.8) requires.

Listing 11.1: Lognormal field and Cox sampling (`code/ch11/lib_lss.py`)

```
class Lognormal:
    """Lognormal field 1 + delta = exp(G - sigma_G^2/2) with a prescribed grid two-point function.

    xi_target is the two-point function the lognormal field should have on the grid. Because
    <(1+d1)(1+d2)> = exp(xi_G(r)) for jointly Gaussian G (the mean of exp of a Gaussian), the
    Gaussian field needs xi_G = ln(1 + xi_target) [Xavier et al. 2016, eq. 7 with shift 1].
    Its spectrum P_G is the FFT of xi_G; rare negative values are clipped to zero.
    """

    def __init__(self, xi_target_grid, N, L, d):
        self.N, self.L, self.d = N, L, d
        D = L / N
        xg = np.log1p(xi_target_grid)
        pg = np.fft.rfftn(xg).real * D ** d          # P_G on the rfft grid
        self.clipped = float(np.mean(pg < 0))
        self.pg = np.clip(pg, 0, None)
        self.pg.flat[0] = 0.0
        w = rfft_weights(N, d)
        self.sigma2 = float(np.sum(w * self.pg) / L ** d)   # variance of G on the grid

    def draw(self, rng, nsim=None, return_gauss=False):
        g = gaussian_from_pgrid(self.pg, self.N, self.L, self.d, rng, nsim)
        out = np.expm1(g - 0.5 * self.sigma2)
        return (out, g) if return_gauss else out

def xi_box_from_pk(Pfun, N, L, d):
    """Exact grid two-point function (1/V) sum_k P(k) e^{ik.r} of a field with spectrum P on the grid."""
    D = L / N
    kmag, _ = kgrid(N, L, d, real=False)
    with np.errstate(divide="ignore", invalid="ignore"):
        pk = np.where(kmag > 0, Pfun(np.where(kmag > 0, kmag, 1.0)), 0.0)
    return np.real(np.fft.ifftn(pk)) / D ** d

def poisson_sample(density, nbar, L, rng, window=None):
    """Counts per cell of a Cox process: N_cell ~ Poisson(nbar * dV * W * (1 + delta)).

    density : 1 + delta on the grid (must be >= 0); window: optional W(x) in [0, 1] (or n(x)/nbar).
    """
```

```
    d = density.ndim
    dV = (L / density.shape[0]) ** d
    lam = nbar * dV * density * (1.0 if window is None else window)
    return rng.poisson(np.clip(lam, 0, None))
```

The class `Lognormal` does the three steps just described: line 142 takes $\ln(1+\xi)$, line 143 Fourier transforms it into P_G (the factor ΔV turns the grid sum into the continuum normalisation of Section 7.4.1), and lines 144–146 clip and record the negative modes. The method `draw` makes a Gaussian field with that spectrum and applies (11.9). `poisson_sample` is (11.1) in one line: every cell gets a Poisson count with mean $\bar{n}\Delta V(1+\delta)$, optionally multiplied by a survey window, which we use in the next two sections.

11.1.5 Checking the shot noise and the counts in cells

The script `code/ch11/01_poisson_sampling.py` draws 10 lognormal fields in a box of side $600\,h^{-1}$Mpc with 96^3 cells. Their target spectrum is $b^2P_{\rm lin}(k)$ with $b = 1.5$ and $P_{\rm lin}$ the CAMB linear spectrum at $z = 0$ (Section T1.4). Each field is sampled at three densities, $\bar{n} = 10^{-4}, 10^{-3}, 10^{-2}\,h^3\mathrm{Mpc}^{-3}$.

Listing 11.2: Sampling one field at three densities (`code/ch11/01_poisson_sampling.py`)

```
for s in range(NSIM):
    delta = ln.draw(rng)
    p_field.append(kb.avg(power_raw(delta, L)))
    for nb in NBARS:
        c = poisson_sample(1 + delta, nb, L, rng)
        dn = c / (nb * dV) - 1                  # density contrast of the points
        p_pts[nb].append(kb.avg(power_raw(dn, L)))
        p_eps[nb].append(kb.avg(power_raw(dn - delta, L)))   # the sampling noise alone
        if nb == 1e-3:
            for m in cic:                       # counts in cubes of m^3 cells
                cs = c.reshape(N // m, m, N // m, m, N // m, m).sum(axis=(1, 3, 5))
                ds = (1 + delta).reshape(N // m, m, N // m, m, N // m, m).mean(axis=(1, 3, 5)) - 1
                cic[m].append((cs.mean(), cs.var(), ds.var()))
    cu = poisson_sample(np.ones_like(delta), 1e-3, L, rng)
    p_unif.append(kb.avg(power_raw(cu / (1e-3 * dV) - 1, L)))
```

Line 42 turns the counts into the galaxy contrast δ_n. Line 43 stores its shell-averaged power, line 44 the power of $\delta_n - \delta_g$, which is the sampling noise alone, and lines 46–49 add up the counts in cubes of 1, 2, 4 and 8 cells on a side for the counts-in-cells test. Lines 50–51 sample a perfectly uniform field for comparison.

Figure 11.3 shows the result. At every density the galaxy power is the field power lifted by $1/\bar{n}$, and at $\bar{n} = 10^{-4}$ the lift is so large that beyond $k \approx 0.1\,h\,\mathrm{Mpc}^{-1}$ the galaxies tell us almost nothing about the field. The power of the sampling noise alone, multiplied by $\bar{n}$, averages 0.987, 0.981 and 1.000 at the three densities, against the predicted 1; the uniform field gives 0.982.

Figure 11.4 checks (11.7). In the smallest cubes the measured ratio is 2.170 against the predicted 2.173; in the largest, 19.59 against 19.62. Both differ from the prediction by less than the scatter between realisations.

Where the inputs break. Each input can fail, and each failure has a signature in the data.

- (G2) fails on small scales. Two galaxies cannot overlap, and two massive dark matter haloes cannot sit closer than their own radii. That exclusion makes counts in small cells *less* variable than Poisson, and the effective shot noise smaller than $1/\bar{n}$ [Bernardeau2002 p. 136, footnote 60].

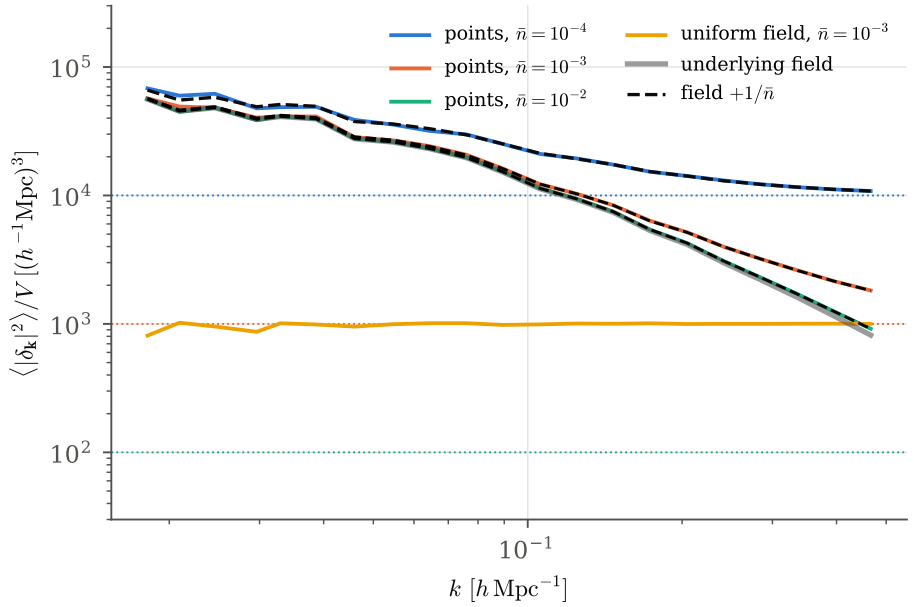

Figure 11.3: Power spectra of Poisson samples of one lognormal field. The grey band is the field itself. Each coloured curve is the galaxy power at one mean density, and the dashed black curves are the field plus $1/\bar{n}$; the dotted horizontal lines mark $1/\bar{n}$. The sparsest sample (blue) is dominated by the flat noise beyond $k \approx 0.1\,h\,\mathrm{Mpc}^{-1}$. The yellow curve is a uniform field sampled at $\bar{n} = 10^{-3}$: flat at $1000\,h^{-3}\mathrm{Mpc}^3$.

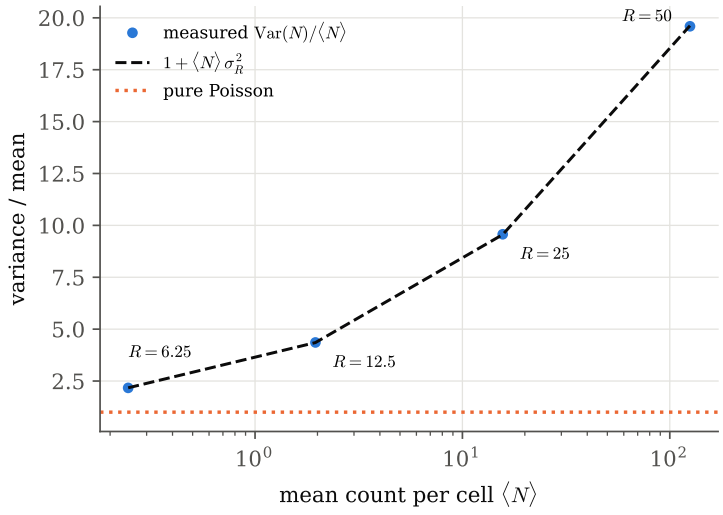

Figure 11.4: Variance over mean of the counts in cubes of side $R = 6.25$ to $50\,h^{-1}\mathrm{Mpc}$, for $\bar{n} = 10^{-3}\,h^3\mathrm{Mpc}^{-3}$. The dots are the measured ratios, the dashed curve is $1 + \bar{N}\sigma_R^2$ from (11.7) with σ_R^2 measured from the field in the same cubes, and the dotted line is the pure Poisson value 1.

- (G2) also fails in the opposite direction. Several galaxies often share one halo, so finding one makes another nearby more likely, beyond what the smooth field predicts. In the halo model this appears as an extra, nearly constant term in $P(k)$ that looks like shot noise but is not $1/\bar{n}$, and the number of galaxies in low-mass haloes is closer to binomial than Poisson [102]. Describing galaxies through the haloes they live in is the job of the halo model.

- (G1) assumes the rate depends only on the local density. If galaxy formation also depends on the environment on larger scales, the relation $\delta_g = b\delta$ becomes scale-dependent, which shows up as a bias that changes with k.

In practice the measured shot noise of a sample is a free parameter of the fit, allowed to differ from $1/\bar{n}$ by tens of percent. On the scales of the acoustic peak, where the following sections work, the Cox model is an excellent description.

11.2 Estimating the correlation function from pair counts

A survey is never a periodic box. The Sloan footprint is an irregular patch of sky with holes cut out around bright stars, the galaxy density falls with distance because faint galaxies drop out, and the edges are wherever the telescope stopped. The pair probability (11.6) of Section 11.1 tells us what to measure: count the pairs of galaxies at separation r, and compare with the number we would have found if the galaxies had no clustering at all. The difficulty is the comparison. In this oddly shaped survey, with its holes and its falling density, how many pairs at separation r would an *unclustered* set of galaxies have produced? Near an edge a galaxy has fewer partners at large r simply because part of its surroundings was never observed, and that loss has nothing to do with cosmology.

Nobody computes that number analytically for a real survey. Instead we *simulate* it: scatter a large number of points uniformly through the same survey volume, with exactly the same angular mask and the same fall-off with distance, and count their pairs. Such a set of points is a **random catalogue**. It is Monte Carlo integration (Chapter 6) of the survey's pair geometry. The rest of the section asks how best to combine the galaxy–galaxy, galaxy–random and random–random pair counts. Four combinations are in use, and they behave very differently near edges; the reason fits in one expansion.

11.2.1 Pair counts and four estimators

Let the data catalogue hold N_d galaxies and the random catalogue N_r points. For a separation bin $[r, r+\Delta r)$ define the **normalised pair counts**

$$DD(r) = \frac{\#\{\text{ordered galaxy pairs in the bin}\}}{N_d(N_d-1)}, \qquad DR(r) = \frac{\#\{\text{galaxy–random pairs in the bin}\}}{N_d N_r},$$
$$RR(r) = \frac{\#\{\text{ordered random pairs in the bin}\}}{N_r(N_r-1)}. \tag{11.11}$$

Each is the fraction of all possible pairs of its kind that fall in the bin. Dividing by the number of possible pairs makes the three comparable even though N_r is several times N_d.

Working definition 11.2 (pair-count estimators of $\xi(r)$)

With DD, DR, RR as in (11.11) [fractions of all possible pairs that fall in the separation bin],

$$\hat{\xi}_{\mathrm{N}} = \frac{DD}{RR} - 1 \quad \text{natural [191]}, \qquad \hat{\xi}_{\mathrm{DP}} = \frac{DD}{DR} - 1 \quad \text{Davis–Peebles [192]},$$

$$\hat{\xi}_{\mathrm{H}} = \frac{DD\,RR}{DR^2} - 1 \quad \text{Hamilton [193]}, \qquad \hat{\xi}_{\mathrm{LS}} = \frac{DD - 2DR + RR}{RR} \quad \text{Landy–Szalay [194]}.$$

Operationally: build a random catalogue with the survey's mask and selection, count the three kinds of pairs in each bin with a tree code, and combine.

All four are motivated by the same idea. In an unclustered survey DD, DR and RR would agree on average, because galaxies and randoms would then be samples of the same distribution. Clustering raises DD above the other two by the factor $1 + \xi$. The estimators differ only in which of the noisy, edge-affected counts they divide by, and that turns out to matter a great deal.

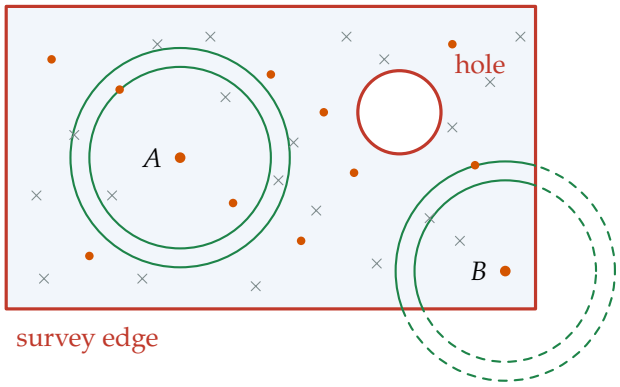

Figure 11.5: Why edges matter. Orange dots are galaxies, grey crosses are random points, the blue region is the observed survey and the red curves are its boundary. Galaxy A sits in the interior: its whole shell of separations $[r, r + \Delta r)$ (the green annulus) is observed. Galaxy B sits in a corner: most of its shell (dashed) lies outside the survey, so it contributes few pairs at this separation whatever the clustering. Random points near B lose the same fraction of their shell, which is what the random catalogue is for.

11.2.2 What each estimator does to first order

To compare the estimators we write every count as its noise-free value plus a fluctuation, and keep track of which fluctuations survive in each combination. This is the calculation of [194], set out here in one notation for all four estimators.

The fields. Let $W(\boldsymbol{x})$ be the survey window, 1 inside the observed region and 0 outside, and $A = \int W \,\mathrm{d}\boldsymbol{x}$ its area (or volume). The galaxy number density, smoothed over a scale much smaller than the bin, is $n_d(\boldsymbol{x}) = (N_d/A)\,W(\boldsymbol{x})\,[1 + \delta_d(\boldsymbol{x})]$. This defines the **data fluctuation** δ_d, which holds the clustering, the Poisson noise of the sampling, and nothing else. Because the normalisation uses the actual number N_d, the window average of δ_d is exactly zero: $\int W\delta_d \,\mathrm{d}\boldsymbol{x} = 0$. The randoms are written the same way, with a fluctuation δ_r that holds only their own Poisson noise.

The pair geometry. Let $\Theta(\boldsymbol{x},\boldsymbol{y})$ be 1 when $|\boldsymbol{x}-\boldsymbol{y}|$ falls in the bin and 0 otherwise, and let

$$G=\frac{1}{A^2}\int\!\!\int W(\boldsymbol{x})W(\boldsymbol{y})\Theta(\boldsymbol{x},\boldsymbol{y})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{y}$$

be the fraction of all pairs of points in the survey that fall in the bin. For any two functions u, v write the **pair average**

$$[u\,v]=\frac{1}{A^2G}\int\!\!\int W(\boldsymbol{x})W(\boldsymbol{y})\Theta(\boldsymbol{x},\boldsymbol{y})\,u(\boldsymbol{x})\,v(\boldsymbol{y})\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{y},$$

and the **bin-weighted mean** $a_d=[\delta_d\,1]$, which is the average of δ_d over all pair members in the bin; $a_r=[\delta_r\,1]$ likewise.

The counts are then pair averages of products of densities (the self-pairs do not enter, since $r>0$):

$$\begin{aligned}
DD &\overset{(1)}{=}\frac{1}{A^2}\int\!\!\int WW\Theta\,(1+\delta_d)(1+\delta_d)\overset{(2)}{=}G\big(1+2a_d+[\delta_d\delta_d]\big),\\
DR &\overset{(3)}{=}G\big(1+a_d+a_r+[\delta_d\delta_r]\big),\qquad RR\overset{(4)}{=}G\big(1+2a_r+[\delta_r\delta_r]\big).
\end{aligned}\tag{11.12}$$

(1) The fraction of galaxy pairs in the bin is the pair integral of the normalised density $n_d/(N_d/A)=W(1+\delta_d)$ at both ends.
(2) Multiply out: the $1\cdot1$ term gives G; the two cross terms are each $G\,a_d$, by symmetry of Θ; the last is $G[\delta_d\delta_d]$.
(3) The same with $1+\delta_r$ at one end.
(4) The same with $1+\delta_r$ at both ends.

The first-order quantities are a_d and a_r; the pair averages $[\delta\,\delta]$ are second order. The one we want is $[\delta_d\delta_d]$, whose expectation is $\xi(r)$ up to the small correction derived below. Now insert (11.12) into each estimator and expand to first order in a_d, a_r, keeping the second-order pair averages:

$$\begin{aligned}
\hat\xi_{\mathrm{N}} &\overset{(1)}{=}\frac{1+2a_d+[\delta_d\delta_d]}{1+2a_r+[\delta_r\delta_r]}-1\approx[\delta_d\delta_d]-[\delta_r\delta_r]+2(a_d-a_r),\\
\hat\xi_{\mathrm{DP}} &\overset{(2)}{=}\frac{1+2a_d+[\delta_d\delta_d]}{1+a_d+a_r+[\delta_d\delta_r]}-1\approx[\delta_d\delta_d]-[\delta_d\delta_r]+(a_d-a_r),\\
\hat\xi_{\mathrm{H}} &\overset{(3)}{=}\frac{(1+2a_d+[\delta_d\delta_d])(1+2a_r+[\delta_r\delta_r])}{(1+a_d+a_r+[\delta_d\delta_r])^2}-1\approx\big[(\delta_d-\delta_r)(\delta_d-\delta_r)\big]-(a_d-a_r)^2,\\
\hat\xi_{\mathrm{LS}} &\overset{(4)}{=}\frac{[\delta_d\delta_d]-2[\delta_d\delta_r]+[\delta_r\delta_r]}{1+2a_r+[\delta_r\delta_r]}=\frac{\big[(\delta_d-\delta_r)(\delta_d-\delta_r)\big]}{1+2a_r+[\delta_r\delta_r]}.
\end{aligned}\tag{11.13}$$

(1) The common factor G cancels; to first order $1/(1+\epsilon)\approx1-\epsilon$.
(2) The same, with DR in the denominator: the first-order terms are $2a_d-(a_d+a_r)=a_d-a_r$.
(3) Keeping only the a's, the numerator minus the denominator is $1+2a_d+2a_r+4a_da_r-(1+a_d+a_r)^2=-(a_d-a_r)^2$: the first-order terms cancel identically. The pair averages enter as $[\delta_d\delta_d]+[\delta_r\delta_r]-2[\delta_d\delta_r]$.
(4) In $DD-2DR+RR$ every term of $G(1+\dots)$ that is zeroth or first order cancels: $1-2+1=0$ and $2a_d-2(a_d+a_r)+2a_r=0$. What is left is the pair average of the product of the two *differences* $\delta_d-\delta_r$.

So the natural estimator carries the first-order term $2(a_d-a_r)$, the Davis–Peebles estimator carries half of it, and the Hamilton and Landy–Szalay estimators carry none. What is a_d, physically? It is the average of the data fluctuation over the members of all pairs in the bin.

Every point of the survey is weighted by the fraction of its shell that lies inside the survey. Interior points (like A in Figure 11.5) get full weight; points near an edge (like B) get less. The plain survey average of δ_d is zero by construction, but this *edge-weighted* average is not. If the interior of the survey happens to be overdense and the edges underdense, a_d is positive. It is a large-scale fluctuation, of first order in δ, and at the separations where ξ is small it is far larger than the signal.

Key idea: Why Landy–Szalay wins

The Landy–Szalay numerator is the pair average of $(\delta_d - \delta_r)(\delta_d - \delta_r)$: the product of the data fluctuation and the random fluctuation at the two ends of each pair. It contains no term linear in either fluctuation, so the edge-weighted large-scale fluctuations a_d and a_r that dominate the error of $DD/RR - 1$ and $DD/DR - 1$ at large separations cancel exactly. What remains is the scatter of the pair average itself, which no pair-count estimator can avoid.

In the weak-correlation limit Landy and Szalay showed that this residual scatter is just the Poisson scatter of the pair counts, the smallest possible, while the variances of DD/RR and DD/DR are considerably larger than Poisson [LandySzalay1993 §4]. The Hamilton estimator also cancels the first-order term, only through a product rather than a difference, and it performs almost as well; a systematic comparison of nine estimators on large simulations ranks the two together at the top [195] [Bernardeau2002 §6.4.1, p. 139].

How much does the edge term cost? The claim that LS reaches the smallest scatter can be checked in the simplest case, where both errors can be computed by hand: galaxies with no clustering at all ($\xi = 0$), and a random catalogue so large that its own noise vanishes ($\delta_r = 0$, so $a_r = 0$). Then LS reduces to $[\delta_d\delta_d]$ and the natural estimator to $[\delta_d\delta_d] + 2a_d$. Two questions remain. How much does the pair average $[\delta_d\delta_d]$ scatter? And how much does a_d?

The pair term. The bin contains on average $N_p = \frac{1}{2}N_d^2 G$ distinct galaxy pairs. With no clustering, whether a given pair lands in the bin is a rare event that hardly depends on the other pairs, so the count of pairs scatters like a Poisson count (Section 2.5.1), with fractional standard deviation $N_p^{-1/2}$. Since $DD = G(1 + [\delta_d\delta_d])$ when a_d is set aside, that fractional scatter is the scatter of $[\delta_d\delta_d]$: its variance is $1/N_p$.

The edge term. Write $e(\boldsymbol{x})$ for the fraction of the survey that lies in the shell around $\boldsymbol{x}$, divided by its average over the survey; $e = 1$ on average, $e < 1$ near edges and holes. Then

$$a_d \overset{(1)}{=} \frac{1}{A}\int W(\boldsymbol{x})\,\delta_d(\boldsymbol{x})\,e(\boldsymbol{x})\,\mathrm{d}\boldsymbol{x} \overset{(2)}{=} \frac{1}{N_d}\sum_{i=1}^{N_d} e(\boldsymbol{x}_i) - 1,$$
$$\mathrm{Var}(a_d) \overset{(3)}{=} \frac{\sigma_e^2}{N_d}, \qquad \sigma_e^2 = \frac{1}{A}\int W\,(e-1)^2\,\mathrm{d}\boldsymbol{x}. \tag{11.14}$$

(1) In the definition of $a_d = [\delta_d\,1]$, do the integral over the partner $\boldsymbol{y}$ first: it gives the area of $\boldsymbol{x}$'s shell inside the survey, which is $A\,G\,e(\boldsymbol{x})$ by the definitions of e and of G.

(2) Replace $W\delta_d$ by $(A/N_d)\,n_d - W$, from the definition of δ_d. The density n_d is a sum of spikes at the galaxies, so its integral against e is $\sum_i e(\boldsymbol{x}_i)$; the integral of We is A, since e averages to 1.

(3) Unclustered galaxies are N_d independent uniform points in the survey, so the $e(\boldsymbol{x}_i)$ are independent with mean 1 and variance σ_e^2; the variance of their mean is σ_e^2/N_d.

So a_d is simply the average edge weight of the galaxies we happened to get, minus its expected

value. Comparing the two contributions to the natural estimator,

$$\frac{\mathrm{Var}(2a_d)}{\mathrm{Var}([\delta_d\delta_d])} = \frac{4\sigma_e^2/N_d}{1/N_p} = 2\,\sigma_e^2\,N_dG. \tag{11.15}$$

The product N_dG is the average number of neighbours a galaxy has in the bin. For a square survey of side $700\,h^{-1}$Mpc and $r = 100\,h^{-1}$Mpc, a direct numerical average of the shell fraction over the square gives $\sigma_e^2 \approx 0.064$. A galaxy with 1000 neighbours in the bin then makes the edge term ≈ 130 times the pair noise in variance, about eleven times in standard deviation. LS removes that term and keeps only the $1/N_p$ that no pair-count estimator can avoid. In a periodic box $e = 1$ everywhere, so $\sigma_e^2 = 0$ and the edge term is absent from every estimator.

Example: a periodic box. In a periodic box there are no edges: every point has its whole shell inside the box, so the edge weighting is uniform and a_d equals the plain average of δ_d, which is zero. The same holds for a_r. The first-order terms of the natural and Davis–Peebles estimators then vanish, and all four estimators are equivalent to first order. Simulations of a periodic box should show four nearly identical scatters; any difference must come from the survey's edges.

Example: how big is the edge weight? Take a square survey of side $700\,h^{-1}$Mpc and $r = 100\,h^{-1}$Mpc. A point at the centre has its whole shell inside. A point in a corner has a quarter of it. A point on an edge, away from the corners, has exactly half: a straight edge through the centre of a circle cuts it into two equal halves. So the edge weight varies by a factor of four across the survey. Within $100\,h^{-1}$Mpc of the boundary lies a fraction $1 - (500/700)^2 \approx 0.49$ of the area: half of the survey's galaxies take part in pairs with reduced weight. If that outer half happens to be 1% underdense, which is typical of fluctuations on scales of hundreds of Mpc, then a_d is of order 10^{-3}, a sizeable fraction of ξ itself at $r = 100\,h^{-1}$Mpc, which is a few $\times 10^{-3}$.

Example: how many randoms? The random catalogue's own Poisson noise enters through δ_r. In the natural estimator it appears at first order, through $-2a_r$, whose variance falls only as $1/N_r$; so the natural estimator needs a random catalogue far larger than the data to be competitive. In Landy–Szalay δ_r enters only through the difference $\delta_d - \delta_r$, inside a product, and a random catalogue a few times larger than the data is enough. Eisenstein and collaborators used at least sixteen times as many randoms as galaxies [Eisenstein2005 §3.1]; our simulation uses five.

11.2.3 The integral constraint

Removing the first-order terms does not remove every bias. The trouble is the normalisation by the observed N_d. In a survey that happens to be overdense as a whole, dividing by the observed mean density makes the survey look average, and pairs everywhere look less correlated than they are. We can say how much less.

Write the true field as δ and its plain survey average as $\bar\delta_W = \frac{1}{A}\int W\delta\,\mathrm{d}\boldsymbol{x}$. Leaving out the Poisson noise, which does not correlate distinct points (Section 11.1.2), the normalised data fluctuation is $1 + \delta_d = (1+\delta)/(1+\bar\delta_W)$, so $\delta_d \approx \delta - \bar\delta_W$ to first order. Then

$$\begin{aligned}\mathbb{E}\big[\,[\delta_d\delta_d]\,\big] &\overset{(1)}{=} \mathbb{E}\big[\,[(\delta-\bar\delta_W)(\delta-\bar\delta_W)]\,\big] \overset{(2)}{=} \mathbb{E}\big[[\delta\delta]\big] - 2\,\mathbb{E}\big[[\delta\,1]\,\bar\delta_W\big] + \mathbb{E}\big[\bar\delta_W^2\big] \\ &\overset{(3)}{=} \xi(r) - 2\,\mathbb{E}\big[[\delta\,1]\,\bar\delta_W\big] + \bar\xi \overset{(4)}{=} \xi(r) - \bar\xi, \qquad \bar\xi \equiv \frac{1}{A^2}\int\!\!\int W(\boldsymbol{x})W(\boldsymbol{y})\,\xi(|\boldsymbol{x}-\boldsymbol{y}|)\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{y}.\end{aligned} \tag{11.16}$$

(1) $\delta_d \approx \delta - \bar{\delta}_W$.
(2) Multiply out the product; $\bar{\delta}_W$ is a number, the same at both ends of every pair, and $[1\,1] = 1$.
(3) The expectation of $\delta(\boldsymbol{x})\delta(\boldsymbol{y})$ is ξ at their separation, which is fixed within the bin; $\mathbb{E}[\bar{\delta}_W^2]$ is the double window average of ξ, called $\bar{\xi}$.
(4) $\mathbb{E}\big[[\delta\,1]\,\bar{\delta}_W\big]$ is the average of ξ between a pair member and a random point of the survey. Ignoring the edge weighting it equals $\bar{\xi}$ as well, and $-2\bar{\xi} + \bar{\xi} = -\bar{\xi}$.

All four estimators share this bias, because all of them normalise by the observed number of galaxies. It is called the **integral constraint**: the measured correlation function, integrated over the survey, is forced to be close to zero, because the survey's own mean density was taken as the truth. It shifts $\hat{\xi}$ down by the constant $\bar{\xi}$, the variance of the mean density of the survey, and it cannot be removed by any combination of pair counts, only modelled [Bernardeau2002 eq. (393) and p. 141]. At small separations, where $\xi \gg \bar{\xi}$, it is negligible; at the scale of the acoustic peak it is not. A commonly used form that also holds when ξ is not small is $\mathbb{E}[\hat{\xi}] \approx (1+\xi)/(1+\bar{\xi}) - 1$, which reduces to $\xi - \bar{\xi}$ to first order.

Watch out: The randoms must have the survey's selection, exactly

Every estimator derivation so far assumes that the randoms are a uniform sample of the *same* window as the data, including the fall-off of density with distance and every masked region. If the randoms are a little too dense in one part of the survey (an error in the photometric calibration of one patch of sky, say), then δ_d acquires a large-scale pattern that is not cosmology, and its pair average adds a spurious ξ at every separation. Eisenstein and collaborators found that a 1% shift in the $r - i$ colour changes the LRG number density by 8–10% [Eisenstein2005 §3.2]. Real analyses spend much of their effort building the random catalogue and its weights.

11.2.4 Testing the estimators in a survey with holes

The script `code/ch11/02_xi_estimators.py` makes the question concrete in two dimensions, where pair counts are cheap. The field is a lognormal field (Section 11.1.4) of unit variance on a grid of 256^2 cells in a box of side $1000\,h^{-1}$Mpc; its two-point function is known exactly on the grid, and it is 0.212 at $r = 30\,h^{-1}$Mpc and -0.0089 at $r = 100\,h^{-1}$Mpc. The survey window is a 700×700 square with five circular holes and a notch, of area $448 \times 10^3\ h^{-2}\mathrm{Mpc}^2$ (Figure 11.6). Each of 300 mock catalogues is a Poisson sample with $\bar{n} = 0.012\,h^2\mathrm{Mpc}^{-2}$ inside the window, about 5379 galaxies, and each mock gets its own random catalogue of 26896 points.

Listing 11.3: Pair counts and the four estimators (`code/ch11/02_xi_estimators.py`)

```
def counts(t1, t2, edges):
    c = t1.count_neighbors(t2, edges)     # ordered pairs with separation <= edge
    return np.diff(c).astype(float)

def randoms(rng):
    cand = rng.random((int(nr / (W.mean()) * 1.3), 2)) * L
    inw = W[(cand[:, 0] // D).astype(int), (cand[:, 1] // D).astype(int)] > 0
    t = cKDTree(cand[inw][:nr])
    return t, counts(t, t, EDGES) / (nr * (nr - 1))

tr_fix, rr_fix = randoms(rng)          # one catalogue reused for every mock (the
    comparison)

def estimators(dd, dr, rr):
```

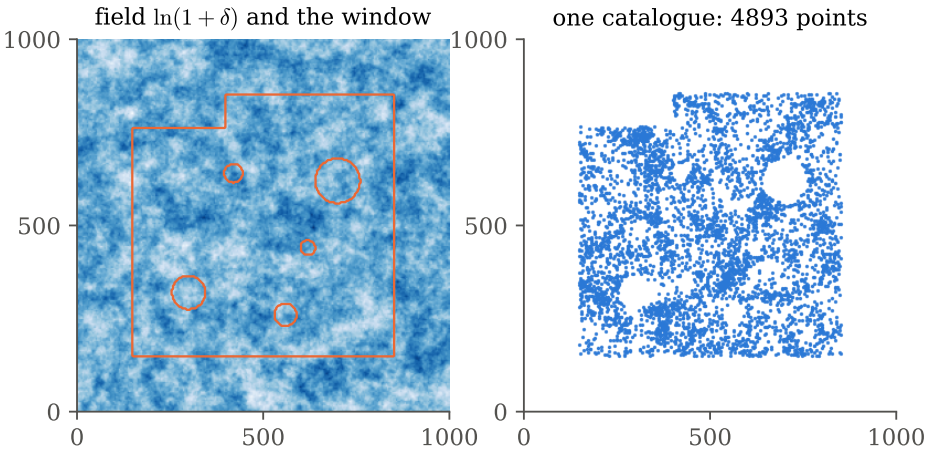

Figure 11.6: The test survey. Left: one lognormal field (shown as $\ln(1+\delta)$) with the survey boundary and holes in orange. Right: one Poisson catalogue drawn from a field inside that window.

```
80      return np.array([dd / rr - 1, dd / dr - 1, dd * rr / dr ** 2 - 1, (dd - 2 * dr + rr) /
        rr])
81
82
83  NAMES = ["natural $DD/RR-1$", "Davis--Peebles $DD/DR-1$", "Hamilton $DD\\,RR/DR^2-1$",
        "Landy--Szalay"]
84  t0 = time.time()
85  est, est_fix, ddpairs = [], [], []
86  for s in range(NSIM):
87      delta = ln.draw(rng)
88      c = poisson_sample(1 + delta, NBAR, L, rng, window=W)
89      g = points_from_counts(c, L, rng)
90      ng = len(g)
91      tg = cKDTree(g)
92      ddc = counts(tg, tg, EDGES)
93      dd = ddc / (ng * (ng - 1))
94      tr_r, rr = randoms(rng)              # a fresh random catalogue for this mock
95      dr = counts(tg, tr_r, EDGES) / (ng * nr)
96      est.append(estimators(dd, dr, rr))
97      dr_fix = counts(tg, tr_fix, EDGES) / (ng * nr)
98      est_fix.append(estimators(dd, dr_fix, rr_fix))
99      ddpairs.append(ddc / 2)
100     if s == 0:
101         g_example = g
```

`counts` uses `cKDTree.count_neighbors`, which returns, for each bin edge, the number of ordered pairs closer than that edge; differencing gives the pairs per bin. A tree visits only nearby branches, so the cost grows much more slowly than the N^2 of a double loop. Lines 73, 93 and 95 divide by the numbers of possible pairs, (11.11), and line 80 forms the four estimators. The same estimators are also computed in a periodic box with the same number of points and no edges, as the control of the first example above. Finally, the integral constraint $\bar{\xi}$ of (11.16) is evaluated exactly on the grid (lines 56–58 of the script) by a Fourier transform: the double window integral is the window's autocorrelation times ξ, summed. It is $\bar{\xi} = 0.0016$ for this window.

Figure 11.7 answers the question. On the right, in the survey with holes, the natural estimator's scatter at $r = 100\,h^{-1}$Mpc is 1.87 times that of Landy–Szalay, Davis–Peebles is 1.29 times, and Hamilton is 0.99 times: exactly the ordering of the first-order terms in (11.13), coefficient 2, 1, 0 and 0. At $r = 30\,h^{-1}$Mpc, where ξ is large and the first-order term is

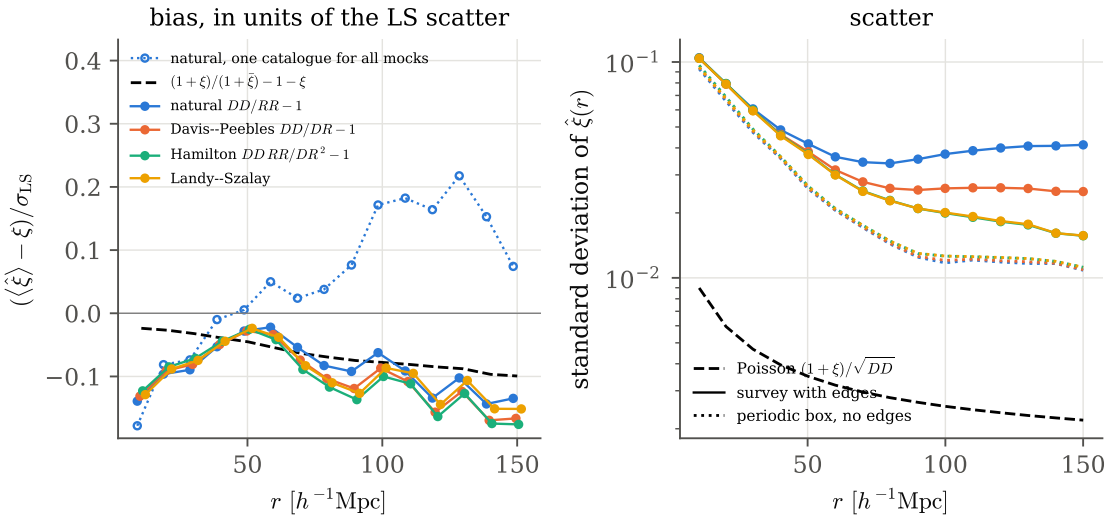

Figure 11.7: The four estimators over 300 mock surveys. Left: the mean minus the true $\xi(r)$, in units of the Landy–Szalay scatter; the dashed curve is the integral-constraint expectation $(1+\xi)/(1+\bar{\xi})-1-\xi$; the open circles are the natural estimator when one random catalogue is reused for every mock. Right: the standard deviation of each estimator in the survey with holes (solid) and in a periodic box with the same number of points (dotted), with the Poisson floor $(1+\xi)/\sqrt{DD}$ (dashed black).

relatively unimportant, the ratios shrink to 1.02 and 1.00. In the periodic control the four scatters nearly coincide (the natural-to-LS ratio is 0.93 at $100\,h^{-1}$Mpc): without edges there is nothing for Landy–Szalay to cancel. On the left, all four means follow the integral-constraint curve. At $r = 100\,h^{-1}$Mpc the prediction is -0.0105 (the true ξ is -0.0089); Landy–Szalay gives -0.0107 ± 0.0012, Hamilton -0.0109, Davis–Peebles -0.0107, and the natural estimator -0.0102 ± 0.0022. On average, then, none of them is biased beyond the integral constraint; they differ in how much they scatter.

That agreement needs one precaution, and it is easy to miss. Suppose we save time and make a single random catalogue for all 300 mocks. Landy–Szalay and Hamilton do not notice: their means become -0.0104 and -0.0106. But the natural estimator's mean moves, in this run to -0.0055, and Davis–Peebles' to -0.0082. How far they move, and in which direction, depends on which random catalogue happened to be drawn; another catalogue would shift them by a different amount. The reason is the first-order random term of the previous example. Each random catalogue has its own small lumps, and the natural estimator carries them straight into $\hat{\xi}$. With a fresh catalogue for every mock those lumps differ from mock to mock and average away. With one shared catalogue they are the same in every mock, so averaging 300 mocks cannot remove them, and the error bar computed from the scatter of the mocks does not even know they are there. Landy–Szalay cancels the random lumps by construction, which is one more reason to prefer it.

Notice also how far the scatter is above the Poisson floor: at $r = 100\,h^{-1}$Mpc the LS standard deviation is 0.0201 and the Poisson floor is 0.0025. Landy and Szalay's optimality is a statement about the noise their estimator *adds*. The scatter that remains is mostly the sample variance of the field: the survey holds only a few independent patches of size $100\,h^{-1}$Mpc, and the field in those patches is one draw. No estimator removes that; only a bigger survey does.

11.3 The power spectrum of a survey: the FKP estimator

A flux-limited survey is dense nearby and sparse far away. Close to us we see faint galaxies as well as bright ones, so the mean density $\bar{n}(\boldsymbol{x})$ is high; at the far edge only the most luminous galaxies make it into the catalogue, and $\bar{n}$ may be a hundred times lower. Both parts of the survey carry information about $P(k)$, but of different quality. The nearby part is limited by its small volume: it holds few independent Fourier modes, and its error is sample variance. The distant part has plenty of volume but few galaxies: its error is shot noise. If we Fourier transform the galaxy density with every galaxy counted equally, the crowded nearby region dominates the answer and the huge distant volume is wasted.

The question in words: *how much weight should a galaxy get, depending on where it sits, so that the estimated power spectrum has the smallest possible error?* Feldman, Kaiser and Peacock answered it in 1994, and the answer, the FKP weight, is used in essentially every galaxy power-spectrum measurement since [196]. Its derivation needs only the Cox model of Section 11.1 and the Gaussian statistics of Fourier modes from Chapter 7.

11.3.1 The weighted field and its mean power

Write the galaxy catalogue as a sum of spikes, $n_g(\boldsymbol{x}) = \sum_i \delta_D(\boldsymbol{x} - \boldsymbol{x}_i)$, and do the same for a random catalogue with the same selection but $1/\alpha$ times as many points, $n_s(\boldsymbol{x})$. Here $\bar{n}(\boldsymbol{x})$ is the expected galaxy density at $\boldsymbol{x}$ in the absence of clustering, set by the survey's angular mask and its fall-off with distance, and $w(\boldsymbol{x})$ is a weight still to be chosen. FKP's weighted fluctuation field is

$$F(\boldsymbol{x}) = \frac{w(\boldsymbol{x})\,\big[n_g(\boldsymbol{x}) - \alpha\, n_s(\boldsymbol{x})\big]}{I^{1/2}}, \qquad I = \int \bar{n}^2(\boldsymbol{x})\, w^2(\boldsymbol{x})\, \mathrm{d}^3x \tag{11.17}$$

[FKP1994 eq. (2.1.3)]. The randoms subtract the mean density, so F is zero on average; the weight shapes how much each place counts; and I is chosen so that $\mathbb{E}\,|F_{\boldsymbol{k}}|^2$ comes out, in the calculation below, as $P(k)$ itself.

The two-point functions of the catalogues follow from Section 11.1.2, now with a mean density that varies with position. For galaxies, the pair term (11.5) becomes $\bar{n}(\boldsymbol{x})\bar{n}(\boldsymbol{y})[1+\xi(\boldsymbol{x}-\boldsymbol{y})]$, and the Poisson variance of a single cell, $\bar{n}\Delta V$, becomes the self-pair spike $\bar{n}(\boldsymbol{x})\delta_D(\boldsymbol{x}-\boldsymbol{y})$ in the continuum. Randoms are an unclustered Cox sample with density $\bar{n}/\alpha$, independent of the galaxies:

$$\begin{aligned} \mathbb{E}[n_g(\boldsymbol{x})n_g(\boldsymbol{y})] &= \bar{n}(\boldsymbol{x})\bar{n}(\boldsymbol{y})\big[1+\xi(\boldsymbol{x}-\boldsymbol{y})\big] + \bar{n}(\boldsymbol{x})\,\delta_D(\boldsymbol{x}-\boldsymbol{y}), \\ \mathbb{E}[n_s(\boldsymbol{x})n_s(\boldsymbol{y})] &= \alpha^{-2}\bar{n}(\boldsymbol{x})\bar{n}(\boldsymbol{y}) + \alpha^{-1}\bar{n}(\boldsymbol{x})\,\delta_D(\boldsymbol{x}-\boldsymbol{y}), \qquad \mathbb{E}[n_g(\boldsymbol{x})n_s(\boldsymbol{y})] = \alpha^{-1}\bar{n}(\boldsymbol{x})\bar{n}(\boldsymbol{y}) \end{aligned} \tag{11.18}$$

[FKP1994 eq. (2.1.5)]. With the Fourier convention $F_{\boldsymbol{k}} = \int F(\boldsymbol{x})e^{-i\boldsymbol{k}\cdot\boldsymbol{x}}\mathrm{d}^3x$, so that an infinite field has $\mathbb{E}[\delta_{\boldsymbol{k}}\delta^*_{\boldsymbol{k}'}] = (2\pi)^3\delta_D(\boldsymbol{k}-\boldsymbol{k}')P(k)$,

$$\begin{aligned} \mathbb{E}\,|F_{\boldsymbol{k}}|^2 &\overset{(1)}{=} \frac{1}{I}\int\!\!\int w(\boldsymbol{x})w(\boldsymbol{y})\;\mathbb{E}\big[(n_g-\alpha n_s)_{\boldsymbol{x}}(n_g-\alpha n_s)_{\boldsymbol{y}}\big]e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})}\mathrm{d}^3x\,\mathrm{d}^3y \\ &\overset{(2)}{=} \frac{1}{I}\int\!\!\int w(\boldsymbol{x})w(\boldsymbol{y})\Big[\bar{n}(\boldsymbol{x})\bar{n}(\boldsymbol{y})\,\xi(\boldsymbol{x}-\boldsymbol{y}) + (1+\alpha)\,\bar{n}(\boldsymbol{x})\,\delta_D(\boldsymbol{x}-\boldsymbol{y})\Big]e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})}\mathrm{d}^3x\,\mathrm{d}^3y \\ &\overset{(3)}{=} \int \frac{\mathrm{d}^3k'}{(2\pi)^3}\,P(k')\,\big|\tilde{G}(\boldsymbol{k}-\boldsymbol{k}')\big|^2 + P_{\rm shot}, \\ \tilde{G}(\boldsymbol{q}) &\equiv \frac{1}{I^{1/2}}\int \bar{n}(\boldsymbol{x})w(\boldsymbol{x})\,e^{-i\boldsymbol{q}\cdot\boldsymbol{x}}\,\mathrm{d}^3x, \qquad P_{\rm shot} \equiv \frac{(1+\alpha)}{I}\int \bar{n}(\boldsymbol{x})\,w^2(\boldsymbol{x})\,\mathrm{d}^3x. \end{aligned} \tag{11.19}$$

(1) Square the Fourier transform of (11.17) and take the expectation inside the integrals.

(2) Expand the bracket with (11.18): the four $\bar{n}\bar{n}$ terms are $1-1-1+1=0$, leaving the clustering term $\bar{n}\bar{n}\,\xi$; the spikes come in with coefficients 1 (galaxies) and $\alpha^2\cdot\alpha^{-1}=\alpha$ (randoms).

(3) In the first term write $\xi(\boldsymbol{x}-\boldsymbol{y})=\int\frac{\mathrm{d}^3k'}{(2\pi)^3}P(k')e^{i\boldsymbol{k}'\cdot(\boldsymbol{x}-\boldsymbol{y})}$; the $\boldsymbol{x}$ and $\boldsymbol{y}$ integrals then factorise into $\tilde{G}(\boldsymbol{k}-\boldsymbol{k}')$ and its complex conjugate. In the second term the spike sets $\boldsymbol{y}=\boldsymbol{x}$ and the exponential becomes 1.

The first term is the true spectrum blurred by the window. The function $\left|\tilde{G}\right|^2$ is the power spectrum of the weighted survey shape $\bar{n}w$; for a survey of size D it is a blob of width about $1/D$ around $\boldsymbol{q}=0$, and by Parseval's theorem its integral $\int\frac{\mathrm{d}^3q}{(2\pi)^3}\left|\tilde{G}\right|^2=\frac{1}{I}\int\bar{n}^2w^2\,\mathrm{d}^3x=1$. So on scales much smaller than the survey, $k\gg1/D$, where P hardly changes across the blob, (11.19) becomes

$$\mathbb{E}\,|F_{\boldsymbol{k}}|^2\approx P(k)+P_{\mathrm{shot}},\qquad \hat{P}(k)=\frac{1}{V_k}\int_{\mathrm{shell}}\left(|F_{\boldsymbol{k}'}|^2-P_{\mathrm{shot}}\right)\mathrm{d}^3k' \tag{11.20}$$

[FKP1994 eqs. (2.1.8)–(2.1.11)], where V_k is the volume of the shell of wavevectors averaged over. This is the **FKP estimator**: Fourier transform the weighted field, square, subtract the known shot noise, average over a shell.

Two corrections are hidden in the "$\approx$". On scales comparable to the survey, $k\sim1/D$, the window convolution in (11.19) is not negligible: it smooths out features and suppresses power at the lowest k. It is the same mode coupling met for masked skies in Section 8.10, and it is handled the same way, by convolving the *model* with the window before comparing it with the data. And the shot noise subtracted is the Poisson value; Section 11.1 listed why real galaxies need not be exactly Poisson.

Example: a uniform survey. For constant $\bar{n}$ and w inside a volume V, $I=\bar{n}^2w^2V$ and $P_{\mathrm{shot}}=(1+\alpha)\bar{n}w^2V/(\bar{n}^2w^2V)=(1+\alpha)/\bar{n}$. With a random catalogue much larger than the data, $\alpha\to0$, and we recover the $1/\bar{n}$ of (11.8). A finite random catalogue adds its own shot noise, $\alpha/\bar{n}$: with twenty times as many randoms as galaxies that is a 5% addition, which is why the randoms are made large.

11.3.2 The error, and the weight that minimises it

To choose w we need the variance of $\hat{P}(k)$. Assume the Fourier modes $F_{\boldsymbol{k}}$ are Gaussian; for the long-wavelength modes of a survey this is a good approximation, because each $F_{\boldsymbol{k}}$ is a sum over a huge number of galaxies (the central limit theorem of Section 3.3.4). Write $C(\boldsymbol{k},\boldsymbol{k}')=\mathbb{E}[F_{\boldsymbol{k}}F^*_{\boldsymbol{k}'}]$. Repeat the first two steps of (11.19), but keep the two wavevectors different, so that the phases are $e^{-i\boldsymbol{k}\cdot\boldsymbol{x}+i\boldsymbol{k}'\cdot\boldsymbol{y}}$. The spike term then gives, after the δ_D sets $\boldsymbol{y}=\boldsymbol{x}$, the number $\tilde{S}(\boldsymbol{q})=\frac{1+\alpha}{I}\int\bar{n}w^2e^{-i\boldsymbol{q}\cdot\boldsymbol{x}}\mathrm{d}^3x$ at $\boldsymbol{q}=\boldsymbol{k}-\boldsymbol{k}'$. The clustering term, with ξ written as the integral of P as before, is $\int\frac{\mathrm{d}^3k''}{(2\pi)^3}P(k'')\,\tilde{G}(\boldsymbol{k}-\boldsymbol{k}'')\,\tilde{G}^*(\boldsymbol{k}'-\boldsymbol{k}'')$. Both $\tilde{G}$ factors are blobs of width $\sim1/D$, so only $\boldsymbol{k}''$ within $1/D$ of $\boldsymbol{k}$ contributes, and there P is nearly the constant $P(k)$. Pulling it out leaves the convolution of $\tilde{G}$ with its own conjugate, which is the Fourier transform of $|G(\boldsymbol{x})|^2=\bar{n}^2w^2/I$: that is $\tilde{Q}(\boldsymbol{q})$. So $C(\boldsymbol{k},\boldsymbol{k}')\approx P(k)\,\tilde{Q}(\boldsymbol{k}-\boldsymbol{k}')+\tilde{S}(\boldsymbol{k}-\boldsymbol{k}')$ [FKP1994 eqs. (2.2.2)–(2.2.5)], with $\tilde{Q}$ the Fourier transform of $\bar{n}^2w^2/I$. Both $\tilde{Q}$ and $\tilde{S}$ are blobs of width $\sim1/D$ around zero, and the covariance of two modes dies away once they are more than $1/D$ apart. Then

$$\begin{aligned}\operatorname{Var}\hat{P}(k)&\overset{(1)}{=}\frac{1}{V_k^2}\int_{\mathrm{shell}}\int_{\mathrm{shell}}\Big[|C(\boldsymbol{k},\boldsymbol{k}')|^2+|C(\boldsymbol{k},-\boldsymbol{k}')|^2\Big]\mathrm{d}^3k\,\mathrm{d}^3k'\\&\overset{(2)}{=}\frac{2}{V_k}\int\left|P\,\tilde{Q}(\boldsymbol{q})+\tilde{S}(\boldsymbol{q})\right|^2\mathrm{d}^3q\overset{(3)}{=}\frac{2(2\pi)^3}{V_k\,I^2}\int\left[\bar{n}^2w^2P+(1+\alpha)\bar{n}w^2\right]^2\mathrm{d}^3x,\end{aligned}$$

$$\frac{\operatorname{Var}\hat{P}(k)}{P^2(k)} \overset{(4)}{=} \frac{2(2\pi)^3}{V_k} \frac{\int \bar{n}^4 w^4 \big[1 + 1/(\bar{n}P)\big]^2 \mathrm{d}^3x}{\big[\int \bar{n}^2 w^2 \,\mathrm{d}^3x\big]^2}. \tag{11.21}$$

(1) The covariance of $|F_{\boldsymbol{k}}|^2$ and $|F_{\boldsymbol{k}'}|^2$ for complex Gaussian modes, by Isserlis' theorem (Section 7.2.1). The second term is there because the field is real, $F_{-\boldsymbol{k}'} = F^*_{\boldsymbol{k}'}$, so a mode near $-\boldsymbol{k}$ is the same mode as one near $\boldsymbol{k}$.
(2) C depends only on $\boldsymbol{q} = \boldsymbol{k} - \boldsymbol{k}'$ and is narrow compared with the shell, so for each $\boldsymbol{k}$ the $\boldsymbol{k}'$ integral covers the whole blob; the remaining $\boldsymbol{k}$ integral gives V_k. The second term gives the same.
(3) Parseval: $\int |\tilde{g}(\boldsymbol{q})|^2 \,\mathrm{d}^3q = (2\pi)^3 \int |g(\boldsymbol{x})|^2 \,\mathrm{d}^3x$, with $g = [\bar{n}^2 w^2 P + (1+\alpha)\bar{n}w^2]/I$.
(4) Divide by P^2, take $\alpha \to 0$, and insert $I = \int \bar{n}^2 w^2$.

This is FKP's eq. (2.3.2), up to the factor 2.[1]

Now the question becomes a small optimisation problem. Write $u = \bar{n}^2 w^2 \geq 0$ and $c = 1 + 1/(\bar{n}P)$. The fractional variance is proportional to $R[u] = \int u^2 c^2 / \big(\int u\big)^2$, and we want the u that makes it smallest. The Cauchy–Schwarz inequality does it in one line:

$$\Big(\int u \,\mathrm{d}^3x\Big)^2 \overset{(1)}{=} \Big(\int (u\,c)\,\frac{1}{c}\,\mathrm{d}^3x\Big)^2 \overset{(2)}{\leq} \int u^2c^2\,\mathrm{d}^3x \int \frac{1}{c^2}\,\mathrm{d}^3x,$$
$$R[u] \overset{(3)}{\geq} \frac{1}{\int c^{-2}\,\mathrm{d}^3x} \overset{(4)}{=} \frac{1}{\int \big[\frac{\bar{n}P}{1+\bar{n}P}\big]^2 \mathrm{d}^3x}. \tag{11.22}$$

(1) Multiply and divide by $c > 0$.
(2) Cauchy–Schwarz for integrals, $\big(\int fg\big)^2 \leq \int f^2 \int g^2$, with $f = uc$ and $g = 1/c$. Equality holds exactly when $f \propto g$.
(3) Divide both sides by $(\int u)^2 \int c^{-2}$.
(4) $1/c = \bar{n}P/(1+\bar{n}P)$.

The bound is reached when $uc \propto 1/c$, that is $\bar{n}^2 w^2 \propto [\bar{n}P/(1+\bar{n}P)]^2$, or

$$w_{\mathrm{FKP}}(\boldsymbol{x}) = \frac{1}{1 + \bar{n}(\boldsymbol{x})\,P(k)} \tag{11.23}$$

[FKP1994 eq. (2.3.5)], up to an irrelevant constant. At the minimum, (11.21) becomes

$$\frac{\operatorname{Var}\hat{P}(k)}{P^2(k)} = \frac{2(2\pi)^3}{V_k\,V_{\mathrm{eff}}(k)}, \qquad V_{\mathrm{eff}}(k) \equiv \int \Big[\frac{\bar{n}(\boldsymbol{x})P(k)}{1+\bar{n}(\boldsymbol{x})P(k)}\Big]^2 \mathrm{d}^3x. \tag{11.24}$$

Working definition 11.3 (effective volume)

The **effective volume** $V_{\mathrm{eff}}(k)$ of a survey is the volume of a noise-free survey that would measure $P(k)$ as well [with the same number of independent Fourier modes] as the real one does with optimal weights. Every volume element counts with the factor $[\bar{n}P/(1+\bar{n}P)]^2$: fully where the signal-to-noise per mode $\bar{n}P \gg 1$, hardly at all where $\bar{n}P \ll 1$. *Operationally:* integrate $[\bar{n}P/(1+\bar{n}P)]^2$ over the survey; the fractional error of P in a shell of volume V_k is then $\sqrt{2(2\pi)^3/(V_k V_{\mathrm{eff}})}$.

Read (11.24) next to the sample variance of a periodic box (Section 7.5.2): there a shell holds $N_{\mathrm{modes}} = VV_k/(2\pi)^3$ modes, half of them independent, and $\operatorname{Var}\hat{P}/P^2 = 2/N_{\mathrm{modes}}$. The survey

[1] FKP keep only the neighbourhood $\boldsymbol{k}' \approx \boldsymbol{k}$ in their eq. (2.3.1). For a real field the neighbourhood $\boldsymbol{k}' \approx -\boldsymbol{k}$ is the same set of modes counted again, which doubles the variance, as in the mode counting of [SeoEisenstein2003 eq. (8)]. The factor does not change the optimal weight.

formula is the same with V replaced by $V_{\rm eff}$. And read the weight (11.23) in its two limits. Where galaxies are plentiful, $\bar{n}P \gg 1$, the weight is $1/(\bar{n}P) \propto 1/\bar{n}$: each galaxy is down-weighted so that each *volume* counts equally, because the error there is sample variance, which depends on volume, not on galaxies. Where galaxies are scarce, $\bar{n}P \ll 1$, the weight is 1: each *galaxy* counts equally, because the error there is shot noise. The weight on a region's contribution to the power, $\bar{n}^2 w^2 \propto [P/(P + 1/\bar{n})]^2$, is the inverse of that region's fractional variance per mode: it is inverse-variance weighting, the same rule that gave the best combination of measurements in Section 3.7.

Example: a uniform survey. With constant $\bar{n}$ the weight is a constant, so weighting changes nothing, and $V_{\rm eff} = V[\bar{n}P/(1 + \bar{n}P)]^2$. At $\bar{n}P = 1$ the survey is worth a quarter of its volume; at $\bar{n}P = 3$, 56%; at $\bar{n}P = 10$, 83%. Beyond $\bar{n}P \approx 3$ more galaxies buy little: the error is already close to the sample-variance floor of the volume.

Example: Eisenstein's survey, rebuilt. The SDSS LRG sample has $\bar{n} \approx 10^{-4}\,h^3\mathrm{Mpc}^{-3}$ out to $z = 0.36$, falling beyond, with $\bar{n}P_w \approx 4$ at $z < 0.36$ and ≈ 1 at $z = 0.47$ for $P_w = 4 \times 10^4\,h^{-3}\mathrm{Mpc}^3$, over $3816\,\mathrm{deg}^2$ and $0.16 < z < 0.47$ [Eisenstein2005 §2, §3.1]. Those numbers fix $\bar{n}(z)$: 10^{-4} up to $z = 0.36$, then falling to 2.5×10^{-5} at $z = 0.47$ (we interpolate in $\ln \bar{n}$). The script `code/ch11/05_bao_fisher.py` builds this survey and evaluates (11.24). It gives a total volume of $0.72\,h^{-3}\mathrm{Gpc}^3$ (paper: 0.72) and effective volumes of 0.13, 0.38 and $0.54\,h^{-3}\mathrm{Gpc}^3$ for $P = 10^4$, 4×10^4 and $10^5\,h^{-3}\mathrm{Mpc}^3$ (paper: 0.13, 0.38, 0.55). The paper's effective volumes follow from its stated densities through (11.24). On the scales of the acoustic peak, $P \approx 10^4$, the survey is worth less than a fifth of its volume.

Example: one weight for all scales. The optimal weight depends on k through $P(k)$. In practice one picks a single P_w for all scales, so that the weighting and hence the effective bias of the sample do not change with k. Eisenstein and collaborators chose $P_w = 4 \times 10^4\,h^{-3}\mathrm{Mpc}^3$, optimal at $k \approx 0.05\,h\,\mathrm{Mpc}^{-1}$ and within 5% of the optimal error at every $k \lesssim 0.15\,h\,\mathrm{Mpc}^{-1}$ [Eisenstein2005 §3.1]. The minimum in (11.22) is flat: a weight that is only roughly right costs little.

11.3.3 Checking the FKP weight on a simulated survey

The script `code/ch11/03_fkp.py` makes a survey that is dense in the middle and sparse at the edge: a sphere of radius $450\,h^{-1}\mathrm{Mpc}$ around an observer at the centre of a $1000\,h^{-1}\mathrm{Mpc}$ box, with $\bar{n}(r) = 0.003\,e^{-(r/200)^2}\,h^3\mathrm{Mpc}^{-3}$. It holds about 131×10^3 galaxies in a geometric volume of $0.38\,h^{-3}\mathrm{Gpc}^3$ (Figure 11.8). The galaxies are Cox samples of 100 lognormal fields with spectrum $b^2 P_{\rm lin}$, $b = 1.5$. Each catalogue is analysed twice, once with $w = 1$ and once with the FKP weight for $P_0 = 10000\,h^{-3}\mathrm{Mpc}^3$.

Listing 11.4: The FKP estimator, its expectation and its predicted variance (`code/ch11/03_fkp.py`)

```
def fkp_setup(w):
    norm = np.sum(nbar ** 2 * w ** 2) * dV
    pshot = np.sum(nbar * w ** 2) * dV / norm              # FKP eq. (2.1.9) with
    infinitely many randoms
    # exact expectation: FT of xi(r) times the window autocorrelation Q(r) of n_bar w
    g = np.fft.rfftn(nbar * w)
    Q = np.fft.irfftn(np.abs(g) ** 2, s=nbar.shape) * dV / norm      # Q(0) = 1
    pconv = kb.avg(np.fft.rfftn(Q * xi_grid).real * dV)
    # FKP variance (their 2.3.2) evaluated at each shell's P: (2pi)^3/V_k * int n^4 w^4
    (1+1/nP)^2 / norm^2,
```

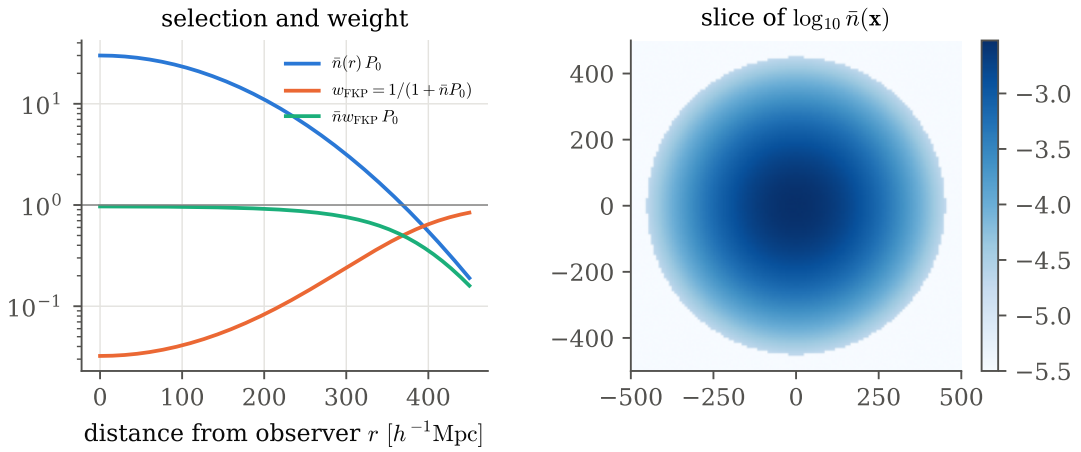

Figure 11.8: The simulated survey. Left: against distance from the observer, the signal-to-noise per mode $\bar{n}P_0$ (blue), the FKP weight (orange) and the weighted density $\bar{n}w\,P_0$ (green). Near the observer $\bar{n}P_0 \approx 30$ and the weight suppresses the crowded centre; beyond $r \approx 370\,h^{-1}$Mpc, where $\bar{n}P_0 < 1$, the weight is close to one. Right: a slice through the box showing $\log_{10}\bar{n}$.

```
56      # times 2 because the shell holds every independent mode twice (k and -k carry the same
        |F_k|^2)
57      vk = 4 * np.pi * k ** 2 * np.diff(edges)
58      sel = nbar > 0
59      frac = np.array([np.sum(nbar[sel] ** 4 * w[sel] ** 4 * (1 + 1 / (nbar[sel] * p)) ** 2)
        * dV / norm ** 2
60                       for p in ptrue]) * 2 * (2 * np.pi) ** 3 / vk
61      return norm, pshot, pconv, frac
62
63
64  setups = {name: fkp_setup(w) for name, w in weights.items()}
65  est = {name: [] for name in weights}
66  for s in range(NSIM):
67      delta = ln.draw(rng)
68      ng = poisson_sample(1 + delta, 1.0, L, rng, window=nbar) / dV      # galaxies per unit
        volume
69      for name, w in weights.items():
70          norm, pshot, _, _ = setups[name]
71          F = w * (ng - nbar) / np.sqrt(norm)
72          pk = np.abs(np.fft.rfftn(F) * dV) ** 2
73          est[name].append(kb.avg(pk) - pshot)
```

`fkp_setup` computes, for one weight, the normalisation I (line 49), the shot noise $P_{\rm shot}$ with $\alpha \to 0$ (line 50), and the exact expectation (11.19) (lines 52–54). The last uses the real-space form of the convolution: the window term is the Fourier transform of $\xi(\boldsymbol{r})$ times the autocorrelation of $\bar{n}w$, which is cheaper on a grid than the convolution itself. Lines 57–60 evaluate the predicted variance (11.21) for every shell. The main loop (lines 66–73) is (11.17) and (11.20) in four lines; the random catalogue is replaced by the exact $\bar{n}$, which is the limit $\alpha \to 0$.

Figure 11.9 shows three things. First, the estimator is unbiased once the window is accounted for: with the FKP weight the mean at $k = 0.10\,h\,\mathrm{Mpc}^{-1}$ is 1.001 times the window-convolved expectation, and at the lowest $k = 0.02$ the window itself pulls the expectation down to 0.98 of the true P. Second, the FKP weight about halves the error: the ratio of the FKP scatter to the $w = 1$ scatter is 0.46 at $k = 0.04$ and 0.54 at $k = 0.10\,h\,\mathrm{Mpc}^{-1}$, against 0.46 and 0.51 predicted by (11.21). The gain comes despite a shot-noise term that is five times larger with the FKP weight ($P_{\rm shot} = 4794$ against $926\,h^{-3}\mathrm{Mpc}^3$), because the weight spends shot noise to buy volume. Third, the absolute scatter is larger than the Gaussian prediction, by a factor 1.13 at $k = 0.04$ and

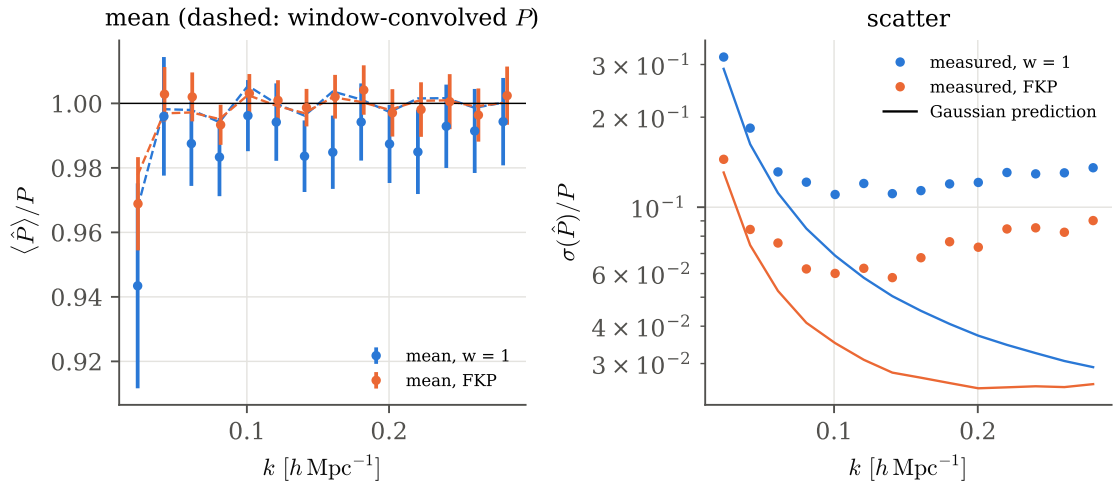

Figure 11.9: The FKP estimator over 100 simulated surveys. Left: the mean of $\hat{P}$ divided by the true spectrum, for $w = 1$ (blue) and the FKP weight (orange); the dashed curves are the window-convolved expectation (11.19). Right: the scatter of $\hat{P}/P$ (points) against the Gaussian prediction (11.21) (lines).

1.60 at $k = 0.10\,h\,\mathrm{Mpc}^{-1}$ for $w = 1$. The Gaussian assumption of (11.21) ignores the four-point function of the field, and a lognormal field at $z = 0$ has a large one on these scales. The excess affects both weightings alike, so the *ratio* still follows the Gaussian prediction. For the absolute error, real analyses do not trust (11.21); they measure the covariance from mock catalogues (Section 11.6). For the effective volume of this survey, (11.24) gives 0.23 $h^{-3}\mathrm{Gpc}^3$ at $k = 0.04$ and 0.16 at $k = 0.10\,h\,\mathrm{Mpc}^{-1}$, out of 0.38.

11.4 The acoustic peak: a ruler in the galaxy distribution

Before the Universe was 400,000 years old, photons and baryons formed a single fluid, and every overdensity sent out a spherical sound wave through it. When the baryons were released from the photons, at the drag epoch $z_d \approx 1060$, the waves stopped where they were. Each initial lump of matter is therefore surrounded by a faint shell of extra baryons at a fixed comoving radius, the **sound horizon at the drag epoch**

$$r_d = \int_{z_d}^{\infty} \frac{c_s(z)\,\mathrm{d}z}{H(z)}, \qquad c_s = \frac{c}{\sqrt{3(1+R)}}, \qquad R = \frac{3\rho_b}{4\rho_\gamma} \tag{11.25}$$

[DESI2024VI eqs. (2.3)–(2.4)]; this is the sound horizon $r_s(\eta)$ of Section T1.4 written as an integral over redshift (see the cosmology notes). For the Planck fiducial model CAMB gives $r_d = 147.10\,\mathrm{Mpc}$. Galaxies form where matter is dense, so galaxy pairs separated by r_d are slightly more common than their neighbours: the bump in $\xi(r)$ near $100\,h^{-1}\mathrm{Mpc}$ that we met in Figure T1.5 and that [42] first detected.

What makes the bump valuable is that its length is known. The CMB measures the physical densities that enter (11.25) so well that r_d is fixed to a fraction of a percent. A galaxy survey that locates the bump therefore measures how far away the galaxies are, the way a known ruler seen at an unknown distance measures the distance through its apparent size. Turning that idea into a measurement raises three statistical questions. What exactly does a shifted bump tell us? How significant is a bump in a noisy correlation function? And how precisely can a survey of given size locate it?

11.4.1 What a misplaced bump means: the dilation α

The event. We turned angles and redshifts into comoving positions using a fiducial cosmology, computed $\xi(r)$, and found the bump not at $r_d^{\rm fid}$, the fiducial model's sound horizon, but a few percent away.

What could have put it there? The ruler's true length is r_d, which may differ from the fiducial value. And the distances we used to convert the catalogue may be wrong. The second effect has two parts, because angles and redshifts are converted with different distances. Two galaxies at redshift z separated by a small angle $\Delta\theta$ are a transverse distance $r_\perp = D_M(z)\,\Delta\theta$ apart, where D_M is the comoving angular diameter distance; two galaxies on the same line of sight separated by Δz are a radial distance $r_\parallel = c\,\Delta z/H(z) \equiv D_H(z)\,\Delta z$ apart. (The definitions of D_M and $H(z)$ are in Section T1.2.) We computed both with the fiducial model, so

$$r_\perp^{\rm fid} \overset{(1)}{=} D_M^{\rm fid}\,\Delta\theta \overset{(2)}{=} \frac{D_M^{\rm fid}}{D_M}\,r_\perp \equiv \frac{r_\perp}{\alpha_\perp}, \qquad r_\parallel^{\rm fid} \overset{(3)}{=} \frac{D_H^{\rm fid}}{D_H}\,r_\parallel \equiv \frac{r_\parallel}{\alpha_\parallel}. \tag{11.26}$$

(1) The observed angle converted with the fiducial distance.
(2) The true separation is $r_\perp = D_M\Delta\theta$, so $\Delta\theta = r_\perp/D_M$.
(3) The same for the radial direction, with $D_H = c/H$ in place of D_M.

A true shell of radius r_d therefore appears in the fiducial coordinates with transverse radius $r_d/\alpha_\perp$ and radial radius $r_d/\alpha_\parallel$. Measuring both positions relative to the fiducial ruler gives the two numbers that modern surveys report: $\alpha_\perp = (D_M/r_d)/(D_M/r_d)^{\rm fid}$ and $\alpha_\parallel = (D_H/r_d)/(D_H/r_d)^{\rm fid}$, once the ruler's own length is included [DESI2024VI §2.3]. Only the ratios D_M/r_d and D_H/r_d are measured. A survey cannot tell a longer ruler from a smaller distance.

The angle average. The spherically averaged $\xi(r)$ of a sample with few galaxies cannot separate the two directions, and sees one overall stretch. A small volume element is stretched by $\alpha_\perp$ in two directions and $\alpha_\parallel$ in one, so its volume changes by $\alpha_\perp^2\alpha_\parallel$, and the isotropic stretch with the same effect on volume is the cube root,

$$\alpha = \left(\alpha_\perp^2\alpha_\parallel\right)^{1/3} = \frac{D_V/r_d}{(D_V/r_d)^{\rm fid}}, \qquad D_V(z) \equiv \left[z\,D_M^2(z)\,D_H(z)\right]^{1/3} \tag{11.27}$$

[Eisenstein2005 eq. (2)], [Anderson2012 eq. (21)]; the factor z is a convention that gives D_V the units and low-redshift limit of a distance. Finally, what does a dilation do to the measured correlation function? A pair with true separation s is placed at $r = s/\alpha$ in the fiducial coordinates, so

$$\xi_{\rm obs}(r) = \xi_{\rm true}(\alpha r), \qquad P_{\rm obs}(k) = \alpha^{-3}P_{\rm true}(k/\alpha). \tag{11.28}$$

The second form follows from the first by the substitution $\boldsymbol{s} = \alpha\boldsymbol{r}$ in the Fourier integral; the α^{-3} is the Jacobian.

Key idea: The acoustic peak measures a ratio of distances

A galaxy survey that finds the acoustic peak at a fraction $1/\alpha$ of its fiducial position measures $D_V(z)/r_d = \alpha\,(D_V/r_d)^{\rm fid}$ at the survey's redshift. Splitting the clustering by direction measures D_M/r_d and D_H/r_d separately. The ruler's length r_d comes from the early Universe; the distances come from the late Universe; BAO compares the two.

The Alcock–Paczyński idea. Even without knowing r_d, the *shape* of the clustering carries information. Structures that are statistically round in the true coordinates look squashed or stretched along the line of sight if $\alpha_\parallel \neq \alpha_\perp$, that is, if the fiducial cosmology got the product D_MH wrong. Testing for that apparent anisotropy is the Alcock–Paczyński test [DESI2024VI §2.3].

Its difficulty is that galaxy motions also squash the clustering along the line of sight (Section 11.5), so the two effects must be modelled together; for the acoustic peak, a sharp feature at a known scale, they separate cleanly. Figure 11.10 shows the three cases.

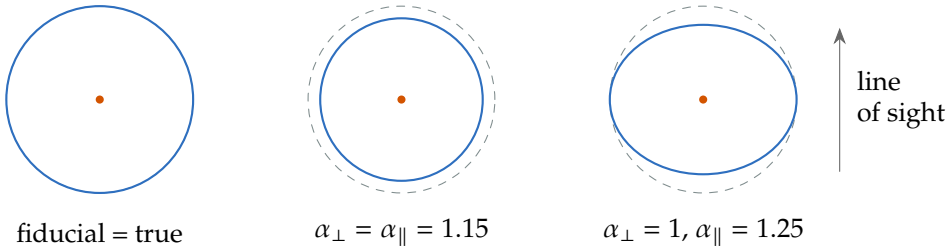

Figure 11.10: The acoustic shell around a galaxy, drawn in the fiducial coordinates. The dashed circle is where it would appear if the fiducial distances were right. Middle: true distances 15% larger in every direction make the shell look 15% smaller, an isotropic dilation. Right: a radial distance 25% too small in the fiducial model, with the transverse one right, squashes the shell along the line of sight; that anisotropy is the Alcock–Paczyński signal.

11.4.2 A model for the peak, and a fit

To locate the bump we fit a template whose bump position is controlled by α. Two physical effects decide what the template looks like.

The bump is smeared. Since the drag epoch, galaxies have moved by several h^{-1}Mpc, pushed by large-scale flows. Model each pair separation as shifted by a Gaussian random displacement with variance $\Sigma_{\rm nl}^2$ per component. Then the observed ξ is the true ξ convolved with a Gaussian, and by the convolution theorem (Section 7.6.1) the power spectrum is multiplied by the Fourier transform of that Gaussian, $e^{-k^2\Sigma_{\rm nl}^2/2}$. Only the oscillating part of $P(k)$ needs this damping, because the smooth part is handled by the free broad-band terms below. Writing $P_{\rm nw}$ for a smooth "no-wiggle" spectrum with the same broad shape [104], the template is

$$P_t(k) = \left[P_{\rm lin}(k) - P_{\rm nw}(k)\right] e^{-k^2\Sigma_{\rm nl}^2/2} + P_{\rm nw}(k) \tag{11.29}$$

[Anderson2012 eq. (26)], with $\Sigma_{\rm nl} = 8\,h^{-1}$Mpc for galaxies as observed and about $4\,h^{-1}$Mpc after "reconstruction", a step that estimates the flows from the galaxy field and moves the galaxies back [DESI2024VI §2.3]. Its correlation function $\xi_t(r)$ follows from the Fourier integral of Section T1.4.

The broad band is uncertain. Galaxy bias, non-linear growth and the integral constraint all change the smooth shape of ξ by amounts we do not want to model. So the fit includes an amplitude and a few smooth nuisance terms:

$$\xi_{\rm fit}(r) = B^2\,\xi_t(\alpha r) + a_0 + \frac{a_1}{r} + \frac{a_2}{r^2} \tag{11.30}$$

[Anderson2012 eqs. (23), (25)]. For a fixed α the model is linear in (B^2, a_0, a_1, a_2), so for each α on a grid we solve for them by generalised least squares with the covariance matrix $\mathbf{C}$ of the binned $\hat{\xi}$ (Section 3.10.5), and record the minimum $\chi^2(\alpha) = [\hat{\xi} - \xi_{\rm fit}]^{\mathsf{T}}\mathbf{C}^{-1}[\hat{\xi} - \xi_{\rm fit}]$. This is profiling the nuisance parameters out (Section 3.14).

What the fit asks. The observed event is the measured vector $\hat{\xi}$. The possible explanations are the values of α. For one trial value, the model predicts a vector $\xi_{\rm fit}$, and the measurement differs from that prediction by noise, a Gaussian scatter with covariance $\mathbf{C}$ (the mock covariance). So for a given α the question is: how plausible is the particular noise realisation $\hat{\xi} - \xi_{\rm fit}$ that would turn the model's prediction into the data we actually have? A Gaussian assigns that realisation

a density proportional to $e^{-\chi^2/2}$, and the same density read as a function of α, with the data held fixed, is the likelihood (Chapter 3). The best α is where the required noise is least surprising, that is, where $\chi^2(\alpha)$ is smallest. With a flat prior in α the posterior is $p(\alpha) \propto e^{-\chi^2(\alpha)/2}$, and its width is the uncertainty [Anderson2012 eqs. (27)–(29)].

11.4.3 How significant is a bump? $\Delta\chi^2$ and the number of sigma

Eisenstein and collaborators quoted their detection as "3.4σ", from the difference in χ^2 between the best model without the acoustic feature and the best model with it, $\Delta\chi^2 = 11.7$ [Eisenstein2005 §4.3]. Before reproducing the number we should see why $\sqrt{\Delta\chi^2}$ is a number of sigma.

Give the bump an amplitude A: the model is the smooth part plus A times the difference between the templates with and without the feature, so $A = 1$ is the full acoustic signal and $A = 0$ is none. The model is linear in A, and with Gaussian errors χ^2 is then exactly quadratic in A (Section 3.10.3): $\chi^2(A) = \chi^2_{\text{min}} + (A - \hat{A})^2/\sigma_A^2$, where $\hat{A}$ is the best fit and σ_A its standard error. Then

$$\Delta\chi^2 \equiv \chi^2(0) - \chi^2(1) \overset{(1)}{=} \frac{\hat{A}^2 - (1-\hat{A})^2}{\sigma_A^2} \overset{(2)}{=} \frac{2\hat{A} - 1}{\sigma_A^2}, \qquad \text{and if } \hat{A} = 1: \quad \sqrt{\Delta\chi^2} \overset{(3)}{=} \frac{\hat{A}}{\sigma_A}. \tag{11.31}$$

(1) Insert $A = 0$ and $A = 1$ into the quadratic; χ^2_{min} cancels.
(2) $\hat{A}^2 - (1 - 2\hat{A} + \hat{A}^2) = 2\hat{A} - 1$.
(3) With $\hat{A} = 1$, $\Delta\chi^2 = 1/\sigma_A^2 = (\hat{A}/\sigma_A)^2$.

So when the data prefer the full acoustic amplitude, $\sqrt{\Delta\chi^2}$ is the number of standard errors by which the bump's amplitude differs from zero: a signal-to-noise ratio.

The same number can be read as a test. Let A float and take as the null hypothesis "there is no acoustic bump", $A = 0$. It is the hypothesis whose sampling distribution we know: if it were true, $\chi^2(0) - \chi^2(\hat{A})$ would follow a χ^2 distribution with one degree of freedom (Wilks' theorem, Section 4.7). The question for the data is then: if there were no bump, would a $\Delta\chi^2$ as large as 11.7, or larger, be something we would reasonably expect from noise alone? The tail probability of a χ^2_1 beyond 11.7 is 6×10^{-4}, which is the two-sided Gaussian probability of lying more than $\sqrt{11.7} = 3.4$ standard deviations out (Section 4.9.1). So noise alone would produce a bump this strong about once in sixteen hundred surveys. Both readings give the same rule of thumb: for one extra parameter, the square root of the drop in χ^2 counts the sigmas.

11.4.4 Reproducing the first detection on mock surveys

What the paper compared. Eisenstein and collaborators measured $\xi(s)$ in redshift space, spherically averaged, with the Landy–Szalay estimator (Section 11.2) and FKP-like weights with $P_w = 4{\times}10^4$, in 20 bins out to 180 h^{-1}Mpc. The covariance came from 1278 mock catalogues. They fitted models of ξ with a free amplitude and free $\Omega_m h^2$ and a dilation of the scale, (11.28). The best model with baryons had $\chi^2 = 16.1$ for 17 degrees of freedom; the best pure cold-dark-matter model, which has no acoustic feature, had $\chi^2 = 27.8$, so $\Delta\chi^2 = 11.7$, "3.4σ" by (11.31) [Eisenstein2005 §3.1, §4.3, Fig. 6]. The quantity to reproduce is $\Delta\chi^2$: how strongly a survey of that size prefers a template with the peak over one without it.

Our nerfed version. The script `code/ch11/04_bao_mocks.py` replaces the survey by a periodic box of the same volume, side 900 h^{-1}Mpc (0.73 h^{-3}Gpc^3), holding the same number of galaxies, $\bar{n} = 6.49 \times 10^{-5}\ h^3\text{Mpc}^{-3}$ (about 47329 per box). The galaxy field is lognormal with spectrum $b^2 D^2(z)\, K_0\, P_t(k)$, with $z = 0.35$, $b = 2$, growth factor $D = 0.831$, damping $\Sigma_{\text{nl}} = 8\ h^{-1}$Mpc, and

$K_0 = 1.260$ the angle-averaged boost of the clustering amplitude by galaxy motions (Section 11.5). Its amplitude, $\sigma_{8,g} = 1.51$, is close to the value 1.8 that the paper assumed for the LRGs. In the box there are no edges, so ξ is estimated by Fourier-transform pair counting on the grid (96^3 cells), which is what all four estimators of Section 11.2 reduce to without edges. We use 16 bins of 10 h^{-1}Mpc from 20 to 180 h^{-1}Mpc. 1500 mocks give the covariance, with the Hartlap factor 0.989 (Section 8.13.2); 500 further mocks are each fitted with (11.30), once with the template (11.29) and once with the no-wiggle template, on a grid of $\alpha \in [0.8, 1.2]$.

Listing 11.5: Templates, mocks and the fit (`code/ch11/04_bao_mocks.py`)

```
def template_bins(P, alpha):
    """Bin-averaged grid two-point function of the spectrum P(k/alpha)/alpha^3, i.e. xi(alpha r)."""
    return rb(xi_box_from_pk(lambda k: P(k / alpha) / alpha ** 3, N, L, 3))

t0 = time.time()
T_w = np.array([template_bins(P_w, a) for a in ALPHAS])     # (n_alpha, n_bins)
T_nw = np.array([template_bins(P_nw, a) for a in ALPHAS])
print(f"templates: {time.time()-t0:.0f} s")

# ---- mocks: lognormal galaxy field with the template spectrum, Poisson galaxies, xi by FFT

    for i, t in enumerate(T):
        X = design(t, poly)
        A = X.T @ Ci @ X
        beta = np.linalg.solve(A, X.T @ Ci @ d)
        res = d - X @ beta
        chi2[i] = res @ Ci @ res
```

`template_bins` builds the model for any α through the Fourier form of (11.28): the spectrum $P(k/\alpha)/\alpha^3$ is turned into the grid correlation function and averaged in the same bins as the data, so that the model and the measurement see exactly the same grid. The mock loop (lines 67–72) is Section 11.1 in four lines: lognormal field, Poisson galaxies, density contrast with the

box's own mean (so the integral constraint is present), pair counting by FFT. Lines 76–79 form the covariance and its Hartlap-corrected inverse. In `fit`, line 93 is the generalised least-squares solution $(X^{\mathsf{T}}\mathbf{C}^{-1}X)^{-1}X^{\mathsf{T}}\mathbf{C}^{-1}\hat{\boldsymbol{\xi}}$ for the four linear coefficients at each α.

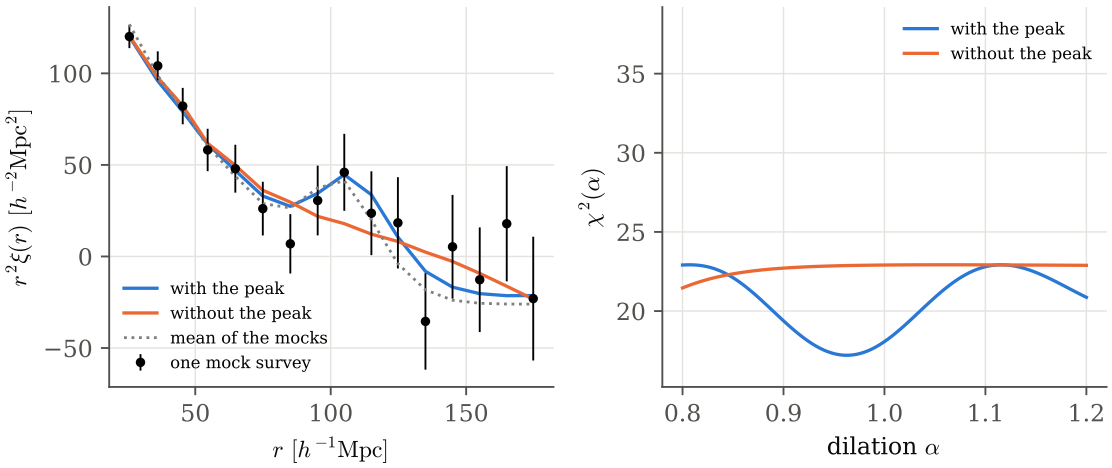

Figure 11.11: One mock survey, chosen as the one with the median $\Delta\chi^2$ among the 500 fitted. Left: $r^2\hat{\xi}(r)$ (points, with the diagonal errors of the mock covariance; neighbouring points are correlated), the mean over mocks (dotted) and the best fits with and without the acoustic feature. Right: $\chi^2(\alpha)$ for both templates. The template with the peak has a minimum near $\alpha = 1$; the one without is almost flat, because nothing in it marks a scale.

Figure 11.11 shows a typical mock. Its best fit with the peak has $\chi^2 = 17.2$ for 11 degrees of freedom and $\hat{\alpha} = 0.963$; the no-wiggle template is worse by $\Delta\chi^2 = 4.3$. Over all fitted mocks the mean χ^2 of the peak template is 10.8, close to the 11 expected if the covariance is right, and the mean $\hat{\alpha}$ is 0.9971 ± 0.0028: the fit is unbiased.

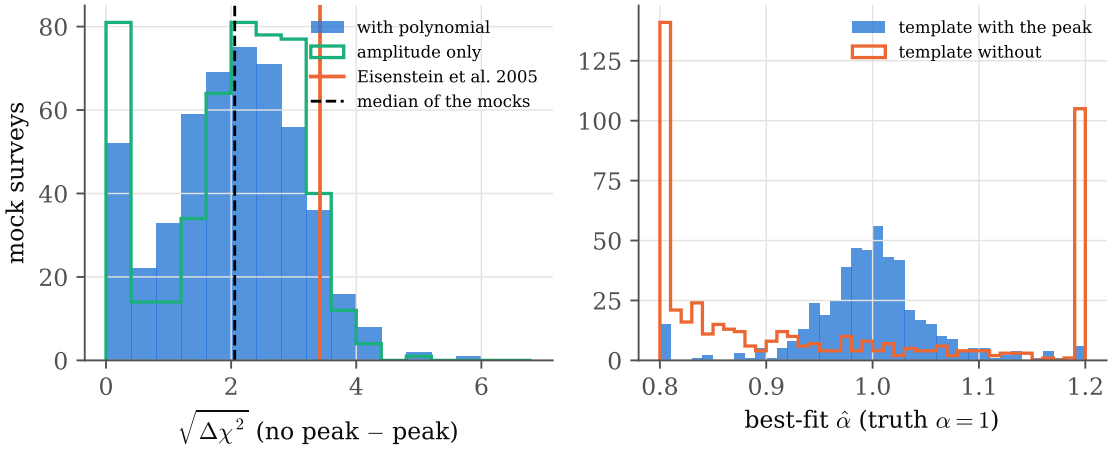

Figure 11.12: Left: the detection significance $\sqrt{\Delta\chi^2}$ over 500 mock surveys of the size of the SDSS LRG sample, with the broad-band polynomial (filled) and with the amplitude as the only free coefficient (green outline). The dashed line is the median, the orange line the 3.4σ of the 2005 paper. Right: the best-fit dilation with the peak template (filled) and with the no-wiggle template (outline), which wanders to the edges of the allowed range.

Figure 11.12 is the reproduction. A survey of that volume and density typically detects the acoustic peak at $\sqrt{\Delta\chi^2} = 2.1$ (the middle 68% of mocks lie between 0.9 and 3.1), and 7% of mock surveys reach the paper's $\Delta\chi^2 = 11.7$. Fitting as the paper did, with the amplitude

as the only free coefficient, changes little: median 2.2, and 6% reach 3.4σ. So the qualitative result reproduces: a survey of $0.7\,h^{-3}\mathrm{Gpc}^3$ at $\bar{n}P \sim 1$ does see the peak, at a modest significance. The 2005 detection sits in the upper tail. Part of that is the luck of one realisation, which the paper's own Figure 2 hints at (the measured points sit above every model). Part is that their comparison model, cold dark matter without baryons, differs from the baryonic model in its broad shape as well as in the peak, and their fit reached down to $10\,h^{-1}\mathrm{Mpc}$, where that shape difference adds to $\Delta\chi^2$; our no-wiggle template differs from the peak template *only* in the peak.

The dilation is measured to 6.3% (standard deviation of $\hat{\alpha}$ over mocks; the median per-mock error from $p(\alpha)$ is 5.9%), against the paper's 4.7% on $D_V(0.35)$, which also includes the shape information. Without the peak, the dilation is barely constrained (15.6%, limited by the edges of the grid). The paper found the same contrast: its pure-CDM fit constrained the scale a factor of two worse [Eisenstein2005 §4.3]. The distance information is in the peak.

11.4.5 How well can a survey locate the peak? A Fisher forecast

The mocks answer the question for one survey at the cost of two thousand simulations. The Fisher matrix of Chapter 10 answers it for any survey in a fraction of a second. The data are the Fourier modes $\delta_{\boldsymbol{k}}$ of the galaxy field; the parameter is α. For a Gaussian mode whose variance depends on the parameter, the Fisher information is $F = \frac{1}{2}\,\mathrm{tr}[\mathbf{C}^{-1}\mathbf{C}_{,\alpha}\mathbf{C}^{-1}\mathbf{C}_{,\alpha}]$ (Section 10.3; [HobsonBMC §5.3.1, eq. (5.17)]). A complex mode $\delta_{\boldsymbol{k}}$ is two real Gaussian numbers, its real and imaginary parts, each with variance $\frac{V}{2}[P(k) + 1/\bar{n}]$ in a box of volume V with uniform density (Section 7.3.3). Modes at $\boldsymbol{k}$ and $-\boldsymbol{k}$ are the same mode, so a shell of width $\mathrm{d}k$ holds $\frac{1}{2}\,V\,4\pi k^2\mathrm{d}k/(2\pi)^3$ independent complex modes. Then

$$F_{\alpha\alpha} \overset{(1)}{=} \sum_{\text{modes}} 2 \times \frac{1}{2}\left(\frac{\partial_\alpha P}{P + 1/\bar{n}}\right)^2 \overset{(2)}{=} \int \frac{V\,4\pi k^2\,\mathrm{d}k}{2(2\pi)^3}\left(\frac{\bar{n}P}{1+\bar{n}P}\right)^2\left(\frac{\partial \ln P}{\partial \alpha}\right)^2$$
$$\overset{(3)}{=} \int \frac{k^2\,\mathrm{d}k}{4\pi^2}\,V_{\mathrm{eff}}(k)\left(\frac{\partial \ln P}{\partial \alpha}\right)^2. \tag{11.32}$$

(1) For one real Gaussian variable of variance $v(\alpha)$, $\frac{1}{2}(v_{,\alpha}/v)^2$; each complex mode contributes two such variables, and the shot noise does not depend on α.
(2) Replace the sum by the mode count of the shell, and write $\partial_\alpha P/(P + 1/\bar{n}) = \frac{\bar{n}P}{1+\bar{n}P}\,\partial_\alpha \ln P$.
(3) $4\pi/(2(2\pi)^3) = 1/(4\pi^2)$, and $V[\bar{n}P/(1+\bar{n}P)]^2 = V_{\mathrm{eff}}(k)$, which for a survey with varying $\bar{n}$ becomes the integral (11.24).

This is the forecast formula of Seo and Eisenstein [SeoEisenstein2003 eq. (9)], and it is the same effective volume that measured the error of $\hat{P}$ in Section 11.3. The derivative must contain only the information in the peak, since the broad band is marginalised in the fit. With $P(k;\alpha) = P_{\mathrm{nw}}(k)\,[1 + O(k/\alpha)]$, where $O = (P_t - P_{\mathrm{nw}})/P_{\mathrm{nw}}$ is the damped wiggle pattern,

$$\left.\frac{\partial \ln P}{\partial \alpha}\right|_{\alpha=1} = -\frac{k\,O'(k)}{1 + O(k)}. \tag{11.33}$$

The error forecast is $\sigma_\alpha = F_{\alpha\alpha}^{-1/2}$.

Listing 11.6: The Fisher error on α (`code/ch11/05_bao_fisher.py`)

```
def dlnp_dalpha(sig_nl):
    """d ln P(k/alpha)/d alpha at alpha = 1 with the broad band held fixed: -k O'(k)/(1 + O)."""
    O = (p_lin / p_nw - 1) * np.exp(-0.5 * (k * sig_nl) ** 2)
    return -k * np.gradient(O, k) / (1 + O)

```

```python
def sigma_alpha(veff_of_P, P, sig_nl, kmin=2e-3, kmax=0.3):
    """Fisher error on alpha. veff_of_P maps the galaxy power P(k) to V_eff(k)
    [(Mpc/h)^3]."""
    sel = (k >= kmin) & (k <= kmax)
    integrand = k ** 2 / (4 * np.pi ** 2) * veff_of_P(P) * dlnp_dalpha(sig_nl) ** 2
    F = np.trapezoid(integrand[sel], k[sel])
    return 1 / np.sqrt(F), integrand
```

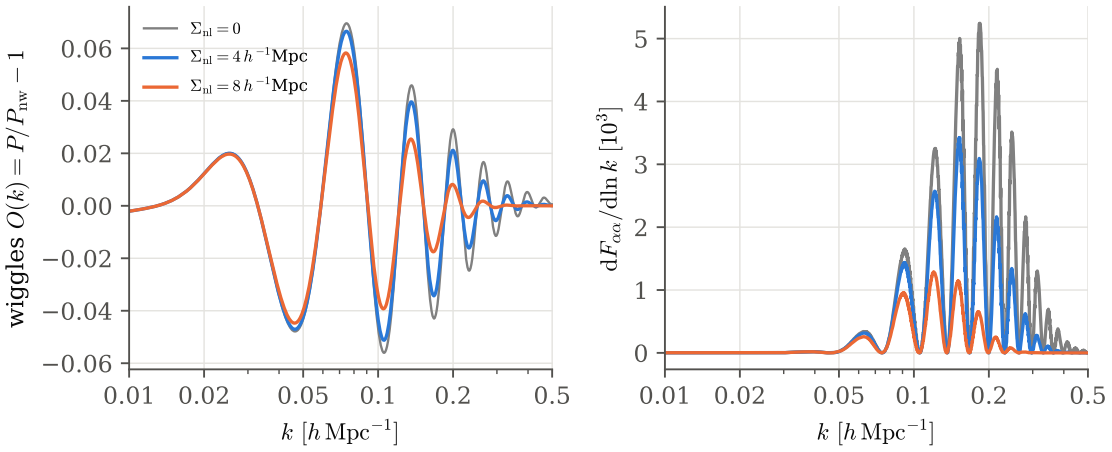

Figure 11.13: Where the information on α comes from. Left: the wiggle pattern $O(k)$ undamped (grey) and damped with $\Sigma_{\rm nl} = 4$ (blue) and $8\,h^{-1}$Mpc (orange). Right: the Fisher integrand of (11.32) per $\ln k$ for the mock box, with the same colours. The information sits in the wiggles between $k \approx 0.05$ and $0.3\,h\,\mathrm{Mpc}^{-1}$; damping erases the higher harmonics.

Example: the mock box. For the box of Section 11.4.4, (11.32) predicts $\sigma_\alpha = 4.1\%$. The mocks gave 6.3% (scatter of $\hat{\alpha}$) and 5.9% (median per-mock error). The forecast is optimistic, and it is supposed to be: the inverse Fisher matrix is a lower bound (Section 10.2), reached only when the likelihood for α is close to Gaussian. At a typical detection of 2σ it is not: $\chi^2(\alpha)$ in Figure 11.11 is shallow, with secondary minima where a noise fluctuation mimics the peak, and in some mocks the fit wanders to the edge of the grid. The bound becomes accurate only for high signal-to-noise. The lognormal field's non-Gaussian covariance, seen already in Section 11.3.3, adds to the gap.

Example: the 2005 survey. For the survey rebuilt from the paper's numbers in Section 11.3 (with $\bar{n}(z)$, the paper's galaxy amplitude $\sigma_{8,g} = 1.8$, and $\Sigma_{\rm nl} = 8\,h^{-1}$Mpc), the forecast is $\sigma_\alpha = 3.4\%$. The paper reports $D_V(0.35) = 1370 \pm 64$ Mpc, a 4.7% distance. Compared with the distance to the last-scattering surface it is the ratio $R_{0.35} = D_V(0.35)/D_M(1089) = 0.0979 \pm 0.0036$, a 3.7% measurement. And the dimensionless combination $A = D_V(0.35)\sqrt{\Omega_m H_0^2}/(0.35\,c) = 0.469 \pm 0.017$ (3.6%) is the distance measured in units of $c/(\sqrt{\Omega_m} H_0)$, a combination that depends on the other parameters only weakly [Eisenstein2005 Table 1].

Example: DESI's bright galaxies. DESI's first data release measured, from 300,017 bright galaxies at $0.1 < z < 0.4$, $D_V/r_d = 7.93 \pm 0.15$ at $z_{\rm eff} = 0.295$, a 1.9% measurement, after reconstruction, with a quoted effective volume of $1.7\,\mathrm{Gpc}^3$ [DESI2024VI Table 1]. In our units that is $0.52\,h^{-3}\mathrm{Gpc}^3$. Taking that $V_{\rm eff}$ as if it held at every k, (11.32) forecasts 1.1% with the post-reconstruction damping $\Sigma_{\rm nl} = 4\,h^{-1}$Mpc and 2.2% with the pre-reconstruction $8\,h^{-1}$Mpc. The measured error lies between the two. The simple forecast is optimistic for the same reasons

as before, plus one: a single $V_{\rm eff}$ quoted at one reference wavenumber overstates the information at higher k, where $\bar{n}P$ is smaller.

How this is used in real research

Our mock boxes play the role of a *verification*: the Fisher formula (11.32) is a known answer for Gaussian modes, and the mocks check it and show where it fails (low signal-to-noise, non-Gaussian covariance). In a survey analysis the same machinery becomes the *research instrument*. For a real footprint, with its mask, its varying $\bar{n}$, fibre collisions and reconstruction, there is no formula for the covariance of $\hat{\xi}$ or for the scatter of $\hat{\alpha}$; the only way to obtain them is to push a thousand or so mock catalogues through the full pipeline, or to calibrate a semi-analytic covariance against them (Section 11.6).

11.4.6 Comparing with the data: DESI distances against Planck

Figure 11.14 puts the DESI DR1 distances next to the prediction of the Planck 2018 ΛCDM model. For the anisotropic measurements we form $D_V/r_d = (z\,(D_M/r_d)^2\,(D_H/r_d))^{1/3}$ from the published D_M/r_d and D_H/r_d, with the error from the delta method (Section 3.6.3): for $\ln D_V = \tfrac{1}{3}(2\ln D_M + \ln D_H + \ln z)$,

$$\frac{\sigma_{D_V}}{D_V} = \frac{1}{3}\sqrt{4\left(\frac{\sigma_{D_M}}{D_M}\right)^2 + \left(\frac{\sigma_{D_H}}{D_H}\right)^2 + 4\rho\,\frac{\sigma_{D_M}}{D_M}\frac{\sigma_{D_H}}{D_H}}, \tag{11.34}$$

where ρ is the published correlation coefficient between the two.

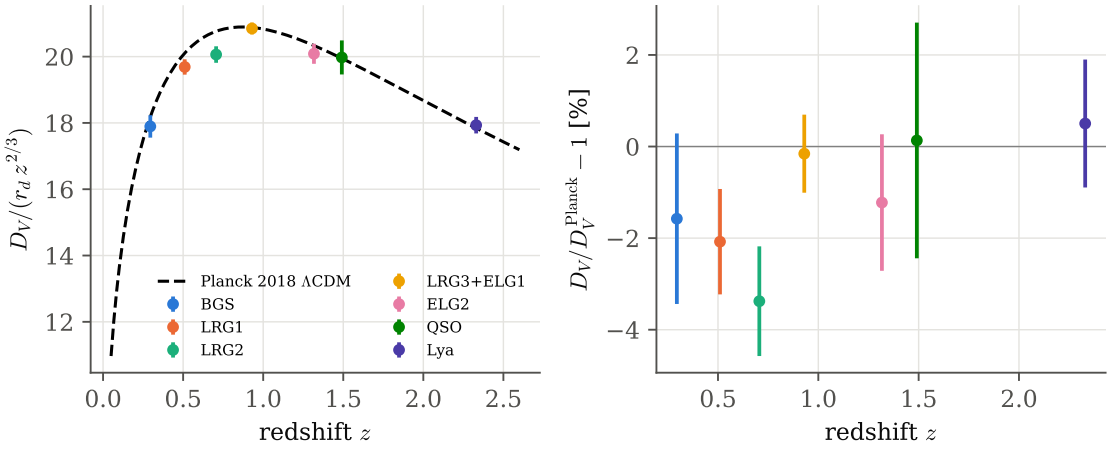

Figure 11.14: DESI DR1 BAO distances (points; [101], Table 1) against the Planck 2018 ΛCDM prediction (dashed). Left: D_V/r_d, divided by $z^{2/3}$ to flatten the curve. Right: the fractional difference from the prediction.

The bright-galaxy point, 7.93 ± 0.15, sits -0.8σ from the Planck prediction 8.06. The largest deviation is the luminous red galaxy bin at $z = 0.71$, 15.91 ± 0.20 against 16.46, a 2.8σ pull. Taken together, the 7 points give $\chi^2 = 12.8$ for 7 degrees of freedom, a p-value of 0.08. How surprised should we be by one 2.8σ point? Among 7 independent points, the chance that at least one deviates by that much is 0.03, which is the look-elsewhere correction of Section 4.14. The data are compatible with the Planck model at the level of this simple comparison; the cosmological fits in the DESI paper, which use the two directions separately and add other data, are where the interesting tensions are argued.

Where we have met H_0 before. These are the same twelve DESI numbers that Section T2.15 fitted on a grid in (Ω_m, hr_d), finding $hr_d = 101.8 \pm 1.3$ Mpc; with the sound horizon $r_d = 147.09$ Mpc

taken from the CMB, that became an inverse distance ladder, $H_0 = 69.2 \pm 0.9$, near Planck's 67.36 ± 0.54 and well below the 73.04 ± 1.04 of the supernova ladder (Section T2.12.3). The degeneracy is the same here: every D/r_d depends on H_0 and r_d only through their product, as the supernova magnitudes of Section 3.17.4 depended on H_0 and M only through $M - 5\log_{10} H_0$. What differs is that nothing is fitted. Planck's model, with its $H_0 = 67.36$ and $r_d = 147.10\,\mathrm{Mpc}$, is held fixed, so the comparison tests their product, $hr_d = 99.1\,\mathrm{Mpc}$, and the shape of the distance curve, never H_0 on its own; and each bin is reduced to the single number D_V/r_d. The verdicts differ for that reason: there, $\Delta\chi^2 = 8.3$ between the Planck point and the best fit, with two degrees of freedom, gave $p = 0.016$; here the absolute χ^2 spreads the same disagreement over 7 degrees of freedom and gives $p = 0.08$. Section 11.20 sets this route beside the other routes to H_0.

11.5 Galaxy motions: clustering in redshift space

A survey never measures how far away a galaxy is. It measures a redshift, and turns it into a distance with the Hubble law of a fiducial cosmology. The redshift, though, is not only the stretching of light by the expansion. Every galaxy also moves through space with its own **peculiar velocity**, a few hundred kilometres per second, and the part of that velocity along our line of sight adds a Doppler shift. The survey therefore places each galaxy a little in front of or a little behind its true position, and only along the line of sight.

If these velocities were random, the displacement would be a nuisance that blurs the map. They are not random. Galaxies fall towards overdense regions and stream out of empty ones, pulled by the same gravity that makes the overdensities grow. On large scales a galaxy in front of a supercluster falls away from us, towards the supercluster, and is placed further away; a galaxy behind it falls towards us and is placed nearer. Both move towards the centre in the map. The supercluster looks squashed along the line of sight and denser than it is. The size of the squashing is set by how fast the infall is, and that is set by how fast structure grows. A direction-dependent clustering pattern thus becomes a measurement of the growth rate of structure, the second number, after the acoustic scale of Section 11.4, that a galaxy survey hands to cosmology.

The question, in words:

> *If every galaxy is moved along the line of sight by its own velocity, and the velocities are the ones that gravity produces while structure is still small, how does the power spectrum of the moved galaxies depend on the angle between a Fourier mode and the line of sight?*

11.5.1 From a redshift to a misplaced galaxy

The event. A galaxy is observed at redshift z_{obs}, and we put it at the comoving distance $\chi(z_{\mathrm{obs}})$.

What produced that redshift? Two shifts, one after the other. Think of a comoving observer [one at rest with respect to the expansion] sitting right next to the galaxy. The galaxy moves away from this neighbour with line-of-sight velocity u_r, so the neighbour sees light of emitted frequency ν_e at $\nu' = \nu_e/(1 + u_r/c)$, the ordinary non-relativistic Doppler shift ($u_r \sim 300\,\mathrm{km\,s^{-1}}$ is a thousandth of c). That light then travels to us through the expanding Universe and is stretched by the cosmological factor $1 + z_c$, where z_c is the redshift the galaxy would have if it were at rest: $\nu_0 = \nu'/(1 + z_c)$. Frequency ratios multiply, so

$$1 + z_{\mathrm{obs}} = \frac{\nu_e}{\nu_0} = (1 + z_c)\Big(1 + \frac{u_r}{c}\Big). \tag{11.35}$$

(Our own motion adds a third factor of the same kind; it is the same for every galaxy in a given direction and is removed by quoting redshifts in the rest frame of the CMB.) The peculiar velocity is $\boldsymbol{u} = a\,\dot{\boldsymbol{x}}$, the rate of change of comoving position $\boldsymbol{x}$ times the scale factor a, which is how the cosmology notes define it; $u_r = \boldsymbol{u}\cdot\hat{\boldsymbol{r}}$ is its component along the line of sight $\hat{\boldsymbol{r}}$.

Where does the galaxy land? We convert $z_{\rm obs}$ with the comoving distance $\chi(z) = \int_0^z c\,\mathrm{d}z'/H(z')$. Calling the assigned distance s,

$$s \equiv \chi(z_{\rm obs}) \overset{(1)}{=} \chi(z_c) + \left.\frac{\mathrm{d}\chi}{\mathrm{d}z}\right|_{z_c}(z_{\rm obs}-z_c) \overset{(2)}{=} \chi + \frac{c}{H(z)}\,(1+z)\,\frac{u_r}{c} \overset{(3)}{=} \chi + \frac{u_r}{aH}. \tag{11.36}$$

(1) A first-order Taylor expansion; the shift $z_{\rm obs}-z_c$ is of order $10^{-3}(1+z)$, so the next term is a million times smaller than χ.
(2) $\mathrm{d}\chi/\mathrm{d}z = c/H(z)$ from the integral, and $z_{\rm obs}-z_c = (1+z_c)\,u_r/c$ from (11.35). We drop the subscript on z_c in factors that multiply a small quantity.
(3) $1+z = 1/a$.

The true comoving distance is χ; the galaxy is placed at s, displaced by $u_r/(aH)$ along the line of sight. In vector form, $\boldsymbol{s} = \boldsymbol{x} + \left(u_r/aH\right)\hat{\boldsymbol{r}}$. The space of the assigned positions $\boldsymbol{s}$ is called **redshift space**; the space of the true positions $\boldsymbol{x}$ is **real space**.

Example: how far is a galaxy moved? Near us, $a = 1$ and $H = H_0 = 100\,h\,\mathrm{km\,s^{-1}Mpc^{-1}}$. A galaxy falling at $300\,\mathrm{km\,s^{-1}}$ is moved by $300/100 = 3\,h^{-1}\mathrm{Mpc}$. A galaxy orbiting inside a rich cluster at $1000\,\mathrm{km\,s^{-1}}$ is moved by $10\,h^{-1}\mathrm{Mpc}$. The first number is small against the $100\,h^{-1}\mathrm{Mpc}$ acoustic scale, but not against the 10–30 $h^{-1}\mathrm{Mpc}$ separations where most pairs sit; the second is larger than the cluster itself.

For the rest of the section we look at a patch of the survey far from us and small on the sky, so that every line of sight in it points in nearly the same direction. Call that direction $\hat{\boldsymbol{z}}$. This is the **distant-observer approximation**. The mapping is then a shift along one fixed axis,

$$\boldsymbol{s} = \boldsymbol{x} + v_z(\boldsymbol{x})\,\hat{\boldsymbol{z}}, \qquad v_z \equiv \frac{u_z}{aH}, \tag{11.37}$$

where v_z is the line-of-sight velocity expressed as a comoving distance. For a Fourier mode with wavevector $\boldsymbol{k}$, let $\mu = \hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{z}}$ be the cosine of its angle with the line of sight: $\mu = \pm 1$ for a wave whose crests are perpendicular to the line of sight, $\mu = 0$ for crests along it.

11.5.2 Counting galaxies twice: the Kaiser factor

We want the density contrast of the galaxies in redshift space, $\delta_s(\boldsymbol{s})$, in terms of the real-space field. We state the inputs first, as in Section 11.1.1.

Physical inputs:

(K1) *Galaxies are conserved by the mapping.* Each galaxy appears exactly once in the redshift-space catalogue. This is bookkeeping, and exact.

(K2) *Linear theory.* The density contrast and the velocities are small, and the matter velocity field obeys the linear continuity equation of the cosmology notes,

$$\theta \equiv \frac{\nabla\cdot\boldsymbol{u}}{aH} = -f\,\delta, \qquad f \equiv \frac{\mathrm{d}\ln D}{\mathrm{d}\ln a}, \tag{11.38}$$

with δ the matter contrast, $D(a)$ the linear growth factor [how much a small fluctuation has grown by scale factor a] and f the **growth rate**. The velocity field has no curl (linear rotational modes decay; see the cosmology notes).

(K3) *Galaxies trace the matter.* Their density contrast is $\delta_g = b\,\delta$ with a constant linear bias b, and they move with the matter, because gravity accelerates a galaxy and the dark matter around it in the same way.

Geometric input: the distant-observer approximation of (11.37). *Mathematical input:* the mapping $\boldsymbol{x} \mapsto \boldsymbol{s}$ is smooth and one-to-one, which holds while v_z changes by much less than the distance over which it changes, that is while $|\partial_z v_z| \ll 1$. (In a collapsing cluster it fails: two galaxies at different true positions can land at the same $\boldsymbol{s}$.)

The galaxies in a small volume, counted twice. The galaxies inside a small real-space volume d^3x around $\boldsymbol{x}$ end up inside a redshift-space volume d^3s around $\boldsymbol{s}$, and by (K1) they are the same galaxies. With $\bar{n}$ the mean density (the same in both spaces, since the shifts average to zero), $\bar{n}[1+\delta_s(\boldsymbol{s})]\,\mathrm{d}^3s = \bar{n}[1+\delta_g(\boldsymbol{x})]\,\mathrm{d}^3x$. The ratio of the volumes is the Jacobian of the mapping (11.37). Its matrix $\partial s_i/\partial x_j$ has rows $(1,0,0)$, $(0,1,0)$ and $(\partial_x v_z, \partial_y v_z, 1+\partial_z v_z)$; it is triangular, so its determinant is the product of the diagonal entries, $1+\partial_z v_z$. Hence

$$1+\delta_s(\boldsymbol{s}) \overset{(1)}{=} \frac{1+\delta_g(\boldsymbol{x})}{1+\partial_z v_z(\boldsymbol{x})} \overset{(2)}{=} 1+\delta_g(\boldsymbol{x}) - \partial_z v_z(\boldsymbol{x}) + O(\delta^2),$$
$$\delta_s(\boldsymbol{x}) \overset{(3)}{=} \delta_g(\boldsymbol{x}) - \partial_z v_z(\boldsymbol{x}) + O(\delta^2). \tag{11.39}$$

(1) Number conservation, divided by $\bar{n}\,\mathrm{d}^3s$, with $\mathrm{d}^3x/\mathrm{d}^3s = 1/(1+\partial_z v_z)$.
(2) $1/(1+\epsilon) = 1-\epsilon+\epsilon^2-\ldots$, and the product $\delta_g\,\partial_z v_z$ is second order, so it is dropped with the rest.
(3) $\delta_s(\boldsymbol{s}) = \delta_s(\boldsymbol{x}+v_z\hat{\boldsymbol{z}}) = \delta_s(\boldsymbol{x}) + v_z\,\partial_z\delta_s + \ldots$; the correction is again a product of two small quantities.

So in linear theory the redshift-space contrast is the real-space contrast minus the line-of-sight gradient of the line-of-sight velocity. Where galaxies on the near side move away from us and those on the far side move towards us, $\partial_z v_z < 0$: the galaxies crowd together in the map and δ_s grows.

The velocity in terms of the density. Now use (K2). Since the velocity field has no curl it is a gradient, $\boldsymbol{u}/(aH) = \nabla\phi$ for some potential ϕ. In Fourier space a gradient is multiplication by $i\boldsymbol{k}$. Then

$$-k^2\phi_{\boldsymbol{k}} \overset{(1)}{=} i\boldsymbol{k}\cdot\left(i\boldsymbol{k}\,\phi_{\boldsymbol{k}}\right) \overset{(2)}{=} \theta_{\boldsymbol{k}} \overset{(3)}{=} -f\,\delta_{\boldsymbol{k}}, \qquad \text{so} \qquad \left(\frac{\boldsymbol{u}}{aH}\right)_{\boldsymbol{k}} = i\boldsymbol{k}\,\phi_{\boldsymbol{k}} = \frac{i\boldsymbol{k}}{k^2}\,f\,\delta_{\boldsymbol{k}},$$
$$\left(\partial_z v_z\right)_{\boldsymbol{k}} \overset{(4)}{=} (ik_z)\,\frac{ik_z}{k^2}\,f\,\delta_{\boldsymbol{k}} \overset{(5)}{=} -f\mu^2\,\delta_{\boldsymbol{k}}. \tag{11.40}$$

(1) $\boldsymbol{k}\cdot\boldsymbol{k} = k^2$ and $i^2 = -1$.
(2) The divergence of $\boldsymbol{u}/(aH) = \nabla\phi$ is θ by the definition in (11.38); in Fourier space a divergence is $i\boldsymbol{k}\cdot$.
(3) The continuity equation (11.38).
(4) v_z is the z component of $\boldsymbol{u}/(aH)$, and ∂_z is multiplication by ik_z.
(5) $i^2 = -1$ and $k_z/k = \mu$.

Putting (11.40) into (11.39) with $\delta_g = b\,\delta$ from (K3),

$$\delta_{s,\boldsymbol{k}} = \left(b + f\mu^2\right)\delta_{\boldsymbol{k}}, \qquad P_s(k,\mu) = \left(b+f\mu^2\right)^2 P(k) = b^2\left(1+\beta\mu^2\right)^2 P(k), \quad \beta \equiv \frac{f}{b}, \tag{11.41}$$

where $P(k)$ is the matter power spectrum and $P_s(k,\mu)$ is defined, as in Section 11.1, by $\mathbb{E}\,|\delta_{s,\boldsymbol{k}}|^2 = V\,P_s(k,\mu)$ for a box of volume V. This is the **Kaiser formula** [103]. The density term carries the bias; the velocity term does not, because galaxies move with the matter whatever

their bias. So the shape of P_s in μ measures the ratio $\beta = f/b$, and the μ^4 term on its own measures f times the amplitude of the matter field, with no bias in it. Shot noise, from Section 11.1, adds $1/\bar{n}$ to (11.41) unchanged: the mapping moves galaxies but does not make or destroy them.

Key idea: The Kaiser formula

In linear theory and for a distant observer, infall moves galaxies along the line of sight in such a way that a Fourier mode at angle $\arccos\mu$ to the line of sight is amplified by $b + f\mu^2$ instead of b: $P_s(k,\mu) = (b + f\mu^2)^2 P(k)$. Modes across the line of sight ($\mu = 0$) are unchanged; modes along it are boosted by $(1+\beta)^2$.

Example: one wave along the line of sight. Take a single matter wave $\delta = A\cos kz$ with crests perpendicular to the line of sight ($\mu = 1$), $b = 1$ and a small amplitude A. For a wave that depends only on z, the divergence is ∂_z, so the continuity equation (11.38) reads $\partial_z v_z = -fA\cos kz$, and integrating, $v_z = -(fA/k)\sin kz$. Just above the crest at $z = 0$, $\sin kz > 0$ and $v_z < 0$: galaxies are moved down, towards the crest. Just below it they are moved up. Around a trough, at $kz = \pi$, the signs reverse and galaxies are moved away. Crests are piled up and troughs are emptied, and (11.39) gives the size:

$$1 + \delta_s \overset{(1)}{=} \frac{1 + A\cos kz}{1 - fA\cos kz} \overset{(2)}{=} 1 + (1+f)\,A\cos kz + O(A^2).$$

(1) $\partial_z v_z = -fA\cos kz$ in the denominator of (11.39).
(2) Expand the denominator to first order in A.

The amplitude grows from A to $(1+f)A$, which is $b + f\mu^2$ at $b = 1$, $\mu = 1$. With $f = 0.8$ the power of this mode rises by $(1.8)^2 = 3.24$. Figure 11.15 draws it.

Example: one wave across the line of sight. Now take $\delta = A\cos kx$, crests running along the line of sight ($\mu = 0$). The velocity points along $\hat{\boldsymbol{x}}$, so $u_z = 0$, nobody is moved along the line of sight, and $\delta_s = \delta$. The factor $b + f\cdot 0^2 = b$ agrees.

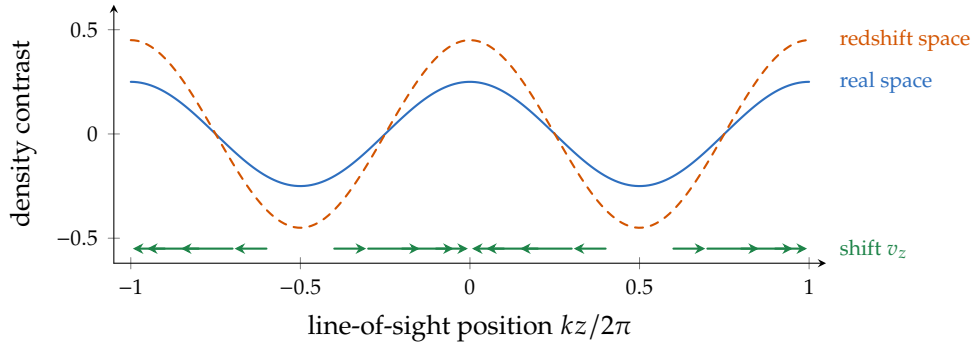

Figure 11.15: A density wave along the line of sight (blue) and the same wave in redshift space (orange, dashed), drawn for $f = 0.8$ and an exaggerated amplitude. The green arrows at the bottom are the line-of-sight shifts $v_z = -(fA/k)\sin kz$: they point towards the crests at $kz/2\pi = 0, \pm 1$ and away from the troughs at $\pm\frac{1}{2}$. Galaxies pile up on the crests, and the wave's amplitude grows by the factor $1 + f$.

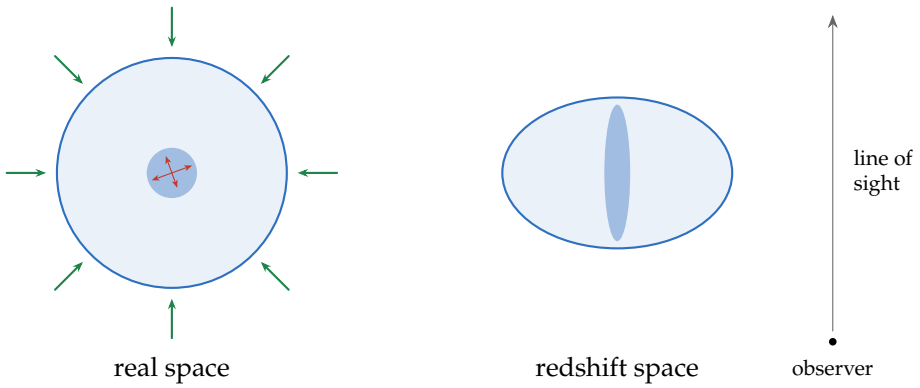

Figure 11.16: Left: a spherical overdensity in real space. On large scales matter falls in coherently (green arrows); in the virialised core galaxies orbit with large random velocities (red). Right: the same structure in redshift space. The coherent infall squashes the large shell along the line of sight (the Kaiser effect); the random motions in the core stretch it into a finger pointing at the observer (the finger of God, Section 11.5.5).

11.5.3 Multipoles: three numbers per wavenumber

The Kaiser formula turns the one-variable power spectrum $P(k)$ into a function of two variables, $P_s(k,\mu)$. Measuring a two-dimensional function in fine bins of both k and μ spreads the modes thin. But (11.41) is a polynomial in μ^2 of degree two, so a few numbers per k hold all of its μ dependence. The natural numbers are the coefficients in Legendre polynomials, because those are orthogonal on $-1 \le \mu \le 1$: $\int_{-1}^{1} L_\ell(\mu) L_{\ell'}(\mu)\,\mathrm{d}\mu = \frac{2}{2\ell+1}\delta_{\ell\ell'}$, with $L_0 = 1$, $L_2 = \frac{1}{2}(3\mu^2-1)$ and $L_4 = \frac{1}{8}(35\mu^4 - 30\mu^2 + 3)$.

Working definition 11.4 (Redshift-space multipoles)

The **multipoles** of the redshift-space power spectrum are

$$P_\ell(k) = \frac{2\ell+1}{2}\int_{-1}^{1} P_s(k,\mu)\,L_\ell(\mu)\,\mathrm{d}\mu, \qquad P_s(k,\mu) = \sum_\ell P_\ell(k)\,L_\ell(\mu),$$

the monopole P_0, quadrupole P_2 and hexadecapole P_4. *Operationally:* in a shell of modes of length near k, average $|\delta_{s,\boldsymbol{k}}|^2/V$ times $(2\ell+1)L_\ell(\mu)$ over the modes [each mode with its own $\mu = k_z/k$]; this replaces the integral by an average over the directions present in the shell.

The factor $(2\ell+1)/2$ is what orthogonality requires: multiply the expansion by L_ℓ, integrate, and only the ℓ-th term survives, with weight $2/(2\ell+1)$.

The integrals we need. Write $\langle g\rangle = \frac{1}{2}\int_{-1}^{1} g(\mu)\,\mathrm{d}\mu$ for the average over directions. Then $\langle\mu^{2n}\rangle = \frac{1}{2}\cdot\frac{2}{2n+1} = \frac{1}{2n+1}$: $\langle\mu^2\rangle = \frac{1}{3}$, $\langle\mu^4\rangle = \frac{1}{5}$, $\langle\mu^6\rangle = \frac{1}{7}$, $\langle\mu^8\rangle = \frac{1}{9}$. With $(b+f\mu^2)^2 = b^2 + 2bf\mu^2 + f^2\mu^4$,

$$\begin{aligned}
\frac{P_0}{P} &\overset{(1)}{=} \left\langle b^2 + 2bf\mu^2 + f^2\mu^4\right\rangle \overset{(2)}{=} b^2 + \frac{2bf}{3} + \frac{f^2}{5},\\
\frac{P_2}{P} &\overset{(3)}{=} \frac{5}{2}\left\langle (b^2 + 2bf\mu^2 + f^2\mu^4)(3\mu^2-1)\right\rangle \overset{(4)}{=} \frac{5}{2}\left[b^2\left(1-1\right) + 2bf\left(\frac{3}{5}-\frac{1}{3}\right) + f^2\left(\frac{3}{7}-\frac{1}{5}\right)\right]\\
&\overset{(5)}{=} \frac{4bf}{3} + \frac{4f^2}{7},\\
\frac{P_4}{P} &\overset{(6)}{=} \frac{9}{8}\left[b^2\left(7-10+3\right) + 2bf\left(5-6+1\right) + f^2\left(\frac{35}{9}-\frac{30}{7}+\frac{3}{5}\right)\right] \overset{(7)}{=} \frac{8f^2}{35}.
\end{aligned} \tag{11.42}$$

(1) The definition with $\ell = 0$, $L_0 = 1$: the monopole is the average over directions.
(2) $\langle\mu^2\rangle = \frac{1}{3}$, $\langle\mu^4\rangle = \frac{1}{5}$.
(3) $(2\ell+1)/2 \cdot 2\langle\cdot\rangle$ with $\ell = 2$ and $L_2 = \frac{1}{2}(3\mu^2 - 1)$: the factors give $5 \cdot \frac{1}{2} = \frac{5}{2}$.
(4) Multiply out and average each power: $b^2(3\langle\mu^2\rangle - 1)$, $2bf(3\langle\mu^4\rangle - \langle\mu^2\rangle)$, $f^2(3\langle\mu^6\rangle - \langle\mu^4\rangle)$.
(5) $\frac{3}{5} - \frac{1}{3} = \frac{4}{15}$ and $\frac{3}{7} - \frac{1}{5} = \frac{8}{35}$; then $\frac{5}{2} \cdot 2 \cdot \frac{4}{15} = \frac{4}{3}$ and $\frac{5}{2} \cdot \frac{8}{35} = \frac{4}{7}$.
(6) The same with $\ell = 4$: $9 \cdot \frac{1}{8}$ in front, and $35\langle\mu^{2n+4}\rangle - 30\langle\mu^{2n+2}\rangle + 3\langle\mu^{2n}\rangle$ for $n = 0, 1, 2$: $35 \cdot \frac{1}{5} - 30 \cdot \frac{1}{3} + 3 = 0$, $35 \cdot \frac{1}{7} - 30 \cdot \frac{1}{5} + 3 \cdot \frac{1}{3} = 0$.
(7) $\frac{35}{9} - \frac{30}{7} + \frac{3}{5} = \frac{1225-1350+189}{315} = \frac{64}{315}$, and $\frac{9}{8} \cdot \frac{64}{315} = \frac{8}{35}$.

Higher multipoles vanish. L_ℓ is orthogonal to every polynomial of degree below ℓ, and $(b + f\mu^2)^2$ has degree 4, so $P_\ell = 0$ for $\ell \geq 6$; the odd multipoles vanish because P_s is even in μ. Dividing by b^2 puts them in Kaiser's form: $P_0 = b^2(1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2)P$, $P_2 = b^2(\frac{4}{3}\beta + \frac{4}{7}\beta^2)P$, $P_4 = b^2\,\frac{8}{35}\beta^2 P$.

Example: the boost used in the acoustic-peak mocks. The mock surveys of Section 11.4.4 were isotropic lognormal boxes whose amplitude was raised by the angle-averaged redshift-space boost. For their luminous red galaxies at $z = 0.35$ with $b = 2$ and $f = 0.706$, $\beta = 0.353$ and the monopole factor is $1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2 = 1.260$. The quadrupole, which a box with an isotropic spectrum cannot have, was left out; for the position of the acoustic peak in the monopole that does not matter.

Example: β without knowing the amplitude. The ratio of the quadrupole to the monopole,

$$\frac{P_2}{P_0} = \frac{\frac{4}{3}\beta + \frac{4}{7}\beta^2}{1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2}, \tag{11.43}$$

contains neither b^2 nor the amplitude of $P(k)$: both cancel. A sample with $b = 2$ and $f = 0.7$ has $\beta = 0.35$, and $P_2/P_0 = (0.467 + 0.070)/(1 + 0.233 + 0.0245) = 0.427$. Conversely, a measured ratio of 0.43 gives back $\beta \approx 0.35$ by solving the quadratic. This is the oldest use of redshift-space distortions: a ratio of two measured multipoles gives β with no knowledge of the bias. To go further, from β to f, needs the bias, which is the subject of Section 11.5.4.

11.5.4 What the anisotropy measures: $f\sigma_8$

The Kaiser formula has three unknowns, b, f and the amplitude of $P(k)$. A galaxy survey cannot tell all three apart, and it pays to see exactly which combinations it does measure.

Split the spectrum into shape and amplitude. The shape of the linear $P(k)$ is fixed by the CMB to high precision; its amplitude at the survey's redshift is conveniently measured by $\sigma_8(z)$, the rms linear matter fluctuation in spheres of $8\,h^{-1}$Mpc (Section T1.2). Write $P(k, z) = \sigma_8^2(z)\,\hat{P}(k)$, where $\hat{P}$ is the spectrum normalised to unit variance in such spheres. Then (11.41) becomes

$$P_s(k, \mu) = \left[b\sigma_8 + f\sigma_8\,\mu^2\right]^2 \hat{P}(k) = \left[(b\sigma_8)^2 + 2\mu^2(b\sigma_8)(f\sigma_8) + \mu^4(f\sigma_8)^2\right]\hat{P}(k). \tag{11.44}$$

Only the products $b\sigma_8$ and $f\sigma_8$ appear. Rescaling $(b, f, \sigma_8) \to (b/\lambda, f/\lambda, \lambda\sigma_8)$ for any $\lambda > 0$ leaves every term unchanged, so no measurement of galaxy clustering alone can separate them. Percival and White wrote the same statement for the variance in $8\,h^{-1}$Mpc spheres seen at a fixed angle μ: integrating (11.44) against the top-hat window gives $\sigma^2_{8,g}(\mu) = (b\sigma_8)^2 + 2\mu^2(b\sigma_8)(f\sigma_8) + \mu^4(f\sigma_8)^2$ [PercivalWhite2009 eq. (14)], because $\hat{P}$ integrates to one by construction. The monopole-to-quadrupole ratio (11.43) fixes $\beta = f\sigma_8/b\sigma_8$; the monopole's amplitude then fixes $b\sigma_8$; and together they give $f\sigma_8$.

Why $f\sigma_8$ is the natural number. With D normalised to $D = 1$ today, the amplitude grows as $\sigma_8(z) = \sigma_8\, D(z)$, and

$$f\sigma_8(z) \overset{(1)}{=} \frac{\mathrm{d}\ln D}{\mathrm{d}\ln a}\,\sigma_8\, D \overset{(2)}{=} \frac{\mathrm{d}(\sigma_8 D)}{\mathrm{d}\ln a} \overset{(3)}{=} \frac{\mathrm{d}\sigma_8(z)}{\mathrm{d}\ln a}.$$

(1) The definition of f in (11.38), times $\sigma_8(z) = \sigma_8 D$.
(2) $\mathrm{d}\ln D/\mathrm{d}\ln a = (1/D)\,\mathrm{d}D/\mathrm{d}\ln a$; the D cancels and σ_8 is a constant.
(3) The definition of $\sigma_8(z)$.

So $f\sigma_8$ is the rate at which the amplitude of structure grows per e-fold of expansion. In general relativity with ΛCDM, f follows from the expansion history alone (close to a power of $\Omega_m(z)$; see the cosmology notes). A theory of gravity that changes how fast structure grows, while leaving the expansion the same, changes $f\sigma_8$ and not the acoustic distances. That is why the two features of Figure 11.1 are complementary tests.

Example: what a 10% bias error would do. Suppose we knew $\sigma_8(z)$ perfectly from the CMB and tried to extract f from a measured β using a bias taken from somewhere else. With $f = \beta b$, a 10% error in b is a 10% error in f. Measuring $f\sigma_8$ directly from (11.44) avoids that external bias entirely; it uses the μ^4 term, which contains no bias at all. The price is that the quoted number is a product, and comparing it with a model needs the model's $\sigma_8(z)$ as well as its $f(z)$.

11.5.5 Fingers of God

Inside a galaxy cluster, the linear picture fails. The galaxies are not falling in; they orbit in a virialised halo with random line-of-sight velocities of several hundred to a thousand kilometres per second. The mapping (11.36) spreads such a cluster along the line of sight by $\sigma_v/(aH)$, up to $10\,h^{-1}$Mpc, into a long thin streak pointing at the observer, the **finger of God** (Figure 11.16, the red core). On large scales these streaks do not move the centre of any structure, but they smear the pattern along the line of sight and lower the power of modes with μ near ±1 at high k. They act against the Kaiser boost and grow in importance as k increases.

A model from first principles, in its simplest form. Give every galaxy, in addition to its coherent shift, an independent random line-of-sight shift Δ, Gaussian with mean zero and standard deviation σ (in comoving distance, $\sigma = \sigma_v/aH$). The power spectrum is the Fourier transform of the distribution of pair separations, and the shifts change every pair separation along $\hat{\boldsymbol{z}}$ by $\Delta_1 - \Delta_2$. A pair of distinct galaxies therefore contributes $e^{-i\boldsymbol{k}\cdot(\boldsymbol{r}_{12}+(\Delta_1-\Delta_2)\hat{\boldsymbol{z}})}$ instead of $e^{-i\boldsymbol{k}\cdot\boldsymbol{r}_{12}}$, and averaging over the shifts,

$$\mathbb{E}\left[e^{-ik_z(\Delta_1-\Delta_2)}\right] \overset{(1)}{=} e^{-\frac{1}{2}k_z^2(2\sigma^2)} \overset{(2)}{=} e^{-k^2\mu^2\sigma^2}, \qquad \text{so} \qquad P_s^{\mathrm{obs}}(k,\mu) = \left(b + f\mu^2\right)^2 P(k)\, e^{-k^2\mu^2\sigma^2} + \frac{1}{\bar{n}}. \tag{11.45}$$

(1) $\Delta_1 - \Delta_2$ is the difference of two independent Gaussians, hence Gaussian with variance $2\sigma^2$, and its characteristic function at k_z is $e^{-k_z^2\cdot 2\sigma^2/2}$ ((2.50)).
(2) $k_z = k\mu$.

The shot-noise term is untouched: it comes from each galaxy paired with itself, for which $\Delta_1 - \Delta_2 = 0$. The damping $e^{-k^2\mu^2\sigma^2}$ is the square of the single-galaxy factor $e^{-(k\sigma\mu)^2/2}$ used in the halo model [CooraySheth2002 eqs. (163)–(165)]. It is a phenomenological model: real velocity dispersions depend on the halo a galaxy lives in, and the shifts of galaxies in the same halo are not independent. Analyses therefore treat σ as a nuisance parameter and marginalise over it, and cut the fit at a maximum k beyond which no simple model is trusted.

Example: where the fingers matter. For $\sigma_v = 400\,\mathrm{km\,s^{-1}}$ near $z = 0$, $\sigma = 4\,h^{-1}\mathrm{Mpc}$. Along the line of sight the damping $e^{-k^2\sigma^2}$ reaches e^{-1} at $k = 1/\sigma = 0.25\,h\,\mathrm{Mpc}^{-1}$ and is $e^{-0.16} = 0.85$ already at $k = 0.1\,h\,\mathrm{Mpc}^{-1}$. The acoustic wiggles of Section 11.4 sit at 0.05–0.3 $h\,\mathrm{Mpc}^{-1}$; this is one more reason a redshift-space analysis must model the two effects together.

11.5.6 Checking the Kaiser formula on moving particles

To test (11.41) we need a catalogue of particles that carry both a position and a velocity, with the velocities obeying the continuity equation. The lognormal fields of Section 11.1.4 have no velocities. The simplest model that has them is the **Zel'dovich approximation**: every particle starts on a regular grid at its initial (Lagrangian) position $\boldsymbol{q}$ and is moved by a displacement that grows with the linear growth factor,

$$\boldsymbol{x}(\boldsymbol{q}, t) = \boldsymbol{q} + \boldsymbol{\Psi}(\boldsymbol{q}, t), \qquad \boldsymbol{\Psi}(\boldsymbol{q}, t) = D(t)\,\boldsymbol{\Psi}_0(\boldsymbol{q}). \tag{11.46}$$

Which displacement gives the right density? Mass conservation counts the particles twice, exactly as in (11.39): the particles of a small Lagrangian cell d^3q at uniform density $\bar\rho$ land in d^3x, so $1 + \delta = \mathrm{d}^3q/\mathrm{d}^3x = 1/\det(\mathbb{1} + \partial\boldsymbol{\Psi}/\partial\boldsymbol{q}) \approx 1 - \nabla\cdot\boldsymbol{\Psi}$ to first order. We want this to be the linear field δ, so $\nabla\cdot\boldsymbol{\Psi} = -\delta$, and a curl-free $\boldsymbol{\Psi}$ with that divergence is, by the same steps as (11.40), $\boldsymbol{\Psi}_{\boldsymbol{k}} = i\boldsymbol{k}\,\delta_{\boldsymbol{k}}/k^2$.

Which velocity does it give? Differentiating (11.46),

$$\boldsymbol{u} \overset{(1)}{=} a\,\dot{\boldsymbol{x}} \overset{(2)}{=} a\,\frac{\dot D}{D}\,\boldsymbol{\Psi} \overset{(3)}{=} a\,H\,\frac{\mathrm{d}\ln D}{\mathrm{d}\ln a}\,\boldsymbol{\Psi} \overset{(4)}{=} aHf\,\boldsymbol{\Psi}, \qquad \text{so} \qquad v_z = \frac{u_z}{aH} = f\,\Psi_z.$$

(1) The definition of the peculiar velocity; $\boldsymbol{q}$ does not change.
(2) $\boldsymbol{\Psi} = D\boldsymbol{\Psi}_0$ and $\boldsymbol{\Psi}_0$ is fixed, so $\dot{\boldsymbol{\Psi}} = \dot D\,\boldsymbol{\Psi}_0 = (\dot D/D)\boldsymbol{\Psi}$.
(3) $\dot D/D = \mathrm{d}\ln D/\mathrm{d}t = (\mathrm{d}\ln D/\mathrm{d}\ln a)(\mathrm{d}\ln a/\mathrm{d}t)$ and $\mathrm{d}\ln a/\mathrm{d}t = \dot a/a = H$.
(4) The definition of f.

As a check, $\nabla\cdot\boldsymbol{u}/(aH) = f\nabla\cdot\boldsymbol{\Psi} = -f\delta$, the continuity equation (11.38). So in redshift space each particle sits at $\boldsymbol{s} = \boldsymbol{q} + \boldsymbol{\Psi} + f\Psi_z\hat{\boldsymbol{z}}$: one extra line of code.

Listing 11.7: Zel'dovich particles in real and redshift space (`code/ch11/06_rsd_kaiser.py`)

```

The script draws 24 Gaussian linear fields at $z = 1$ (growth factor $D = 0.607$, growth rate $f = 0.877$ for the Planck 2018 model) in boxes of side 1000 h^{-1}Mpc with 128^3 particles. Line 74 draws δ_k with the recipe of Section 7.3.3; line 75 is $\boldsymbol{\Psi}_k = i\boldsymbol{k}\,\delta_k/k^2$, transformed back to the grid; lines 77–80 place the particles in real space and in redshift space, the only difference being the term $f\Psi_z$ in line 79. Both catalogues are assigned to the mesh with cloud-in-cell weights, and `power` divides out the cloud-in-cell window. Line 86 keeps, for every mode with $k < 0.08\,h\,\mathrm{Mpc}^{-1}$, the square root of the ratio of its redshift-space to its real-space power, which by (11.41) with $b = 1$ should be $1 + f\mu^2$.

Taking the ratio mode by mode is what lets a few dozen boxes suffice. Both powers come from the same δ_k, so the random amplitude of each mode, the cosmic variance of Section 7.5.2, cancels in the ratio, and what remains scatters only through the non-linear terms of the Zel'dovich mapping. A real survey has no real-space catalogue to divide by; this is a verification of the formula, not a way to measure f.

Estimating f. With $r_j = \sqrt{P_s/P_r}$ for mode j and the model $r_j - 1 = f\mu_j^2$, least squares minimises $\sum_j (r_j - 1 - f\mu_j^2)^2$. Setting the derivative in f to zero, $-2\sum_j \mu_j^2(r_j - 1 - f\mu_j^2) = 0$, gives $\hat{f} = \sum_j \mu_j^2(r_j - 1)/\sum_j \mu_j^4$ (line 98 of the script).

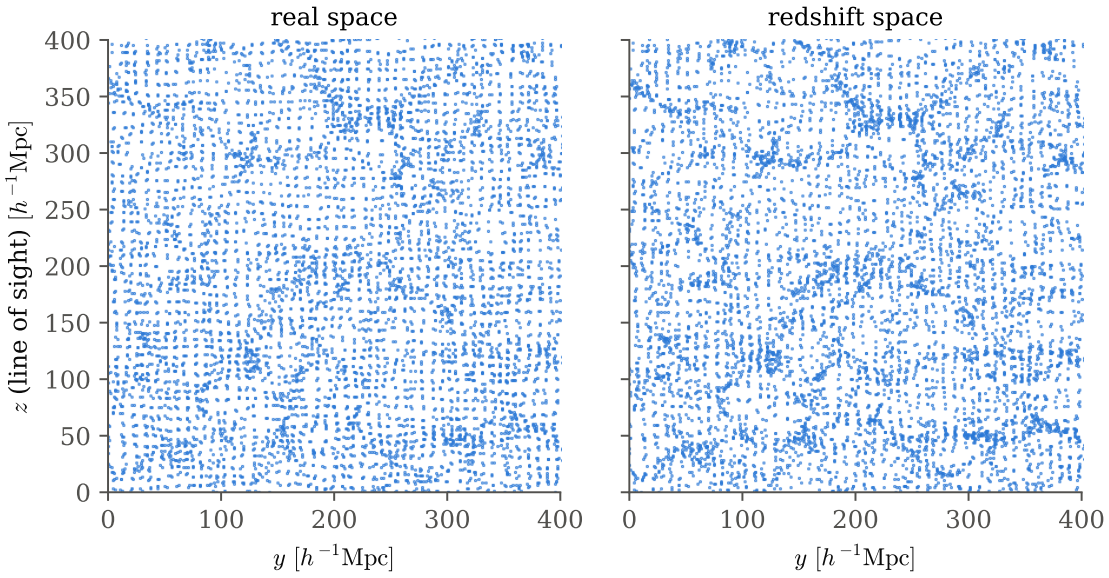

Figure 11.17: A slab 20 h^{-1}Mpc thick from one Zel'dovich box at $z = 1$, in real space (left) and redshift space (right), with the line of sight vertical. The faint grid pattern is the starting lattice, not yet erased by the small displacements. Every particle on the right is moved vertically only, by $f\Psi_z$. By eye the difference is slight at this amplitude; the power spectra of Figure 11.18 measure it.

What the boxes show. The left panel of Figure 11.18 follows $(1 + f\mu^2)^2$ from $\mu = 0$, where the two powers agree, to $\mu = 1$, where the redshift-space power is more than three times larger. The least-squares fit gives $\hat{f} = 0.864$ against the input $f = 0.877$. The scatter of $\hat{f}$ between boxes is 0.014, so the mean of 24 boxes is uncertain by 0.003; the difference $\hat{f} - f = -0.013$ is -4.6 times that error, too large to be chance. What could make the boost slightly too small? Not the linear physics, which the derivation covers exactly, but the part of the displacements that is not coherent on large scales. The rms Zel'dovich displacement per axis is $\sigma_\Psi = 3.4\,h^{-1}$Mpc, so the redshift-space shift $f\Psi_z$ has an rms of 3.0 h^{-1}Mpc, and its small-scale part smears the field along the line of sight much like the random shifts of (11.45): a finger of God in miniature. If that is the cause, the deficit must grow with k and hit the quadrupole hardest, since the

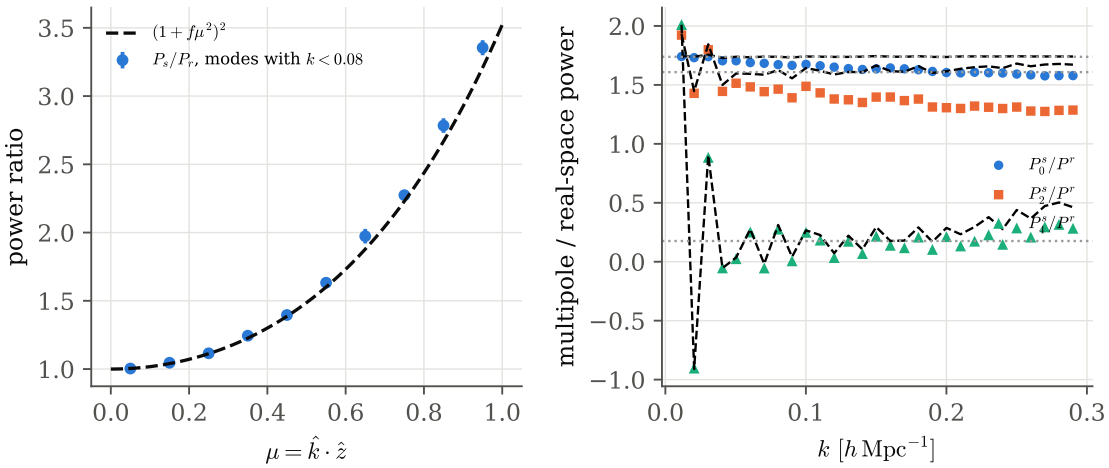

Figure 11.18: Left: the ratio of redshift-space to real-space power for modes with $k < 0.08\,h\,\mathrm{Mpc}^{-1}$, averaged in bins of μ, against the Kaiser factor $(1 + f\mu^2)^2$ (dashed). Right: the monopole (blue), quadrupole (orange) and hexadecapole (green) of the redshift-space power, each divided by the real-space power. Dotted grey lines are the continuum Kaiser values $1 + \frac{2}{3}f + \frac{1}{5}f^2$, $\frac{4}{3}f + \frac{4}{7}f^2$ and $\frac{8}{35}f^2$; the black dashed curves apply $(1 + f\mu^2)^2$ to the boxes' own real-space modes and then take the multipoles with the same discrete average.

damping acts at μ near ±1. At $k = 0.2\,h\,\mathrm{Mpc}^{-1}$ the exponent $(kf\sigma_\Psi)^2$ is already 0.35, and the quadrupole in the right panel falls below the Kaiser value there. At the small k of the fit the effect is small but visible.

For the multipoles averaged over $k < 0.06\,h\,\mathrm{Mpc}^{-1}$, the monopole ratio is 1.724, against 1.738 from (11.42) and 1.741 for the Kaiser factor applied to the same discrete modes. The quadrupole ratio is 1.622, against 1.664 for the same discrete modes, but 1.608 for the continuum formula. The measured quadrupole falls 2.5% below the discrete-mode prediction, the same small shortfall from the smearing. The two predictions differ by 3%, and how much depends on the boxes drawn, since the few modes at low k carry random amplitudes. So a measured quadrupole can land near the continuum value or far from it by chance. The gap between the two predictions is not physics but counting, and it is a trap.

Watch out: Multipoles of a few modes

The continuum results (11.42) assume that the directions in a k shell are spread uniformly in μ. At low k in a box, a shell holds a few dozen modes, and $\mu^2 = k_z^2/k^2$ takes only a handful of values set by the integer grid (for the smallest shell, values such as 0, $\frac{1}{5}$, $\frac{1}{3}$, $\frac{1}{2}$, $\frac{4}{5}$, 1). Then $\langle\mu^4\rangle$ and the Legendre averages are not $\frac{1}{5}$, $\frac{1}{3}$, ..., and even a perfect Kaiser field gives a quadrupole far from $\frac{4}{3}f + \frac{4}{7}f^2$ in the first bins (the jagged dashed curves in Figure 11.18). Always compare a measured multipole with the model evaluated on the same modes, or with a model convolved with the survey's window, which does the same thing for a survey (Section 11.3).

11.5.7 Comparing with the data: the growth rate from BOSS

Their question. By 2016 the Baryon Oscillation Spectroscopic Survey had measured redshifts for 1.2 million massive galaxies over 9329 deg^2 [Alam2017 abstract]. Besides the acoustic peak, the collaboration asked whether structure at $z \approx 0.4$–0.6 had grown at the rate predicted by the ΛCDM model that fits the CMB, a test of gravity on scales of tens of megaparsecs.

Their setup. The galaxies were divided into three overlapping redshift slices with effective redshifts 0.38, 0.51 and 0.61. Four teams fitted the full anisotropic clustering: the monopole and quadrupole of ξ between 25 and 150 h^{-1}Mpc; three μ-wedges of ξ; the power-spectrum multipoles P_0, P_2 up to $k = 0.15\,h\,\mathrm{Mpc}^{-1}$ and P_4 up to 0.1; and power-spectrum wedges up to $0.2\,h\,\mathrm{Mpc}^{-1}$ [Alam2017 §7]. Each used a perturbation-theory model of the non-linear redshift-space clustering, which reduces to (11.41) on large scales and contains a velocity damping in the spirit of (11.45), with the bias, the nuisance parameters and the two dilations of Section 11.4.1 free, and a covariance from one to two thousand mock catalogues. The four results were combined into one consensus value of $f\sigma_8$ per slice. The quantity compared with theory is exactly the $f\sigma_8$ of (11.44), because, as we derived, nothing else in the redshift-space spectrum can be separated from the bias.

What we compute. The prediction is $f(z)\,\sigma_8\,D(z)$ for the Planck 2018 model, with D and f from the linear growth equation of the cosmology notes (`growth` in `lib_lss.py`) and σ_8 from CAMB. The data are the consensus values with statistical and systematic errors added in quadrature.

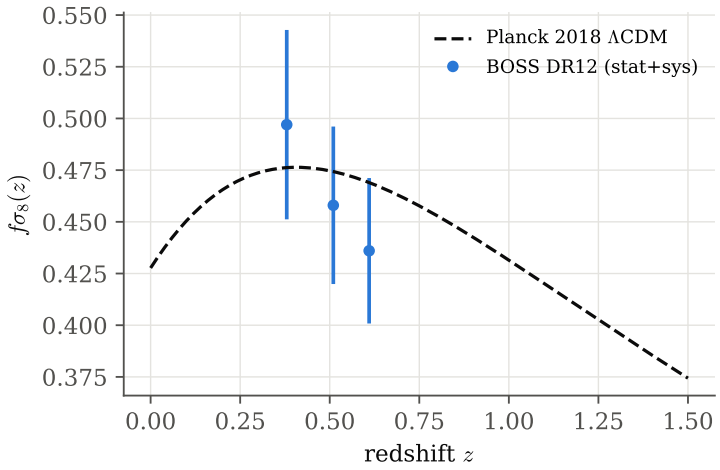

Figure 11.19: The growth rate $f\sigma_8(z)$ of the Planck 2018 ΛCDM model (dashed) and the BOSS DR12 consensus measurements in three redshift slices (points, statistical and systematic errors combined; [197], Table 7).

z_{eff}	BOSS DR12 $f\sigma_8$ (stat, sys)	Planck ΛCDM	pull
0.38	$0.497 \pm 0.039 \pm 0.024$	0.476	0.5
0.51	$0.458 \pm 0.035 \pm 0.015$	0.474	−0.4
0.61	$0.436 \pm 0.034 \pm 0.009$	0.469	−0.9

Side by side. All three points lie within one standard deviation of the prediction (Figure 11.19). The pulls are not three independent draws: the slices overlap in redshift, so neighbouring measurements share galaxies and are positively correlated, and a full test would use the published covariance between them rather than adding three squared pulls. Even so, at 8–9% precision per slice, growth at $z \approx 0.5$ is what ΛCDM with the Planck parameters predicts.

The lesson. Of the three quantities in the Kaiser formula, the survey can deliver only the product $f\sigma_8$; once that is understood, a direction-dependent clustering measurement becomes a test of how fast gravity builds structure.

11.6 How surveys do it, and what our shortcuts cost

Table 1 of the DESI first-year cosmology paper has one line per galaxy sample: a redshift range, a number of objects, an effective volume and a distance ratio such as $D_V/r_d = 7.93 \pm 0.15$ [DESI2024VI Table 1]. Behind each line sits the chain of ideas developed above: points treated as a Poisson sample of a field (Section 11.1), clustering measured against a random catalogue (Section 11.2) or through a weighted Fourier field (Section 11.3), a template fitted for the dilation α (Section 11.4), and the line-of-sight squashing of Section 11.5. Our scripts ran every one of those steps on a laptop. The survey runs each of them at full scale, on data with real defects, with an error budget that has to survive referees who did not take part. The question, in words:

> *At each step from the catalogue to a published distance or growth rate, what does a survey do that our scaled-down versions left out, and what does leaving it out cost?*

11.6.1 The pipeline of a modern survey

Figure 11.20 shows the steps. We take them in order.

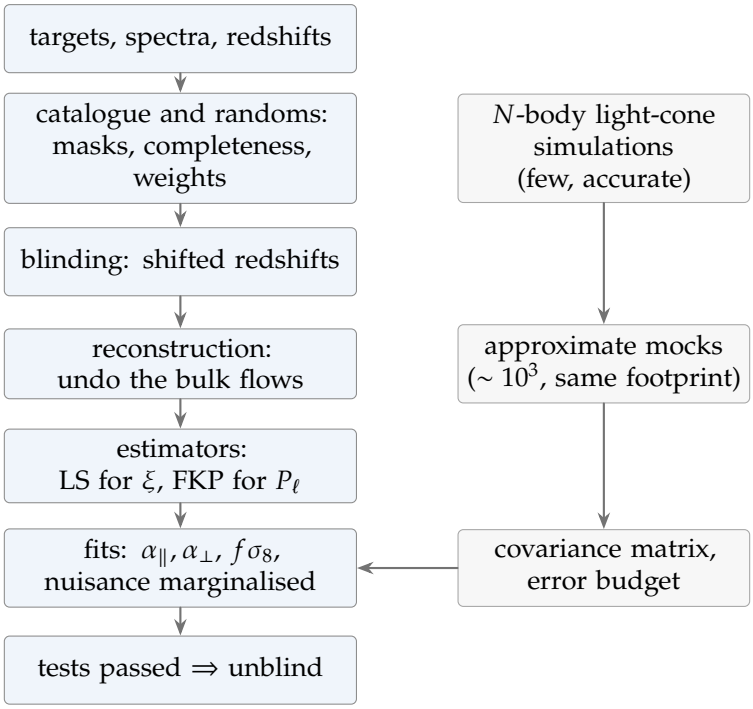

Figure 11.20: The steps from a spectroscopic survey to a distance or growth rate (left column) and the simulations that support them (right). Approximate mock catalogues, calibrated on a few accurate N-body simulations, are run through the same pipeline as the data; their scatter becomes the covariance matrix used in the fits.

The catalogue and its randoms. A real footprint is not a square with a few holes. In BOSS the veto masks, for bright stars, poor imaging, plate centre-posts and similar defects, removed 6.6% and 9.3% of the area in the two galactic caps, leaving a completeness-weighted area of 9329 deg^2; the galaxies carry weights that undo the dependence of the target density on stellar density and seeing, and corrections for fibre collisions and failed redshifts [Alam2017 §2]. In DESI's first year only 35% of the emission-line galaxy targets had received a fibre [DESI2024VI §2.1]. Every one of these effects modulates the observed density without any cosmological cause. The random

catalogue of Section 11.2 must carry every one of them, and the pitfall there (the randoms must have the survey's selection, exactly) is the reason survey teams spend more effort on the randoms than on the estimator. The FKP weights of Section 11.3 multiply these systematic weights.

Blinding. *The problem.* An analysis has hundreds of choices: which weights, which range of scales, which model of the broad band. Each choice is defended by tests, and tests are run until they pass. If the analysts can see the cosmological answer while they work, there is a mechanism that biases the result without anyone intending it. The DESI paper describes it plainly: a result that does not match expectation is attributed to an unknown systematic, and the search for systematics stops when the result agrees [DESI2024VI §2.3.1].

Why that is a statistical bias. Think of the analysis as drawing an estimate $\hat{\theta}$ from its sampling distribution. Suppose an analyst looks at $\hat{\theta}$, keeps it if it lies within 2σ of the expected value, and otherwise searches for, finds, and corrects some small effect, which redraws part of the noise. The rule for when to stop depends on the value obtained. The published estimates are then a sample from the sampling distribution *conditioned on agreeing with expectation*: they are pulled towards the expected value, they scatter less than the quoted error says, and a genuine discrepancy is the one result the procedure is built to remove. It is the same mechanism as stopping an experiment when the p-value first drops below 0.05, run in the opposite direction.

What DESI did. Before analysis the redshifts in the galaxy and quasar catalogues were shifted, by an amount unknown to the analysts, in a way that moves the acoustic feature and changes the redshift-space distortion signal, and the weights were altered to hide the large-scale signal of primordial non-Gaussianity. All tests were run on the blinded catalogues; only after the pipeline was frozen and a prescribed list of validation tests had passed were the true redshifts used. Two changes made after unblinding were reported with their size: a correction to the BAO model, which moved the results by less than 0.3σ, and a completeness fix in the catalogues, by at most 0.6σ [DESI2024VI §2.3.1]. BOSS blinded the methods rather than the data: the four full-shape analyses of Section 11.5.7 were first run on high-fidelity mocks whose parameters the teams did not know, and their errors there entered the systematic budget [Alam2017 §7].

Reconstruction. The acoustic peak is blurred because galaxies have moved a few megaparsecs since the drag epoch, the damping $\Sigma_{\rm nl}$ of Section 11.4. The displacements are not random: on large scales they are the Zel'dovich field $\boldsymbol{\Psi}_{\boldsymbol{k}} = i\boldsymbol{k}\,\delta_{\boldsymbol{k}}/k^2$ of Section 11.5.6, and the observed galaxy field gives an estimate of δ. **Reconstruction** computes that $\boldsymbol{\Psi}$ from the smoothed galaxy field (divided by the bias, and with the redshift-space term $f\Psi_z$ removed), and moves every galaxy and random back by it [DESI2024VI §2.3]. The peak sharpens, roughly halving $\Sigma_{\rm nl}$ from 8 to $4\,h^{-1}$Mpc [Anderson2012 §5.2], and the small non-linear shift of the peak position, below 0.3%, is largely undone. In the Fisher forecast of Section 11.4 for DESI's bright galaxies this was the difference between 2.2% and 1.1% on α: halving the error is worth a factor four in survey volume, so reconstruction is worth about as much as quadrupling the survey, at the cost of one more step to validate on mocks.

Estimators and fits. The estimators are the ones we derived: Landy–Szalay pair counts against random catalogues many times larger than the data ([42] used sixteen times as many randoms), and FKP-weighted Fourier fields, now with fast-Fourier estimators for the multipoles P_0, P_2, P_4 [Alam2017 §7]. The BAO fit uses a template with two dilations, $\alpha_\parallel$ and $\alpha_\perp$, and nuisance parameters for the broad band that are marginalised over [DESI2024VI §2.3]; it is Section 11.4.2 with one more dilation and the Alcock–Paczyński information of Section 11.4.1 kept. The

theoretical systematic errors of this procedure are estimated at 0.1% for the isotropic and 0.2% for the anisotropic BAO parameters, with up to 0.2% more from how galaxies populate haloes; they are added in quadrature to the statistical error [DESI2024VI §2.3].

Mocks for the covariance. Every fit needs the covariance matrix of the measured ξ or P_ℓ. The Gaussian formula of Section 11.3 is not trusted for this: in Section 11.3.3 the scatter of the lognormal field already exceeded it by a factor 1.60 at $k = 0.10\,h\,\mathrm{Mpc}^{-1}$. Surveys instead run a thousand or more mock catalogues through the full pipeline, each with the survey's footprint, completeness, fibre collisions and $n(z)$. Full N-body simulations are too expensive at that number, so the mocks use approximate dynamics: Eisenstein et al. used 1278 PTHalos mocks, and BOSS DR12 used 1000 MultiDark-Patchy mocks (second-order Lagrangian perturbation theory plus a stochastic model for haloes) and 1000 QPM mocks (a low-resolution particle-mesh code), both populated with galaxies to match the observed clustering [Alam2017 §4]. DESI's first-year BAO analysis used semi-analytic covariance matrices validated against such mocks [DESI2024VI §2.3]. A few accurate N-body light-cone simulations serve as the reference that the approximate mocks and the models are checked against; one public set provides 108 full-sky realisations with haloes resolved down to the hosts of the BOSS CMASS and luminous red galaxies [51].

The cost of a finite number of mocks is the subject of Section 8.13.2. With N_S mocks and N_D data bins, the inverse of the sample covariance must be multiplied by the Hartlap factor $(N_S - N_D - 2)/(N_S - 1)$ (Eq. (3.43)), and even then the variance of each parameter is itself uncertain by a fraction $\varepsilon = \sqrt{2/(N_S - N_D - 4)}$ (Section 8.13.4). Since the error bar is the square root of the variance, its fractional scatter is $\varepsilon/2$ by the delta method (Section 3.6.3).

Example: our acoustic-peak mocks against the 2005 analysis. The covariance in Section 11.4.4 came from 1500 mocks for 16 bins: Hartlap factor 0.989 and $\varepsilon = 3.7\%$, so each error bar is uncertain by 1.8%. The 2005 analysis, 1278 mocks for 20 bins, had 0.984 and 2.0%. On this count our nerfed run is as good as the original, which is a statement about bins: a data vector of a few tens of bins is cheap.

Example: a joint fit of many multipoles. A modern full-shape fit uses P_0, P_2, P_4 in several redshift bins and both galactic caps, easily a hundred numbers. With $N_D = 100$ and 1000 mocks the Hartlap factor is 0.899: a 10% correction to every χ^2. For an error bar good to 5%, Eq. (8.79) asks for 304 mocks with $N_D = 100$ against 220 with $N_D = 16$. The mocks are cheap compared with their validation; what limits a survey is not their number but how well their clustering matches the real galaxies'.

Designing the survey. The same Fisher forecast that we checked against mocks in Section 11.4 is how surveys are planned: one writes the error on the BAO distances as a function of area, depth, redshift range and target density, and optimises it under the constraints of the instrument, the field of view, the number of fibres and the total observing time [HobsonBMC §5.3.3]. The effective volume V_{eff} of Section 11.3 is the quantity being traded: more area at fixed time means fewer galaxies per unit volume and a smaller $\bar{n}P$.

11.6.2 What our shortcuts cost

Every script ran in minutes on a laptop. Table 11.1 lists, step by step, what the research version does instead and what the simplification costs. Two kinds of cost appear. Some only widen error bars or shrink the range of scales and could be removed with more computing time; the

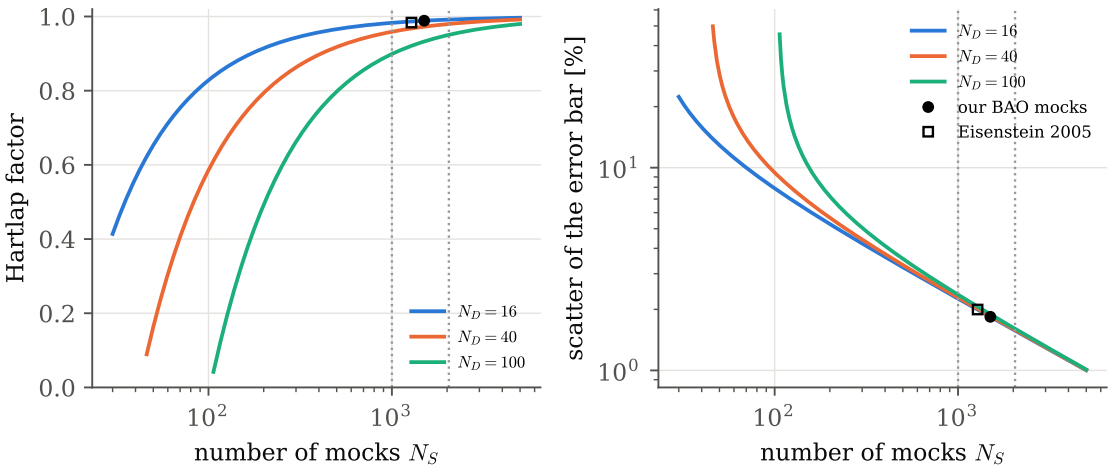

Figure 11.21: The price of a covariance matrix estimated from N_S mocks, for data vectors of $N_D = 16$, 40 and 100 bins. Left: the Hartlap factor that de-biases the inverse covariance. Right: the fractional scatter of a parameter's error bar, $\varepsilon/2$. Black points: our acoustic-peak mocks (filled) and the 2005 analysis (open). Dotted lines: the BOSS DR12 mock sets of 1000 and 2045.

cluster versions of the scripts would do so. Others leave a physical effect out altogether, and no amount of computing in the same model brings it back.

step	research	ours	what it costs
density field	N-body or 2LPT dynamics, galaxies placed in haloes	Gaussian and lognormal fields; Zel'dovich particles	covariance only roughly right (scatter 1.60× Gaussian in the FKP test); no realistic three-point function
geometry	light cone, true footprint and $n(z)$, curved sky	masked 2-D square for ξ; sphere with $\bar{n}(r)$ for FKP; periodic boxes for BAO and RSD	no window in the BAO fit; distant observer only; no evolution with redshift inside a sample
mocks	10^3–2×10^3 approximate mocks, a few N-body	1500 (BAO), 300 (ξ), 100 (FKP), 24 (RSD)	error bars uncertain by 1.8% for BAO; RSD only a verification
reconstruction	yes	no	σ_α forecast 2.2% instead of 1.1% for DESI's bright galaxies
BAO fit	$\alpha_\parallel$, $\alpha_\perp$, broad band marginalised	isotropic α	no separate D_M and D_H, no Alcock–Paczyński information
RSD model	perturbation theory with nuisance parameters, $k \lesssim 0.15$–0.2	linear Kaiser on $k < 0.08\,h\,\mathrm{Mpc}^{-1}$	$\hat{f} - f = -0.013$ (−4.6 errors), from the smearing; fewer modes
systematics	weights for stars, seeing, fibre collisions; blinding	none	nothing in simulations, which have no systematics; fatal on real data

Table 11.1: Each step of the analysis at research scale and in the scripts, with the cost of the simplification.

The first row is the one that matters most and the one we can do least about on a laptop. A lognormal field has the right one- and two-point statistics by construction and the wrong higher-order ones. Every statement that depends only on the two-point function, the shot

noise, the estimators' first-order behaviour, the FKP weight, the Kaiser factor, transferred correctly from our simulations to the theory. Every statement that depends on the four-point function, the absolute covariance and therefore the absolute error bars, transferred only roughly. That is precisely why surveys build mocks with realistic dynamics and why the cosmic web's higher-order structure, which the two-point function does not see, carries information of its own, which the halo model, voids and the topological summaries of Chapter 12 set out to extract.

The lesson. A survey measurement is the same short chain of estimators we derived, wrapped in a much longer chain of corrections, simulations and checks; the estimators fix what is measured, and the mocks and the blinding decide whether the quoted error can be believed.

Recap

- Galaxies are modelled as a Cox process: Poisson given a smooth field $\bar{n}(1+\delta_g)$. Counts in cells have variance $\langle N\rangle + \langle N\rangle^2\sigma_R^2$, pairs have density $\bar{n}^2(1+\xi)$, and the power of the points is $P(k) + 1/\bar{n}$ (Section 11.1).
- $\xi(r)$ is estimated by comparing data pairs with pairs of a random catalogue that has the survey's selection. Written to first order in the fluctuations, Landy–Szalay $(DD - 2DR + RR)/RR$ cancels the edge terms that the natural and Davis–Peebles estimators keep; every estimator carries the integral constraint (Section 11.2).
- The FKP estimator weights the data-minus-randoms field by $w = 1/(1+\bar{n}P)$, the weight that minimises the variance of $\hat{P}$; its mean is the window-convolved spectrum plus shot noise, and its information is measured by $V_{\rm eff}$ (Section 11.3).
- The acoustic peak is a ruler of length r_d; fitting a template with dilation α measures D_V/r_d, the detection significance is $\sqrt{\Delta\chi^2}$ between peaked and smooth templates, and the Fisher forecast on α is a lower bound reached only at high signal-to-noise (Section 11.4).
- Peculiar velocities move galaxies along the line of sight by $u_r/(aH)$. Number conservation and the linear continuity equation give $P_s(k,\mu) = (b + f\mu^2)^2 P(k)$, with multipoles P_0, P_2, P_4 only; clustering alone measures $b\sigma_8$ and $f\sigma_8$, and $f\sigma_8$ is the growth rate of the amplitude of structure (Section 11.5).
- Surveys add masks, weights, blinding, reconstruction and a thousand or more mocks for the covariance; our laptop versions keep the estimators and lose the realistic covariance (Section 11.6).

11.7 Two universes with one power spectrum

In Section 7.7 we took a map of thin rings, kept the amplitude $|\delta_k|$ of every Fourier mode, replaced every phase by a random number, and transformed back. The power spectrum did not change at all, and the rings became featureless noise. That map was a toy. The matter in the real Universe is not a toy: gravity has spent thirteen billion years pulling it into compact clumps, stretching it into filaments and emptying the space between them. If we play the same trick on an evolved matter field, how much of what gravity built does the power spectrum keep?

The answer decides how much of the rest of the chapter can be done with $\xi(r)$ and $P(k)$ alone. The BAO and RSD measurements of Sections 11.4 and 11.5 use the two-point function on large scales, where the field is nearly Gaussian and the power spectrum is, by Section 7.2, a complete description. On the scales of galaxies and clusters that is no longer true. The power

spectrum answers exactly one question, how strongly the fluctuation at one place is tied to the fluctuation at a place a distance r away, and whatever else the field holds is invisible to it. The question becomes concrete:

> *Two matter fields have exactly the same power spectrum. In what measurable ways can they still differ, and which physical structures carry the difference?*

11.7.1 The experiment

We need an evolved field we can make on a laptop. The Zel'dovich approximation of (11.46) is the simplest: put one particle at the centre of every cell of a regular grid (its Lagrangian position $\boldsymbol{q}$) and move it by the displacement $\boldsymbol{\Psi}(\boldsymbol{q})$ that linear theory predicts for today, $\boldsymbol{\Psi}_{\boldsymbol{k}} = i\boldsymbol{k}\,\delta_{\boldsymbol{k}}/k^2$, with $\delta_{\boldsymbol{k}}$ drawn from the CAMB linear spectrum at $z = 0$. The script `08_same_spectrum.py` does this for 192^3 particles in a periodic box of side $600\,h^{-1}$Mpc and deposits them on the grid with cloud-in-cell weights, which gives the density $1 + \delta(\boldsymbol{x})$ of the *Zel'dovich universe*. Particles that started in a slightly overdense patch converge, those in an underdense patch diverge, and the result already shows sheets, filaments and empty regions (Figure 11.22, left).

The *twin* is built from it exactly as in Section 7.7. Fourier transform δ, keep $|\delta_{\boldsymbol{k}}|$, take the phases from the transform of fresh white noise (which makes them uniformly random and keeps the reality condition), and transform back. The ratio of the two power spectra, mode by mode, differs from one by at most 2.519×10^{-12}, which is the rounding error of the FFT. Any analysis that measures only $P(k)$ would call the two fields the same universe. Figure 11.22 shows that they are not.

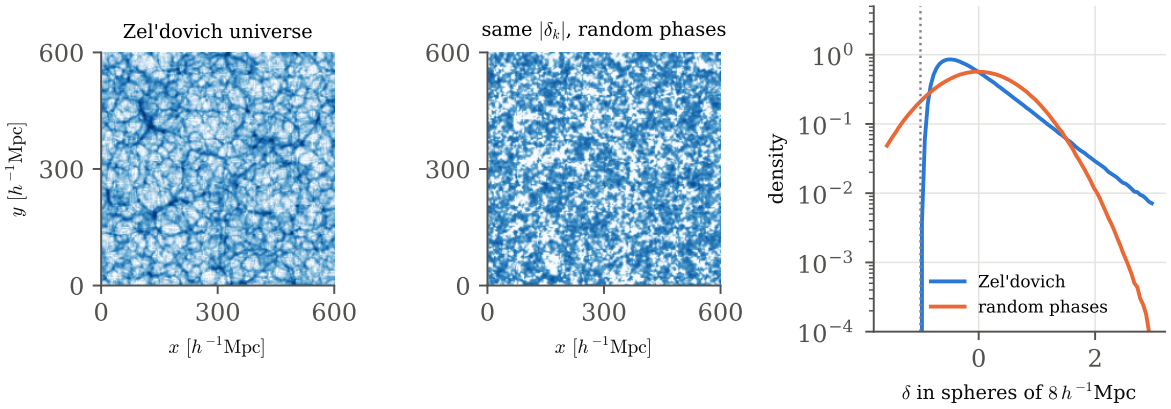

Figure 11.22: Left: a slice $9\,h^{-1}$Mpc thick through the Zel'dovich universe, darker where denser (logarithmic scale). Middle: the same slice of its twin, which has the same $|\delta_{\boldsymbol{k}}|$ for every mode and random phases. Right: the distribution of the density contrast averaged in spheres of radius $8\,h^{-1}$Mpc. The Zel'dovich field is bounded below by $\delta = -1$ (dotted) and has a long tail to high densities; the twin is symmetric and spills below -1.

11.7.2 What the two fields share, and what they do not

Example: the variance in spheres is the same. Average the density contrast over a sphere of radius R about every point; call the result δ_R. Its variance is the number σ_R^2 we met in the definition of σ_8 (Section T1.4). Write the sphere average as a convolution with the normalised top hat W_R, whose Fourier transform is $W(kR) = 3(\sin kR - kR\cos kR)/(kR)^3$. Then

$$\sigma_R^2 \overset{(1)}{=} \left\langle \left| \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, \delta_{\boldsymbol{k}} W(kR)\, e^{i\boldsymbol{k}\cdot\boldsymbol{x}} \right|^2 \right\rangle \overset{(2)}{=} \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, P(k)\, W(kR)^2 \overset{(3)}{=} \int \frac{\mathrm{d}k}{k}\, \frac{k^3 P(k)}{2\pi^2}\, W(kR)^2. \quad (11.47)$$

(1) A convolution in real space is a product in Fourier space, so δ_R is the inverse transform of $\delta_{\boldsymbol{k}} W(kR)$.
(2) Distinct modes are uncorrelated in a homogeneous field, $\langle \delta_{\boldsymbol{k}} \delta^*_{\boldsymbol{k}'} \rangle = (2\pi)^3 \delta_D(\boldsymbol{k} - \boldsymbol{k}') P(k)$ (Section 7.3.2), so the double integral collapses to one, and the phases $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$ cancel against their conjugates.
(3) P and W depend only on $k = |\boldsymbol{k}|$, so the angular integral gives $4\pi k^2$, and $4\pi k^2 \mathrm{d}k/(2\pi)^3 = (k^3/2\pi^2)\,\mathrm{d}k/k$.

Only $|\delta_{\boldsymbol{k}}|^2$ enters. The measured values agree: $\sigma_R = 0.7111$ in the Zel'dovich universe and 0.7111 in the twin, for $R = 8\,h^{-1}$Mpc. Every quantity built from $P(k)$, the correlation function, σ_8, the shot-noise-corrected FKP spectrum of Section 11.3, is identical in the two fields.

Example: the skewness is not. The third moment of δ_R involves three modes at once. Write $\delta_{\boldsymbol{k}} = |\delta_{\boldsymbol{k}}| e^{i\varphi_{\boldsymbol{k}}}$; then

$$\begin{aligned} \langle \delta_R^3 \rangle &\overset{(1)}{=} \int \frac{\mathrm{d}^3k_1\,\mathrm{d}^3k_2\,\mathrm{d}^3k_3}{(2\pi)^9} W_1 W_2 W_3 \left\langle \delta_{\boldsymbol{k}_1} \delta_{\boldsymbol{k}_2} \delta_{\boldsymbol{k}_3} \right\rangle e^{i(\boldsymbol{k}_1+\boldsymbol{k}_2+\boldsymbol{k}_3)\cdot\boldsymbol{x}} \\ &\overset{(2)}{=} \int \frac{\mathrm{d}^3k_1\,\mathrm{d}^3k_2}{(2\pi)^6} W_1 W_2 W_3 \left\langle |\delta_{\boldsymbol{k}_1}||\delta_{\boldsymbol{k}_2}||\delta_{\boldsymbol{k}_3}|\, e^{i(\varphi_{\boldsymbol{k}_1}+\varphi_{\boldsymbol{k}_2}+\varphi_{\boldsymbol{k}_3})} \right\rangle_{\boldsymbol{k}_3=-\boldsymbol{k}_1-\boldsymbol{k}_2}, \end{aligned} \tag{11.48}$$

(1) Cube the Fourier representation of δ_R, with the shorthand $W_i = W(k_i R)$.
(2) Homogeneity forces the three wavevectors to close into a triangle, $\boldsymbol{k}_1 + \boldsymbol{k}_2 + \boldsymbol{k}_3 = 0$ (the average of a product of modes is invariant under translations only if the total wavevector vanishes).

In the twin every phase is independent and uniform, so $\langle e^{i(\varphi_1+\varphi_2+\varphi_3)} \rangle = 0$ for every triangle and the third moment vanishes, up to the noise of one realisation. In the Zel'dovich universe the phases of the three sides of a triangle are correlated, because gravity couples modes: a dense clump is a place where many modes are in phase. The measured skewness $\langle \delta_R^3 \rangle / \sigma_R^3$ is 1.883 for the Zel'dovich universe and 0.01497 for the twin. The skewness is the simplest number that the power spectrum cannot predict; its Fourier-space counterpart is the bispectrum, the average over triangles in (11.48).

Example: the twin is not even a possible density. A density cannot be negative, so $\delta \geq -1$ everywhere. In the Zel'dovich universe the fraction of spheres with $\delta_R < -1$ is 0%. In the twin it is 7.992%. The twin's one-point distribution is the symmetric bell of a Gaussian, and a bell with $\sigma = 0.7111$ puts weight below -1. The real field has to fit its whole variance into the range $\delta > -1$, so it piles up just above -1, in the broad, nearly empty regions, and compensates with a long tail of rare dense regions (Figure 11.22, right). Where the mass cannot go below a floor, matter that leaves a region must end up concentrated somewhere else.

Example: the two fields have different voids. The spherical void finder of Section 11.11.2 grows a sphere about every local density minimum until the mean density inside reaches 20% of the cosmic mean, and keeps the non-overlapping spheres larger than $8\,h^{-1}$Mpc. It returns 3607 voids filling 8.482% of the Zel'dovich box, the largest of radius $23.16\,h^{-1}$Mpc, and only 2546 voids filling 4.569% of the twin (with the unphysical negative densities set to zero first), the largest of radius $15.9\,h^{-1}$Mpc. Same power spectrum, half the empty volume.

11.7.3 Where the extra information lives

The four examples point at two places. The positive tail of the distribution is made of compact, dense objects: the clumps in which the particles of the Zel'dovich universe have crossed one another. In the real Universe these are **dark matter haloes**, gravitationally bound and in rough virial equilibrium, and every galaxy lives inside one. The broad pile-up just above $\delta = -1$ is made of **voids**, large regions that matter has streamed out of, which fill most of the volume. Figure 11.23 draws the two along a line through a field.

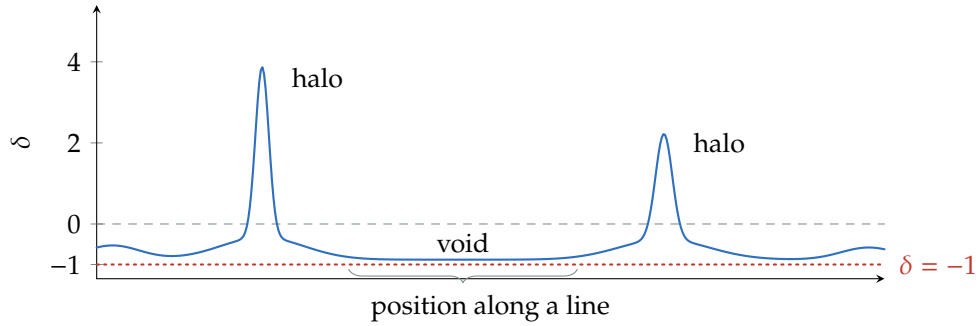

Figure 11.23: The two kinds of structure along a line through an evolved matter field (a drawn cartoon, not data). Haloes are narrow and tall, reaching hundreds of times the mean density; a void is a broad basin whose floor sits just above the hard limit $\delta = -1$ (dotted), and which fills most of the line. A Gaussian field with the same power spectrum would have neither.

This suggests two ways forward, and both pay.

(1) *Build the field out of its structures.* If all matter sits in haloes, the statistics of the field follow from three properties of haloes: how many there are of each mass, how matter is arranged inside each, and how haloes cluster. This is the **halo model**. Its first payoff is a prediction of the non-linear $P(k)$ from linear theory plus these ingredients; its second is a model of how galaxies sit in haloes, which explains the shape of the galaxy correlation function (Sections 11.8 to 11.10).

(2) *Count and measure the structures themselves.* The number of voids of each size, their average density profile and their average shape are summary statistics that, as the last example showed, respond to information the power spectrum discards. They need their own theory of what to expect, and their own estimators (Sections 11.11 and 11.12).

In the language of the pipeline that runs through the book (physical model, field, choice of information, summary, sampling distribution, inference), the halo model is a better *physical model* for the field on small scales, and the void statistics are new *summaries* whose distributions we have to derive. Both use the same mathematical engine, the statistics of random walks, which is where we start.

Key idea: The power spectrum keeps amplitudes and throws away phases

Two fields with identical $|\delta_k|$ have identical $P(k)$, $\xi(r)$ and σ_R, but can differ in their skewness, in their one-point distribution and in the number and size of their voids. For an evolved matter field the difference is carried by haloes, on the dense side, and by voids, on the empty side.

11.8 How many haloes of each mass

The most massive objects in the Universe are clusters of galaxies, haloes of 10^{14}–10^{15} solar masses. They are rare: a cube $1\,h^{-1}$Gpc on a side holds only a few hundred of the largest. Their number is extremely sensitive to the amplitude of the initial fluctuations, because building a $10^{15}M_\odot$ object needs a large region to have been unusually dense, and unusual events in a Gaussian field are exponentially rare. Counting clusters has therefore been a cosmological probe since the 1970s, and the abundance of haloes of every mass is the first ingredient of the halo model. The question, in words:

> *Given the linear density field, Gaussian with a known power spectrum, what fraction of all the mass sits today in haloes with mass between M and $M + \mathrm{d}M$?*

This is a prediction, in the sense of Chapter 5: from a hypothesis about the initial field to the frequency of an outcome. Its answer becomes a likelihood for cluster counts, and an input to everything else in this part.

11.8.1 The inputs

The field. Let $\delta(\boldsymbol{x})$ be the linear density contrast extrapolated to today with the linear growth factor, as CAMB returns it. Smooth it with a sphere of radius R; the sphere holds, at the mean density $\bar\rho$, the mass $M = \frac{4\pi}{3}\bar\rho R^3$, so every smoothing scale is also a mass. The smoothed contrast $\delta_M(\boldsymbol{x})$ has variance $\sigma^2(M)$, given by (11.47) with $R = (3M/4\pi\bar\rho)^{1/3}$. It falls as M grows: in our fiducial cosmology $\sigma = 2.891$ for $M = 10^{11}\,h^{-1}M_\odot$ and $\sigma = 0.5348$ for $M = 10^{15}\,h^{-1}M_\odot$.

Collapse. A spherical region whose linear contrast exceeds a critical value δ_c has, according to the exact solution for a uniform spherical perturbation, stopped expanding, turned around and collapsed by today. The spherical-collapse solution belongs to cosmology and is taken from there (see the cosmology notes); for an Einstein–de Sitter background it gives

$$\delta_c = \frac{3}{5}\left(\frac{3\pi}{2}\right)^{2/3} = 0.6 \times 2.811 = 1.686, \tag{11.49}$$

with a very weak dependence on Ω_m that we ignore [CooraySheth2002 eq. (53)]. The collapsed object settles at a mean density a few hundred times $\bar\rho$; in an Einstein–de Sitter universe $\Delta_{\rm vir} = 18\pi^2 \approx 178$, and for ΛCDM today about 330 relative to the mean matter density, which is the value we use for halo edges in Section 11.9. The important property of (11.49) is that it does not depend on the mass: the collapse of a uniform sphere depends only on its density contrast, not on its size [CooraySheth2002 p. 20].

We now list what we assume, separating physics from mathematics, as for the Poisson process of Section 2.5.1.

Physical inputs.

(H1) The linear field is Gaussian, with the CAMB linear power spectrum.

(H2) A region of mass M around a point has collapsed into a halo by today if $\delta_M > \delta_c$ there. Collapse is spherical, so the threshold is the same constant for all masses.

(H3) A mass element belongs to the most massive collapsed region that contains it. A small clump inside a large collapsed region is part of the large halo, not a halo of its own.

Mathematical choice.

(M1) The smoothing is done with a sharp filter in Fourier space (keep all modes with $k < k_c$, drop the rest) rather than a sphere in real space.

(H1) is the standard inflationary initial condition, well tested by the CMB. (H2) is an idealisation: real collapse is ellipsoidal, and its correction is the subject of Section 11.8.5. (H3) is the rule that turns "collapsed regions" into a count of distinct objects. (M1) has no physics in it; it is chosen because it makes the problem exactly solvable, and Section 11.8.4 measures what it costs.

11.8.2 Press and Schechter's count, and the missing half

The simplest guess. Fix a mass M. By (H1), δ_M at a randomly chosen point is Gaussian with mean zero and variance $\sigma^2(M)$. By (H2), the point sits inside a collapsed region of mass at least M if $\delta_M > \delta_c$. Press and Schechter [198] identified the fraction of mass in haloes heavier than M with the fraction of points where this happens. Choosing a point at random is choosing a mass element at random, because the linear field is almost uniform, so

$$\mathrm{P}(\delta_M > \delta_c) = \int_{\delta_c}^{\infty} \frac{\mathrm{d}\delta}{\sqrt{2\pi}\,\sigma}\, e^{-\delta^2/2\sigma^2} = \frac{1}{2}\,\mathrm{erfc}\Big(\frac{\nu}{\sqrt{2}}\Big), \qquad \nu \equiv \frac{\delta_c}{\sigma(M)}. \tag{11.50}$$

The variable ν is the threshold in units of the standard deviation: a halo of mass M is a "ν-sigma" event. At $\nu = 1$ the fraction is 0.159, at $\nu = 2$ it is 0.023, at $\nu = 3$ it is 0.0013; this is the exponential sensitivity of cluster counts.

What goes wrong. Let $M \to 0$. Then $\sigma \to \infty$, $\nu \to 0$, and (11.50) tends to $\frac{1}{2}$. Half of the mass never belongs to any halo, however small. But every mass element in a Gaussian field is, on some scale, inside an overdense region. Where does the other half go? The points with $\delta_M < \delta_c$ on scale M include points that *are* inside a collapsed region on a larger scale $M' > M$. By (H3) they belong to a halo of mass M', but the count at scale M never sees them. Press and Schechter multiplied their result by 2 by hand. The reason the factor is exactly 2 became clear only when the problem was reformulated as a random walk [199].

11.8.3 The excursion set: a random walk in smoothing scale

Fix one point $\boldsymbol{x}$ and watch its smoothed contrast as the filter shrinks, from infinitely large (where $\delta = 0$, the mean) to infinitely small. With the sharp filter of (M1),

$$\delta(\boldsymbol{x}; k_c) = \int_{|\boldsymbol{k}|<k_c} \frac{\mathrm{d}^3k}{(2\pi)^3}\, \delta_{\boldsymbol{k}}\, e^{i\boldsymbol{k}\cdot\boldsymbol{x}}, \qquad S(k_c) \equiv \mathrm{Var}\big[\delta(\boldsymbol{x}; k_c)\big] = \int_{|\boldsymbol{k}|<k_c} \frac{\mathrm{d}^3k}{(2\pi)^3}\, P(k). \tag{11.51}$$

S grows from 0 as k_c grows, so we may use S itself as the "time" of the trajectory. Large S means a small smoothing scale and a small mass; we write $S = \sigma^2(M)$ for the mass associated with each scale.

How does δ change when the filter shrinks a little? Raising the cut from k_c to $k_c + \Delta k_c$ adds the modes in a thin shell,

$$\Delta\delta \overset{(1)}{=} \int_{k_c<|\boldsymbol{k}|<k_c+\Delta k_c} \frac{\mathrm{d}^3k}{(2\pi)^3}\, \delta_{\boldsymbol{k}} e^{i\boldsymbol{k}\cdot\boldsymbol{x}},$$

$$\big\langle \Delta\delta\, \delta(\boldsymbol{x}; k_c)\big\rangle \overset{(2)}{=} 0, \qquad \big\langle(\Delta\delta)^2\big\rangle \overset{(3)}{=} \int_{\text{shell}} \frac{\mathrm{d}^3k}{(2\pi)^3} P(k) = S(k_c + \Delta k_c) - S(k_c) \equiv \Delta S. \tag{11.52}$$

(1) The difference of two sharp-k integrals is the integral over the shell between them.

(2) The increment contains only modes in the shell, the old value only modes inside it. In a homogeneous field distinct modes are uncorrelated (Section 7.3.2).

(3) The same orthogonality applied to the shell alone.

For a Gaussian field, uncorrelated means independent (Section 7.3.3). So every step of the trajectory is a Gaussian of variance ΔS, independent of everything before it. That is the definition of Brownian motion, with S as time and $\delta = 0$ at $S = 0$. Taking two times $S_1 < S_2$ and writing $\delta(S_2) = \delta(S_1) + [\delta(S_2) - \delta(S_1)]$ gives, from the independence of the bracket, $\langle \delta(S_1)\delta(S_2)\rangle = S_1 = \min(S_1, S_2)$.

Working definition 11.5 (excursion set, first crossing)

At a fixed point, the **excursion-set walk** is the smoothed linear contrast $\delta(S)$ as a function of the variance $S = \sigma^2(M)$ of the filter. With a sharp-k filter it is a Brownian motion starting at $\delta(0) = 0$. The point belongs to a halo of mass M if the walk **first crosses** the threshold δ_c at $S = \sigma^2(M)$: no larger scale had collapsed, so by (H3) the largest collapsed region around the point has mass M. *Operational:* the fraction of mass in haloes heavier than M is the fraction of walks that have crossed δ_c at some $S' < \sigma^2(M)$.

The question in walk language. Out of all walks, what fraction has reached δ_c at least once before time S? Press and Schechter counted only the walks that are *above* δ_c at time S. A walk that went above earlier and came back down by time S is also inside a halo of mass larger than M, and it is missing from their count.

The reflection argument. Split the walks that have crossed by time S into those that end above the barrier and those that end below:

$$\mathrm{P}(\text{crossed by } S) = \mathrm{P}\big(\delta(S) > \delta_c\big) + \mathrm{P}\big(\text{crossed by } S \text{ and } \delta(S) < \delta_c\big). \tag{11.53}$$

Take any walk in the second group. It touched δ_c for the first time at some $S_1 < S$. Reflect the part of the walk after S_1 in the line $\delta = \delta_c$, replacing $\delta(S')$ by $2\delta_c - \delta(S')$ for $S' > S_1$ (Figure 11.24). The reflected walk ends above δ_c. Its steps after S_1 are the original steps with their signs flipped, and a Gaussian step of mean zero is as likely as its negative, so the reflected walk is exactly as probable as the original. The map is one to one, and every walk ending above the barrier is the image of exactly one walk in the second group (reflect it back after its own first crossing). The two groups have equal probability, and

$$\mathrm{P}(\text{crossed by } S) \overset{(1)}{=} 2\,\mathrm{P}\big(\delta(S) > \delta_c\big) \overset{(2)}{=} \operatorname{erfc}\!\Big(\frac{\delta_c}{\sqrt{2S}}\Big). \tag{11.54}$$

(1) The second term of (11.53) equals the first, by the reflection. A walk that ends above the barrier has necessarily crossed it.

(2) $\delta(S)$ is Gaussian with variance S, so the first term is (11.50) with $\sigma^2 = S$.

As $S \to \infty$ the right side tends to $\operatorname{erfc}(0) = 1$: every mass element ends up in some halo. The factor of 2 is not a fudge. It is the contribution of the walks that went up and came back down, the cloud-in-cloud mass that the single-scale count missed.

From the first-crossing distribution to the mass function. The fraction of walks that first cross between S and $S + \mathrm{d}S$ is the derivative of (11.54), $\mathcal{F}(S)\,\mathrm{d}S$. It is cleaner in terms of $\nu = \delta_c/\sqrt{S}$, so we change variable:

$$\mathcal{F}(S) \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}S}\operatorname{erfc}\!\Big(\frac{\delta_c}{\sqrt{2S}}\Big) \overset{(2)}{=} \frac{2}{\sqrt{\pi}}\,e^{-\delta_c^2/2S}\,\frac{\delta_c}{2\sqrt{2}\,S^{3/2}} = \frac{\delta_c}{\sqrt{2\pi}\,S^{3/2}}\,e^{-\delta_c^2/2S},$$

$$F(\nu) \overset{(3)}{=} \mathcal{F}(S)\left|\frac{\mathrm{d}S}{\mathrm{d}\nu}\right| \overset{(4)}{=} \frac{\delta_c\,\nu^3}{\sqrt{2\pi}\,\delta_c^3}\,e^{-\nu^2/2}\,\frac{2\delta_c^2}{\nu^3} = \sqrt{\frac{2}{\pi}}\,e^{-\nu^2/2}. \tag{11.55}$$

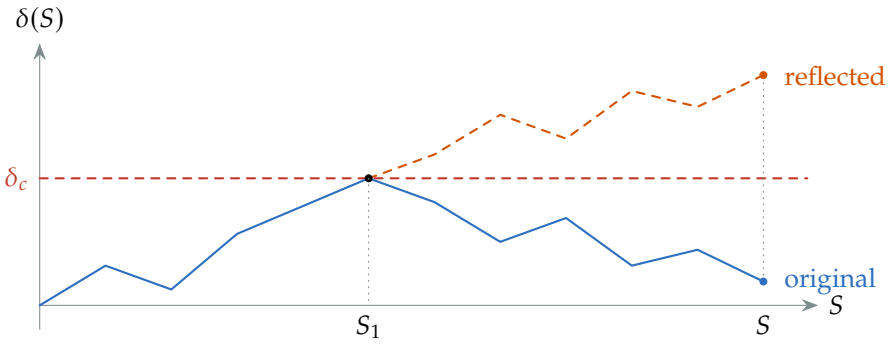

Figure 11.24: The reflection argument. A walk (blue) first reaches δ_c at S_1 and is below it again at S. Reflecting everything after S_1 in the barrier gives a walk (orange) that is equally probable and ends above the barrier. Every walk that crossed and came back is paired with one that ends above, so the walks that have crossed by S are twice those found above δ_c at S.

(1) The first-crossing density is the rate at which the crossed fraction grows.
(2) $\frac{\mathrm{d}}{\mathrm{d}y}\operatorname{erfc}(y) = -\frac{2}{\sqrt{\pi}}e^{-y^2}$ with $y = \delta_c/\sqrt{2S}$ and $\frac{\mathrm{d}y}{\mathrm{d}S} = -\frac{\delta_c}{2\sqrt{2}}S^{-3/2}$; the two minus signs cancel.
(3) The same fraction of walks expressed per unit ν instead of per unit S: a density changes by the Jacobian (Chapter 2).
(4) $S = \delta_c^2/\nu^2$, so $S^{-3/2} = \nu^3/\delta_c^3$ and $|\mathrm{d}S/\mathrm{d}\nu| = 2\delta_c^2/\nu^3$.

$F(\nu)\,\mathrm{d}\nu$ is the fraction of all mass in haloes whose ν lies in $[\nu, \nu + \mathrm{d}\nu]$, and $\int_0^\infty F\,\mathrm{d}\nu = 1$, as it must be now that every mass element is in a halo. It is called the **multiplicity function**, and it is *universal*: the power spectrum, the redshift and the mass have all disappeared into ν.

To turn mass fractions into numbers of haloes, note that a halo of mass M holds mass M. The mass per unit volume in haloes with masses in $[M, M + \mathrm{d}M]$ is $\bar\rho\, F(\nu)|\mathrm{d}\nu/\mathrm{d}M|\,\mathrm{d}M$; dividing by M counts them:

$$\frac{\mathrm{d}n}{\mathrm{d}\ln M} \overset{(1)}{=} \frac{\bar\rho}{M}F(\nu)\left|\frac{\mathrm{d}\nu}{\mathrm{d}\ln M}\right| \overset{(2)}{=} \frac{\bar\rho}{M}\nu F(\nu)\left|\frac{\mathrm{d}\ln\sigma}{\mathrm{d}\ln M}\right|. \tag{11.56}$$

(1) Haloes per unit volume per unit $\ln M$: the mass density in that range divided by the mass of one halo, with $\mathrm{d}M = M\,\mathrm{d}\ln M$.
(2) $\nu = \delta_c/\sigma$, so $\mathrm{d}\ln\nu = -\mathrm{d}\ln\sigma$ and $\mathrm{d}\nu/\mathrm{d}\ln M = -\nu\,\mathrm{d}\ln\sigma/\mathrm{d}\ln M$.

This is the Press–Schechter mass function. In the notation of [CooraySheth2002 eqs. (56)–(57)], who write ν for our ν^2, it reads $m^2 n/\bar\rho\;\mathrm{d}m/m = \nu f(\nu)\,\mathrm{d}\nu/\nu$ with $\nu f(\nu) = \sqrt{\nu/2\pi}\,e^{-\nu/2}$; substituting $\nu \to \nu^2$ gives $\nu F(\nu)/2$, the same thing.

Watch out: Two meanings of ν

Papers on the mass function use $\nu = \delta_c/\sigma$ (Press–Schechter's and ours) or $\nu = (\delta_c/\sigma)^2$ (Sheth and Tormen's, and Cooray and Sheth's). The multiplicity "$\nu f(\nu)$" then differs by a factor of 2, because $\mathrm{d}\ln\nu^2 = 2\,\mathrm{d}\ln\nu$. Check the definition before comparing a formula or a plot.

Example: the characteristic mass and the clusters. The mass M_* at which $\sigma(M_*) = \delta_c$, so $\nu = 1$, separates common haloes from rare ones. For our cosmology at $z = 0$, $M_* = 4.413\times10^{12}\,h^{-1}M_\odot$. A Milky-Way-sized halo of $10^{12}\,h^{-1}M_\odot$ has $\nu = 0.7941$, and the fraction of all mass in haloes heavier than it is $\int_\nu^\infty F\,\mathrm{d}\nu' = \operatorname{erfc}(\nu/\sqrt{2}) = 0.4269$: a bit under half of all matter sits in haloes at least as massive as ours. For clusters the number density follows from integrating (11.56) over $\ln M$: $n(>10^{14}) = 3.185\times10^{-5}\,h^3\mathrm{Mpc}^{-3}$ and $n(>10^{15}) = 1.083\times10^{-7}\,h^3\mathrm{Mpc}^{-3}$ (masses

in $h^{-1}M_\odot$), so a box $1\,h^{-1}$Gpc on a side holds about $10^9 \times 1.083 \times 10^{-7} \approx 100$ haloes above $10^{15}\,h^{-1}M_\odot$, where $\sigma = 0.5348$ and $\nu \approx 3$.

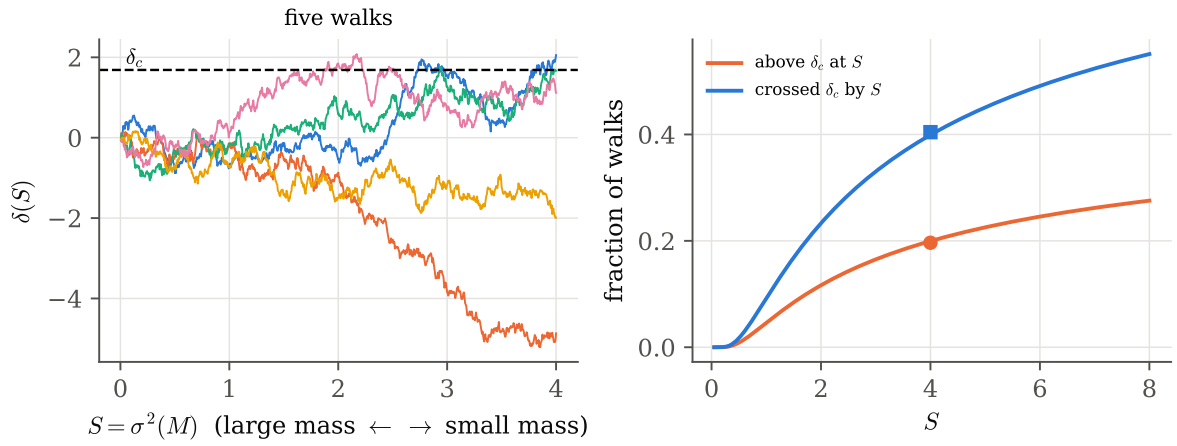

Figure 11.25: Left: five excursion-set walks with independent Gaussian steps, against the threshold δ_c; moving right means smoothing on smaller scales. Right: the fraction of walks above δ_c at S (orange) and the fraction that have crossed it at least once by S (blue), with the simulated values at $S = 4$ as points. The second curve is twice the first at every S.

11.8.4 Random walks on a computer

The reflection argument is short enough to doubt, so we simulate it. `09_mass_function.py` draws 50000 walks on a grid of 4000 values of S between 10^{-3} and 60, each step a Gaussian of variance equal to the grid spacing, and records the first grid point at which each walk exceeds δ_c. A walk sampled only at grid points can cross the barrier and come back between two of them unseen. For Brownian motion the probability of such a hidden excursion is known exactly, again by reflection: between two neighbouring points at heights $x_0, x_1 < \delta_c$, separated by ΔS, the walk crosses with probability

$$\frac{p_{\Delta S}(x_1 - x_0 \text{ via } \delta_c)}{p_{\Delta S}(x_1 - x_0)} = \frac{e^{-(2\delta_c - x_0 - x_1)^2/2\Delta S}}{e^{-(x_1 - x_0)^2/2\Delta S}} = \exp\!\left[-\frac{2(\delta_c - x_0)(\delta_c - x_1)}{\Delta S}\right], \tag{11.57}$$

because the paths from x_0 to x_1 that touch δ_c are, after reflection of their end, the paths from x_0 to $2\delta_c - x_1$, and the difference of the two squares in the exponent is $4(\delta_c - x_0)(\delta_c - x_1)$. The function `first_crossings` in `lib_web.py` draws this event too, which makes the simulated crossings those of the continuous walk.

Listing 11.8: The excursion-set walks and their first crossings. (`code/ch11/lib_web.py`)

```
def first_crossings(S_grid, nwalk, rng, barrier=DELTA_C, lower=None, chunk=2000):
    """Excursion-set walks delta(S) with independent N(0, dS) steps on the grid S_grid.

    Returns, per walk, the S of the first up-crossing of 'barrier' (np.inf if none) and, if
    'lower' is given, the S of the first down-crossing of 'lower' that happens before any
    up-crossing (np.inf otherwise). Between two grid points the walk is a Brownian bridge,
    which
    crosses a level b that both end points lie below with probability
    exp(-2 (b - x0)(b - x1)/dS); drawing that event too makes the result exact for
    continuous
    Brownian motion instead of only for the discrete walk.
    """
    dS = np.diff(np.concatenate([[0.0], S_grid]))
```

```
    up = np.full(nwalk, np.inf)
    down = np.full(nwalk, np.inf)
    done = 0
    while done < nwalk:
        n = min(chunk, nwalk - done)
        walk = np.cumsum(rng.standard_normal((n, len(S_grid))) * np.sqrt(dS), axis=1)
        prev = np.concatenate([np.zeros((n, 1)), walk[:, :-1]], axis=1)
        u = rng.random((n, len(S_grid)))
        bridge = np.exp(-2 * np.clip(barrier - prev, 0, None) * np.clip(barrier - walk, 0,
    None) / dS)
        hit = (walk >= barrier) | (u < bridge)
        first = np.where(hit.any(1), hit.argmax(1), -1)
        up[done:done + n] = np.where(first >= 0, S_grid[np.maximum(first, 0)], np.inf)
        if lower is not None:
            bridge_v = np.exp(-2 * np.clip(prev - lower, 0, None) * np.clip(walk - lower,
    0, None) / dS)
            hitv = (walk <= lower) | (rng.random((n, len(S_grid))) < bridge_v)
            fv = np.where(hitv.any(1), hitv.argmax(1), -1)
            ok = (fv >= 0) & ((first < 0) | (fv < first))
            down[done:done + n] = np.where(ok, S_grid[np.maximum(fv, 0)], np.inf)
        done += n
    return up, down
```

The loop works in chunks of walks to keep memory small. `walk` is the cumulative sum of the Gaussian steps; `prev` is the same walk shifted by one point, so each pair `(prev, walk)` is one step. `hit` marks a step where the walk is above the barrier at its end or crossed it in between (the uniform number `u` decides the hidden crossing with probability (11.57)), and `argmax` finds the first such step. The optional lower barrier is used for voids in Section 11.11.

The factor of 2, measured. At $S = 4$ ($\nu = 0.843$) the fraction of walks above δ_c is 0.1965, against $\frac{1}{2}\operatorname{erfc}(\nu/\sqrt{2}) = 0.1996$, and the fraction that have crossed by then is 0.4043, against $\operatorname{erfc}(\nu/\sqrt{2}) = 0.3992$ (Figure 11.25, right). This check uses 20000 walks, so the binomial standard error of each fraction, $\sqrt{p(1-p)/N}$, is 0.0028 and 0.0035. Each measured fraction should be judged against its own error bar. The ratio of the two measured fractions is 2.058 ± 0.034, against 2.

The multiplicity function, measured. Histogramming $\nu = \delta_c/\sqrt{S_{\text{first}}}$ over all walks gives the blue points of Figure 11.26 (left), on top of $\sqrt{2/\pi}\, e^{-\nu^2/2}$. Over the 26 bins with more than fifty walks the χ^2 of the points about (11.55), with Poisson errors, is 23.1; the expected value for a correct formula is the number of bins, with a standard deviation of about $\sqrt{2 \times 26} \approx 7$. The grey dotted curve, without the factor 2, misses every point.

The same field, two filters. A real field is not smoothed with a sharp-k filter: a halo is a region in real space. The second experiment in the script makes 4 Gaussian fields on a 160^3 grid and reads the walk at every cell by smoothing each field at 120 scales, once with the sharp-k filter and once with a top hat. The error bars come from the scatter between the fields. The cells of one field are not independent: neighbours share the same smoothed modes, so counting cells as independent would give error bars far too small. With the sharp-k filter (green squares) the points follow Press–Schechter; at $\nu \approx 2.475$ they lie a factor 0.72 ± 0.05 below it. Part of the gap is that these walks are read at only 120 scales, without the correction (11.57), so crossings between two scales are missed; part is the luck of the fields, since one field alone scatters by 0.10 in this ratio. With the top hat (orange triangles) the points fall clearly below Press–Schechter at $\nu \lesssim 1.5$ and reach it, even slightly exceed it, at large ν (a factor 1.07 ± 0.02 at $\nu \approx 2.475$). A top hat in real space has a broad Fourier transform, so neighbouring scales share most of their

modes. The steps of the walk are then strongly correlated, the walk is smooth, and a smooth walk rarely makes the brief excursions above the barrier that the reflection argument pairs with the walks ending above it. The factor of 2 belongs to the sharp-k filter; with a realistic filter the exact first-crossing distribution has no closed form, which is one reason the theory is calibrated on simulations [199].

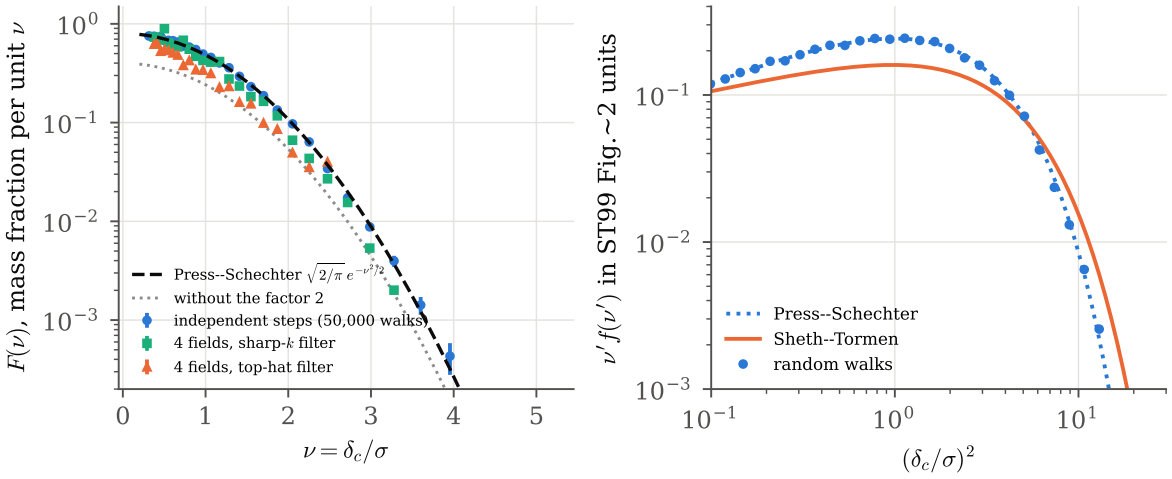

Figure 11.26: Left: the fraction of mass per unit ν from 50000 walks with independent steps (blue), from walks read off 4 Gaussian fields with a sharp-k filter (green) and a top-hat filter (orange), against Press–Schechter (dashed) and the same formula without the factor 2 (dotted). Right: Press–Schechter (dotted) and Sheth–Tormen (solid) on the axes of [ShethTormen1999 Fig. 2], with the random walks again as points.

11.8.5 Reproducing Sheth and Tormen

Their question. By the late 1990s N-body simulations were large enough to count haloes over four decades of mass. Press–Schechter got the shape roughly right and the details wrong: too many small haloes and too few large ones [CooraySheth2002 Fig. 3]. Sheth and Tormen [200] asked for a mass function that fits the simulated haloes at all masses and redshifts, and for the halo bias that goes with it (the bias is the subject of Section 11.9.3).

Their setup. They used the GIF simulations of three cold-dark-matter cosmologies, identified haloes at several output times, and plotted the abundance against the scaled variable $\nu_{\rm ST} = (\delta_c/\sigma)^2$, the square of ours. If the excursion-set picture is right in spirit, the points from all times should lie on one curve, and they did [ShethTormen1999 Fig. 2].

Their key equation. The curve they fitted is [ShethTormen1999 eq. (10)]; translated to our $\nu = \delta_c/\sigma$ by $\nu_{\rm ST} = \nu^2$ and $F(\nu)\,\mathrm{d}\nu = f(\nu_{\rm ST})\,\mathrm{d}\nu_{\rm ST}$, it reads

$$F_{\rm ST}(\nu) = A\sqrt{\frac{2a}{\pi}}\left[1 + (a\nu^2)^{-p}\right] e^{-a\nu^2/2}, \qquad a = 0.707, \quad p = 0.3. \tag{11.58}$$

The two shape parameters have direct meanings. $a < 1$ stretches the exponential cut-off to higher ν, which gives more massive haloes. The bracket $1 + (a\nu^2)^{-p}$ with $p > 0$ rises toward small ν as a weak power, where Press–Schechter has a constant. Together with the smaller normalisation A below (Press–Schechter's is $\frac{1}{2}$), the net effect over the masses that matter for

galaxies and groups is fewer haloes than Press–Schechter. The constant A is not free: every mass element is in some halo, so $\int_0^\infty F_{\rm ST}\,\mathrm{d}\nu = 1$. With $t = a\nu^2/2$,

$$\int_0^\infty F_{\rm ST}\,\mathrm{d}\nu \overset{(1)}{=} A\sqrt{\frac{2a}{\pi}}\int_0^\infty \left[1+(2t)^{-p}\right]e^{-t}\,\frac{\mathrm{d}t}{\sqrt{2at}} \overset{(2)}{=} \frac{A}{\sqrt{\pi}}\left[\Gamma\left(\tfrac12\right)+2^{-p}\,\Gamma\left(\tfrac12-p\right)\right]$$
$$\overset{(3)}{=} A\left[1+\frac{2^{-p}\,\Gamma(\frac12-p)}{\sqrt{\pi}}\right]=1 \quad\Longrightarrow\quad A=\left[1+\frac{2^{-p}\,\Gamma(\frac12-p)}{\sqrt{\pi}}\right]^{-1}=0.3222. \tag{11.59}$$

(1) $\nu=\sqrt{2t/a}$, so $\mathrm{d}\nu=\mathrm{d}t/\sqrt{2at}$, and $a\nu^2=2t$.
(2) The prefactors combine to $A/\sqrt{\pi}$; the two terms are Gamma integrals, $\int_0^\infty t^{s-1}e^{-t}\mathrm{d}t=\Gamma(s)$ with $s=\frac12$ and $s=\frac12-p$.
(3) $\Gamma(\frac12)=\sqrt{\pi}$.

For $p=0.3$, $\Gamma(0.2)=4.591$ and $2^{-0.3}=0.812$, giving the value quoted by [CoorayShether2002 eq. (59)]. With $a=1$ and $p=0$ the bracket is 2, so $A=\frac12$ and (11.58) becomes $\frac12\sqrt{2/\pi}\,(1+1)\,e^{-\nu^2/2}$, which is Press–Schechter: the fit contains the excursion-set result as a special case.

What we compute. `lib_web.py` implements both multiplicities and (11.56), with $\sigma(M)$ from the CAMB linear spectrum; `09_mass_function.py` plots them on Sheth and Tormen's axes, $\nu_{\rm ST}f(\nu_{\rm ST})=\nu F(\nu)/2$ against $\nu_{\rm ST}$ (Figure 11.26, right), and converts both to numbers of haloes (Figure 11.27).

Side by side. The right panel of Figure 11.26 reproduces the two theory curves of their Fig. 2: Sheth–Tormen lies below Press–Schechter for $0.05 \lesssim \nu_{\rm ST} \lesssim 5$ and above it beyond, by a growing factor (it overtakes Press–Schechter again only at masses far below the range plotted). In numbers of haloes at $z=0$ (Figure 11.27), Sheth–Tormen predicts 0.7214 times as many haloes as Press–Schechter at $10^{11}\,h^{-1}M_\odot$, 0.6643 times as many at 10^{13}, and 1.809 times as many at 10^{15}. Above $10^{15}\,h^{-1}M_\odot$ it gives $2.435\times10^{-7}\,h^3\mathrm{Mpc}^{-3}$ against 1.083×10^{-7}, about 240 instead of 100 such clusters per $(h^{-1}\mathrm{Gpc})^3$. The mass in haloes above $10^{12}\,h^{-1}M_\odot$ drops from 0.4269 to 0.3125 of the total.

Why they differ. Each difference has one cause: input (H2). Real perturbations are triaxial, and a triaxial region feels the tidal pull of its surroundings, which resists collapse along the longest axis. Small haloes come from regions with large σ, where tides are relatively strong; they need a higher linear contrast than δ_c to collapse, so there are fewer of them. Massive haloes come from rare, high peaks, which are nearly spherical and collapse almost as the spherical model says. In walk language, ellipsoidal collapse replaces the flat barrier δ_c by one that rises with S, a *moving barrier*. Sheth and Tormen pointed to this explanation [ShethTormen1999 §4], and the first crossings of such a barrier were later shown to reproduce the shape of (11.58) [201]. The random walks themselves cannot tell us this: they verify the mathematics of (H1)–(H3), and the simulations test (H2).

The lesson. The Press–Schechter factor of 2 is the cloud-in-cloud mass, recovered exactly by the first-crossing problem; what remains between Press–Schechter and the simulations, a factor of two at the extremes, is the physics of non-spherical collapse.

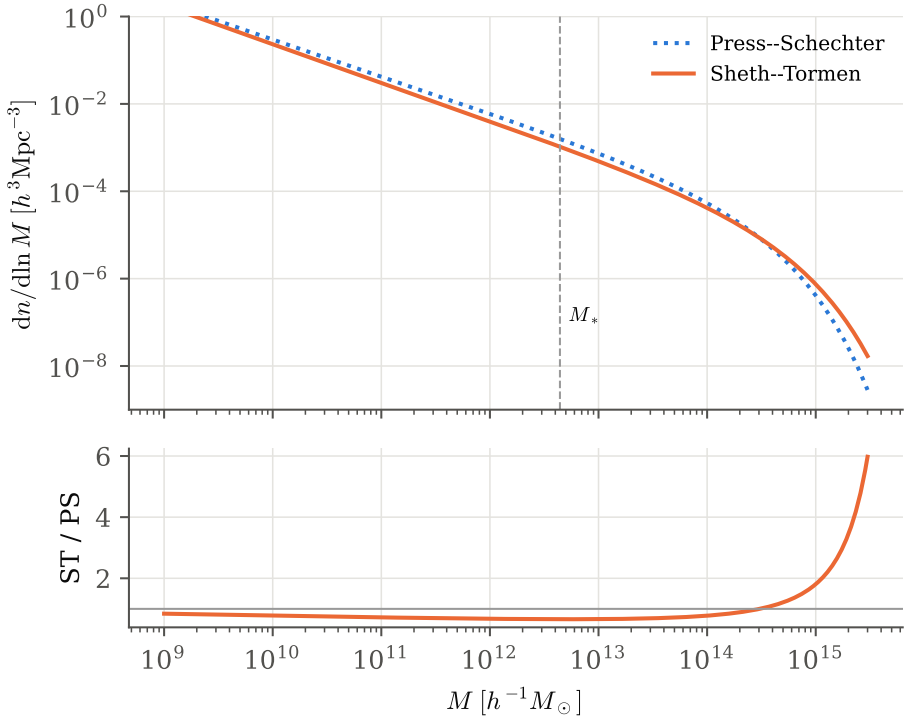

Figure 11.27: Haloes per unit volume per unit $\ln M$ at $z = 0$ in the fiducial cosmology, from (11.56) with the Press–Schechter (dotted) and Sheth–Tormen (solid) multiplicities; the dashed line marks M_*. Lower panel: their ratio. The abundance falls exponentially beyond M_*, and there the two formulas differ most.

Key idea: The halo mass function from first crossings

With a sharp-k filter the smoothed linear contrast at a point is a Brownian motion in $S = \sigma^2(M)$. The fraction of mass in haloes of mass M is the fraction of walks that first cross δ_c at $S = \sigma^2(M)$; by reflection it is twice the naive Press–Schechter fraction, and $\mathrm{d}n/\mathrm{d}\ln M = (\bar\rho/M)\,\nu F(\nu)\,|\mathrm{d}\ln\sigma/\mathrm{d}\ln M|$ with $F = \sqrt{2/\pi}\,e^{-\nu^2/2}$. Simulations prefer the Sheth–Tormen form (11.58), the signature of ellipsoidal collapse.

11.9 Inside and around a halo

The mass function of Section 11.8 tells us how many haloes there are of each mass. To build a density field out of haloes we need two more facts, one for each end of the range of scales. On small scales, inside one halo, the field is the halo's own density profile: how is the mass arranged between its centre and its edge? On large scales, the field is made by how haloes are placed relative to one another: do they follow the matter, or do they cluster more strongly? In words, the two questions are:

(1) *How is the mass of a halo of mass M spread around its centre, and what does that look like to a Fourier mode of wavenumber k?*

(2) *If a large region is slightly denser than average, by how much does its number of haloes of mass M go up?*

11.9.1 The density profile of a halo

N-body haloes of all masses, in all the cold-dark-matter cosmologies that have been simulated, have nearly the same spherically averaged profile [89],

$$\rho(r\,|\,M) = \frac{\rho_s}{(r/r_s)\,(1+r/r_s)^2}, \tag{11.60}$$

the **NFW profile**. It falls as r^{-1} well inside the scale radius r_s and as r^{-3} well outside it. There is no complete derivation of this shape from first principles; it is a description of what simulations produce [CooraySheth2002 p. 34]. We take it as an input.

Where does a halo end? The r^{-3} tail would hold an infinite mass, so the profile must be cut. We cut it at the radius $r_{\rm vir}$ inside which the mean density is $\Delta_{\rm vir} = 330$ times the mean matter density, the virialised density of the spherical-collapse model for ΛCDM today (Section 11.8.1): $M = \frac{4\pi}{3}\,330\,\bar\rho\,r_{\rm vir}^3$. The ratio $c = r_{\rm vir}/r_s$ is the **concentration**. Simulated haloes of lower mass are more concentrated, because they formed earlier, when the Universe was denser, and on average

$$c(M) = 9\left(\frac{M}{M_*}\right)^{-0.13} \tag{11.61}$$

at $z = 0$, with a log-normal scatter of about 0.25 in $\ln c$ that we ignore [CooraySheth2002 eqs. (77)–(78)].

How much mass is inside a radius? Integrate the profile in shells, with $x = r/r_s$:

$$\begin{aligned} M(<r) &\overset{(1)}{=} \int_0^r 4\pi r'^2\rho(r')\,\mathrm{d}r' \overset{(2)}{=} 4\pi\rho_s r_s^3\int_0^{r/r_s}\frac{x\,\mathrm{d}x}{(1+x)^2} \overset{(3)}{=} 4\pi\rho_s r_s^3\left[\ln(1+x)+\frac{1}{1+x}\right]_0^{r/r_s} \\ &\overset{(4)}{=} 4\pi\rho_s r_s^3\, m\!\left(\frac{r}{r_s}\right), \qquad m(y)\equiv \ln(1+y)-\frac{y}{1+y}. \end{aligned} \tag{11.62}$$

(1) The mass of a thin shell is its area times its thickness times the density.
(2) Substitute $r' = r_s x$; then $r'^2\rho\,\mathrm{d}r' = r_s^3\rho_s\,x^2\mathrm{d}x/[x(1+x)^2]$.
(3) Write $x/(1+x)^2 = 1/(1+x) - 1/(1+x)^2$ and integrate each term.
(4) At $x = 0$ the bracket is 1; subtracting it gives $\ln(1+y) + 1/(1+y) - 1 = \ln(1+y) - y/(1+y)$.

The total mass is $M = 4\pi\rho_s r_s^3\,m(c)$ [CooraySheth2002 eq. (76)], so a halo is fixed completely by M: M gives $r_{\rm vir}$, (11.61) gives c and hence r_s, and $M = 4\pi\rho_s r_s^3 m(c)$ gives ρ_s.

Example: a group of $10^{14}\,h^{-1}M_\odot$. Here $c = 5.999$, $r_{\rm vir} = 0.9387\,h^{-1}$Mpc and $r_s = 0.1565\,h^{-1}$Mpc. The fraction of the mass inside r_s is $m(1)/m(c) = (\ln 2 - \frac{1}{2})/(\ln 7 - \frac{6}{7}) = 0.193/1.089 = 0.18$: less than a fifth of the mass, in less than $1/c^3 = 0.5\%$ of the volume. The characteristic density follows from equating the two expressions for M, $\frac{4\pi}{3}330\bar\rho\,c^3 r_s^3 = 4\pi\rho_s r_s^3 m(c)$, so $\rho_s/\bar\rho = (330/3)\,c^3/m(c) \approx 2.2\times10^4$.

11.9.2 A halo as seen by a Fourier mode

Power spectra are built from Fourier modes, so we need the transform of the profile. Normalise it by the mass, so that it describes the shape alone:

$$u(\boldsymbol{k}\,|\,M) = \frac{1}{M}\int \mathrm{d}^3x\;\rho(\boldsymbol{x}\,|\,M)\,e^{-i\boldsymbol{k}\cdot\boldsymbol{x}}. \tag{11.63}$$

For a spherical profile only $k = |\boldsymbol{k}|$ matters. Put $\boldsymbol{k}$ along the polar axis, so $\boldsymbol{k}\cdot\boldsymbol{x} = kr\cos\theta$:

$$u(k\,|\,M) \overset{(1)}{=} \frac{1}{M}\int_0^{r_{\rm vir}} r^2\rho(r)\,\mathrm{d}r\int_0^{2\pi}\mathrm{d}\phi\int_{-1}^{1} e^{-ikr\mu}\,\mathrm{d}\mu \overset{(2)}{=} \frac{1}{M}\int_0^{r_{\rm vir}} 4\pi r^2\rho(r)\,\frac{\sin kr}{kr}\,\mathrm{d}r. \tag{11.64}$$

(1) Spherical coordinates, with $\mu = \cos\theta$ and $\mathrm{d}^3x = r^2 \mathrm{d}r\,\mathrm{d}\phi\,\mathrm{d}\mu$.
(2) $\int_{-1}^{1} e^{-ikr\mu}\mathrm{d}\mu = (e^{ikr} - e^{-ikr})/(ikr) = 2\sin(kr)/(kr)$, and the ϕ integral gives 2π.

Two limits are visible at once. For $k\,r_{\rm vir} \ll 1$, $\sin(kr)/(kr) \approx 1 - k^2r^2/6$, so $u \approx 1 - k^2\langle r^2\rangle/6$: a mode much longer than the halo sees a point mass, $u \to 1$. For $k\,r_s \gg 1$ the factor $\sin(kr)/(kr)$ oscillates rapidly and u falls: the mode resolves the halo and averages over its interior.

The NFW transform in closed form. With $x = r/r_s$, $\kappa = kr_s$ and $4\pi\rho_s r_s^3/M = 1/m(c)$ from (11.62),

$$
\begin{aligned}
u(k\,|\,M) &\overset{(1)}{=} \frac{1}{m(c)\,\kappa}\int_0^c \frac{\sin\kappa x}{(1+x)^2}\,\mathrm{d}x \overset{(2)}{=} \frac{1}{m(c)\,\kappa}\left\{\left[-\frac{\sin\kappa x}{1+x}\right]_0^c + \kappa\int_0^c \frac{\cos\kappa x}{1+x}\,\mathrm{d}x\right\} \\
&\overset{(3)}{=} \frac{1}{m(c)}\left\{-\frac{\sin c\kappa}{(1+c)\kappa} + \int_\kappa^{(1+c)\kappa}\frac{\cos(t-\kappa)}{t}\,\mathrm{d}t\right\} \\
&\overset{(4)}{=} \frac{1}{m(c)}\left\{\sin\kappa\,\big[\mathrm{Si}((1+c)\kappa) - \mathrm{Si}(\kappa)\big] + \cos\kappa\,\big[\mathrm{Ci}((1+c)\kappa) - \mathrm{Ci}(\kappa)\big] - \frac{\sin c\kappa}{(1+c)\kappa}\right\}. \qquad (11.65)
\end{aligned}
$$

(1) Insert (11.60) into (11.64): $4\pi r^2\rho\,\mathrm{d}r/M = x^2\,\mathrm{d}x/[m(c)\,x(1+x)^2]$, and $\sin(kr)/(kr) = \sin(\kappa x)/(\kappa x)$; one x cancels.
(2) Integrate by parts, with $(1+x)^{-2} = \frac{\mathrm{d}}{\mathrm{d}x}[-(1+x)^{-1}]$.
(3) The boundary term at $x = 0$ vanishes. In the integral substitute $t = \kappa(1+x)$, so $\kappa x = t - \kappa$ and $\mathrm{d}x/(1+x) = \mathrm{d}t/t$.
(4) $\cos(t-\kappa) = \cos t\cos\kappa + \sin t\sin\kappa$, and $\int \sin t/t\,\mathrm{d}t$ and $\int \cos t/t\,\mathrm{d}t$ are the sine and cosine integrals, $\mathrm{Si}(y) = \int_0^y \sin t/t\,\mathrm{d}t$ and $\mathrm{Ci}(y) = -\int_y^\infty \cos t/t\,\mathrm{d}t$.

This is [CooraySheth2002 eq. (81)]. `lib_web.py` evaluates it with `scipy.special.sici`:

Listing 11.9: The halo edge, the concentration and the NFW transform. (`code/ch11/lib_web.py`)

```
def concentration(M, mstar):
    """Mean NFW concentration c(M) = 9 (M/M*)^-0.13 (Cooray & Sheth 2002, eq. 78, z = 0)."""
    return 9.0 * (np.asarray(M, float) / mstar) ** (-0.13)

def r_halo(M, delta=DELTA_HALO):
    """Halo radius: the sphere of mean density DELTA_HALO * rho_m (the virial radius) that
    holds M."""
    return (3 * np.asarray(M, float) / (4 * np.pi * delta * RHO_M)) ** (1 / 3)

def u_nfw(k, M, c, delta=DELTA_HALO):
    """Normalised Fourier transform of an NFW profile truncated at r_halo (CS02 eq. 81).

    k may be 1-D and M, c 1-D; returns shape (len(M), len(k)).
    """
    k = np.atleast_1d(k)[None, :]
    M = np.atleast_1d(M)[:, None]
    c = np.atleast_1d(c)[:, None]
    rs = r_halo(M, delta) / c
    x = k * rs
    si1, ci1 = sici((1 + c) * x)
    si0, ci0 = sici(x)
    mnorm = np.log(1 + c) - c / (1 + c)
    return (np.sin(x) * (si1 - si0) - np.sin(c * x) / ((1 + c) * x) + np.cos(x) * (ci1 -
    ci0)) / mnorm
```

`r_halo` inverts $M = \frac{4\pi}{3}\Delta\bar\rho r^3$; `u_nfw` builds $r_s = r_{\rm vir}/c$, $\kappa = kr_s$, and returns the bracket of (11.65) divided by $m(c)$, for a whole grid of masses and wavenumbers at once. `10_halo_model.py`

checks it against the integral (11.64) done numerically for $M = 10^{14}\,h^{-1}M_\odot$ at three wavenumbers; the largest relative difference is 8.295×10^{-10}.

Example: when does a mode see inside a halo? At $k = 1\,h\,\mathrm{Mpc}^{-1}$, $u = 0.9598$ for the group of the previous example and $u = 0.9984$ for a $10^{12}\,h^{-1}M_\odot$ halo. A mode of wavelength $2\pi/k \approx 6\,h^{-1}$Mpc is still long compared with either halo, and both look nearly like points. Figure 11.28 (left) shows that u drops below $\frac{1}{2}$ at $k \approx 2\,h\,\mathrm{Mpc}^{-1}$ for $10^{15}\,h^{-1}M_\odot$, at $k \approx 4$ for 10^{14} and only near $k \approx 50$ for 10^{11}: the smallest scales are resolved inside the smallest haloes, which therefore control the power at the largest k [CooraySheth2002 Fig. 9].

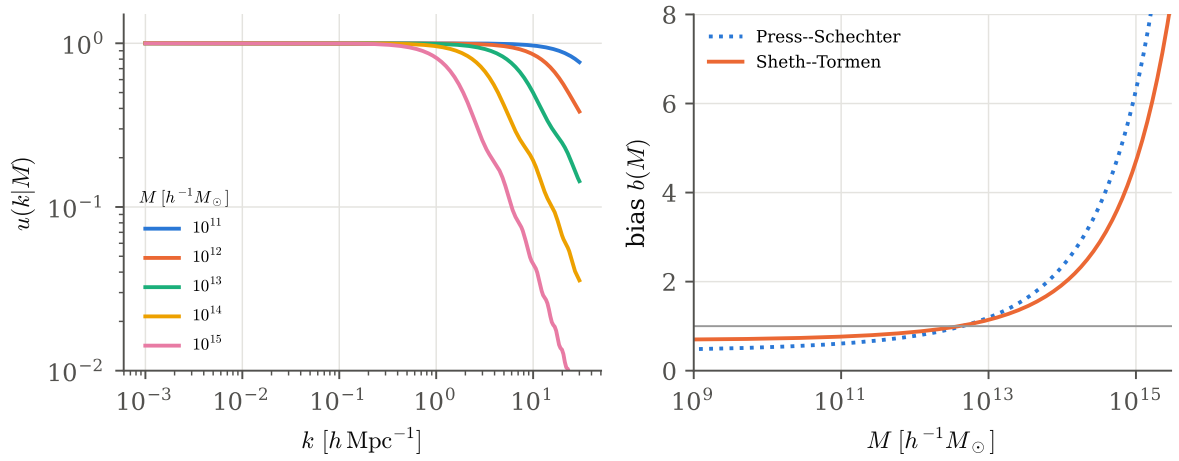

Figure 11.28: Left: the normalised Fourier transform $u(k\,|\,M)$ of NFW haloes with the concentrations (11.61), for five masses. Each curve is 1 for modes longer than the halo and falls once the mode resolves its interior; heavier haloes are larger and fall at smaller k. Right: the large-scale bias of haloes from the peak-background split with the Press–Schechter (dotted) and Sheth–Tormen (solid) mass functions. Haloes much heavier than $M_* = 4.413 \times 10^{12}\,h^{-1}M_\odot$ are several times more clustered than the matter.

11.9.3 Where haloes sit: the peak-background split

Clusters of galaxies are far more strongly clustered than galaxies, and galaxies more than the dark matter. The excursion set explains why, with no new input. Picture the linear density as a sum of a long wave, the *background*, and short-wavelength ripples on top of it (Figure 11.29). Haloes form where the total crosses δ_c. Where the background is high, the ripples need to climb less far, and the threshold is crossed more often; where it is low, hardly ever. Haloes therefore end up concentrated where the long wave is high: their number density is modulated by the large-scale density, and modulated more strongly than the matter is. That is **halo bias**.

The question in walk language. Consider a large region, of Lagrangian volume V, whose linear contrast smoothed on its own scale is δ_ℓ. Its variance on that scale is $S_\ell = \sigma^2(\bar\rho V)$, small because the region is large. Every walk starting from a point inside it passes through (S_ℓ, δ_ℓ). How many of these walks first cross δ_c at the much larger $S = \sigma^2(M)$ of a small halo?

Move the origin. From (S_ℓ, δ_ℓ) onwards the walk is again a Brownian motion, independent of its past. Measured from that point, it has to climb $\delta_c - \delta_\ell$ in time $S - S_\ell$. For $S_\ell \ll S$ the time is $\approx S$, and the problem is the one we solved with δ_c replaced by $\delta_c - \delta_\ell$ [CooraySheth2002 eq. (63)], [Bernardeau2002 eqs. (550)–(551)]. The number of haloes per unit Lagrangian volume in the region is therefore the mass function with a lowered barrier, $n(M\,|\,\delta_\ell) = n(M)|_{\delta_c \to \delta_c - \delta_\ell}$.

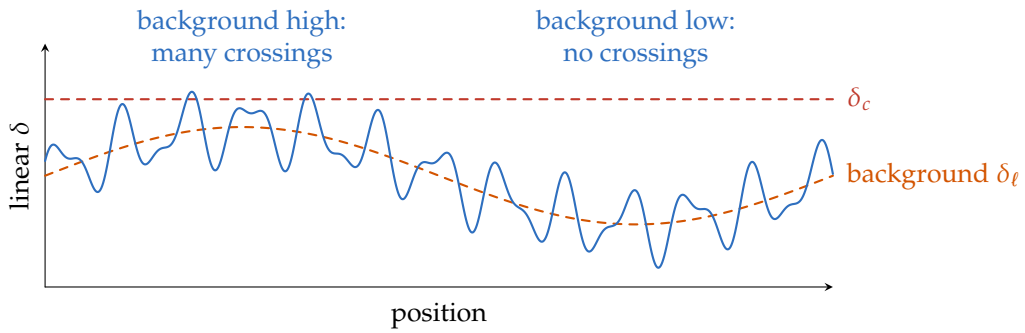

Figure 11.29: The peak-background split. The linear field (blue) is a long wave, the background δ_ℓ (orange), plus short ripples. The ripples are statistically the same everywhere, but they reach the collapse threshold δ_c only where the background lifts them; haloes form there, so their number follows the long wave with an amplified amplitude.

How large is the change? Expand to first order in δ_ℓ, which is small for a large region. In (11.56) only $\nu = \delta_c/\sigma$ depends on δ_c, through the factor $\nu F(\nu)$, and $\partial\nu/\partial\delta_c = \nu/\delta_c$. Hence

$$\delta_h^L \equiv \frac{n(M\,|\,\delta_\ell)}{n(M)} - 1 \overset{(1)}{=} -\delta_\ell \frac{\partial \ln n}{\partial \delta_c} \overset{(2)}{=} -\frac{\delta_\ell}{\delta_c}\frac{\mathrm{d}\ln[\nu F(\nu)]}{\mathrm{d}\ln\nu} \equiv b_L(M)\,\delta_\ell. \tag{11.66}$$

(1) Taylor expansion of n in its δ_c argument, with step $-\delta_\ell$.
(2) Chain rule: $\partial \ln n/\partial\delta_c = (\partial \ln \nu/\partial\delta_c)\,\mathrm{d}\ln(\nu F)/\mathrm{d}\ln\nu$ and $\partial\ln\nu/\partial\delta_c = 1/\delta_c$.

δ_h^L is the excess of haloes per unit *initial* volume, so b_L is the **Lagrangian bias**. For the two multiplicities:

$$\begin{aligned}
\text{Press–Schechter:}\quad & \frac{\mathrm{d}\ln(\nu F)}{\mathrm{d}\ln\nu} \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}\ln\nu}\left[\ln\nu - \frac{\nu^2}{2}\right] = 1-\nu^2, \qquad b_L = \frac{\nu^2-1}{\delta_c},\\
\text{Sheth–Tormen:}\quad & \frac{\mathrm{d}\ln(\nu F)}{\mathrm{d}\ln\nu} \overset{(2)}{=} 1 - a\nu^2 + \frac{\mathrm{d}\ln[1+(a\nu^2)^{-p}]}{\mathrm{d}\ln\nu} \overset{(3)}{=} 1 - a\nu^2 - \frac{2p}{1+(a\nu^2)^p},\\
& b_L = \frac{a\nu^2-1}{\delta_c} + \frac{2p}{\delta_c\,[1+(a\nu^2)^p]}.
\end{aligned} \tag{11.67}$$

(1) $\nu F \propto \nu\, e^{-\nu^2/2}$ by (11.55), and $\mathrm{d}(\nu^2/2)/\mathrm{d}\ln\nu = \nu^2$.
(2) $\nu F_{\rm ST} \propto \nu\,[1+(a\nu^2)^{-p}]\,e^{-a\nu^2/2}$ by (11.58); the first and last factors give $1-a\nu^2$ as before.
(3) $\frac{\mathrm{d}}{\mathrm{d}\ln\nu}(a\nu^2)^{-p} = -2p\,(a\nu^2)^{-p}$, so the derivative of the logarithm is $-2p(a\nu^2)^{-p}/[1+(a\nu^2)^{-p}]$; multiply top and bottom by $(a\nu^2)^p$.

From the initial volume to today's. We observe haloes per unit volume today, not per unit initial volume. The region has contracted: by mass conservation its volume today is $V/(1+\delta)$, where δ is its actual density contrast, which to first order is the linear δ_ℓ. The haloes it contains are the same, so the halo density contrast today, the *Eulerian* one, is

$$1+\delta_h \overset{(1)}{=} (1+\delta)\,(1+\delta_h^L) \overset{(2)}{=} 1 + \delta_\ell + b_L\delta_\ell + O(\delta_\ell^2) \quad\Longrightarrow\quad b(M) = 1 + b_L(M). \tag{11.68}$$

(1) Same number of haloes in a volume smaller by a factor $1+\delta$.
(2) To first order $\delta = \delta_\ell$; drop the product of two small terms.

With (11.67) this is the Mo–White bias for Press–Schechter, $b = 1 + (\nu^2-1)/\delta_c$ [202], and [ShethTormen1999 eq. (12)] for Sheth–Tormen; [CooraySheth2002 eq. (66)] and [Bernardeau2002 eq. (554)] write the same results with ν^2 in place of our ν.

Working definition 11.6 (large-scale halo bias)

On scales much larger than a halo, the number density of haloes of mass M follows the matter, $\delta_h(\boldsymbol{x} \mid M) = b(M)\,\delta(\boldsymbol{x})$, so their power spectrum is $b^2(M)P(k)$. In the peak-background split $b(M) = 1 - \delta_c^{-1}\,\mathrm{d}\ln[\nu F(\nu)]/\mathrm{d}\ln\nu$ at $\nu = \delta_c/\sigma(M)$. *Operational:* measure $b(M)$ in a simulation as $\sqrt{P_{hh}(k)/P(k)}$ at small k, or as P_{hm}/P from the halo–matter cross-spectrum.

Example: bias across the mass range. At M_*, $\nu = 1$ and the Press–Schechter bias is exactly 1: typical haloes cluster like the matter. For $\nu \gg 1$, $b \approx \nu^2/\delta_c$, which grows fast: $b(10^{15}\,h^{-1}M_\odot) = 6.301$ (Press–Schechter) or 4.701 (Sheth–Tormen). For $\nu \to 0$ the Press–Schechter bias approaches $1 - 1/\delta_c = 0.41$: small haloes are anti-biased, because they avoid the dense regions, where their mass has been swallowed by bigger haloes [CooraySheth2002 p. 25]. On our mass grid the smallest values are 0.4485 and 0.6894. A Milky-Way halo of $10^{12}\,h^{-1}M_\odot$ has $b = 0.8707$ (Sheth–Tormen), a group of 10^{14} has $b = 1.93$ (Figure 11.28, right). Sheth–Tormen gives smaller biases at the top end because its exponential cut-off sits at $\sqrt{a}\,\nu$, so a given mass is a less extreme event; that agrees better with the simulations [CooraySheth2002 Fig. 4].

A consistency relation. Average the bias over all the mass. In the region of the previous paragraphs, all the mass is in haloes before and after the background is added. Per unit Lagrangian volume the mass is $\bar\rho$ in both cases, because a Lagrangian volume is defined by the mass it holds:

$$\bar\rho \overset{(1)}{=} \int \mathrm{d}M\, M\, n(M \mid \delta_\ell) \overset{(2)}{=} \int \mathrm{d}M\, M\, n(M)\,[1 + b_L(M)\delta_\ell] \overset{(3)}{=} \bar\rho + \delta_\ell \int \mathrm{d}M\, M\, n(M)\, b_L(M),$$
$$\Longrightarrow \quad \int \mathrm{d}M\, \frac{M\,n(M)}{\bar\rho}\, b(M) \overset{(4)}{=} \int \mathrm{d}M\, \frac{M\,n(M)}{\bar\rho}\,[1 + b_L(M)] = 1. \tag{11.69}$$

(1) All mass in haloes, counted per unit initial volume in the region.
(2) (11.66).
(3) The unperturbed mass function also puts all the mass in haloes, $\int M\,n\,\mathrm{d}M = \bar\rho$; this needs $\int F\,\mathrm{d}\nu = 1$.
(4) The first line forces the δ_ℓ term to vanish for every δ_ℓ, so $\int Mn\,b_L = 0$; then use $b = 1 + b_L$.

The mass-weighted mean bias of all haloes is 1 [CooraySheth2002 eq. (71)]: the matter, which is all in haloes, is unbiased with respect to itself. The relation becomes the large-scale limit of the halo model in Section 11.10.

Key idea: Peak-background split

A large-scale overdensity δ_ℓ lowers the collapse barrier of the small-scale walks inside it to $\delta_c - \delta_\ell$. To first order this raises the halo density by $b_L\delta_\ell$ with $b_L = -\delta_c^{-1}\mathrm{d}\ln(\nu F)/\mathrm{d}\ln\nu$, and the contraction of the region adds δ_ℓ, so $b = 1 + b_L$. The bias is fixed by the shape of the mass function alone, and its mass-weighted mean is 1.

11.10 The power spectrum built from haloes

Linear theory predicts $P(k)$ on large scales; on small scales gravity makes the real spectrum climb far above it. In Section T1.4 we took that non-linear spectrum from halofit, a formula fitted to N-body simulations [41]. A fit reproduces a simulation; it does not explain it. The

three facts about haloes from Sections 11.8 and 11.9 let us *build* the non-linear spectrum and see where each part of it comes from:

> *If every particle of matter belongs to a halo, haloes come in the numbers of the mass function, have NFW profiles and cluster with the peak-background-split bias, what is the power spectrum of the matter?*

The construction mirrors the one in Section 11.1, where galaxies were points scattered by a smooth field. Here the matter is made of haloes scattered by a smooth field, and every halo carries a profile instead of being a point.

11.10.1 The inputs

Physical inputs.

(K1) All matter is in haloes. Halo i, of mass M_i, centred at $\boldsymbol{x}_i$, contributes the density $M_i\, u(\boldsymbol{x}-\boldsymbol{x}_i \mid M_i)$, where $u(\cdot \mid M)$ is the NFW profile divided by its mass, so $\int u\, \mathrm{d}^3x = 1$ (Section 11.9.1). Haloes of equal mass have equal profiles.

(K2) Haloes of mass M have mean number density $n(M)\,\mathrm{d}M$, the Sheth–Tormen mass function (Section 11.8.5).

(K3) The probability of finding the centres of two haloes, of masses M_1 and M_2, in volumes $\mathrm{d}V_1$ and $\mathrm{d}V_2$ a distance r apart is $n(M_1)n(M_2)\,[1+\xi_{hh}(r)]\,\mathrm{d}V_1\mathrm{d}V_2$, with $\xi_{hh}(r) = b(M_1)b(M_2)\,\xi_{\mathrm{lin}}(r)$: halo centres trace the linear field with the bias of Section 11.9.3.

Mathematical choice. We work in a periodic box of volume V, where $\delta_{\boldsymbol{k}} = \int_V \delta(\boldsymbol{x}) e^{-i\boldsymbol{k}\cdot\boldsymbol{x}}\mathrm{d}^3x$ and $\langle|\delta_{\boldsymbol{k}}|^2\rangle = V\,P(k)$ for $\boldsymbol{k}\neq 0$ (Section 7.4.1).

(K3) is the weakest input. It is right on large scales, where Section 11.9.3 derived it, and wrong on small ones: two haloes cannot overlap, so ξ_{hh} must fall to -1 below the sum of their radii, while $b_1b_2\xi$ does not. Where this matters will show up in the comparison with simulations.

11.10.2 One halo and two haloes

The density is a sum over haloes, $\rho(\boldsymbol{x}) = \sum_i M_i u(\boldsymbol{x}-\boldsymbol{x}_i \mid M_i)$, and a shift in real space is a phase in Fourier space, so $\rho_{\boldsymbol{k}} = \sum_i M_i\, u(k\mid M_i)\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}_i}$, with $u(k\mid M)$ the transform (11.65). For $\boldsymbol{k}\neq 0$, $\delta_{\boldsymbol{k}} = \rho_{\boldsymbol{k}}/\bar\rho$. The power is the average of $|\delta_{\boldsymbol{k}}|^2 = \delta_{\boldsymbol{k}}\delta^*_{\boldsymbol{k}}$, a double sum over haloes, and the terms fall into two groups: both factors from the same halo, or from two different haloes.

$$
\begin{aligned}
\bar\rho^2\,\langle|\delta_{\boldsymbol{k}}|^2\rangle &\overset{(1)}{=} \Big\langle \sum_i M_i^2\, u_i^2 \Big\rangle + \Big\langle \sum_{i\neq j} M_i M_j\, u_i u_j\, e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}_i-\boldsymbol{x}_j)} \Big\rangle \\
&\overset{(2)}{=} V\int \mathrm{d}M\, n(M)\, M^2 u^2(k\mid M) + \int \mathrm{d}M_1\mathrm{d}M_2\, n_1 n_2\, M_1 M_2\, u_1 u_2 \\
&\qquad \times \int_V \mathrm{d}^3x_1 \int_V \mathrm{d}^3x_2\, [1+\xi_{hh}(\boldsymbol{x}_1-\boldsymbol{x}_2)]\, e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}_1-\boldsymbol{x}_2)} \\
&\overset{(3)}{=} V\int \mathrm{d}M\, n(M)\, M^2 u^2(k\mid M) + V\int \mathrm{d}M_1\mathrm{d}M_2\, n_1 n_2\, M_1 M_2\, u_1 u_2\, b_1 b_2\, P_{\mathrm{lin}}(k). \qquad (11.70)
\end{aligned}
$$

(1) Expand the square. We write $u_i = u(k\mid M_i)$, which is real for a spherical profile; the phase cancels against its conjugate when $i=j$.

(2) First sum: the expected number of haloes of mass M in the box is $V\,n(M)\,\mathrm{d}M$ (K2). Second sum: the expected number of pairs is the pair density of (K3) integrated over both positions.
(3) The "1" in the bracket gives $\int \mathrm{d}^3r\, e^{-i\boldsymbol{k}\cdot\boldsymbol{r}} = 0$ for $\boldsymbol{k} \neq 0$ in a periodic box. With $\boldsymbol{r} = \boldsymbol{x}_1 - \boldsymbol{x}_2$, the ξ_{hh} term gives V times the Fourier transform of $b_1 b_2 \xi_{\rm lin}$, which is $b_1 b_2 P_{\rm lin}(k)$.

Dividing by $V\bar\rho^2$ gives the **halo model** power spectrum [CooraySheth2002 eqs. (88)–(89)], [203]:

$$P(k) = P_{1h}(k) + P_{2h}(k),$$
$$P_{1h}(k) = \int \mathrm{d}M\, n(M) \Big(\frac{M}{\bar\rho}\Big)^2 u^2(k\,|\,M), \qquad P_{2h}(k) = P_{\rm lin}(k)\Big[\int \mathrm{d}M\, n(M)\,\frac{M}{\bar\rho}\,b(M)\,u(k\,|\,M)\Big]^2. \tag{11.71}$$

The **one-halo term** P_{1h} counts pairs of mass elements in the same halo; the **two-halo term** P_{2h} counts pairs in different haloes.

Example: the large-scale limit. For $k \to 0$ every $u \to 1$, and the bracket in P_{2h} is $\int \mathrm{d}M\, n\,(M/\bar\rho)\,b = 1$ by the consistency relation (11.69). So $P_{2h} \to P_{\rm lin}$: on large scales the model returns linear theory, as it must. This is where the consistency relation earns its place. If it failed, the halo model would predict a large-scale amplitude different from the one it was built on.

Example: the one-halo term is a shot noise. For $k \to 0$, $P_{1h} \to \int \mathrm{d}M\, n\, M^2/\bar\rho^2$, a constant. To see what it is, suppose all haloes had one mass M_0. Then $n\,M_0 = \bar\rho$, and $P_{1h} = M_0^2 n/\bar\rho^2 = 1/n$: exactly the Poisson shot noise $1/\bar n$ of a catalogue of points, (11.8), with the haloes as the points. Matter made of discrete lumps has the shot noise of the lumps. For the Sheth–Tormen mass function the constant is $342.9\,(h^{-1}\mathrm{Mpc})^3$, the shot noise of a population of haloes all of mass $\bar\rho \times 342.9 \approx 3\times10^{13}\,h^{-1}M_\odot$, the mass-weighted mean halo mass.

11.10.3 Computing it, and comparing with simulations

`10_halo_model.py` evaluates (11.71) at $z = 0$ on a grid of 500 masses from 1.000×10^7 to $3\times10^{15}\,h^{-1}M_\odot$ and 300 wavenumbers, with the CAMB linear spectrum, Sheth–Tormen abundances and biases, and the NFW transform with the concentrations (11.61).

Listing 11.10: The one- and two-halo terms. (`code/ch11/10_halo_model.py`)

```
w1 = n_st * (M / RHO_M) ** 2                        # weight per dlnM of the one-halo term
P1h = np.trapezoid(w1[:, None] * u ** 2, lnM, axis=0)
I2 = np.trapezoid((n_st * M / RHO_M * b_st)[:, None] * u, lnM, axis=0) + (1 - bias_int) *
    u[0]
P2h = P_lin * I2 ** 2
```

`w1` is the weight $n(M)(M/\bar\rho)^2$ per unit $\ln M$ (the array `n_st` already holds $\mathrm{d}n/\mathrm{d}\ln M$); `P1h` integrates it against u^2 over $\ln M$ for all k at once. `I2` is the bracket of P_{2h}, with one correction. The mass grid ends at $1.000\times10^7\,h^{-1}M_\odot$, but Sheth–Tormen keeps putting mass into ever smaller haloes: on our grid $\int n\,(M/\bar\rho)\,\mathrm{d}M = 0.592$ and $\int n\,(M/\bar\rho)\,b\,\mathrm{d}M = 0.7056$ instead of 1. The missing haloes are so small that $u = 1$ for them at every k we use, so their only role is to carry their share of the large-scale bias; the term `(1 - bias_int) * u[0]` adds that share to the smallest bin, which makes $P_{2h} \to P_{\rm lin}$ exactly at small k. Their one-halo contribution, weighted by M^2, is negligible.

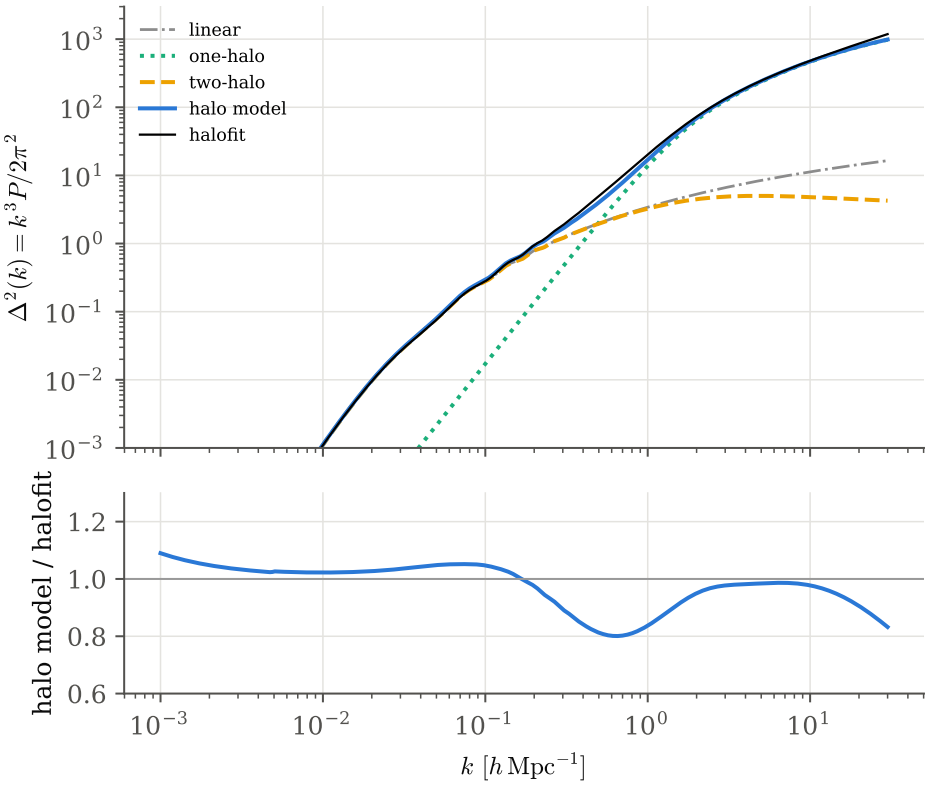

Figure 11.30: The matter power spectrum at $z = 0$ as $\Delta^2(k) = k^3P/2\pi^2$, the contribution of each logarithmic interval of k to the variance. The two-halo term (dashed) follows linear theory (dash-dotted) and is cut off when k resolves the haloes; the one-halo term (dotted) rises as k^3 and takes over beyond $k \approx 0.4957\,h\,\mathrm{Mpc}^{-1}$. Their sum (blue) is compared with halofit (black). Lower panel: the ratio of the two.

Side by side with halofit. Figure 11.30 shows the result. The two terms are equal at $k = 0.4957\,h\,\mathrm{Mpc}^{-1}$. The ratio of the halo model to halofit is 1.022 at $k = 0.01$, 1.047 at 0.1, 0.8937 at 0.3, 0.837 at 1, 0.9773 at 3 and 0.9775 at $10\,h\,\mathrm{Mpc}^{-1}$. Between $k = 0.05$ and 10 the worst point is 0.8007 at $k = 0.6311\,h\,\mathrm{Mpc}^{-1}$. A handful of numbers about haloes (a and p of the mass function, the amplitude and slope of the concentration relation, the halo edge and δ_c), each fixed by simulated or spherical-collapse haloes and none adjusted to the power spectrum, reproduce a fit to simulations to within 20% over three decades in k, and to about 2% between $k = 3$ and $10\,h\,\mathrm{Mpc}^{-1}$.

Which haloes make the small-scale power? At $k = 1\,h\,\mathrm{Mpc}^{-1}$ the one-halo term dominates, and the script measures how it is shared among masses: 10% of it comes from haloes below $4.381 \times 10^{13}\,h^{-1}M_\odot$ and 10% from haloes above 116×10^{13}. The non-linear power on the scale of a few megaparsecs is the internal structure of groups and clusters. That is why it is sensitive to σ_8 and to everything that changes the cluster abundance, and why baryonic processes inside clusters (gas blown out by active nuclei) change it measurably.

Where the halo model fails, and why. Each of the three disagreements traces back to one of the inputs.

- *The largest scales.* The one-halo term tends to a constant. Real matter has no such term: halo formation moves mass around locally and conserves it, and a local rearrangement of

mass cannot create power that stays constant as $k \to 0$ (it must vanish as k^4). The model's white noise adds 2% at $k = 0.01\,h\,\mathrm{Mpc}^{-1}$, more at smaller k (Figure 11.30, lower panel). The cause is (K1): the matter that went into a halo came from a surrounding region that is now underdense, and the model forgets the hole [CooraySheth2002 §4.4].

- *The transition,* $k \approx 0.3$–$1\,h\,\mathrm{Mpc}^{-1}$. Here the model is up to 20% low. The two-halo term uses linear P and linear bias (K3), with no halo exclusion and no quasi-linear growth of the field between haloes, and the one-halo term only counts the matter inside r_{vir}, not the infalling matter around it. Neither term is accurate where both are comparable. Research versions repair this region with fitted extra parameters [204].
- *The smallest scales.* At $k \gtrsim 3$ the answer depends on the concentration and on where the halo is cut. Keeping (11.61) but cutting haloes at $200\bar{\rho}$ instead of $330\bar{\rho}$ changes the ratio at $k = 10$ from 0.9775 to 0.6821. The concentration relation is calibrated together with a halo definition, and only the pair is meaningful [CooraySheth2002 §5.4].

The halo model is therefore a physical interpretation of the non-linear spectrum accurate at the 10–20% level, and a precise tool only after calibration. Its value is that every piece has a meaning that can be changed on purpose: massive neutrinos change $\sigma(M)$, baryons change $u(k\,|\,M)$, modified gravity changes δ_c, and the model says which scales respond.

11.10.4 Galaxies in haloes

Galaxies are not mass. Their correlation function is close to a power law, $\xi_{gg} \propto r^{-\gamma}$ with $\gamma \approx 1.8$, over two decades in separation, while the matter correlation function is not a power law at all [CooraySheth2002 §6]. Why should galaxies obey so simple a law when the matter does not? In the halo model the answer comes from one more ingredient. Every galaxy lives in a halo, so the galaxy field is the halo field reweighted by the number of galaxies each halo hosts:

> *If a halo of mass M hosts on average $\langle N\,|\,M\rangle$ galaxies, arranged in a known way, what are the galaxy power spectrum and correlation function?*

The occupation. A halo either has a galaxy at its centre or not; a central galaxy appears once the halo is massive enough to cool gas and form stars. Further galaxies, the satellites, orbit inside large haloes, distributed like the dark matter. A standard form [205] is

$$\langle N_c\,|\,M\rangle = \frac{1}{2}\Big[1 + \mathrm{erf}\Big(\frac{\log_{10} M - \log_{10} M_{\mathrm{min}}}{\sigma_{\log M}}\Big)\Big], \qquad \langle N_s\,|\,M\rangle = \langle N_c\,|\,M\rangle \Big(\frac{M - M_0}{M_1}\Big)^{\alpha}, \quad (11.72)$$

the **halo occupation distribution** (HOD). The central count is a Bernoulli variable (zero or one) with a smooth step in $\log M$; given a central, the number of satellites is Poisson with mean $\lambda(M) = [(M - M_0)/M_1]^{\alpha}$, and there are no satellites without a central. We take illustrative values, $\log_{10} M_{\mathrm{min}} = 12.8$, $\sigma_{\log M} = 0.5$, $\log_{10} M_0 = 12.6$, $\log_{10} M_1 = 14$ and $\alpha = 1.1$ (masses in $h^{-1}M_\odot$), roughly those of luminous galaxies (Figure 11.31, left).

The pairs inside one halo. The one-halo term of the matter came from pairs of mass elements in one halo, weighted by M^2. For galaxies it comes from pairs of distinct galaxies in one halo, so we need the mean number of ordered pairs, $\langle N(N-1)\,|\,M\rangle$. Write $N = C + S$ with $C \in \{0, 1\}$ the central and S the satellites:

$$\langle N(N-1)\,|\,M\rangle \overset{(1)}{=} \langle N_c\rangle\ \mathbb{E}\big[(1+S)S\,|\,C=1\big] \overset{(2)}{=} \langle N_c\rangle\,\big(\lambda + \lambda + \lambda^2\big) \overset{(3)}{=} 2\langle N_s\rangle + \langle N_c\rangle\lambda^2. \quad (11.73)$$

(1) Without a central there are no galaxies and no pairs; with one, $N = 1 + S$, and this happens with probability $\langle N_c \rangle$.
(2) $\mathbb{E}[S] = \lambda$ and $\mathbb{E}[S^2] = \lambda + \lambda^2$ for a Poisson variable (Chapter 2).
(3) $\langle N_s \rangle = \langle N_c \rangle \lambda$.

The two terms are different kinds of pair. $2\langle N_s \rangle$ counts the ordered pairs of the central with each satellite: one member sits at the centre and the other is displaced by the profile, so in Fourier space such a pair carries one factor $u(k \mid M)$. $\langle N_c \rangle \lambda^2$ counts the ordered pairs of two satellites, both displaced independently, which carry u^2 [CooraySheth2002 pp. 65–66]. A Monte Carlo of 2×10^6 haloes of $10^{14}\, h^{-1} M_\odot$ ($\langle N_c \rangle = 0.9997$, $\lambda = 0.9541$) gives $\langle N(N-1) \rangle = 2.818 \pm 0.002864$ against 2.818 from (11.73).

The galaxy power spectrum. Replacing the mass weights $M/\bar{\rho}$ of (11.70) by galaxy counts divided by the mean galaxy density $\bar{n}_g = \int \mathrm{d}M\, n(M) \langle N \mid M \rangle$, and the self-pairs by the pair counts just derived, gives

$$P_{gg}^{1h}(k) = \frac{1}{\bar{n}_g^2} \int \mathrm{d}M\, n(M) \left[2\langle N_s \mid M \rangle\, u(k \mid M) + \langle N_c \mid M \rangle \lambda^2(M)\, u^2(k \mid M) \right],$$
$$P_{gg}^{2h}(k) = P_{\mathrm{lin}}(k) \left[\frac{1}{\bar{n}_g} \int \mathrm{d}M\, n(M)\, b(M) \left(\langle N_c \mid M \rangle + \langle N_s \mid M \rangle\, u(k \mid M) \right) \right]^2, \tag{11.74}$$

[CooraySheth2002 eqs. (128)–(129)]. The pair of a galaxy with itself, which we excluded, is the Poisson shot noise $1/\bar{n}_g$ of (11.8), added on top when a catalogue is analysed. At small k the two-halo bracket becomes the **galaxy bias** $b_g = \bar{n}_g^{-1} \int \mathrm{d}M\, n\, b\, \langle N \mid M \rangle$, the number-weighted mean bias of the host haloes, so $P_{gg} \to b_g^2 P_{\mathrm{lin}}$ [CooraySheth2002 eqs. (130)–(131)].

Example: what the illustrative HOD predicts. The script gives $\bar{n}_g = 0.00116\, h^3\mathrm{Mpc}^{-3}$, a satellite fraction of 0.1287, and $b_g = 1.298$. The mean host mass, weighted by galaxy number, is $4.112 \times 10^{13}\, h^{-1} M_\odot$. The one-halo term tends to $462.2\, (h^{-1}\mathrm{Mpc})^3$ at small k, on top of the Poisson shot noise $1/\bar{n}_g = 861.8$ of the catalogue itself: galaxies sharing a halo add pairs that a Poisson sample of a smooth field would not have, and this extra white noise is about half the size of the Poisson term. This is the excess over the input (G2) of Section 11.1.1, "no memory between places", which holds between haloes but not inside one. The correlation function, the Fourier transform of P_{gg}, is close to a power law with $\gamma = 1.917$ and correlation length $r_0 = 7.161\, h^{-1}\mathrm{Mpc}$ between 0.2 and $10\, h^{-1}\mathrm{Mpc}$ (Figure 11.31, right), while the matter curve bends.

Why a power law? Below about $1\, h^{-1}\mathrm{Mpc}$ almost all pairs of galaxies sit in the same halo, and the one-halo term, steep because it comes from the inner profiles of massive haloes, sets ξ_{gg}. Above a few megaparsecs, pairs sit in different haloes and $\xi_{gg} \approx b_g^2 \xi_{\mathrm{lin}}$. Where the two hand over, the one-halo term is falling and the two-halo term is flattening, and for galaxies whose occupation is concentrated in massive haloes they happen to join smoothly. Change the occupation and the slope changes. The power law is not a law; it is a coincidence of two terms, and the HOD parameters are what a galaxy clustering measurement on small scales actually constrains [CooraySheth2002 p. 66].

11.11 Voids

A redshift survey of the nearby Universe shows galaxies arranged in walls and filaments around nearly empty regions tens of megaparsecs across. Bond, Kofman and Pogosyan called the

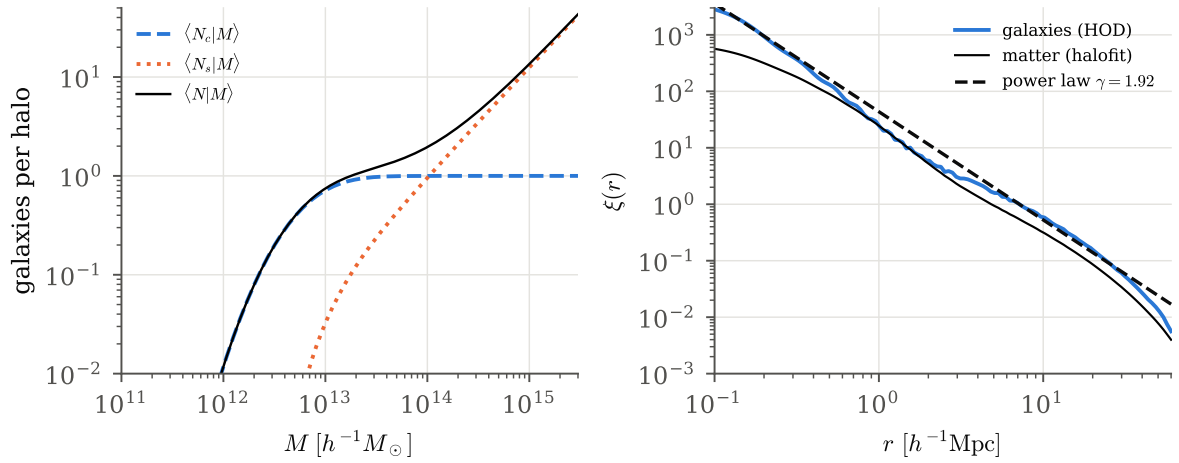

Figure 11.31: Left: the illustrative occupation (11.72): centrals (dashed) switch on near $10^{13}\,h^{-1}M_\odot$, satellites (dotted) grow almost in proportion to the halo mass. Right: the galaxy correlation function from (11.74) (blue) against the matter correlation function from halofit (black) and a power law (dashed). The galaxy curve is steeper than the matter on small scales, where it is all one-halo pairs, and joins the scaled matter curve on large scales.

arrangement the **cosmic web** and showed that it is already present, in embryonic form, in the initial Gaussian field: gravity only sharpens the image [206]. Clusters sit at the nodes, the filaments join them, and the space in between, most of the volume, belongs to the voids [4]. In Section 11.7 the voids were where the Zel'dovich universe and its phase-scrambled twin differed most. To use them as data we need three things, which we take in turn:

(1) *What exactly counts as a void?* A rule that a computer can apply to a catalogue or a simulated field.

(2) *How many voids of each size should a universe contain?* The prediction that turns a void count into a likelihood.

(3) *What do voids look like on average, and what can their shape measure?* This is the subject of Section 11.12.

11.11.1 How an empty region evolves

Start with the simplest void, a uniform spherical region of linear contrast $\delta_{\rm lin} < 0$ (extrapolated to today) in an Einstein–de Sitter background. It is the spherical-collapse problem of Section 11.8.1 run backwards: the region expands faster than its surroundings and empties. The exact solution is again taken from cosmology. For an underdense sphere of initial comoving radius R_0 and linear contrast δ_0 today, its comoving radius R and the redshift are given, in terms of a parameter θ, by [CooraySheth2002 eq. (50)]

$$\frac{R}{R_0} = \frac{(1+z)}{(5/3)|\delta_0|}\,\frac{\cosh\theta - 1}{2}, \qquad \frac{1}{1+z} = \left(\frac{3}{4}\right)^{2/3}\frac{(\sinh\theta - \theta)^{2/3}}{(5/3)|\delta_0|}. \tag{11.75}$$

What are the actual and the linear contrast at a given θ? The mass inside the sphere is fixed, so its actual mean contrast is $1 + \Delta = (R_0/R)^3$; its linear contrast at that time is δ_0 times the growth

factor, which in Einstein–de Sitter is $1/(1+z)$. Then

$$\delta_{\rm lin} \overset{(1)}{=} \frac{\delta_0}{1+z} \overset{(2)}{=} -\frac{3}{5}\Big(\frac{3}{4}\Big)^{2/3}(\sinh\theta-\theta)^{2/3},$$
$$1+\Delta \overset{(3)}{=} \Big[\frac{2\,(5/3)|\delta_0|}{(1+z)(\cosh\theta-1)}\Big]^3 \overset{(4)}{=} \Big[2\Big(\frac{3}{4}\Big)^{2/3}\frac{(\sinh\theta-\theta)^{2/3}}{\cosh\theta-1}\Big]^3 = \frac{9}{2}\,\frac{(\sinh\theta-\theta)^2}{(\cosh\theta-1)^3}. \tag{11.76}$$

(1) Linear growth in Einstein–de Sitter is $D \propto a = 1/(1+z)$, normalised so that $D = 1$ today.
(2) Insert $1/(1+z)$ from (11.75), with $\delta_0 = -|\delta_0|$; the $|\delta_0|$ cancels.
(3) $1+\Delta = (R_0/R)^3$, with R/R_0 from (11.75).
(4) Again insert $1/(1+z)$; the $|\delta_0|$ cancels, and $8\,(3/4)^2 = 9/2$.

Figure 11.32 plots the curve. Two numbers on it define voids in practice. First, the conventional threshold $\Delta = -0.8$ is reached at $\delta_{\rm lin} = -2.781$. Second, a void whose density decreases outwards does not stay smooth: its inner shells, more underdense, expand faster than the outer ones and catch up with them, piling matter into a ridge at the edge. For a top hat this *shell crossing* happens at $\theta \approx 3.53$, where $\delta_{\rm lin} = -2.811$ and $\Delta = -0.8021$ [ShethvdWeygaert2004 §3.1]. The void has then become a distinct object with a wall, the counterpart of collapse for a halo, and the threshold

$$\delta_v = -2.81 \tag{11.77}$$

plays the role of δ_c. That is why void finders look for regions with $\Delta \approx -0.8$. Since the mass inside is fixed, a void with $\Delta = -0.8$ is larger than the Lagrangian region it came from by

$$\frac{R}{R_L} = (1+\Delta)^{-1/3} = 0.2^{-1/3} = 1.71, \tag{11.78}$$

[ShethvdWeygaert2004 eq. (7)].

Example: the same void in the Zel'dovich approximation. Our simulated voids live in a Zel'dovich box, whose dynamics differ from the exact spherical solution. For a uniform sphere of linear contrast $\delta_{\rm lin}$, the Zel'dovich displacement is radial and, from $\nabla\cdot\boldsymbol{\Psi} = -\delta_{\rm lin}$ (Section 11.5.6), equal to $\boldsymbol{\Psi} = -\frac{1}{3}\delta_{\rm lin}\,\boldsymbol{q}$, because $\nabla\cdot\boldsymbol{q} = 3$. A shell starting at q moves to $r = q(1-\delta_{\rm lin}/3)$, so

$$1+\Delta_{\rm ZA} \overset{(1)}{=} \Big(\frac{q}{r}\Big)^3 = \Big(1-\frac{\delta_{\rm lin}}{3}\Big)^{-3}, \qquad \Delta_{\rm ZA} = -0.8 \overset{(2)}{=} \delta_{\rm lin} = -3\,(5^{1/3}-1) = -2.13. \tag{11.79}$$

(1) Mass conservation inside the shell, as for the exact solution.
(2) Solve $(1-\delta/3)^{-3} = 0.2$: $1-\delta/3 = 5^{1/3}$.

The same formula with $\delta_{\rm lin} > 0$ makes an overdense sphere collapse to a point at $\delta_{\rm lin} = 3$, in place of $\delta_c = 1.686$. A Zel'dovich void empties too fast (it keeps its initial velocities, while real gravity decelerates the outflow), so it reaches $\Delta = -0.8$ at a smaller $|\delta_{\rm lin}|$. These thresholds will matter when we compare the counted voids with a prediction.

11.11.2 Finding voids

There is no unique definition of a void, only rules, and different rules find different objects. Two families are in use.

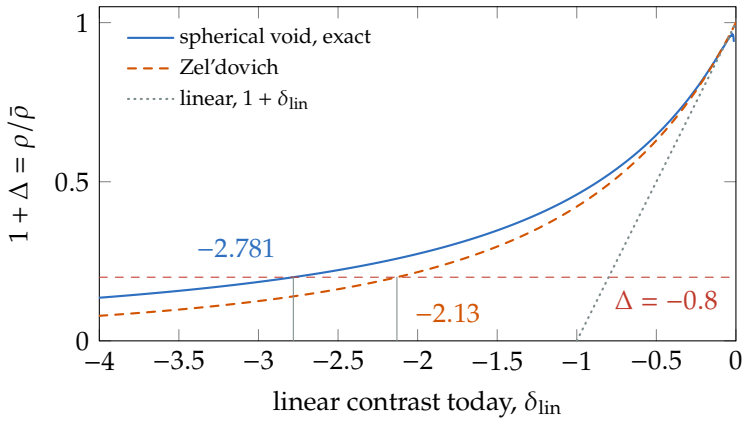

Figure 11.32: The mean density inside a spherical void against its linear contrast. Linear theory (dotted) reaches zero density at $\delta_{\rm lin} = -1$ and then goes negative; the exact solution (blue) empties smoothly and reaches 20% of the mean density at $\delta_{\rm lin} = -2.781$; the Zel'dovich approximation (orange, dashed) gets there earlier, at -2.13.

Working definition 11.7 (void (two operational definitions))

Spherical underdensity: a sphere about a local density minimum, grown until the mean contrast inside it, $\Delta(<R)$, first rises to a threshold, usually -0.8; overlapping spheres are pruned, largest first. The void radius is R. *Watershed:* treat the density as a landscape and flood it from every local minimum; a void is the basin of one minimum, ending on the density ridges that separate it from its neighbours [207, 208]. Its effective radius is that of the sphere of equal volume, $R = (3V/4\pi)^{1/3}$.

The spherical rule ties directly to the theory of Section 11.11.1: it finds exactly the regions that have reached $\Delta = -0.8$. The watershed rule needs no threshold and follows the real shapes of voids; it is what most research catalogues use, including the ZOBOV code behind the profiles of Section 11.12.2.

Listing 11.11: The spherical void finder. (`code/ch11/lib_web.py`)

```
def find_voids(rho, L, radii, smooth=1.0, seed_max=-0.5, threshold=-0.8, rmin=0.0):
    """Spherical underdensity void finder.

    rho      : 1 + delta on an N^3 periodic grid
    radii    : increasing trial radii [Mpc/h]
    Seeds are local minima of rho smoothed by a Gaussian of 'smooth' cells with delta <
    seed_max.
    About each seed the mean enclosed contrast Delta(<R) is read off sphere-averaged copies
    of
    rho; the void radius is where Delta(<R) first rises through 'threshold' (linear
    interpolation).
    Overlapping spheres are removed, largest first. Returns centres (n, 3) and radii (n,).
    """
    from scipy import ndimage
    N = rho.shape[0]
    cell = L / N
    rs = ndimage.gaussian_filter(rho, smooth, mode="wrap")
    mins = (rs == ndimage.minimum_filter(rs, size=3, mode="wrap")) & (rs - 1 < seed_max)
    idx = np.argwhere(mins)
    Dl = np.empty((len(idx), len(radii)))
    for j, R in enumerate(radii):
        Dl[:, j] = sphere_average(rho, R, L)[tuple(idx.T)] - 1
    rv = np.full(len(idx), np.nan)
    for i in range(len(idx)):
```

```
        above = np.nonzero(Dl[i] >= threshold)[0]
        if len(above) == 0 or above[0] == 0:
            continue
        j = above[0]
        d0, d1 = Dl[i, j - 1], Dl[i, j]
        rv[i] = radii[j - 1] + (threshold - d0) / (d1 - d0) * (radii[j] - radii[j - 1])
    ok = np.isfinite(rv) & (rv >= rmin)
    cen = (idx[ok] + 0.5) * cell
    rv = rv[ok]
    order = np.argsort(rv)[::-1]
    keep_c, keep_r = [], []
    for i in order:
        c = cen[i]
        if keep_c:
            d = np.array(keep_c) - c
            d -= L * np.round(d / L)
            if np.any(np.sqrt((d ** 2).sum(1)) < np.array(keep_r) + rv[i]):
                continue
        keep_c.append(c)
        keep_r.append(rv[i])
    return np.array(keep_c), np.array(keep_r)
```

The finder smooths the gridded density with a Gaussian of one cell and takes as seeds the cells that are lower than all 26 neighbours, with $\delta < -0.5$. For every trial radius it computes the mean density in a sphere about *every* cell at once, by a Fourier-space convolution (`sphere_average`); reading those maps at the seeds gives $\Delta(<R)$ for every seed and every radius. The void radius is where $\Delta(<R)$ first rises through the threshold, interpolated between trial radii. Finally the voids are sorted by size and each is kept only if it does not overlap a larger one already kept, with distances measured across the periodic boundary.

Example: the voids of the Zel'dovich box. On the Zel'dovich universe of Section 11.7 ($600\,h^{-1}$Mpc, 192^3 particles, cells of $3.1\,h^{-1}$Mpc) the finder returns 3607 voids larger than $8\,h^{-1}$Mpc, with median radius $9.732\,h^{-1}$Mpc and largest $23.16\,h^{-1}$Mpc. Together they fill only 8.482% of the box. That is not a contradiction of "voids fill most of the volume": the spherical rule keeps only the cores of the deepest regions, and the non-overlap condition discards everything between them. The watershed rule, run on the same field with the requirement that the basin floor be below $\delta = -0.8$, gives 7801 basins of median effective radius $14.68\,h^{-1}$Mpc, and the basins tile the box. The two catalogues describe the same field and agree on neither number nor size, which is why every void statistic must be predicted with the same rule that measures it.

11.11.3 How many voids: a walk between two barriers

The obvious guess, and why it is wrong. By symmetry with haloes, a point should belong to a void of mass M if its excursion-set walk first crosses δ_v, now from above, at $S = \sigma^2(M)$. That counts the *void-in-void* process correctly: a small void inside a larger one is part of the larger one, exactly as a small halo inside a larger one is. But voids have a second process with no counterpart for haloes [ShethvdWeygaert2004 §3.2]. A small underdense region inside a large region that is collapsing is crushed along with it. This is the *void-in-cloud* process. In walk language: a walk that crossed δ_c on some larger scale lies inside a halo, and any later crossing of δ_v is not a void. So

> *a point belongs to a void of mass M if its walk first crosses δ_v at $S = \sigma^2(M)$ without having crossed δ_c at any smaller S.*

This is a random walk between two absorbing barriers, δ_v below and δ_c above (Figure 11.33, right).

What fraction of the mass ends up in voids? Let $p(x)$ be the probability that a walk now at height x, between the barriers, reaches δ_v before δ_c. Over a small step ΔS the walk moves to $x+\epsilon$ with ϵ Gaussian of mean 0 and variance ΔS, and from there the same question starts afresh, so

$$p(x) \overset{(1)}{=} \mathbb{E}\big[p(x+\epsilon)\big] \overset{(2)}{=} p(x) + p'(x)\,\mathbb{E}[\epsilon] + \tfrac{1}{2}p''(x)\,\mathbb{E}[\epsilon^2] + \ldots \overset{(3)}{=} p(x) + \tfrac{1}{2}p''(x)\,\Delta S + \ldots$$
$$\implies \quad p''(x) = 0 \quad \overset{(4)}{=} \quad p(x) = \frac{\delta_c - x}{\delta_c - \delta_v} \quad \implies \quad p(0) = \frac{\delta_c}{\delta_c + |\delta_v|} \equiv 1 - D. \tag{11.80}$$

(1) Independent increments: after one step, the probability is that of a walk started from the new position, averaged over the step.
(2) Taylor expansion of p about x.
(3) $\mathbb{E}[\epsilon] = 0$, $\mathbb{E}[\epsilon^2] = \Delta S$; higher terms are of higher order in ΔS.
(4) A function with zero second derivative is a straight line; the boundary conditions $p(\delta_v) = 1$ and $p(\delta_c) = 0$ fix it.

This is the gambler's ruin of probability theory, and the result is [ShethvdWeygaert2004 eq. (3)], with the void-and-cloud parameter $D = |\delta_v|/(\delta_c + |\delta_v|)$. For $\delta_v = -2.781$ and $\delta_c = 1.686$, $1 - D = 0.3774$: a bit over a third of the mass ends up in voids, the rest in haloes. With $\delta_c = 1.06$, the threshold for turnaround rather than full collapse, it is 0.276. The script `11_voids.py` runs 40000 walks with both barriers, using `first_crossings` of Section 11.8.4 with its lower barrier switched on, and finds 0.3765 and 0.2752; the binomial standard error is 0.0024.

When do they cross? Now the distribution of the crossing scale. Let $p(\delta, S)$ be the density of walks that are at height δ at time S and have touched neither barrier. A walk at δ after $S + \Delta S$ was at $\delta - \epsilon$ at S; the same Taylor expansion as in (11.80), now in δ, gives the diffusion equation $\partial p/\partial S = \frac{1}{2}\partial^2 p/\partial\delta^2$. Walks that touch a barrier are removed, so $p = 0$ at $\delta = \delta_v$ and at $\delta = \delta_c$; all walks start at 0, so $p(\delta, 0) = \delta_D(\delta)$. Write $L = \delta_c - \delta_v$ for the gap between the barriers. Sine waves that vanish at both ends solve the equation, each decaying at its own rate:

$$p(\delta, S) \overset{(1)}{=} \sum_{j\ge1} A_j \sin\!\Big(\frac{j\pi(\delta - \delta_v)}{L}\Big) e^{-j^2\pi^2 S/2L^2}, \qquad A_j \overset{(2)}{=} \frac{2}{L}\sin\!\Big(\frac{j\pi|\delta_v|}{L}\Big) = \frac{2}{L}\sin(j\pi D),$$
$$\mathcal{F}_v(S) \overset{(3)}{=} \frac{1}{2}\frac{\partial p}{\partial\delta}\Big|_{\delta_v} \overset{(4)}{=} \sum_{j\ge1} \frac{j\pi}{L^2}\,\sin(j\pi D)\, e^{-j^2\pi^2 S/2L^2}. \tag{11.81}$$

(1) Separation of variables: $\sin(j\pi(\delta-\delta_v)/L)$ vanishes at both barriers, and its second derivative is $-(j\pi/L)^2$ times itself, so the diffusion equation makes it decay as $e^{-j^2\pi^2 S/2L^2}$.
(2) The coefficients of a delta function at $\delta = 0$ in this sine series (Fourier sine series on an interval of length L); $0 - \delta_v = |\delta_v|$ and $|\delta_v|/L = D$.
(3) The rate at which walks leave through the lower barrier is the probability current there. For the diffusion equation with coefficient $\frac{1}{2}$ the current is $-\frac{1}{2}\partial p/\partial\delta$, which at the lower wall points downward with magnitude $\frac{1}{2}\partial p/\partial\delta$.
(4) Differentiate the series term by term: $\partial_\delta \sin(j\pi(\delta - \delta_v)/L) = j\pi/L$ at $\delta = \delta_v$.

Multiplying by S and writing $1/L = D/|\delta_v|$ turns this into

$$S\,\mathcal{F}_v(S) = \sum_{j\ge1} \frac{j^2\pi^2 D^2}{\delta_v^2/S}\,\frac{\sin(j\pi D)}{j\pi}\,\exp\!\Big(-\frac{j^2\pi^2 D^2}{2\,\delta_v^2/S}\Big), \tag{11.82}$$

which is [ShethvdWeygaert2004 eq. (1)]. The left panel of Figure 11.33 compares it with the simulated walks, for both values of δ_c, and with the single-barrier answer ($\delta_c \to \infty$, $D \to 0$, the void-in-void process alone). The two-barrier curves are cut off at small δ_v^2/S, that is at small voids: those are the walks most likely to have been inside a collapsing region first. At large voids the three agree, because a large underdense region is almost never embedded in a larger collapsing one [ShethvdWeygaert2004 p. 11].

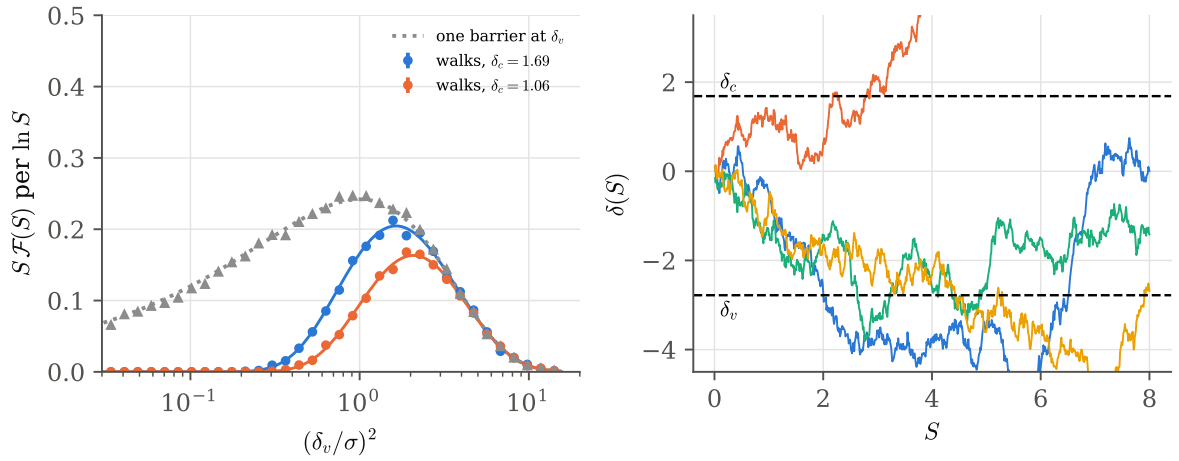

Figure 11.33: Left: the distribution of first down-crossings of δ_v that happen before any crossing of δ_c, per unit ln S, from 40000 simulated walks (points) and the series (11.82) (lines), for $\delta_c = 1.686$ and 1.06; grey: one barrier only. Right: four walks between the two barriers. A walk that hits δ_c first belongs to a halo, and its later dips are voids that have been crushed.

From walks to a size function. $S\mathcal{F}_v \,\mathrm{d}\ln S$ is the fraction of mass in voids whose Lagrangian mass has ln S in that interval. As for haloes, dividing by the mass of one void counts them; a void of Lagrangian radius R_L holds mass $\bar\rho V_L$, with $V_L = \frac{4}{3}\pi R_L^3$, and today has radius $R = 1.71\,R_L$. Hence the number of voids per unit volume and unit ln R,

$$\frac{\mathrm{d}n}{\mathrm{d}\ln R} = \frac{S\mathcal{F}_v(S)}{V_L}\left|\frac{\mathrm{d}\ln S}{\mathrm{d}\ln R_L}\right|, \qquad S = \sigma^2(R_L), \quad R_L = R/1.71, \tag{11.83}$$

[ShethvdWeygaert2004 eq. (6)]. This model has a flaw that Sheth and van de Weygaert point out themselves: every void is counted at the density of its Lagrangian volume, then inflated by $1.71^3 = 5$, so the total void volume can exceed the volume of the Universe [ShethvdWeygaert2004 p. 10]. Jennings, Li and Hu [209] proposed instead that voids, as they expand, merge rather than overlap, conserving the total volume in voids. That replaces V_L by the Eulerian volume $V = \frac{4}{3}\pi R^3$ in (11.83), the "volume-conserving" size function, a factor 1.71^3 lower.

Side by side with the Zel'dovich box. Figure 11.34 compares the voids found in the box with both models, computed with the CAMB $\sigma(R)$. With the thresholds of the dynamics that actually made the box, $\delta_v = -2.13$ and $\delta_c = 3$ from (11.79), the counts lie between the two models: over radii 9–19 h^{-1}Mpc Sheth–van de Weygaert is a factor 2.751 too high (median ratio) and the volume-conserving model a factor 0.5502 too low. With the exact spherical thresholds, $\delta_v = -2.781$ and $\delta_c = 1.686$, both predictions drop steeply at large R; at $R = 20\,h^{-1}$Mpc the Sheth–van de Weygaert curve is 51.83 times lower than with the Zel'dovich thresholds. The void abundance is exponentially sensitive to the threshold, for the same reason as the cluster abundance: large voids are rare events in a Gaussian field. That sensitivity is what makes the size function a probe of cosmology, and what makes it fragile: a threshold that does not

match the finder and the dynamics shifts the prediction more than any change of cosmological parameters. This is why research analyses calibrate the size function on simulations processed with the same finder [210].

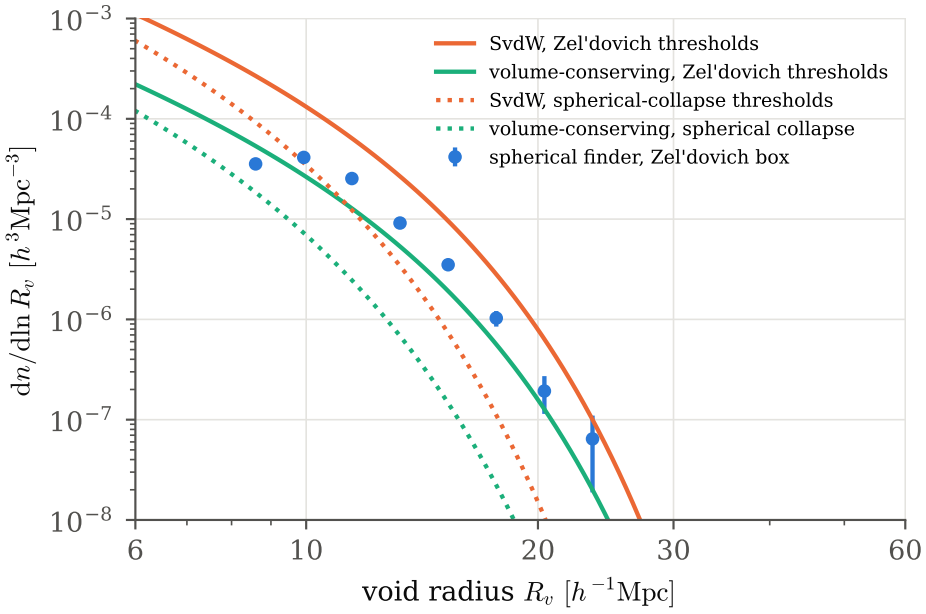

Figure 11.34: The void size function of the Zel'dovich box (points, Poisson errors) against the two-barrier excursion-set models: Sheth–van de Weygaert (orange) and volume-conserving (green), with the thresholds of the Zel'dovich dynamics (solid) and of exact spherical evolution (dotted). Over 9–19 h^{-1}Mpc the measured counts lie between the two solid curves; the smallest bin, next to the finder's minimum radius, falls below both.

Key idea: Voids from two barriers

A point is in a void of Lagrangian mass M if its excursion-set walk first crosses $\delta_v \approx -2.8$ at $S = \sigma^2(M)$ without first crossing δ_c. The mass fraction in voids is $\delta_c/(\delta_c + |\delta_v|)$, and the crossing distribution is the sine series (11.82). Converting it into numbers of voids of each radius needs an assumption about how voids expand, and the result is exponentially sensitive to the thresholds.

11.12 The average void: profile, outflow and shape

A single void is an irregular hole with a lumpy wall. Average a few thousand of them, each centred on its own centre and scaled by its own radius, and the irregularities wash out. Nothing in a homogeneous, isotropic universe picks out a direction, so the stacked void must be spherical, and its density and velocity depend only on the distance from the centre in units of the void radius. That average object is useful twice. Its radial profile records how matter has streamed out of underdense regions, which depends on gravity and on the growth rate. Its *shape*, if we observe it with the wrong distances, is not spherical, which turns the stack into a geometric ruler. We need the profile first.

11.12.1 Matter streams out of voids

The question. At distance r from the centre of a spherical underdense region, how fast does matter move away from it?

Linear theory. The linear continuity equation, $\dot\delta + \nabla\cdot\boldsymbol{v}/a = 0$ ((11.38)), relates the growth of the density contrast to the divergence of the peculiar velocity $\boldsymbol{v}$. Integrate it over a sphere of comoving radius r about the centre, and let $\Delta(r) = \frac{3}{r^3}\int_0^r \delta(r')\,r'^2\mathrm{d}r'$ be the mean contrast inside:

$$\frac{4\pi r^3}{3}\,\dot\Delta \overset{(1)}{=} \int_{|\boldsymbol{x}|<r} \dot\delta\,\mathrm{d}^3x \overset{(2)}{=} -\frac{1}{a}\oint_{|\boldsymbol{x}|=r} \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{A} \overset{(3)}{=} -\frac{4\pi r^2}{a}\,v_r(r),$$
$$v_r(r) \overset{(4)}{=} -\frac{a}{3}\,r\,\dot\Delta \overset{(5)}{=} -\frac{1}{3}\,f\,aH\,r\,\Delta(r). \tag{11.84}$$

(1) The integral of δ over the sphere is its volume times Δ; the comoving sphere has fixed radius, so the time derivative acts on Δ alone.
(2) The continuity equation, and the divergence theorem.
(3) By spherical symmetry the radial velocity is the same all over the sphere.
(4) Solve for v_r.
(5) In linear theory every contrast grows as $D(t)$, so $\dot\Delta = (\dot D/D)\Delta = fH\Delta$ with $f = \mathrm{d}\ln D/\mathrm{d}\ln a$.

At $z = 0$, $a = 1$ and this is [Hamaus2014 eq. (4)] with $f \approx \Omega_m^{0.55}$. Inside a void $\Delta < 0$, so $v_r > 0$: matter flows out, faster where the void is deeper and larger. With r in h^{-1}Mpc and $H_0 = 100\,h\,\mathrm{km\,s^{-1}Mpc^{-1}}$, the factor $fH_0 r$ is in $\mathrm{km\,s^{-1}}$; for our cosmology $f = 0.5273$ at $z = 0$.

Zel'dovich dynamics. Linear theory is not trustworthy where $\Delta \approx -0.8$. In the Zel'dovich approximation a particle moves as $\boldsymbol{x} = \boldsymbol{q} + D\boldsymbol{\Psi}_0$, so its peculiar velocity is $a\dot{\boldsymbol{x}} = a\dot D\boldsymbol{\Psi}_0 = f\,aH\,\boldsymbol{\Psi}$. For a spherical void the displacement is radial, and mass conservation fixes its size: the shell that is now at r started at q with $q^3 = (1+\Delta)r^3$, so $\Psi_r = r - q = r[1-(1+\Delta)^{1/3}]$, and

$$v_r^{\mathrm{ZA}}(r) = f\,aH\,r\left[1-(1+\Delta(r))^{1/3}\right], \tag{11.85}$$

which reduces to (11.84) for small Δ, since $(1+\Delta)^{1/3} \approx 1 + \Delta/3$. For $\Delta = -0.8$ the bracket is $1 - 0.2^{1/3} = 0.42$, against 0.27 in linear theory: the linear formula underestimates the outflow from deep voids by a third.

11.12.2 Reproducing Hamaus, Sutter and Wandelt

Their question. Halo profiles have a universal shape, NFW; do void profiles? In 2014 Hamaus, Sutter and Wandelt [211] asked for a simple formula that describes the stacked density profile of voids of every size, out to several void radii, including the overdense wall around the void, so that void statistics could be modelled analytically rather than read off simulations.

Their setup. They used an N-body simulation of 2048^3 dark matter particles in a box $1\,h^{-1}$Gpc on a side with Planck cosmology, subsampled to $\bar n = 2\times10^{-2}\,h^3\mathrm{Mpc}^{-3}$, about the density of a galaxy survey. Voids were found by the watershed code ZOBOV, keeping zones below $\Delta = -0.8$; each void has an effective radius r_v (the radius of the sphere of the same volume), only voids larger than twice the mean particle separation were used, and the profiles were measured in shells out to $3r_v$ and averaged in eight bins of void radius [Hamaus2014 p. 1].

Their key equation. The formula they proposed is [Hamaus2014 eq. (2)]:

$$\frac{\rho_v(r)}{\bar\rho} - 1 = \delta_{\mathrm{cen}}\,\frac{1-(r/r_s)^\alpha}{1+(r/r_v)^\beta}. \tag{11.86}$$

It is an empirical fit, not a derived law, but every parameter can be read off from the limits of the formula, and that is the derivation available. At $r \to 0$ the fraction is 1, so δ_{cen} is the

central contrast. At $r = r_s$ the numerator vanishes: r_s is where the density crosses the mean, the inner edge of the wall. For $r_s < r \lesssim r_v$ the numerator is negative, so the profile is positive, the wall, with α setting how steeply it rises. For $r \gg r_v$ the profile behaves as $-\delta_{\rm cen}(r/r_s)^\alpha(r_v/r)^\beta$, which goes to zero only if $\beta > \alpha$; β sets how fast the wall fades into the mean. The total missing mass, $\int_0^\infty 4\pi r^2\bar\rho\,\delta(r)\,{\rm d}r$, converges only if the integrand, $\propto r^{2+\alpha-\beta}$ at large r, falls faster than $1/r$, that is if $\beta > \alpha + 3$ [Hamaus2014 eqs. (7)–(8)]. Its sign splits voids into *overcompensated* ones, whose wall holds more than the missing mass (small voids, embedded in collapsing regions), and *undercompensated* ones (large voids, embedded in larger underdense regions). Hamaus et al. also found that α and β follow r_s/r_v [Hamaus2014 eqs. (10)–(11)]: $\alpha \simeq -2(r_s/r_v - 2)$, and $\beta \simeq 17.5\,r_s/r_v - 6.5$ for $r_s/r_v < 0.91$ and $\beta \simeq -9.8\,r_s/r_v + 18.4$ above. The velocity profile they compare with is (11.84), which we derived.

Watch out: Two different "δ_c"

Hamaus et al. call the central void contrast δ_c. It has nothing to do with the collapse threshold $\delta_c = 1.686$ of Section 11.8. We write it $\delta_{\rm cen}$.

What we compute. `11_voids.py` runs the watershed finder of Section 11.11.2 on the Zel'dovich box, which gives 7801 voids, and for each void counts the particles in 30 shells out to $3R_v$ (using a k-d tree with periodic boundaries) and divides by the expected count. It stacks the profiles in four bins of radius, 10–13, 13–16, 16–20 and 20–30 h^{-1}Mpc, with the standard error of the mean as the error bar (never smaller than the Poisson error of the stacked count). It fits (11.86) to each stack with four free parameters, by least squares, ignoring the innermost shells $r < 0.15R_v$. For the velocities, each particle's radial velocity is $fH_0\Psi_r$, and the stacked mean is compared with (11.84) and (11.85), both evaluated with the measured $\Delta(r)$ of the stack.

Side by side. Figure 11.35 shows the stacks and the fits, and Table 11.2 lists the parameters next to the values that the empirical relations for $\alpha(r_s/r_v)$ and $\beta(r_s/r_v)$ quoted above would assign at our r_s/R_v.

$\bar R_v$	N	$\delta_{\rm cen}$	r_s/R_v	α	β	χ^2/dof	α (H14)	β (H14)
11.81	1780	−0.9515	1.065	2.088	25 (bound)	1.302e + 04/25	1.87	7.961
14.48	3165	−0.9162	0.9493	2.35	25 (bound)	3451/25	2.101	9.097
17.5	2245	−0.91	0.9238	2.381	11.08	352/25	2.152	9.347
21.31	313	−0.9216	0.9442	2.618	9.128	38.54/25	2.112	9.147

Table 11.2: Fits of (11.86) to the stacked watershed voids of the Zel'dovich box ($\bar R_v$ in h^{-1}Mpc). The last two columns are the values of α and β that the relations of [Hamaus2014 eqs. (10)–(11)] give for the fitted r_s/R_v. "Bound": the fit ran into the upper limit $\beta = 25$ allowed in the fit.

For the two stacks of large voids the formula gets the shape roughly right. The largest stack is fitted with $\chi^2 = 38.54$ for 25 degrees of freedom, with $r_s/R_v = 0.9442$ close to the compensation value 0.91 of [Hamaus2014 p. 3], and α and β near the values Hamaus's relations assign. The next stack, with more voids and so smaller errors, already has $\chi^2 = 352$: close is not the same as right. The central contrasts, −0.91 to −0.95, are like theirs (−0.95 for their voids of 11.7 h^{-1}Mpc, [Hamaus2014 Fig. 3]). For the two stacks of small voids it fails: β runs to the edge of its allowed range and the χ^2 is thousands. The reason is visible in the left panel. Our small voids have almost no wall: the highest density outside $0.8R_v$ is −0.08312 for the smallest stack, against 0.1142 for the largest, and their density approaches the mean slowly from below out to $3R_v$. Hamaus's small voids have the highest walls of all.

Why they differ. Two causes, both in our simulation rather than in the formula. First, the Zel'dovich approximation has no gravity after the initial kick: particles that meet in a wall do not stop there but stream through it, so walls, which in a real universe are built by matter piling up and staying, are thin and short-lived. The small overcompensated voids of an N-body simulation are surrounded by just such walls, collapsing around them (the void-in-cloud process of Section 11.11.3). Second, the watershed of a smoothed Zel'dovich field splits large underdense regions into several basins, so many of our small "voids" are sub-basins of a larger void, undercompensated by construction. Only large voids, whose walls formed from large-scale linear modes that Zel'dovich treats well, look like the N-body ones. The errors of the stacks are also small (thousands of voids, millions of particles), so the χ^2 detects any mismatch of shape.

The outflow. The right panel of Figure 11.35 shows the stacked radial velocities. For the largest stack the peak outflow is 251.7 km s^{-1}, against 267 from the spherical Zel'dovich formula (11.85) and 181.7 from linear theory (11.84). The linear formula is too low by about a third inside the void, close to the factor estimated after (11.85). The Zel'dovich formula comes within a few per cent, about as close as the few hundred voids of one stack allow. That agreement is partly a consistency check, since the particle velocities in our box are Zel'dovich velocities; it confirms that the stacked void behaves like a spherical one.

The lesson. A fitting formula is universal only within the dynamics that produced it: our large voids follow the Hamaus profile, our small ones do not, because a Zel'dovich universe cannot build the walls that make small voids overcompensated.

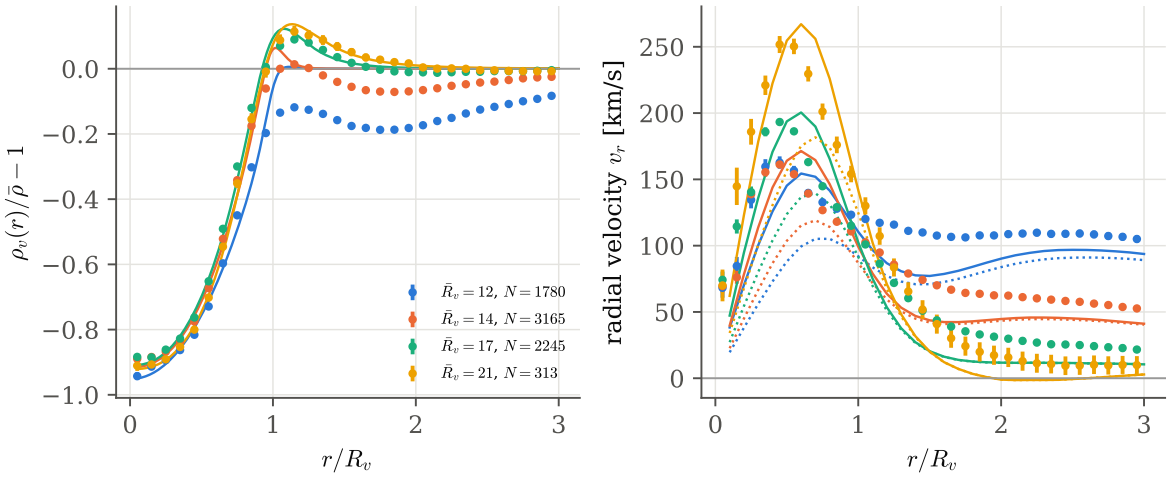

Figure 11.35: Stacked watershed voids of the Zel'dovich box in four bins of radius. Left: density profiles (points) and fits of (11.86) (lines); only the larger voids have an overdense wall near R_v. Right: radial velocity profiles (points) with the spherical Zel'dovich prediction (solid) and linear theory (dotted), both from the measured enclosed contrast.

11.12.3 Voids as standard spheres

The question. In a homogeneous, isotropic universe the stacked void is a sphere. A survey does not measure distances; it measures angles and redshifts, and converts them with a fiducial cosmology (Section 11.4.1). If the fiducial cosmology is wrong, does the stacked void still look round? Lavaux and Wandelt [212] proposed using exactly this, a test of sphericity first suggested by Alcock and Paczyński for any population of round objects.

The geometry. Write $\alpha_\perp = D_M/D_M^{\rm fid}$ and $\alpha_\parallel = D_H/D_H^{\rm fid}$ for the ratios of the true to the fiducial transverse and radial distances, as in (11.26). A sphere of true radius R_0 appears with transverse radius $R_0/\alpha_\perp$ and radial radius $R_0/\alpha_\parallel$, so its apparent axis ratio is

$$q \equiv \frac{R_\parallel^{\rm fid}}{R_\perp^{\rm fid}} = \frac{\alpha_\perp}{\alpha_\parallel} = \frac{D_M/D_M^{\rm fid}}{D_H/D_H^{\rm fid}} = \frac{D_M(z)H(z)}{[D_M(z)H(z)]^{\rm fid}}, \tag{11.87}$$

using $D_H = c/H$. The size of the void depends on the unknown true radius, but the ratio does not: a population of spheres measures the product $D_M H$ without any ruler of known length [LavauxWandelt2012 eqs. (5)–(9)]. This is the **Alcock–Paczyński test**.

What curve do we fit? A sphere of radius R_0 stretched by q along the line of sight has points $(r_\perp, r_\parallel)$ with $r_\perp^2 + (r_\parallel/q)^2 = R_0^2$. In polar form, $r_\perp = r\sqrt{1-\mu^2}$ and $r_\parallel = r\mu$, with μ the cosine of the angle to the line of sight:

$$r^2\left(1 - \mu^2 + \frac{\mu^2}{q^2}\right) = R_0^2 \quad\Longrightarrow\quad r(\mu) = \frac{R_0}{\sqrt{1 - \mu^2\,(1 - 1/q^2)}}. \tag{11.88}$$

The experiment. `12_void_ap.py` takes the 1530 spherical voids with $10 \le R_v < 25\,h^{-1}$Mpc from Section 11.11.2, and stacks the particles around them in bins of r/R_v and $|\mu|$, with the box's z axis as the line of sight. In each of ten μ bins it finds the radius where the stacked density rises through -0.5, and fits (11.88) to those ten radii. The error of q comes from a **jackknife**, a resampling estimate in the spirit of the bootstrap of Section 3.15: cut the box into $G = 27$ sub-cubes and put each void in the group of the sub-cube that holds its centre, repeat the whole measurement G times leaving out one group at a time to get $q_1, \dots, q_G$, and take $\sigma_q^2 = \frac{G-1}{G}\sum_g (q_g - \bar q)^2$. The factor $G-1$ compensates for the leave-one-out values being much closer to each other than independent measurements would be, since any two of them share $G-2$ of the G groups. The groups are regions of space, not voids picked at random, because neighbouring voids sit in the same large-scale waves and are not independent; leaving out a whole region removes those waves too. Even so, every region lies in the same box, and the jackknife cannot see waves longer than the box. The error is a rough one.

The script measures q four times: in real space; with the line of sight stretched by a true $q = 1.05$, as a wrong fiducial cosmology would do; in redshift space, moving each particle by its line-of-sight velocity, $s_z = z + f\Psi_z$ (Section 11.5.1); and with both.

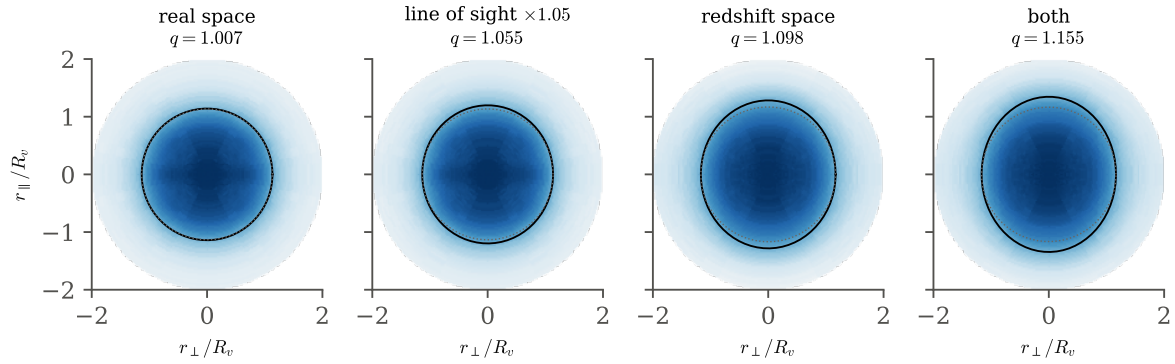

Figure 11.36: The stacked void in the plane of the line of sight (vertical) and a transverse direction, coloured by density (blue empty, red dense), with the fitted ellipse (black) and a circle (dotted). From left to right: real space; real space with distances along the line of sight stretched by 1.05; redshift space; both. Stretching and redshift-space outflow both elongate the stack.

What it finds. In real space $q = 1.007 \pm 0.009846$: the stack is round, as isotropy demands. With the stretched line of sight $q = 1.055 \pm 0.01172$, which recovers the input 1.05. About fifteen hundred voids in $0.2\,(h^{-1}\mathrm{Gpc})^3$ measure the axis ratio to about 1.1%. But in redshift space, with the correct geometry, $q = 1.098 \pm 0.01035$, and with both effects $q = 1.155 \pm 0.01141$, close to the product $1.055 \times 1.098 = 1.159$. The outflow of matter from voids elongates them along the line of sight by more than the geometric signal we inserted.

Why the outflow elongates the void. Redshift space moves every particle along the line of sight by $f\Psi_z$. Near a spherical void the displacement is radial, $\mathbf{\Psi} = \Psi_r(r)\,\hat{\boldsymbol{r}}$, so $\Psi_z = \Psi_r(r)\,z/r$. The density in redshift space is the real density divided by the Jacobian of the map, $1 + f\,\partial\Psi_z/\partial z$ (Section 11.5.2), and

$$\frac{\partial \Psi_z}{\partial z} \overset{(1)}{=} \Psi_r'(r)\,\frac{z}{r}\,\frac{\partial r}{\partial z} + \Psi_r(r)\left(\frac{1}{r} - \frac{z}{r^2}\,\frac{\partial r}{\partial z}\right) \overset{(2)}{=} \mu^2\,\Psi_r'(r) + (1-\mu^2)\,\frac{\Psi_r(r)}{r}. \tag{11.89}$$

(1) Product rule on $\Psi_r(r) \cdot z/r$.
(2) $\partial r/\partial z = z/r = \mu$.

Along the line of sight ($\mu = 1$) the shell at r moves out by $f\Psi_r$ and its density is divided by $1 + f\Psi_r'$. Across it ($\mu = 0$) nothing moves, but the density is still divided by $1 + f\Psi_r/r$, because the outflow stretches the line of sight around every point. Both make the void look emptier, and so larger, but by different amounts, so the void becomes elongated. Using the measured real-space stack and the spherical Zel'dovich Ψ_r, the script predicts that the -0.5 contour moves out by a factor 1.158 along the line of sight and 1.066 across it (linear theory: 1.131 and 1.049), an axis ratio of 1.086 (linear: 1.079), against the measured 1.098 ± 0.01035. The ratio is right. The two radii separately are both overpredicted by a few per cent (measured: 1.116 in the μ bin nearest the line of sight and 1.043 in the bin nearest the transverse direction), a common offset that the spherical model does not capture and that cancels in the ratio.

Example: what the test would measure. At $z = 0.51$, the mean redshift of the BOSS void sample, our fiducial flat ΛCDM has $D_M H/c = 0.5937$, and $\mathrm{d}\ln(D_M H)/\mathrm{d}\Omega_m = 0.3431$. An error of 0.01172 on $q \approx 1.05$ therefore corresponds to $\sigma(\Omega_m) \approx 0.01172/(1.05 \times 0.3431) = 0.03254$, for a stack of the size of ours (as rough as the jackknife error it comes from), if the redshift-space elongation were known exactly. The BOSS analysis of Hamaus et al. [213] fitted the redshift-space distortion (f/b, the growth rate over the galaxy bias) and the geometry at the same time, and found $D_M H/c = 0.588 \pm 0.004$ at $z = 0.51$ (they write D_A for our comoving D_M), with $f/b = 0.540 \pm 0.091$ and, in flat ΛCDM, $\Omega_m = 0.312 \pm 0.020$.

Key idea: Stacked voids as standard spheres

The stacked void is spherical in true coordinates, so its axis ratio in survey coordinates measures $D_M(z)H(z)$ relative to the fiducial value, with no ruler of known length. The outflow from voids elongates the stack along the line of sight by a comparable amount, so the geometry and the growth rate must be fitted together.

11.12.4 What voids are sensitive to

Voids are the regions where the matter is thinnest, and that makes them respond to physics that the dense regions hide [Pisani2019 §2].

- *Dark energy.* A void is the part of the Universe where dark energy dominates first. Its expansion is set by gravity, which empties it, and by the cosmic expansion, which

stretches it, so the size function depends on the dark-energy equation of state; and the Alcock–Paczyński test above measures $D_M H$ directly. The BOSS void size function alone gives $w = -1.1 \pm 0.2$ [210].

- *Modified gravity.* Many alternatives to general relativity add a force that is screened in dense environments, so that solar-system tests are passed. Voids are where screening fails: the extra force makes them expand faster and empty further, which shows up in their size function and in the outflow measured by redshift-space distortions around them.

- *Massive neutrinos.* Neutrinos stream freely over distances comparable to void sizes and do not follow the dark matter out of voids. Their share of the mass is therefore higher in voids than in dense regions, which changes how many voids form, how empty they become, and how they cluster.

Each of these is a change of the inputs of Section 11.11.3 ($\sigma(R)$, the thresholds, the expansion factor) or of the outflow (11.84) (through f), which is why the excursion-set and velocity models are the starting point of every void forecast.

11.12.5 Voids and the topology of the field

Does the way the regions of a field are connected carry information that the power spectrum does not expose? Topology is the tool made for that question, and the cosmic web has an exact topological description, which Chapter 12 builds from the beginning. Take the region where the density exceeds a threshold t, the superlevel set $\{\delta > t\}$. Its Betti numbers count, in three dimensions, its connected pieces (β_0), its independent tunnels (β_1) and the cavities it encloses (β_2) (see the topology notes). A void, seen from the matter, is a cavity: an empty region enclosed by walls. Voids are the β_2 features of the cosmic web [4, 5]. Equivalently, a cavity of the superlevel set is a separate connected piece of the complementary sublevel set $\{\delta < t\}$, and connected pieces are what a computer counts most easily.

`11_voids.py` counts them in the Zel'dovich box, after smoothing by one cell as for the watershed: the number of connected regions of $\{\delta_s < t\}$ (with the periodic faces glued, by a union–find over the labels on opposite faces), and the number of local minima below t, as t rises from -0.95 to 0 (Figure 11.37). Every region is born at a local minimum, so the minima are the births. At $t = -0.8$ there are 6414 regions and 9318 minima: most minima are still separate voids. The number of regions peaks at 6807 near $t = -0.75$ and then falls while minima keep appearing, because regions merge at saddle points of the density; by $t = -0.5$ there are 2257 regions for 18867 minima, and at $t = 0$ only 155. The underdense regions have joined into a network that runs through the box. That the separate voids exist only below $\delta \approx -0.8$ is the same threshold that came out of spherical evolution, and the one Wilding et al. find in N-body simulations, below which voids are the only topological features of the field [Wilding2021 p. 10].

The picture is the one that persistence formalises. Each underdense region is born at the value of its minimum and dies when it merges with an older one at a saddle; the pair (birth, death) is a point of a persistence diagram, and the watershed basins of Section 11.11.2 are the regions between those saddles. A void finder is therefore a particular, hand-tuned reading of the H_0 persistence of the sublevel sets. Chapter 12 turns that reading into a statistic with a sampling distribution and feeds it to the same likelihood machinery as $P(k)$.

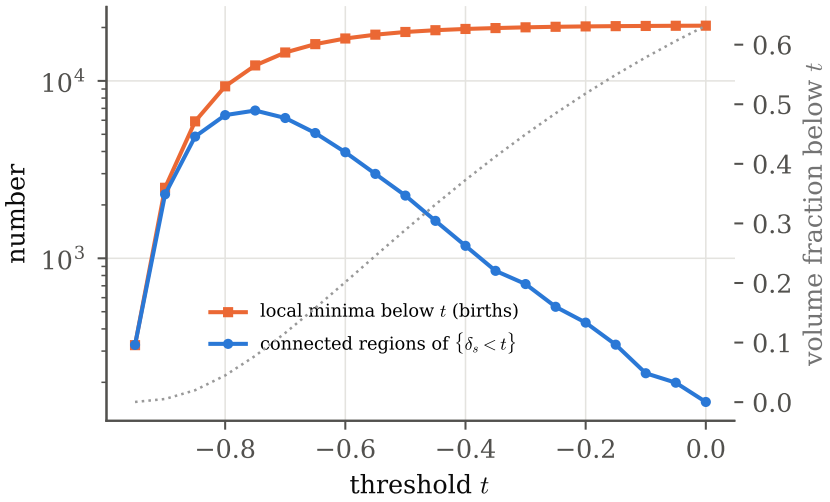

Figure 11.37: Underdense regions of the smoothed Zel'dovich field as the threshold t rises: the number of separate connected regions of $\{\delta_s < t\}$ (blue), the number of local minima below t (orange), and the volume fraction below t (dotted, right axis). Each region is born at a minimum; the gap between the curves counts the mergers at saddles.

11.13 Haloes and voids in research

Every measurement of haloes and voids we have made came from a script that runs in seconds to minutes on a laptop. The research versions keep the same ideas (first crossings, profiles, one- and two-halo terms, two barriers, stacked spheres) and replace almost every ingredient by something measured in large simulations.

Haloes. Research groups do not take the mass function from a formula. They run N-body simulations of 10^9–10^{11} particles in boxes of a few h^{-1}Gpc, identify haloes with a halo finder (linking particles closer than a fraction of the mean separation, or growing spheres to a fixed overdensity, the same choice of edge that mattered in Section 11.10.3), and fit or emulate $\mathrm{d}n/\mathrm{d}\ln M$ and $b(M)$ as functions of cosmology. The excursion set and the peak-background split survive as the reason the fits are nearly universal in ν and as a check on them. For cluster counts the hard part is not the mass function but the mass: clusters are found by their galaxies, hot gas or lensing signal, and the relation between that observable and M is calibrated with weak lensing, which is now the dominant uncertainty.

The non-linear power spectrum. The version of the halo model used in practice is HMcode [204], available in CAMB: the halo model of Section 11.10 with a handful of extra parameters fitted to simulations, which smooth the transition region where our version was 20% low and remove the large-scale one-halo excess. Because each parameter has a physical meaning, the same code models baryonic feedback by changing the concentration and the inner profiles of haloes, which is how weak lensing surveys marginalise over baryons. Halofit [41], which we compared with, plays the same role without the physical parameters, and emulators trained on suites of simulations are replacing both at the per-cent level.

Galaxies. The halo occupation distribution of Section 11.10.4 is fitted to the measured small-scale clustering of each galaxy sample, usually the projected correlation function, with the HOD parameters as nuisance parameters. The fitted HOD is then used to place galaxies in

the haloes of N-body or approximate simulations, which produces the thousands of mock catalogues from which the covariance matrices of Section 11.6 are estimated. So the halo model enters every survey analysis, if only through its mocks.

Voids. Void catalogues are built from the galaxies of spectroscopic surveys (BOSS, eBOSS, and now DESI, with Euclid to follow) with watershed codes descended from ZOBOV [208], run on the survey's light cone with its mask and selection. Galaxies are sparse and biased, so the voids are defined by the tracers, not by the matter, and their sizes depend on the tracer density; every prediction is therefore calibrated on mock catalogues processed by the same finder. The two leading analyses are the ones met above: the joint fit of the redshift-space distortions and the Alcock–Paczyński distortion of the stacked void–galaxy cross-correlation [213], and the void size function with a volume-conserving model extended by calibrated nuisance parameters [210].

How this is used in real research: Verification and research

Our simulations played two roles. The random walks of Sections 11.8.4 and 11.11.3 *verified* results we had derived exactly: the factor of 2, the Press–Schechter multiplicity, the gambler's-ruin void fraction and the two-barrier series. The Zel'dovich box was used as a stand-in for the *research* instrument, the place where no closed form exists: the void size function measured with a particular finder, the stacked profiles, the redshift-space elongation of voids, the topology of the underdense regions. In research that instrument is an N-body simulation with the survey's tracers, mask and finder, and the analytic models are calibrated against it, never the other way round.

11.13.1 What our shortcuts cost

Table 11.3 lists each simplification, what research does instead, and what it costs. As in Section 11.6.2, some costs are only wider error bars or a smaller range of scales; others leave a physical effect out, and no amount of laptop time in the same model brings it back.

The first row matters most. Almost everything that went wrong in our comparisons, the missing walls of small voids, the need for Zel'dovich thresholds in the size function, the close but partly circular agreement of the void outflow, comes from the Zel'dovich dynamics. A particle-mesh N-body code in a 256^3 box would run on the laptop in tens of minutes and would remove most of it; the full research version runs N-body simulations with 10^{10} particles on thousands of cores and identifies haloes and voids in hundreds of snapshots. What the laptop versions do transfer is the mechanism: why the mass function has the shape it has, where each part of the non-linear power spectrum comes from, why the galaxy correlation function is close to a power law, and why voids measure both geometry and growth.

Recap

- Two fields with the same $|\delta_{\boldsymbol{k}}|$ share $P(k)$, $\xi(r)$ and σ_R but can differ in skewness, one-point distribution and voids; the difference lives in the phases and is carried by haloes and voids (Section 11.7).
- With a sharp-k filter the smoothed linear contrast at a point is a Brownian motion in $S = \sigma^2(M)$; by reflection the fraction of walks that have crossed δ_c is $\mathrm{erfc}(\nu/\sqrt{2})$, twice the naive count, giving $F(\nu) = \sqrt{2/\pi}\, e^{-\nu^2/2}$ and $\mathrm{d}n/\mathrm{d}\ln M = (\bar{\rho}/M)\,\nu F|\mathrm{d}\ln\sigma/\mathrm{d}\ln M|$; simulations prefer Sheth–Tormen, the mark of ellipsoidal collapse (Section 11.8).

step	research	ours	what it costs
dynamics	N-body, 10^9–10^{11} particles, Gpc boxes	Zel'dovich particles, 192^3 in 600 h^{-1}Mpc	no bound haloes, walls dissolve after shell crossing; small voids lack their walls (Hamaus fit fails for $R_v \lesssim 15\,h^{-1}$Mpc); void thresholds are the Zel'dovich ones
haloes	found in simulations; mass function and bias fitted or emulated	analytic only (Press–Schechter, Sheth–Tormen)	abundance uncertain by tens of per cent at the extremes; no test of the peak-background split on simulated haloes
first crossings	correlated steps (real-space filters), moving barriers	sharp-k walks; 4 fields of 160^3 cells for the top hat	the factor of 2 is exact only for the sharp-k filter; the top-hat result has no closed form
non-linear $P(k)$	HMcode or emulators, with baryons	plain halo model, one concentration relation	0.8007 at $k = 0.6311\,h\,\mathrm{Mpc}^{-1}$; white-noise excess on large scales; no baryons
galaxies	HOD fitted to measured clustering; mocks	illustrative HOD, no fit	the power-law ξ_{gg} is a demonstration, not a measurement
void tracers	sparse, biased galaxies on the light cone, survey mask	all particles, periodic box, $z = 0$	voids smaller and emptier than in a survey; no mask or edge effects
void finder	ZOBOV/VIDE on tracers; calibrated on mocks	grid-based spherical and watershed finders, one-cell smoothing	size function differs from the two analytic models by factors of about 2–3
geometry	joint fit of AP and RSD on the void–galaxy cross-correlation	ellipse fitted to one contour; AP and RSD separately	$\sigma_q \approx 0.01172$ only for known RSD; no joint posterior
covariance	thousands of mocks	jackknife over 27 subcubes of one box, Poisson errors	error bars approximate; stacked-profile χ^2 not a calibrated test

Table 11.3: The steps of the halo and void analyses at research scale and in our scripts, with the cost of each simplification.

- Haloes have NFW profiles with $c(M)$ falling with mass; their transform $u(k\,|\,M)$ is 1 for long modes and falls once k resolves the halo. A long-wavelength δ_ℓ lowers the barrier to $\delta_c - \delta_\ell$, giving $b = 1 - \delta_c^{-1}\mathrm{d}\ln(\nu F)/\mathrm{d}\ln\nu$, with mass-weighted mean 1 (Section 11.9).
- The halo model $P = P_{1h} + P_{2h}$ follows from summing halo profiles: same-halo pairs give $\int n(M/\bar\rho)^2u^2$, different-halo pairs give $P_{\rm lin}[\int n(M/\bar\rho)bu]^2$. It reproduces halofit to 20%, fails in the transition region and on the largest scales, and with an HOD explains the near power-law ξ_{gg} (Section 11.10).
- A void is a region that reached $\Delta \approx -0.8$, the shell-crossing density of a spherical void ($\delta_v = -2.81$, radius 1.71 times its Lagrangian one). Voids are counted by walks crossing δ_v before δ_c: mass fraction $\delta_c/(\delta_c + |\delta_v|)$, crossing distribution a sine series; the size function needs an expansion model and is exponentially sensitive to the thresholds (Section 11.11).
- Stacked voids have a universal-looking profile where walls form, flow outwards as

$v_r = -\frac{1}{3} f a H r \Delta$ in linear theory, and are spheres whose apparent axis ratio measures $D_M H$; the redshift-space outflow elongates them by a comparable amount, so geometry and growth are fitted together. Voids are the β_2 features of the cosmic web, separate only below $\delta \approx -0.8$ (Section 11.12).

11.14 Hubble's diagram, refitted

In 1929 Edwin Hubble published a table of twenty-four galaxies, then called extra-galactic nebulae. For each he had a distance and a radial velocity, the second measured from the Doppler shift of its spectral lines. Plotted against each other, the points rose to the right: the farther the galaxy, the faster it receded. Hubble drew a straight line through the origin and called its slope K. He found $K \approx 500\,\mathrm{km/s}$ per megaparsec [214]. Today the slope, the Hubble constant H_0, is about 70 in the same units. The data were real, the line was real, and the number was wrong by a factor of seven.

Two different things went into that factor, and they belong to two different parts of statistics. The scatter of the points about the line is the business of the estimator: how the slope is computed from noisy points, and how large its error bar is. The factor of seven is the business of calibration: every one of Hubble's distances was too small by a common factor, and no amount of fitting can see a common factor. Refitting Hubble's own numbers lets us watch both at work. The peculiar velocities that scatter his points are the next subject: where they come from, how large they are, and what they do to every local measurement of the expansion.

Where we have met H_0 before. In Section 3.17 we fitted mock surveys of 100 supernovae made with $H_0 = 70$ and an absolute magnitude M that we simply declared known, and the weighted mean of $5 \log_{10} H_0$ recovered the 70 at the Cramér–Rao bound. Section 3.17.4 then freed M and found that the supernovae fix only $M - 5 \log_{10} H_0$; the real distance ladder, which supplies M from parallaxes and Cepheids, gives 73.04 ± 1.04, 4.8σ above the CMB's 67.36 ± 0.54 (Sections T2.12 and T2.12.3). The model here is the same kind: a linear law, noise that is Gaussian and independent, and a slope found in closed form. What differs is the data and where the noise lives. The numbers are real, so no script supplies the truth; the velocities are measured directly rather than as redshifts of supernovae; and the noise that matters is not the 0.15 mag of a supernova magnitude but the peculiar velocities, half the recession velocity at 1 Mpc on Hubble's scale, together with the Sun's own motion, which must be fitted alongside the slope. What sets the scale is the question of the degeneracy again: Hubble's distances play the role of M, and his calibration of them was wrong by a factor that no fit can see. That is why 465 lies nowhere near 70, 73 or 67: the gap is a calibration error of about 4 mag, more than twenty times the 0.18 mag that separates the ladder from the CMB.

The question. Given Hubble's twenty-four pairs (r_i, v_i),

1. where does the noise live, and which estimator of the slope follows from that;
2. does our fit reproduce his K, including his correction for the motion of the Sun;
3. how much does the answer depend on whether the noise sits in the velocities or in the distances;
4. why does no error bar computed from the scatter warn that K is seven times too large?

11.14.1 Hubble's question and his data

Hubble wanted to know whether the radial velocities of the nebulae, already measured for dozens of them, depend on their distances. Many velocities were large and positive, which hinted at a systematic recession, but a velocity alone says nothing about how it grows with distance. What was new in 1929 was a set of distances. For the nearest galaxies they came from stars that can be recognised individually, Cepheid variables among them; for the more distant ones, from the brightest stars that could be resolved, assumed to have the same luminosity in every galaxy; and the four galaxies of the Virgo cluster were all placed at the distance assigned to the cluster, 2 Mpc. Table 11.4 reproduces the table.

object	r	v	object	r	v	object	r	v
SMC	0.032	170	NGC 4736	0.5	290	NGC 1068	1.0	920
LMC	0.034	290	NGC 5194	0.5	270	NGC 5055	1.1	450
NGC 6822	0.214	−130	NGC 4449	0.63	200	NGC 7331	1.1	500
NGC 598	0.263	−70	NGC 4214	0.8	300	NGC 4258	1.4	500
NGC 221	0.275	−185	NGC 3031	0.9	−30	NGC 4151	1.7	960
NGC 224	0.275	−220	NGC 3627	0.9	650	NGC 4382	2.0	500
NGC 5457	0.45	200	NGC 4826	0.9	150	NGC 4472	2.0	850
			NGC 5236	0.9	500	NGC 4486	2.0	800
						NGC 4649	2.0	1090

Table 11.4: Hubble's twenty-four nebulae with individual distances [214, Table 1]: distance r in Mpc on his scale, radial velocity v in km/s relative to the Sun. NGC 224 is the Andromeda galaxy, NGC 221 its companion, NGC 598 the Triangulum galaxy; the last four are in the Virgo cluster.

Two features of the table matter for what follows. Several nearby galaxies have *negative* velocities: Andromeda approaches us at 220 km/s. So the velocities are not a clean function of distance; something of order a few hundred km/s rides on top of any trend. And the velocities are measured from the Sun, which itself moves. A galaxy in the direction the Sun is heading appears to recede more slowly than it would from a resting observer, and one behind appears to recede faster. Hubble modelled both effects, and we do the same.

11.14.2 The model, and where the noise lives

We state the inputs first, separating physics from bookkeeping, as in Section 2.5.1.

Physical inputs.

(H1) *A linear law.* A galaxy at distance r that partakes only in the general recession moves away at Kr.

(H2) *Peculiar velocities.* On top of that, each galaxy has its own velocity through space, its **peculiar velocity** [its motion relative to the smooth expansion]. Along the line of sight it adds ϵ_i, which we treat as random, with mean zero and spread σ_v, independent from galaxy to galaxy, and Gaussian.

(H3) *The Sun moves* with a fixed velocity $\boldsymbol{v}_\odot$ relative to the mean of the galaxies.

Bookkeeping input. The distances r_i are exact; we relax this in Section 11.14.4.

What the Sun's motion does. Let $\hat{\boldsymbol{n}}_i$ be the unit vector from the Sun towards galaxy i. A velocity measured from a moving platform is the velocity relative to the platform, so the Sun's motion subtracts $\boldsymbol{v}_\odot \cdot \hat{\boldsymbol{n}}_i$ from every radial velocity (Figure 11.38). In equatorial coordinates, with right ascension α_i and declination δ_i, the unit vector has components

$\hat{\boldsymbol{n}}_i = (\cos\alpha_i\cos\delta_i,\ \sin\alpha_i\cos\delta_i,\ \sin\delta_i)$. Writing $(X, Y, Z) \equiv -\boldsymbol{v}_\odot$ for the reflex of the solar motion,

$$v_i = K\, r_i + X\cos\alpha_i\cos\delta_i + Y\sin\alpha_i\cos\delta_i + Z\sin\delta_i + \epsilon_i, \qquad \epsilon_i \sim \mathcal{N}(0, \sigma_v^2). \tag{11.90}$$

This is Hubble's model. It is linear in the four unknowns (K, X, Y, Z).

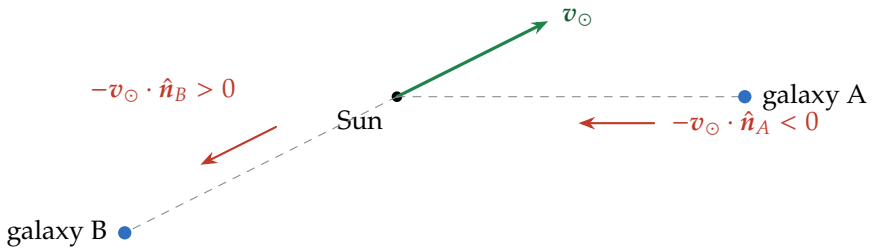

Figure 11.38: The reflex of the Sun's motion. Galaxy A lies ahead of the Sun's motion, so its measured velocity of recession is reduced by the component of $\boldsymbol{v}_\odot$ along its line of sight; galaxy B lies behind, and its measured recession is increased. The term is a dipole on the sky: $-v_\odot\cos\theta$, with θ the angle between the line of sight and the direction of motion.

The event, and what could have produced it. What we observed is a list of twenty-four velocities. For a candidate set of parameters (K, X, Y, Z) the model predicts each velocity, and the only thing that can turn the prediction into the observed number is the peculiar velocity ϵ_i. How plausible that required peculiar velocity is, under the Gaussian of (H2), is the likelihood (Section 3.8). Since the ϵ_i are independent, the likelihood is a product of Gaussians and $-2\ln\mathcal{L} = \chi^2 + \text{const}$ with $\chi^2 = \sum_i (v_i - \text{prediction}_i)^2/\sigma_v^2$, so the maximum-likelihood estimate is the least-squares fit (Section 3.10.1).

The slope alone first. Drop the solar motion for a moment, so the prediction is Kr_i. Then

$$\begin{aligned}
\chi^2(K) &\overset{(1)}{=} \frac{1}{\sigma_v^2}\sum_i \left(v_i - Kr_i\right)^2 = \frac{1}{\sigma_v^2}\Big[\sum_i v_i^2 - 2K\sum_i v_i r_i + K^2\sum_i r_i^2\Big], \\
\frac{\mathrm{d}\chi^2}{\mathrm{d}K} &\overset{(2)}{=} \frac{1}{\sigma_v^2}\Big[-2\sum_i v_i r_i + 2K\sum_i r_i^2\Big] = 0 \quad\Longrightarrow\quad \hat{K} = \frac{\sum_i v_i r_i}{\sum_i r_i^2}, \\
\operatorname{Var}\hat{K} &\overset{(3)}{=} \frac{\sum_i r_i^2\,\operatorname{Var} v_i}{\left(\sum_i r_i^2\right)^2} \overset{(4)}{=} \frac{\sigma_v^2}{\sum_i r_i^2}.
\end{aligned} \tag{11.91}$$

(1) Expand the square; K does not depend on i.
(2) The minimum of a parabola in K; the coefficient of K^2 is positive.
(3) $\hat{K}$ is a fixed linear combination $\sum_i c_i v_i$ with $c_i = r_i/\sum_j r_j^2$; for independent v_i the variance is $\sum_i c_i^2 \operatorname{Var} v_i$.
(4) $\operatorname{Var} v_i = \sigma_v^2$ by (H2), and $\sum_i r_i^2$ cancels once.

Each galaxy enters with weight r_i: distant galaxies, whose recession is large compared with the fixed σ_v, count for more. This is the same weighted ratio as the chronometer estimator of Section 3.17.6, with r_i in the place of E_i: a parameter that multiplies a known regressor gives a closed-form estimator.

Example: Hubble's numbers by hand. From Table 11.4, $\sum_i r_i^2 = 29.518\,\text{Mpc}^2$ and $\sum_i v_i r_i = 12514\,\text{km s}^{-1}\,\text{Mpc}$, so $\hat{K} = 12514/29.518 = 424\,\text{km/s/Mpc}$. The residuals $v_i - \hat{K}r_i$ scatter by 229 km/s; using that as σ_v, $\sigma_{\hat{K}} = 229/\sqrt{29.518} = 42$. The peculiar velocities are not a small nuisance: at 1 Mpc on Hubble's scale they are half the recession velocity.

With the solar motion. Now restore the four parameters. Stack them as $\boldsymbol{p} = (K, X, Y, Z)$ and the data as $\boldsymbol{v}$. Row i of the design matrix A is $(r_i,\ \cos\alpha_i\cos\delta_i,\ \sin\alpha_i\cos\delta_i,\ \sin\delta_i)$, so the prediction is $A\boldsymbol{p}$. Setting the four derivatives of $\chi^2 = |\boldsymbol{v} - A\boldsymbol{p}|^2/\sigma_v^2$ to zero gives the normal equations $A^{\mathsf{T}}A\,\hat{\boldsymbol{p}} = A^{\mathsf{T}}\boldsymbol{v}$, and the covariance of the estimate is $\sigma_v^2(A^{\mathsf{T}}A)^{-1}$; both were derived in Section 3.10.2 ((3.87) and (3.88)). The first column is the one we already had; the other three are what a dipole on the sky looks like in Cartesian components. For the positions we use modern right ascensions and declinations. Precession has moved them by about a degree since 1929, far less than the fit can resolve.

11.14.3 Side by side with Hubble

Script `code/ch11/08_hubble1929.py` types in the table, builds A and solves the normal equations.

Listing 11.12: The two least-squares fits: the slope alone, and the slope with the solar-motion dipole (`code/ch11/08_hubble1929.py`)

```
def fit_origin(r, v):
    """(a) v = K r: K = sum(v r)/sum(r^2), error from the residual scatter."""
    K = np.sum(v * r) / np.sum(r ** 2)
    s2 = np.sum((v - K * r) ** 2) / (len(r) - 1)
    return K, np.sqrt(s2 / np.sum(r ** 2)), np.sqrt(s2)

def design_solar(r, ra, dec):
    return np.column_stack([r, np.cos(ra) * np.cos(dec), np.sin(ra) * np.cos(dec),
    np.sin(dec)])

def fit_solar(r, v, ra, dec):
    """(b) linear least squares for (K, X, Y, Z): normal equations A^T A p = A^T v."""
    A = design_solar(r, ra, dec)
    AtA = A.T @ A
    p = np.linalg.solve(AtA, A.T @ v)
    res = v - A @ p
    s2 = res @ res / (len(v) - A.shape[1])
    cov = s2 * np.linalg.inv(AtA)
    return p, np.sqrt(np.diag(cov)), np.sqrt(s2)
```

`fit_origin` is (11.91), with the residual scatter divided by $N-1$ because one parameter was fitted. `design_solar` writes the four columns, and `fit_solar` solves $A^{\mathsf{T}}A\,\boldsymbol{p} = A^{\mathsf{T}}\boldsymbol{v}$ and estimates σ_v^2 from the residuals with $N-4$ degrees of freedom.

quantity	Hubble (1929)	our fit
K [km/s/Mpc]	465 ± 50	465 ± 56
X [km/s]	-65 ± 50	-70 ± 79
Y [km/s]	$+226 \pm 95$	236 ± 152
Z [km/s]	-195 ± 40	-200 ± 82
apex of the solar motion	$\alpha \approx 286^\circ$, $\delta \approx +40^\circ$	$\alpha = 286^\circ$, $\delta = +39^\circ$
slope without solar motion	—	424 ± 42

The central values agree to a few km/s: we recover Hubble's slope of 465 from his own table. The apex is the direction in which the Sun moves; it is $-(X, Y, Z)$ converted to angles, and the speed is $\sqrt{X^2+Y^2+Z^2} = 317\,\mathrm{km/s}$. That is the Sun's motion relative to the galaxies of the Local Group and their neighbours, a quantity we meet again in Section 11.16. Our standard errors are of the same order as Hubble's uncertainties but larger, by factors between 1.1 and 2;

we do not try to match his error conventions, since the central values are what the reproduction is about. Grouping the nebulae instead of fitting them one by one, Hubble found 513 ± 60, and two years later, with distances reaching the Leo cluster, Hubble and Humason found about 560 [215]. Every version lies near 500.

Dropping the solar motion lowers the slope to 424. The reason is in the sky positions. Many of the galaxies at intermediate distances, 0.45 to 1.4 Mpc on Hubble's scale (NGC 5457, 5194, 4736, 4449, 5055, 7331, 4258), lie in the northern sky, roughly in the direction towards which the Sun is moving. The reflex lowers each of their measured velocities by 100 to 240 km/s, so a line through the uncorrected points comes out shallower. Once the dipole is fitted and added back, those galaxies move up and the slope rises.

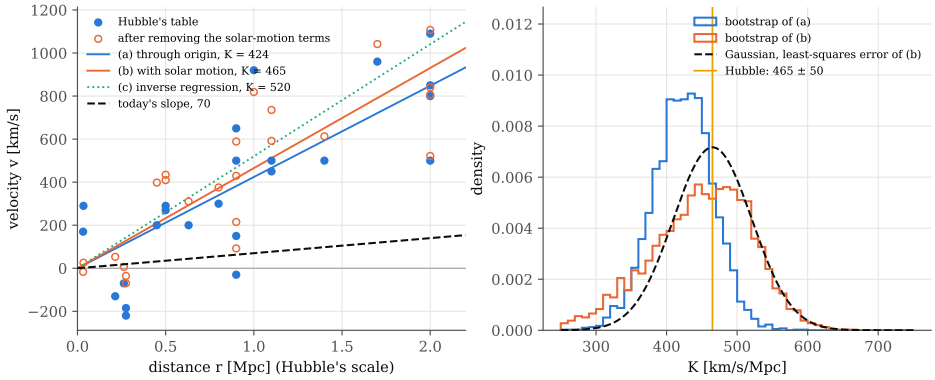

Figure 11.39: Left: Hubble's twenty-four galaxies (filled) and the same velocities with our fitted solar-motion dipole removed (open). The lines are the slope fitted through the origin (a), the slope fitted with the solar motion (b), the inverse regression of distance on velocity (c), and today's slope of 70 (dashed). Right: bootstrap distributions of the slopes (a) and (b), the Gaussian implied by the least-squares error of (b), and Hubble's value.

The error bar from resampling. The least-squares error assumes (H2): independent Gaussian peculiar velocities of a common spread. The bootstrap of Section 3.15 assumes only that the twenty-four galaxies are a fair sample of galaxies like them: draw twenty-four galaxies from the table with replacement, refit, repeat 4000 times. For the slope alone the bootstrap spread, 42, matches the formula. For the four-parameter fit it is 73, wider than 56 and skewed (Figure 11.39, right): a resample that happens to contain few galaxies in some part of the sky cannot pin down the dipole, and the slope wanders with it. With twenty-four points and four parameters the Gaussian error bar is optimistic.

11.14.4 When the distances are noisy too

Hubble's distances were not exact. A distance from the brightest stars of a galaxy is uncertain by a fixed *fraction*, because the luminosity of the brightest star varies from galaxy to galaxy and a magnitude error is a fractional distance error. So now replace the bookkeeping input by a physical one:

(H4) *Lognormal distance errors.* The measured distance is $r_i^{\text{obs}} = r_i\, e^{\eta_i}$ with $\eta_i \sim \mathcal{N}(0, \Delta^2)$ independent of everything else; Δ is the fractional error.

Two simple limits bracket the answer. If all the noise is in the velocities, we regress v on r, which is (11.91). If all the noise is in the distances, the roles swap: the velocity is exact, the distance is the noisy variable, and we should regress r on v, $r = bv$, with $\hat{b} = \sum_i v_i r_i / \sum_i v_i^2$ by

the same chain with r and v exchanged, and $\hat{K} = 1/\hat{b} = \sum_i v_i^2 / \sum_i v_i r_i = 520$. The two lines differ by more than twice the error bar of either. The data have not changed; only the assumption about which number carries the noise has. That is the likelihood at work: it asks how plausible the noise needed to turn the prediction into the data is, and the answer depends on where that noise is allowed to sit.

Both noises at once. The honest model keeps both. To first order in the small η_i, $r_i = r_i^{\mathrm{obs}} e^{-\eta_i} \approx r_i^{\mathrm{obs}}(1-\eta_i)$, so

$$
\begin{aligned}
v_i &\overset{(1)}{=} K r_i + \epsilon_i \overset{(2)}{=} K r_i^{\mathrm{obs}} + \left(\epsilon_i - K r_i^{\mathrm{obs}} \eta_i\right), \\
\mathrm{Var}\left(v_i \mid r_i^{\mathrm{obs}}\right) &\overset{(3)}{=} \sigma_v^2 + K^2 \Delta^2 \left(r_i^{\mathrm{obs}}\right)^2 \equiv s_i^2(K).
\end{aligned}
\tag{11.92}
$$

(1) The model (H1)–(H2), without the solar motion for clarity.
(2) Substitute $r_i \approx r_i^{\mathrm{obs}}(1-\eta_i)$ and collect the noise.
(3) ϵ_i and η_i are independent, so their variances add; the second is multiplied by the square of its coefficient $K r_i^{\mathrm{obs}}$.

The noise of each point now grows with its distance, and its variance depends on the parameter K itself. The likelihood is no longer a plain χ^2:

$$
-2 \ln \mathcal{L}(K, \sigma_v) = \sum_i \left[\frac{\left(v_i - K r_i^{\mathrm{obs}}\right)^2}{s_i^2(K)} + \ln s_i^2(K) \right] + \text{const},
$$

and the $\ln s_i^2$ term, the normalisation of each Gaussian, must be kept: it depends on K, and dropping it would let the fit lower χ^2 simply by making K, and with it every s_i, large. We maximise it numerically over K and σ_v at a fixed Δ. At $\Delta = 0$ it returns 424, the slope through the origin; at $\Delta = 0.2$ (a 0.43 mag distance error) 420; at $\Delta = 0.4$, 397. As Δ grows the distant galaxies are down-weighted, since their variance $K^2\Delta^2 r^2$ grows fastest. The first-order expansion has also dropped something important: given a measured distance, the true distance is not equally likely to lie above and below it, because there are more galaxies at larger distances. That is Malmquist bias, and Section 11.18 treats it properly.

11.14.5 Why 465 and not 70

None of these fits moves the slope anywhere near 70. The reason is a property of the model, not of the estimator. Suppose every distance in the table is too small by the same factor c, so that the true distances are $c r_i$. Refit:

$$
\begin{aligned}
\hat{K}(c\,\boldsymbol{r}) &\overset{(1)}{=} \frac{\sum_i v_i\,(c r_i)}{\sum_i (c r_i)^2} \overset{(2)}{=} \frac{1}{c}\,\hat{K}(\boldsymbol{r}), \\
v_i - \hat{K}(c\,\boldsymbol{r})\, c r_i &\overset{(3)}{=} v_i - \hat{K}(\boldsymbol{r})\, r_i .
\end{aligned}
\tag{11.93}
$$

(1) (11.91) with r_i replaced by $c r_i$.
(2) One factor of c in the numerator, two in the denominator.
(3) The product $\hat{K}\, r_i$ is unchanged, so every residual is unchanged.

The residuals, and so $\chi^2_{\min}$, the estimate of σ_v and the fractional error $\sigma_{\hat{K}}/\hat{K}$, are identical for every c. The data cannot tell $c = 1$ from $c = 6.6$; they constrain only the product Kc. The error bar on Hubble's slope (±50 in his paper, ±56 in our refit) is an honest statement about the scatter of his points and says nothing about c. This is the H_0–M degeneracy of the supernova

Hubble diagram (Section 3.17.4) in its oldest form: a velocity–distance diagram measures H_0 only in units of its distance scale, and the scale has to come from somewhere else.

How large was the error of the scale? To turn 465 into 70, every distance must grow by $465/70 = 6.6$, which in the language of magnitudes is $5 \log_{10} 6.6 = 4.1$ mag: Hubble's standard candles were assumed about four magnitudes fainter than they are. Hubble placed the Virgo cluster at 2 Mpc; today it is at about 16 Mpc. The error was found in pieces. Baade showed that the Cepheids used to calibrate the period–luminosity relation belonged to a different stellar population from those in the nebulae, which doubled the distances [216]. Sandage showed that many of Hubble's "brightest stars" in the more distant galaxies were clouds of ionised gas, intrinsically much brighter, and by 1958 the slope was near 75, still uncertain by a factor of two [217]. A further, quieter bias pushed the same way. The farther galaxies' distances came from the brightest objects that could be seen in them, and near the limit of a survey the objects that can be seen are the ones that happen to be unusually bright, so their distances come out too small; that is the classical Malmquist bias of Section T2.13. The modern version of the scale, Cepheids anchored by geometry and carried to supernovae, is the ladder of Section T2.12.

The lesson. Refitting Hubble's table reproduces his 465 to a few km/s, and shows that the error bar measures the scatter of the points, never the scale they are plotted on: a common multiplicative error is invisible to the fit and does not shrink with more galaxies.

11.15 Peculiar velocities: what moves the galaxies

The scatter in Hubble's diagram was 229 km/s (Section 11.14.2), and Andromeda, our nearest large neighbour, comes towards us at 220 km/s against the general recession. In the refit of Section 11.14 these peculiar velocities were noise: independent random numbers ϵ_i with a spread σ_v to be estimated from the residuals. They are not random in that sense. A galaxy moves because the matter around it pulls on it, and two neighbouring galaxies feel nearly the same pull. Once we know what produces the velocities, three things follow: how large they are in a universe with the measured power spectrum, how strongly the velocities of two galaxies a distance r apart are correlated, and, in the next two sections, what they do to every measurement of the local expansion.

The question.

1. How is a peculiar velocity read off from a redshift and a distance?
2. Given the density contrast everywhere, what is the velocity at one point?
3. How large is the typical velocity today, for the CAMB power spectrum, and which scales produce it?
4. How correlated are the velocities of two galaxies a distance r apart?

11.15.1 Reading a peculiar velocity from a redshift

A galaxy's redshift has two causes, composed one after the other (Section 11.5.1, (11.35)): the expansion stretches the light by $1 + z_c$, where z_c is the **cosmological redshift** the galaxy would have at rest, and its own line-of-sight velocity u_r Doppler-shifts it by $1 + u_r/c$. Solving for u_r,

$$1 + z_{\text{obs}} = (1 + z_c)\Big(1 + \frac{u_r}{c}\Big) \quad \Longrightarrow \quad u_r \overset{(1)}{=} c\,\frac{(1 + z_{\text{obs}}) - (1 + z_c)}{1 + z_c} \overset{(2)}{=} c\,\frac{z_{\text{obs}} - z_c}{1 + z_c}, \tag{11.94}$$

(1) Divide by $1+z_c$, subtract 1, multiply by c.
(2) The ones cancel in the numerator.

which is the definition Hogg uses [99, eq. (10)]. Near us $z_c \ll 1$ and $cz_c = H_0 r$, so $cz_{\rm obs} \approx H_0 r + u_r$: the observed recession velocity is the Hubble flow plus the line-of-sight peculiar velocity. That is the model of Section 11.14.2, with ϵ_i renamed $u_{r,i}$.

To measure u_r for one galaxy we therefore need its distance from something other than its redshift: a Cepheid, a supernova, the Tully–Fisher relation. The error of $u_r = cz_{\rm obs} - H_0 r$ is then $H_0\sigma_r$, and it grows with distance.

Example: how far out can one velocity be measured? A Tully–Fisher distance is uncertain by about 20%. At $r = 10\,$Mpc, with $H_0 = 70\,$km/s/Mpc, the velocity error is $70\times0.2\times10 = 140\,$km/s, smaller than the 300 km/s we will find for a typical peculiar velocity. At 50 Mpc it is 700 km/s, larger. Beyond a few tens of megaparsecs individual peculiar velocities are lost in the distance errors, and only averages over many galaxies survive. That is why the local Universe is the place where velocities are data.

11.15.2 The velocity field of linear theory

Inputs. We take two results of cosmological perturbation theory as given (see the cosmology notes); they are the same inputs as in the redshift-space distortions of Section 11.5.2.

(V1) *Linear continuity.* With $\boldsymbol{u}$ the peculiar velocity, a the scale factor, H the expansion rate, δ the matter density contrast and $f = \mathrm{d}\ln D/\mathrm{d}\ln a$ the growth rate, $\nabla\cdot\boldsymbol{u} = -aHf\,\delta$, which is (11.38) multiplied by aH. Matter flows out of regions where the density falls.

(V2) *No curl.* Rotational velocity perturbations decay as the Universe expands, so $\nabla\times\boldsymbol{u} = 0$ on large scales.

The question: given δ everywhere, what is $\boldsymbol{u}$ at the point $\boldsymbol{x}$?

A field without curl is a gradient. Write $\boldsymbol{u} = \nabla\psi$. Then (V1) is an equation for ψ alone, $\nabla^2\psi = -aHf\,\delta$: Poisson's equation, with $-aHf\,\delta$ as the source. We solve it the way one solves for an electrostatic potential, with the potential of a point source.

The point source. Away from the origin, with $\rho = |\boldsymbol{x}|$, $\nabla^2(1/\rho) = \rho^{-2}\,\mathrm{d}/\mathrm{d}\rho\,\big(\rho^2\,\mathrm{d}(1/\rho)/\mathrm{d}\rho\big) = \rho^{-2}\,\mathrm{d}(-1)/\mathrm{d}\rho = 0$. At the origin it is singular, and its strength follows from the divergence theorem: the flux of $\nabla(1/\rho) = -\hat{\boldsymbol{\rho}}/\rho^2$ out of a sphere of any radius ε is $(-1/\varepsilon^2)(4\pi\varepsilon^2) = -4\pi$. So $\nabla^2(1/\rho)$ is zero everywhere except at the origin and integrates to -4π over any ball around it: $\nabla^2\big(1/|\boldsymbol{x}-\boldsymbol{x}'|\big) = -4\pi\,\delta_D(\boldsymbol{x}-\boldsymbol{x}')$, with δ_D the Dirac delta.

Superpose. A sum of point sources solves Poisson's equation for the summed source. Hence

$$\psi(\boldsymbol{x}) \overset{(1)}{=} \frac{aHf}{4\pi}\int \mathrm{d}^3x'\,\frac{\delta(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|},$$
$$\boldsymbol{u}(\boldsymbol{x}) = \nabla\psi \overset{(2)}{=} \frac{aHf}{4\pi}\int \mathrm{d}^3x'\,\delta(\boldsymbol{x}')\,\frac{\boldsymbol{x}'-\boldsymbol{x}}{|\boldsymbol{x}'-\boldsymbol{x}|^3}. \tag{11.95}$$

(1) Check: $\nabla^2\psi = \frac{aHf}{4\pi}\int \mathrm{d}^3x'\,\delta(\boldsymbol{x}')\,\big(-4\pi\delta_D(\boldsymbol{x}-\boldsymbol{x}')\big) = -aHf\,\delta(\boldsymbol{x})$, which is (V1).
(2) $\nabla_{\boldsymbol{x}}|\boldsymbol{x}-\boldsymbol{x}'|^{-1} = -(\boldsymbol{x}-\boldsymbol{x}')/|\boldsymbol{x}-\boldsymbol{x}'|^3$; the gradient acts on $\boldsymbol{x}$, not on the integration variable.

Key idea: The linear velocity field

In linear theory the peculiar velocity at $\boldsymbol{x}$ is $\boldsymbol{u}(\boldsymbol{x}) = \frac{aHf}{4\pi}\int \mathrm{d}^3x'\,\delta(\boldsymbol{x}')\,(\boldsymbol{x}'-\boldsymbol{x})/|\boldsymbol{x}'-\boldsymbol{x}|^3$ [103, 218]: every overdense patch pulls with an inverse-square law, and the velocity points along the total pull. In Fourier space it is $\boldsymbol{u}_{\boldsymbol{k}} = i\,aHf\,\boldsymbol{k}\,\delta_{\boldsymbol{k}}/k^2$, the relation used for redshift-space distortions in (11.40).

The integral is Newton's gravitational field of the excess mass $\bar\rho\,\delta$, up to a constant. The velocity is parallel to the peculiar gravitational acceleration: in linear theory a galaxy moves in the direction it is pulled. The inverse-square fall-off is offset by the volume of a shell, which grows as the square of its radius, so distant matter is not negligible. A shell of uniform excess pulls equally in all directions and contributes nothing, but a shell whose density differs between one side and the other contributes as much as a nearby clump of the same total mass excess.

Example: one density wave. Take $\delta(\boldsymbol{x}) = A\cos(\boldsymbol{k}\cdot\boldsymbol{x})$ with a small amplitude A. The Fourier form gives $\boldsymbol{u} = -aHf\,A\,(\boldsymbol{k}/k^2)\sin(\boldsymbol{k}\cdot\boldsymbol{x})$: a velocity along $\boldsymbol{k}$, a quarter wavelength out of step with the density, with amplitude $aHfA/k = aHfA\lambda/2\pi$. Matter flows from the troughs towards the crests. For the same density amplitude, a longer wave gives a faster flow, in proportion to its wavelength. With $aH = 100$ km/s per h^{-1}Mpc today, $f = 0.527$, $A = 0.05$ and $\lambda = 100\,h^{-1}$Mpc, the flow amplitude is $100\times0.527\times0.05\times100/(2\pi) \approx 42$ km/s.

11.15.3 How fast, on average

The density contrast on large scales is a Gaussian random field with power spectrum $P(k)$ (Section 7.3.3): $\langle\delta_{\boldsymbol{k}}\rangle = 0$ and $\langle\delta_{\boldsymbol{k}}\delta^*_{\boldsymbol{k}'}\rangle = (2\pi)^3\delta_D(\boldsymbol{k}-\boldsymbol{k}')P(k)$, with $\delta(\boldsymbol{x}) = \int\frac{\mathrm{d}^3k}{(2\pi)^3}\delta_{\boldsymbol{k}}e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$. The velocity is a linear function of δ, and a linear function of a Gaussian field is a Gaussian field (Section 7.2). So each velocity component is Gaussian with mean zero, and all we need is its covariance. For components i and j at two points separated by $\boldsymbol{r}$,

$$\begin{aligned}\big\langle u_i(\boldsymbol{x})\,u_j(\boldsymbol{x}+\boldsymbol{r})\big\rangle &\overset{(1)}{=} \int\frac{\mathrm{d}^3k}{(2\pi)^3}\int\frac{\mathrm{d}^3k'}{(2\pi)^3}\big\langle u_{i,\boldsymbol{k}}\,u^*_{j,\boldsymbol{k}'}\big\rangle\,e^{i\boldsymbol{k}\cdot\boldsymbol{x}-i\boldsymbol{k}'\cdot(\boldsymbol{x}+\boldsymbol{r})}\\ &\overset{(2)}{=} (aHf)^2\int\frac{\mathrm{d}^3k}{(2\pi)^3}\int\frac{\mathrm{d}^3k'}{(2\pi)^3}\,\frac{k_ik'_j}{k^2k'^2}\,(2\pi)^3\delta_D(\boldsymbol{k}-\boldsymbol{k}')P(k)\,e^{i\boldsymbol{k}\cdot\boldsymbol{x}-i\boldsymbol{k}'\cdot(\boldsymbol{x}+\boldsymbol{r})}\\ &\overset{(3)}{=} (aHf)^2\int\frac{\mathrm{d}^3k}{(2\pi)^3}\,P(k)\,\frac{k_ik_j}{k^4}\,e^{i\boldsymbol{k}\cdot\boldsymbol{r}}.\end{aligned}\tag{11.96}$$

(1) u_j is real, so we may write it as its own complex conjugate, $u_j(\boldsymbol{y}) = \int\frac{\mathrm{d}^3k'}{(2\pi)^3}u^*_{j,\boldsymbol{k}'}e^{-i\boldsymbol{k}'\cdot\boldsymbol{y}}$; the average passes inside the integrals.

(2) $u_{i,\boldsymbol{k}} = iaHf\,k_i\delta_{\boldsymbol{k}}/k^2$ and $u^*_{j,\boldsymbol{k}'} = -iaHf\,k'_j\delta^*_{\boldsymbol{k}'}/k'^2$; the factors i and $-i$ multiply to 1; then the spectrum of δ.

(3) The delta function sets $\boldsymbol{k}' = \boldsymbol{k}$ and cancels one $(2\pi)^3$; the $\boldsymbol{x}$ dependence cancels, as homogeneity requires. The sign of the exponent is immaterial because the rest of the integrand is even in $\boldsymbol{k}$.

One point. At $\boldsymbol{r} = 0$, sum over $i = j$: $k_ik_i = k^2$, and with $\mathrm{d}^3k = 4\pi k^2\mathrm{d}k$ for an isotropic integrand,

$$\sigma_v^2 \equiv \big\langle|\boldsymbol{u}|^2\big\rangle = (aHf)^2\int\frac{4\pi k^2\,\mathrm{d}k}{(2\pi)^3}\,\frac{P(k)}{k^2} = \frac{(aHf)^2}{2\pi^2}\int_0^\infty P(k)\,\mathrm{d}k, \qquad \sigma^2_{v,1\mathrm{D}} = \frac{\sigma_v^2}{3},\tag{11.97}$$

the second because isotropy shares the three components equally. Compare the density variance in a sphere of radius R (Section 7.6), $\sigma_R^2 = \frac{1}{2\pi^2}\int k^2P(k)\,W^2(kR)\,\mathrm{d}k$: the velocity carries two fewer

powers of k. That is the wave example again: velocity grows with wavelength, so velocities are made by larger scales than densities.

Example: the numbers today. Script `code/ch11/09_peculiar_velocities.py` integrates (11.97) with the CAMB linear spectrum at $z = 0$ (the one of Section T1.4, $\sigma_8 = 0.811$) and $f = 0.527$. Lengths are in h^{-1}Mpc, so $aH = 100\,\mathrm{km/s}$ per h^{-1}Mpc and h drops out. It finds $\sigma_v = 534\,\mathrm{km/s}$ in three dimensions and $\sigma_{v,1D} = 308\,\mathrm{km/s}$ along one line of sight: the "$\sim 300\,\mathrm{km/s}$" assumed for the peculiar velocities of supernova hosts in Section 3.17.1 and Section T2.11. Figure 11.40 (left) shows where it comes from. Half of σ_v^2 comes from $k < 0.060\,h/\mathrm{Mpc}$, wavelengths longer than $105\,h^{-1}$Mpc, while half of σ_8^2 comes from $k < 0.17$, wavelengths longer than $37\,h^{-1}$Mpc. A galaxy's velocity is set by the distribution of mass over a region several times larger than the region that sets its local density.

This number is the velocity of the smooth large-scale flow. Galaxies inside groups and clusters also orbit in the group's potential, at up to 1000 km/s in rich clusters; linear theory knows nothing of that, and it adds a non-Gaussian, small-scale part on top of (11.97).

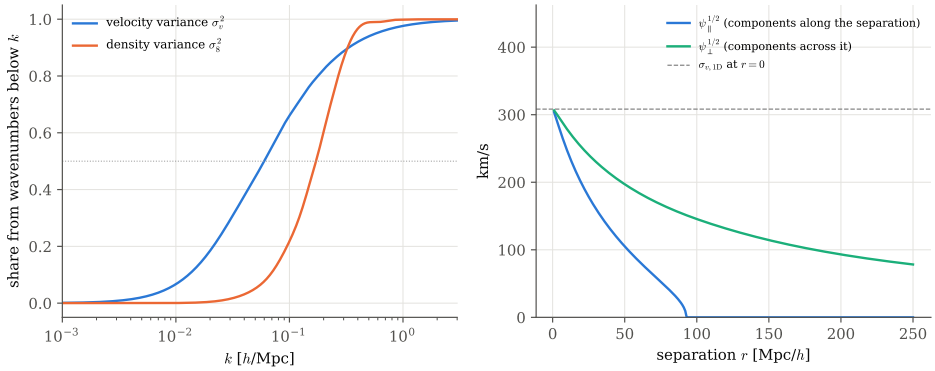

Figure 11.40: Left: the share of the velocity variance σ_v^2 and of the density variance σ_8^2 contributed by wavenumbers below k; velocities come from about three times larger scales. Right: the square roots of the velocity correlation functions for components along the separation ($\psi_\parallel$) and across it ($\psi_\perp$); both start at the one-dimensional rms velocity, and $\psi_\perp$ is still half of it at $100\,h^{-1}$Mpc.

11.15.4 How correlated: the velocity correlation functions

Now keep $\boldsymbol{r} \neq 0$ in (11.96). Isotropy says the answer can only be built from δ_{ij} and $\hat{r}_i\hat{r}_j$: the component of velocity along the separation and the components across it are the only distinguishable directions. So we need the angular average of $\hat{k}_i\hat{k}_j\, e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ over the directions of $\boldsymbol{k}$.

Start from the simplest average. Without the factors $\hat{k}_i\hat{k}_j$ the average over directions is a familiar integral: with μ the cosine of the angle between $\boldsymbol{k}$ and $\boldsymbol{r}$ and $x = kr$, $\frac{1}{4\pi}\int \mathrm{d}\Omega_k\, e^{i\boldsymbol{k}\cdot\boldsymbol{r}} = \frac{1}{2}\int_{-1}^{1} e^{ix\mu}\mathrm{d}\mu = \frac{\sin x}{x} = j_0(x)$, the spherical Bessel function of order zero.

Bring down the factors by differentiating. Each derivative $\partial/\partial r_i$ of $e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ brings down ik_i, so $k_ik_j\, e^{i\boldsymbol{k}\cdot\boldsymbol{r}} = -\partial_i\partial_j e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$, and the angular average of $k_ik_j e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ is $-\partial_i\partial_j\, j_0(kr)$. For a function $g(r)$ of $r = |\boldsymbol{r}|$ alone, $\partial_i g = g'\hat{r}_i$ and $\partial_j\hat{r}_i = (\delta_{ij} - \hat{r}_i\hat{r}_j)/r$, so

$$
\begin{aligned}
-\partial_i\partial_j\, j_0(kr) &\overset{(1)}{=} -\Big[g''\,\hat{r}_i\hat{r}_j + \frac{g'}{r}\big(\delta_{ij} - \hat{r}_i\hat{r}_j\big)\Big]_{g=j_0(kr)} \\
&\overset{(2)}{=} k^2\Big[\Big(j_0(x) - \frac{2j_1(x)}{x}\Big)\hat{r}_i\hat{r}_j + \frac{j_1(x)}{x}\big(\delta_{ij} - \hat{r}_i\hat{r}_j\big)\Big],
\end{aligned}
$$

$$\frac{1}{4\pi}\int \mathrm{d}\Omega_k\, \hat{k}_i\hat{k}_j\, e^{i\boldsymbol{k}\cdot\boldsymbol{r}} \overset{(3)}{=} \frac{j_1(x)}{x}\,\delta_{ij} + \Big(j_0(x) - \frac{3j_1(x)}{x}\Big)\hat{r}_i\hat{r}_j. \tag{11.98}$$

(1) The product rule on $\partial_j(g'\hat{r}_i)$.
(2) $j_0'(x) = -j_1(x)$ and $j_1'(x) = j_0(x) - 2j_1(x)/x$, with $j_1(x) = \sin x/x^2 - \cos x/x$; so $g' = -kj_1$, $g'' = -k^2(j_0 - 2j_1/x)$, and $g'/r = -k^2 j_1/x$.
(3) Divide by k^2 (since $k_ik_j = k^2\hat{k}_i\hat{k}_j$) and collect the $\hat{r}_i\hat{r}_j$ terms: $j_0 - 2j_1/x - j_1/x$.

A check: at $r \to 0$, $j_1(x)/x \to 1/3$ and $j_0 \to 1$, so the average becomes $\delta_{ij}/3$, the average of $\hat{k}_i\hat{k}_j$ over all directions. Putting (11.98) into (11.96) with $\mathrm{d}^3k = k^2\mathrm{d}k\,\mathrm{d}\Omega_k$, the k^2 cancels the k^2 left in $k_ik_j/k^4 = \hat{k}_i\hat{k}_j/k^2$, and for the components across and along the separation (take $i = j$ perpendicular to $\hat{\boldsymbol{r}}$, or $i = j$ along it):

$$\psi_\perp(r) = \frac{(aHf)^2}{2\pi^2}\int_0^\infty \mathrm{d}k\, P(k)\,\frac{j_1(kr)}{kr}, \qquad \psi_\parallel(r) = \frac{(aHf)^2}{2\pi^2}\int_0^\infty \mathrm{d}k\, P(k)\Big[j_0(kr) - \frac{2j_1(kr)}{kr}\Big], \tag{11.99}$$

the two velocity correlation functions of Górski [219]. Both equal $\sigma^2_{v,1\mathrm{D}}$ at $r = 0$.

Figure 11.40 (right) shows them. At $r = 100\,h^{-1}$Mpc, $\psi_\perp^{1/2} = 146\,\mathrm{km/s}$: two galaxies a hundred megaparsecs apart still share about half of their typical transverse velocity. Large regions move together, in **bulk flows**. $\psi_\parallel$ falls faster and turns slightly negative: the components along the separation of two distant galaxies tend to have opposite signs, as they do on the two sides of a region into which matter is falling, or out of which it is streaming.

Watch out: Peculiar velocities are not independent noise

Model (H2) of Section 11.14.2 treated the peculiar velocities of Hubble's galaxies as independent. Within a few tens of megaparsecs they are almost perfectly correlated. A sample of nearby galaxies shares a common flow, which does not average away as $1/\sqrt{N}$: it shifts every velocity the same way. The part of the common flow that grows linearly with distance looks exactly like a change of the Hubble constant (Section 11.17).

11.15.5 Velocities in a simulated box

The derivation assumed a Gaussian field with the CAMB spectrum. We now build such a field and check both results. Script `code/ch11/09_peculiar_velocities.py` draws 4 boxes of side $1000\,h^{-1}$Mpc with 256^3 cells, using the grid conventions of Section 7.4.1, and computes the velocity from the Fourier form of the key idea:

Listing 11.13: Velocity components from a Gaussian density field, and their one- and two-point averages (`code/ch11/09_peculiar_velocities.py`)

```
103         w = rng.standard_normal((N, N, N))
104         dk = np.fft.rfftn(w) * amp                  # delta_k / D^3 in the lib_lss convention
105         vx = np.fft.irfftn(1j * H100 * f * KX * inv_k2 * dk, s=(N, N, N), axes=(0, 1, 2))
106         vy = np.fft.irfftn(1j * H100 * f * KY * inv_k2 * dk, s=(N, N, N), axes=(0, 1, 2))
107         var_meas.append(0.5 * (vx.var() + vy.var()))
108         par_meas.append([np.mean(vx * np.roll(vx, -n, axis=0)) for n in nsep])
109         perp_meas.append([np.mean(vy * np.roll(vy, -n, axis=0)) for n in nsep])
110         hist_v.append(vx[::4, ::4, ::4].ravel().copy())
```

Line 104 colours white noise with $\sqrt{P(k)}$, which makes `dk` the Fourier transform of a Gaussian field with spectrum P on the grid. Lines 105–106 multiply by $iaHf\,k_x/k^2$ and $iaHf\,k_y/k^2$ (with $aH = 100$ and $1/k^2$ set to zero for the $\boldsymbol{k} = 0$ mode) and transform back: these are u_x and u_y in km/s. Line 107 records the one-point variance. Lines 108–109 shift the field along x by n cells

and average the products: u_x with u_x is $\psi_\parallel$ at separation $n \times 1000/256\,h^{-1}$Mpc, and u_y with u_y is $\psi_\perp$.

The theory to compare with is (11.96) restricted to the modes the box contains: the integral over $\boldsymbol{k}$ becomes a sum over the grid modes, divided by the volume (Section 7.4.1). It gives $\sigma_{v,1D} = 302\,\mathrm{km/s}$; the boxes give 298 ± 5, where the $\pm$ is the box-to-box scatter. Both are below the 308 of the full integral because the box has no waves longer than $1000\,h^{-1}$Mpc, and Figure 11.40 showed that such waves carry a few per cent of σ_v^2. The histogram of u_x is Gaussian, and the correlation functions follow the grid-mode sums (Figure 11.41). The points at large separations sit a little below the curves, by about one box-to-box scatter: with four boxes, the longest waves are sampled only a handful of times, which is the sample variance of Section 7.5.2 acting on a quantity dominated by large scales.

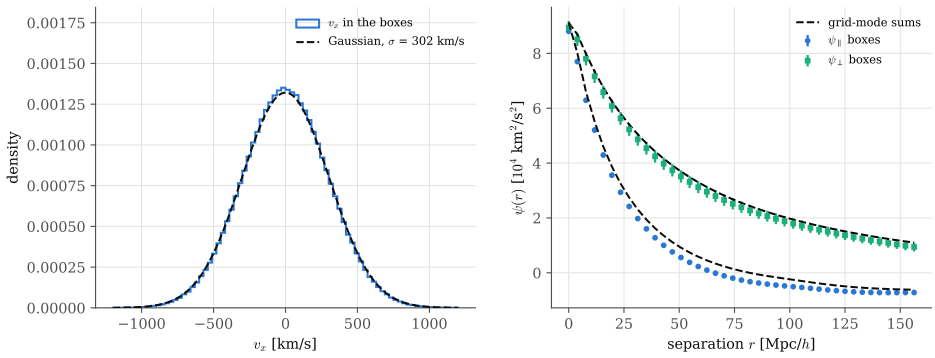

Figure 11.41: Velocities in Gaussian boxes. Left: the distribution of one velocity component against a Gaussian of the predicted width. Right: the two velocity correlation functions measured in the boxes (points, with the error of the mean of four boxes) and the corresponding sums over the box's Fourier modes (dashed).

The lesson. Peculiar velocities are the gradient of a potential sourced by the density contrast; that makes them Gaussian, about 300 km/s along a line of sight today, and coherent over a hundred megaparsecs, because they are made by longer waves than the densities are.

11.16 The local flow: falling towards Virgo

Four of Hubble's twenty-four galaxies were in the Virgo cluster, the nearest rich cluster, a few hundred galaxies at about 16 Mpc. A mass of that size pulls on everything around it, us included. Galaxies between us and Virgo are pulled away from us, towards the cluster; galaxies beyond it are pulled towards us. We ourselves fall towards Virgo, so every velocity we measure is measured from a moving platform. A measurement of H_0 from nearby galaxies that ignores all this fits a straight line to a pattern that is not straight. The linear velocity field of Section 11.15 turns the pattern into a model with one extra parameter, our infall speed, which can be fitted together with H_0.

Where we have met H_0 before. Every fit of H_0 so far treated peculiar velocities as noise. The mock supernovae of Section 3.17.1, made with $H_0 = 70$, carried independent Gaussian velocities of 300 km/s, and Hubble's twenty-four nebulae (Section 11.14) left residuals of 200 to 230 km/s that we fitted as an independent scatter, with only the Sun's motion modelled, as a dipole. The real ladder of Section T2.12 avoids the problem rather than modelling it: its Hubble-flow supernovae start at $z = 0.023$, about 7000 km/s, where a velocity of 250 km/s shifts a distance modulus by less than 0.1 mag (T2.99). Here the galaxies lie within 30 Mpc, where the whole

recession is at most a couple of thousand km/s and a coherent infall of 200 km/s is not small, so the velocities move from the noise into the model. The estimator is the same weighted least squares, now with two columns, H_0 and the infall speed, and the data are mock again, made with $H_0 = 70$ as in Section 3.17, so the question is once more whether a fit recovers a known truth. The low value it returns when the infall is ignored is therefore not a third measurement to set beside 73.04 and 67.36: it is the size of an omitted-variable bias, a measure of how far a local fit can miss without a model of the flow.

The question.

1. What velocity field does linear theory predict around a spherical overdensity?
2. What does an observer who is falling into it measure for the radial velocities of galaxies around them?
3. Can H_0 and the infall speed be fitted together from a local sample, and what goes wrong if the infall is ignored, or if the distances are poor?
4. How fast does the Local Group move with respect to the CMB, and how much of that is Virgo?

11.16.1 Infall around a spherical overdensity

Take a density contrast δ that is spherically symmetric about a centre, the cluster. Let $\boldsymbol{R}$ be the vector from the centre to a point, $R = |\boldsymbol{R}|$, and $\bar{\delta}(<R)$ the mean contrast inside the sphere of radius R. By symmetry the linear velocity $\boldsymbol{u}$ of Section 11.15.2 points along $\pm\hat{\boldsymbol{R}}$ and its size u_R depends only on R. Integrate the continuity equation (V1), $\nabla\cdot\boldsymbol{u} = -aHf\,\delta$, over the ball of radius R:

$$4\pi R^2\, u_R(R) \overset{(1)}{=} \oint_{|\boldsymbol{R}'|=R} \boldsymbol{u}\cdot \mathrm{d}\boldsymbol{S} \overset{(2)}{=} \int_{|\boldsymbol{R}'|<R} \nabla\cdot\boldsymbol{u}\;\mathrm{d}^3R' \overset{(3)}{=} -aHf\,\frac{4\pi}{3}R^3\,\bar{\delta}(<R),$$

$$u_R(R) = -\frac{aHf}{3}\,\bar{\delta}(<R)\,R. \tag{11.100}$$

(1) The velocity is radial and has the same size everywhere on the sphere, so the flux is u_R times the area.
(2) The divergence theorem.
(3) (V1), and the definition of the mean contrast: $\int_{<R}\delta\,\mathrm{d}^3R' = \frac{4\pi}{3}R^3\bar{\delta}(<R)$.

This is Newton's shell theorem in the language of velocities: only the excess inside R matters. An overdensity ($\bar{\delta}>0$) gives an inflow, a void an outflow. Inside a region of uniform contrast the flow is $-\frac{1}{3}aHf\bar{\delta}\,\boldsymbol{R}$, a change of the local expansion rate by $-\frac{1}{3}f\bar{\delta}$ in units of H: the local-void formula (T2.108), which we derived for the H_0 tension in Section T2.12 and will meet again in Section 11.17.

A power-law cluster. Around a cluster the mean contrast falls with radius. Model it as a power law, $\bar{\delta}(<R)\propto R^{-2}$, the shape used in classical models of the Virgocentric flow [220]. Then (11.100) gives a speed that falls as $1/R$. We name the constant by the infall speed of the Local Group, which sits at $R = d_V$, the distance of Virgo:

$$\boldsymbol{u}(\boldsymbol{x}) = -v_{\mathrm{inf}}\,\frac{d_V}{R}\,\hat{\boldsymbol{R}}, \qquad v_{\mathrm{inf}} = \frac{H_0 f}{3}\,\bar{\delta}(<d_V)\,d_V. \tag{11.101}$$

Example: how overdense is our neighbourhood? Literature values of our infall into Virgo lie around 200 km/s. With $H_0 = 70$, $f = 0.53$ and $d_V = 16.5$ Mpc, (11.101) gives $\bar{\delta}(< d_V) = 3 \times 200/(70 \times 0.53 \times 16.5) \approx 1.0$: the sphere centred on Virgo and reaching out to us contains about twice the mean density. A contrast of order one is the edge of linear theory. The model is good for the general shape of the flow and its dependence on H_0; it is not accurate near the cluster, where $\bar{\delta} \gg 1$, and we exclude galaxies closer than 5 Mpc to the centre.

11.16.2 What a falling observer sees

We sit at the origin and move with the Local Group. A galaxy at position $\boldsymbol{x}$, at distance $r = |\boldsymbol{x}|$ in the direction $\hat{\boldsymbol{r}}$, moves with the Hubble flow, $H_0\boldsymbol{x}$ relative to us, plus its own peculiar velocity $\boldsymbol{u}(\boldsymbol{x})$. We measure velocities relative to ourselves, and we have peculiar velocity $\boldsymbol{u}(0)$. The radial velocity we record is therefore

$$v_{\rm obs} \overset{(1)}{=} \left[H_0\boldsymbol{x} + \boldsymbol{u}(\boldsymbol{x}) - \boldsymbol{u}(0)\right] \cdot \hat{\boldsymbol{r}} \overset{(2)}{=} H_0 r + v_{\rm inf}\, g(\boldsymbol{x}),$$
$$g(\boldsymbol{x}) \equiv \left[-\frac{d_V}{R}\,\hat{\boldsymbol{R}} - \hat{\boldsymbol{s}}_V\right] \cdot \hat{\boldsymbol{r}}, \qquad \boldsymbol{R} = \boldsymbol{x} - d_V\hat{\boldsymbol{s}}_V. \tag{11.102}$$

(1) Velocities relative to a moving platform are differences; only the radial component is measured from the Doppler shift.

(2) $\boldsymbol{x} \cdot \hat{\boldsymbol{r}} = r$; insert (11.101), and note that at the origin $\boldsymbol{R} = -d_V\hat{\boldsymbol{s}}_V$, with $\hat{\boldsymbol{s}}_V$ the unit vector from us to Virgo, so $\boldsymbol{u}(0) = v_{\rm inf}\hat{\boldsymbol{s}}_V$: we fall towards the cluster.

The function g is fixed by geometry once the position of Virgo is known (Figure 11.42). It has two parts. The second, $-\hat{\boldsymbol{s}}_V \cdot \hat{\boldsymbol{r}}$, is the reflex of our own fall, a dipole on the sky exactly like the solar motion of Section 11.14.2. The first is the pattern of the other galaxies' fall towards the cluster: positive in front of Virgo, where galaxies are pulled away from us, and negative behind it, where they are pulled towards us. Along the line of sight through Virgo the two together give the S-shaped curve in Figure 11.43 (left, red).

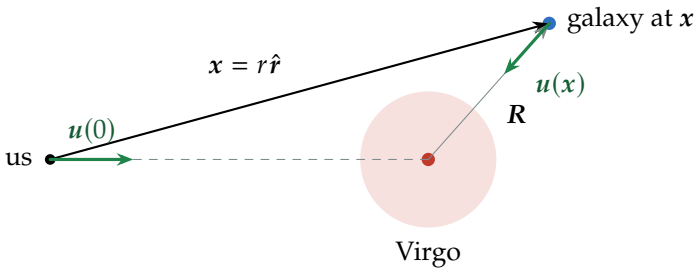

Figure 11.42: The geometry of the Virgocentric flow. Every galaxy, and we ourselves, fall towards the cluster with a speed that falls off as $1/R$. The velocity we record for a galaxy is the radial part of its Hubble velocity plus the difference between its fall $\boldsymbol{u}(\boldsymbol{x})$ and ours $\boldsymbol{u}(0)$.

A model linear in its parameters. Equation (11.102) is linear in the two unknowns $(H_0, v_{\rm inf})$, with known regressors r_i and $g_i = g(\boldsymbol{x}_i)$. It is the solar-motion fit of Section 11.14.2 with a different second column. The noise has two parts. The galaxies' own motions about the smooth flow are small near us: within about ten megaparsecs, galaxies scatter around the local expansion by only some tens of km/s, a surprisingly "cold" flow, and we take $\sigma_{\rm th} = 60$ km/s. The distances carry fractional errors Δ, which by (11.92) add $(H_0\Delta r_i)^2$ to the variance. So the fit is weighted least squares with $w_i = 1/\left(\sigma_{\rm th}^2 + H_0^2\Delta^2 r_i^2\right)$: solve the 2×2 normal equations $A^{\mathsf{T}}WA\,\hat{\boldsymbol{p}} = A^{\mathsf{T}}W\boldsymbol{v}$, with rows (r_i, g_i) in A and $W = \mathrm{diag}(w_i)$, put the new $\hat{H}_0$ into the weights, and repeat until it stops changing; the covariance is $(A^{\mathsf{T}}WA)^{-1}$ (Section 3.10.5).

11.16.3 A simulated local sample

Script `code/ch11/10_virgo_infall.py` places 400 galaxies at random in the volume between 2 and 30 Mpc, outside 5 Mpc of Virgo, which sits at $d_V = 16.5$ Mpc in its true direction on the sky. It gives them velocities from (11.102) with $H_0 = 70$ and $v_{\rm inf} = 200$ km/s, adds the thermal scatter, scatters the distances lognormally, and fits. The observer computes g at the position implied by the *measured* distance, since the true one is unknown.

Listing 11.14: The weighted fit of $(H_0, v_{\rm inf})$, and one mock local sample (`code/ch11/10_virgo_infall.py`)

```
74 def fit(r_obs, g_obs, v, Delta, with_infall=True):
75     """Iterated weighted least squares for (H0, v_inf); returns estimates and covariance."""
76     A = np.column_stack([r_obs, g_obs]) if with_infall else r_obs[:, None]
77     H = 70.0
78     for _ in range(5):
79         w = 1.0 / (SIGTH ** 2 + (H * Delta * r_obs) ** 2)
80         F = A.T @ (w[:, None] * A)
81         p = np.linalg.solve(F, A.T @ (w * v))
82         H = p[0]
83     return p, np.linalg.inv(F)
84
85
86 def mock(rng, Delta, cone=None):
87     x = draw_positions(rng, NGAL, cone)
88     r = np.linalg.norm(x, axis=1)
89     v = H0 * r + VINF * infall_g(x) + rng.normal(0, SIGTH, len(r))
90     r_obs = r * np.exp(Delta * rng.standard_normal(len(r)))
91     # the observer evaluates g at the position implied by the measured distance
92     x_obs = x * (r_obs / r)[:, None]
93     return x, r, v, r_obs, infall_g(x_obs)
```

`fit` builds the two columns, iterates the weights five times and returns the estimate and the inverse of the weighted normal matrix. In `mock`, line 89 is (11.102) plus thermal noise, line 90 scatters the distances by $e^{\Delta\eta}$, and lines 92–93 evaluate g at the measured position.

Good distances. With $\Delta = 0.05$, the precision of distances from the tip of the red giant branch, one mock sample gives $\hat{H}_0 = 69.8 \pm 0.3$ and $\hat{v}_{\rm inf} = 187 \pm 7$ km/s, with a correlation coefficient of 0.61 between the two estimates. Over 2000 mock samples the estimates average 69.84 and 195, and scatter by 0.28 and 7; the error bars from $(A^{\mathsf{T}}WA)^{-1}$ are 0.27 and 7. The fit works, and its errors are right.

Ignoring the infall. Fit the same samples with H_0 alone, as if the flow were pure expansion. The estimates average 65.45 ± 0.38: biased low by more than four km/s/Mpc, sixteen times the statistical error. Where does the bias come from? The omitted term $v_{\rm inf} g_i$ is not zero on average over the sample. Our own fall is a dipole, which averages away over a full sky. The fall of the other galaxies does not: behind Virgo they move towards us, and there is much more volume behind the cluster, out to 30 Mpc, than in front of it. Least squares weights each galaxy by r_i^2, as in (11.91), so these distant infalling galaxies dominate, and the slope comes out low. A sample confined to within 40° of Virgo, as many early studies of the region were, does far worse: the one-parameter fit gives 54.94, while the joint fit on the same samples gives 68.14 ± 0.76.

Poor distances. With $\Delta = 0.2$, the precision of Tully–Fisher distances, the joint fit returns $\hat{H}_0 = 69.73 \pm 0.93$, still close to the truth, but $\hat{v}_{\rm inf} = 145 \pm 25$ km/s, two standard deviations below the true 200. The reason is the regressor: g was computed at the measured position,

which is the true position scattered by 20%. A noisy regressor pulls its coefficient towards zero, the regression dilution of (T2.101). Near Virgo, where g changes fastest with position, the effect is strongest. The same mechanism, galaxies assigned to the wrong place along a line of sight where the density changes rapidly, produces the spurious flows of Section 11.18.

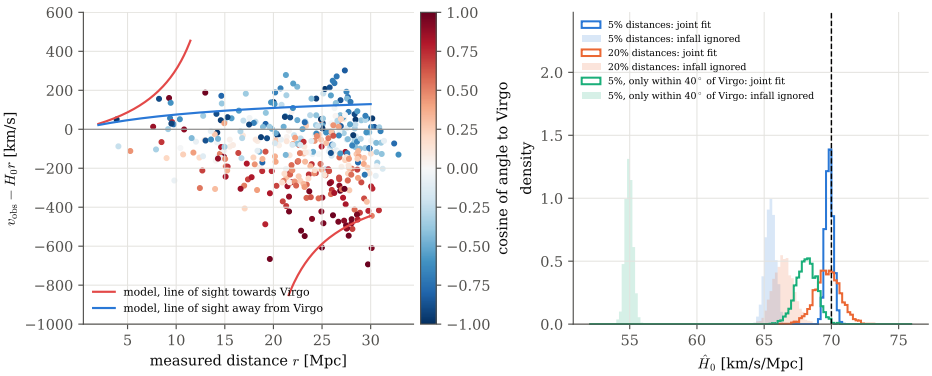

Figure 11.43: Left: one mock local sample with 5% distances. Each point is a galaxy's velocity minus the pure Hubble flow, coloured by the cosine of its angle from Virgo; the curves are the model along the line of sight towards Virgo (red, the S-shape through the cluster) and away from it (blue, mostly the reflex of our own infall). Right: $\hat{H}_0$ over 2000 mock samples, from the joint fit (outlines) and with the infall ignored (filled), for 5% and 20% distances over the whole sky and for 5% distances within 40° of Virgo. The dashed line is the truth.

11.16.4 Our motion through the CMB

There is one frame in which "at rest" has a meaning on cosmological scales: the frame in which the cosmic microwave background looks the same in every direction. An observer moving through it with speed $v = \beta c$ sees the radiation ahead Doppler-shifted to a higher temperature and the radiation behind to a lower one. To first order in β the temperature in a direction at angle θ to the motion is $T(\theta) = T_0(1 + \beta\cos\theta)$ (see the cosmology notes): a pure dipole of amplitude βT_0.

Example: the Sun's speed from the dipole. Planck measures a dipole amplitude of 3362.08 μK and a monopole $T_0 = 2.7255$ K [159, Table 3]. Then $\beta = 3362.08 \times 10^{-6}/2.7255 = 1.2336 \times 10^{-3}$, and $v = \beta c = 369.8$ km/s, towards Galactic longitude and latitude $(l, b) = (264.0°, 48.3°)$: Planck's 369.82 ± 0.11 km/s.

The Sun's velocity is the sum of its motion relative to the Local Group and the Local Group's motion relative to the CMB. The first is measured from the velocities of the Local Group members, as Hubble's solar motion was from his nebulae; Planck adopts 299 ± 15 km/s towards $(98.4°, -5.9°)$ [159, Table 3]. Converting each speed and direction to a vector, with the unit vector $(\cos b\cos l, \cos b\sin l, \sin b)$, and subtracting,

$$\boldsymbol{v}_{\mathrm{LG-CMB}} = \boldsymbol{v}_{\mathrm{Sun-CMB}} - \boldsymbol{v}_{\mathrm{Sun-LG}},$$

gives 620 km/s towards $(272°, 30°)$, which is Planck's 620 ± 15 km/s towards $(271.9°, 29.6°)$. The Local Group moves through the CMB at more than six hundred kilometres per second.

How much of it is Virgo? The direction of Virgo is $(283.8°, 74.5°)$, 45° from the Local Group's motion, so the component of the motion towards Virgo is 437 km/s. An infall of 200 km/s accounts for less than half of that, and subtracting a 200 km/s vector pointing at Virgo leaves 500 km/s pointing elsewhere. That remainder is produced by mass beyond the Local

Supercluster: in the 1980s, the peculiar velocities of elliptical galaxies revealed a large-scale streaming towards a concentration of mass named the Great Attractor [221], and the slow fall-off of the velocity correlation $\psi_\perp$ in Figure 11.40 says that contributions from a hundred megaparsecs and more are expected. Our own velocity is a sum over the whole volume, as (11.95) says it must be.

The lesson. The local flow is a field, not a scatter: modelling the infall into Virgo removes a bias many times larger than the statistical error on H_0, and poor distances bias the infall itself, because the regressor that describes the flow is evaluated at the wrong place.

11.17 How well can a local measurement know H_0?

Every measurement of H_0 from distances and redshifts uses tracers inside some region around us: Hubble's out to a couple of megaparsecs on his scale, the supernovae of the modern distance ladder out to $z \approx 0.15$, some 450 h^{-1}Mpc. Inside that region the matter density is not exactly the cosmic mean, and Section 11.16 showed that a mean contrast inside a sphere changes the expansion rate seen from its centre. So the "local H_0" we measure differs from the global one by an amount that depends on where we happen to live. That amount is random: had we lived elsewhere, it would be different. Its spread over all possible observers is the **cosmic variance** of a local H_0. It sets a floor under every local measurement, no matter how many tracers it uses, and it decides whether the gap between the ladder and the CMB could be the accident of living in an underdense region.

Where we have met H_0 before. The question was first asked in Section T2.12.3. There the ladder's 73.04 ± 1.04 lay 8.4% above Planck's 67.36 ± 0.54, and linear continuity, $\delta H_0/H_0 = -f\delta/3$, said that a void explaining it would have to be almost half empty, $|\delta| \approx 0.45$, over the whole volume of the Hubble-flow supernovae, against an expected scatter of 0.5 to 1% quoted from the literature. The physics here is the same, and so is that relation. What is new is the statistics: there the void was one sphere of chosen depth, here the density is a random field drawn from the CAMB spectrum, the same field that moved the galaxies of Section 11.15 and pulled us towards Virgo in Section 11.16, and the local H_0 is an estimator whose spread over observers we compute rather than quote. The mock samples of Section 3.17 and Section 11.16 asked whether a fit recovers a known $H_0 = 70$ from noisy tracers; here even perfect tracers give a local value that differs from the global one, and the question is by how much. The required depth comes out as 0.48 in Section 11.17.6, not 0.45, only because the gap is kept at 8.4% there instead of being rounded to 8%.

The sentence "the cosmic variance of H_0 inside a sphere of radius R" sounds complete, and is not. It hides a choice: the estimator that turns the tracers' velocities into one number. Two reasonable estimators, applied to the same tracers in the same sphere, have cosmic variances that differ by 12 to 17% at every radius, and two well-known papers quote, in effect, different estimators.

The question.

1. An observer fits H to the radial velocities of tracers inside a sphere of radius R. By how much does the answer differ from the global H_0, as a function of the density field?
2. What is the spread of that difference over observers, for the CAMB spectrum, and how does it depend on R and on the estimator?
3. Do we reproduce the numbers of Wojtak et al. (2014) and Marra et al. (2013)?

4. Could it explain the Hubble tension?

11.17.1 The estimator decides the window

The setup. We sit at the origin. Tracers fill the sphere $|\boldsymbol{x}| < R$ uniformly and densely. Velocities are measured in the frame of the CMB, so our own motion is removed (Section 11.16.4), and tracer i at distance r_i has radial velocity $v_i = H_0 r_i + \boldsymbol{u}(\boldsymbol{x}_i)\cdot\hat{\boldsymbol{r}}_i$, with $\boldsymbol{u}$ the linear velocity field of Section 11.15.2. We assume the distances are exact, so that the only departure from the Hubble law is the flow.

The least-squares slope. The estimator of (11.91) is $\hat{H} = \sum_i v_i r_i / \sum_i r_i^2$. Since $\boldsymbol{u}\cdot\hat{\boldsymbol{r}}\, r = \boldsymbol{u}\cdot\boldsymbol{x}$,

$$\hat{H} - H_0 = \frac{\sum_i \boldsymbol{u}(\boldsymbol{x}_i)\cdot\boldsymbol{x}_i}{\sum_i r_i^2} \;\longrightarrow\; \frac{\int_V \boldsymbol{u}\cdot\boldsymbol{x}\,\mathrm{d}^3x}{\int_V r^2\,\mathrm{d}^3x},$$

where the arrow is the limit of many tracers with uniform number density: each sum becomes the density times an integral over the sphere V, and the density cancels.

What could make the numerator nonzero? Only the divergence of the flow, as we now show. The product rule gives $\nabla\cdot(r^2\boldsymbol{u}) = r^2\,\nabla\cdot\boldsymbol{u} + 2\,\boldsymbol{u}\cdot\boldsymbol{x}$, since $\nabla r^2 = 2\boldsymbol{x}$. So

$$\begin{aligned}
\int_V \boldsymbol{u}\cdot\boldsymbol{x}\,\mathrm{d}^3x &\overset{(1)}{=} \frac{1}{2}\Big[\oint_{r=R} r^2\,\boldsymbol{u}\cdot\mathrm{d}\boldsymbol{S} - \int_V r^2\,\nabla\cdot\boldsymbol{u}\,\mathrm{d}^3x\Big] \overset{(2)}{=} \frac{1}{2}\int_V \big(R^2 - r^2\big)\,\nabla\cdot\boldsymbol{u}\,\mathrm{d}^3x \\
&\overset{(3)}{=} -\frac{H_0 f}{2}\int_V \big(R^2 - r^2\big)\,\delta\,\mathrm{d}^3x, \\
\frac{\hat{H} - H_0}{H_0} &\overset{(4)}{=} -\frac{f}{2}\,\frac{5}{4\pi R^5}\int_V \big(R^2 - r^2\big)\,\delta\,\mathrm{d}^3x \overset{(5)}{=} -\frac{f}{3}\,\delta_W, \qquad \delta_W \equiv \int \mathrm{d}^3x\; W_{\rm LS}(\boldsymbol{x})\,\delta(\boldsymbol{x}).
\end{aligned} \tag{11.103}$$

(1) Integrate the product rule over V and use the divergence theorem on $\nabla\cdot(r^2\boldsymbol{u})$.
(2) On the surface $r = R$, so $r^2 = R^2$ comes out, and $\oint \boldsymbol{u}\cdot\mathrm{d}\boldsymbol{S} = \int_V \nabla\cdot\boldsymbol{u}\,\mathrm{d}^3x$ by the divergence theorem again.
(3) The continuity equation (V1) of Section 11.15.2 today, $a = 1$, $H = H_0$.
(4) Divide by $\int_V r^2\mathrm{d}^3x = 4\pi\int_0^R r^4\mathrm{d}r = 4\pi R^5/5$ and by H_0.
(5) Define the normalised **window** $W_{\rm LS}(\boldsymbol{x}) = \frac{15}{8\pi R^5}(R^2 - r^2)$ for $r < R$ and zero outside. Its integral is $\frac{15}{8\pi R^5}\,4\pi\big(\frac{R^5}{3} - \frac{R^5}{5}\big) = 1$, so $\int_V (R^2 - r^2)\delta = \frac{8\pi R^5}{15}\delta_W$, and $\frac{f}{2}\cdot\frac{5}{4\pi R^5}\cdot\frac{8\pi R^5}{15} = \frac{f}{3}$.

Key idea: The local Hubble rate measures a weighted density

To linear order, a local estimate of H_0 is off by $\delta H/H_0 = -\frac{1}{3}f\,\delta_W$, where δ_W is the density contrast averaged with a window set by the estimator. For the least-squares slope through the origin the window is $\propto R^2 - r^2$ inside the sphere: the sphere's centre counts most.

The surprise is the shape. One might have guessed that the least-squares slope, which weights each tracer by r_i^2 and so favours the distant ones, measures the density near the edge. It measures the opposite. A tracer at the edge feels the mass inside it; a tracer near the centre feels the mass inside its own smaller sphere; the mass near the centre is felt by every tracer, so it accumulates the largest weight.

Other estimators, other windows. Averaging the individual ratios v_i/r_i, the **mean of ratios** $\hat{H} = N^{-1}\sum_i v_i/r_i$, goes the same way with $\boldsymbol{u}\cdot\boldsymbol{x}/r^2 = \boldsymbol{u}\cdot\nabla\ln r$ in place of $\boldsymbol{u}\cdot\boldsymbol{x}$, and the product rule for $\nabla\cdot(\boldsymbol{u}\ln r)$ gives the window $W_{\rm MR} = \frac{9}{4\pi R^3}\ln(R/r)$, even more concentrated at the centre (it diverges there, slowly). And if all tracers sat on the surface $r = R$, the slope would be $u_R(R)/R$, which by (11.100) is $-\frac{1}{3}H_0 f\,\bar{\delta}(<R)$: the mean contrast inside the sphere, a uniform

top-hat window $W_{\rm TH} = 3/(4\pi R^3)$. This is the "Hubble bubble" of Marra et al. and the local-void example of Section T2.12. All three share the same $-\frac{1}{3}f$; they differ only in the window (Figure 11.44, left).

11.17.2 From the window to the variance

The contrast δ_W is a linear functional of a Gaussian field, so it is Gaussian with mean zero and variance $\langle\delta_W^2\rangle = \int \frac{\mathrm{d}^3k}{(2\pi)^3} P(k)\,|\tilde W(\boldsymbol{k})|^2$, where $\tilde W$ is the Fourier transform of the window (Section 7.6, where the same step gave σ_8). For a spherical window $\tilde W(k) = 4\pi\int_0^R W(r)\,r^2 j_0(kr)\,\mathrm{d}r$, the angular integral being the one that gave j_0 in Section 11.15.4. So

$$\sigma^2\!\left(\frac{\delta H}{H_0}\right) = \left(\frac{f}{3}\right)^2 \frac{1}{2\pi^2}\int_0^\infty \mathrm{d}k\; k^2 P(k)\,\tilde W^2(kR). \tag{11.104}$$

The transform of the parabolic window. We need one identity for spherical Bessel functions, $\frac{\mathrm{d}}{\mathrm{d}x}\big[x^{n+1}j_{n+1}(x)\big] = x^{n+1}j_n(x)$. For $n=0$: $x^2 j_1 = \sin x - x\cos x$, whose derivative is $x\sin x = x^2 j_0$. For $n=1$: $x^3 j_2 = (3-x^2)\sin x - 3x\cos x$, whose derivative is $-2x\sin x + (3-x^2)\cos x - 3\cos x + 3x\sin x = x\sin x - x^2\cos x = x^3 j_1$. With $x = kr$, $X = kR$,

$$\begin{aligned}
\int_0^R (R^2-r^2)r^2 j_0(kr)\,\mathrm{d}r &\overset{(1)}{=} \frac{1}{k^5}\int_0^X (X^2-x^2)x^2 j_0(x)\,\mathrm{d}x \\
&\overset{(2)}{=} \frac{1}{k^5}\Big[X^2\cdot X^2 j_1(X) - \Big(X^4 j_1(X) - 2\int_0^X x^3 j_1(x)\,\mathrm{d}x\Big)\Big] \\
&\overset{(3)}{=} \frac{2X^3 j_2(X)}{k^5}, \\
\tilde W_{\rm LS}(kR) &\overset{(4)}{=} 4\pi\,\frac{15}{8\pi R^5}\,\frac{2X^3 j_2(X)}{k^5} = \frac{15\,j_2(kR)}{(kR)^2}.
\end{aligned} \tag{11.105}$$

(1) Substitute $r = x/k$: $R^2 - r^2 = (X^2-x^2)/k^2$ and $r^2\mathrm{d}r = x^2\mathrm{d}x/k^3$.
(2) The first term is the $n=0$ identity integrated. For the second, integrate $x^2\cdot x^2 j_0$ by parts, with $x^2 j_1$ as the antiderivative of $x^2 j_0$.
(3) The $X^4 j_1$ terms cancel, and the $n=1$ identity integrates $x^3 j_1$ to $X^3 j_2$.
(4) Multiply by 4π and the normalisation of $W_{\rm LS}$; $X^3/(R^5k^5) = 1/X^2$.

A check: for small X, $j_2(X) \approx X^2/15$, so $\tilde W_{\rm LS} \to 1$, as a normalised window must. The same steps give $\tilde W_{\rm TH} = 3j_1(kR)/(kR)$ (only the $n=0$ identity) and, integrating $\ln(R/r)$ by parts, $\tilde W_{\rm MR} = 9\big[\mathrm{Si}(kR) - \sin kR\big]/(kR)^3$, with Si the sine integral. Figure 11.44 (right) shows that the more a window concentrates at the centre, the further out in k its transform reaches, and the more small-scale power it lets into the variance.

Example: the numbers. Script `code/ch11/11_local_h0_variance.py` evaluates (11.104) with the CAMB spectrum and $f = 0.527$. At $R = 50\,h^{-1}$Mpc the rms of $\delta H/H_0$ is 2.73% for the top hat, 3.31% for the least-squares slope and 3.72% for the mean of ratios; at $100\,h^{-1}$Mpc, 1.17, 1.45 and 1.67%. The least-squares value falls to 0.83% at 150 and 0.28% at $300\,h^{-1}$Mpc, roughly as $R^{-1.5}$ (Figure 11.45, left). A percent-level local H_0 needs tracers out to at least $100\,h^{-1}$Mpc.

11.17.3 Checking the window on Gaussian boxes

The derivation used two idealisations: a continuum of tracers and the linear velocity field. The second we cannot test with a Gaussian simulation, but the first, and all the algebra, we can. The

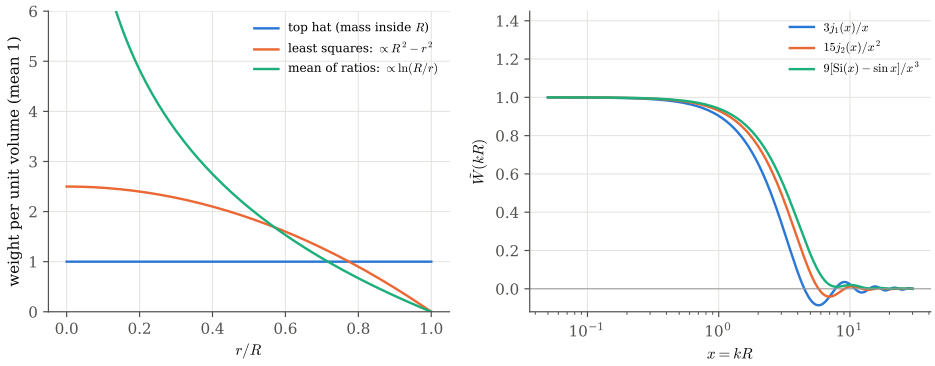

Figure 11.44: The three windows. Left: the weight each estimator gives to the density at radius r inside the sphere, normalised to unit mean over the volume. Right: their Fourier transforms. The parabolic window of the least-squares slope reaches higher k than the top hat, and the logarithmic window of the mean of ratios higher still.

script draws four Gaussian boxes of side 1500 h^{-1}Mpc with 256^3 cells, computes the velocity field as in Section 11.15.5, places 1000 observers at random, and lets each fit the least-squares slope to 3000 tracers inside spheres of five radii.

Listing 11.15: Observers at random positions fit H to tracers inside a sphere (`code/ch11/11_local_h0_variance.py`)

```
        for _ in range(nobs):
            x0 = rng.uniform(0, L, 3)
            for R in Rs:
                rr = R * rng.random(npts) ** (1 / 3)
                mu_ = rng.uniform(-1, 1, npts)
                ph = rng.uniform(0, 2 * np.pi, npts)
                sn = np.sqrt(1 - mu_ ** 2)
                nhat = np.column_stack([sn * np.cos(ph), sn * np.sin(ph), mu_])
                pos = (x0 + rr[:, None] * nhat) % L
                idx = np.floor(pos / D).astype(int) % N
                ur = sum(u[c][idx[:, 0], idx[:, 1], idx[:, 2]] * nhat[:, c] for c in
    range(3))
                meas[R].append(np.sum(ur * rr) / np.sum(rr ** 2) / 100.0)
```

Lines 136–140 draw tracers uniformly in the volume of the sphere: the radius as $R\,U^{1/3}$, so that the number within r grows as r^3, and an isotropic direction. Line 142 finds the cell of each tracer, line 143 takes the radial velocity there, and line 144 is the least-squares slope, divided by 100 km/s per h^{-1}Mpc to give $\delta H/H_0$.

The rms over observers is 3.31, 1.48, 0.86, 0.55 and 0.28% at $R = 50, 100, 150, 200, 300\,h^{-1}$Mpc, against 3.31, 1.45, 0.83, 0.54 and 0.27% from (11.104) summed over the box's modes. The simulation agrees with the prediction to within a few per cent, about what four boxes allow: the observers in one box share its long waves and are far from independent, so the effective number of independent samples is much smaller than 1000. The mean of $\delta H/H_0$ is zero within that scatter: its largest value, 0.16% at $R = 50\,h^{-1}$Mpc, is a small fraction of the 3.31% rms there.

11.17.4 Reproduction: Wojtak et al. (2014)

Their question. By 2013 the supernova measurement of H_0 had a 3% error and differed from Planck's by 2.4σ. Wojtak and collaborators asked how large the scatter of a local H_0 is in a realistic simulated universe, and how much it depends on where the observers sit: at random points, in dark-matter haloes like the one we live in, or in the centres of voids [222].

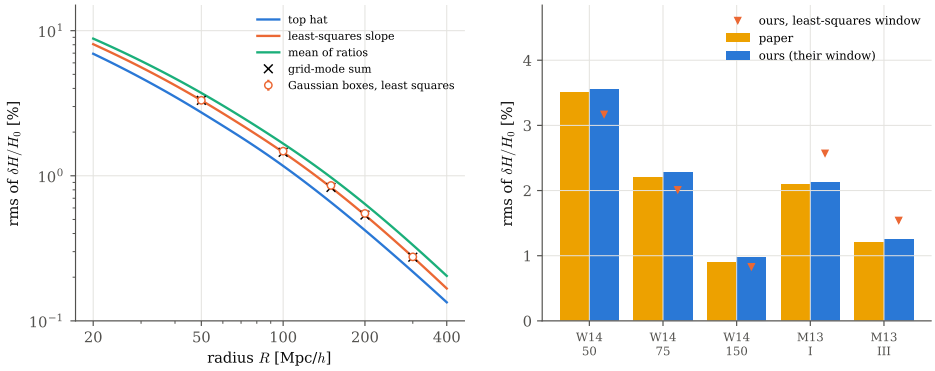

Figure 11.45: Left: the rms deviation of a local Hubble constant from the global one, for the three windows, with the least-squares estimator measured on Gaussian boxes (circles) and the grid-mode sum (crosses). Right: our reproduction of Wojtak et al. (2014) at three radii and of Marra et al. (2013), cases I and III. Orange bars: the paper; blue bars: our calculation with the paper's window; triangles: the same calculation with the least-squares window.

Their setup. An N-body simulation of a $(6\,h^{-1}\mathrm{Gpc})^3$ box in a WMAP-like cosmology ($\Omega_m = 0.27$, $\Omega_b = 0.044$, $h = 0.70$, $\sigma_8 = 0.80$, $n_s = 0.96$), with haloes identified in it. For each of 10^5 observers they fit their eq. (1), $\boldsymbol{u}\cdot\hat{\boldsymbol{r}} + H_0 r = H_{\rm loc} r$, to all haloes within $r_{\rm max}$, with equal weights. Their Table 1 gives the scatter of $H_{\rm loc}/H_0 - 1$ at $r_{\rm max} = 50$, 75 and 150 h^{-1}Mpc, from the simulation and from a linear-theory formula, their eq. (3), with $f = \Omega_m^{0.55}$.

Their equation, derived. Their eq. (3) reads, in our notation,

$$\sigma^2\!\left(\frac{\delta H}{H_0}\right) = \frac{f^2}{2\pi^2 R^2}\int_0^\infty \mathrm{d}k\, P(k)\left[\frac{3(\sin x - \mathrm{Si}\, x)}{x^2}\right]^2, \qquad x = kR.$$

This is (11.104) with the mean-of-ratios window:

$$\left(\frac{f}{3}\right)^2 \frac{1}{2\pi^2}\int \mathrm{d}k\, k^2 P\, \tilde{W}_{\rm MR}^2 \overset{(1)}{=} \frac{f^2}{9}\,\frac{1}{2\pi^2}\int \mathrm{d}k\, k^2 P\, \frac{81(\mathrm{Si}\, x - \sin x)^2}{x^6} \overset{(2)}{=} \frac{f^2}{2\pi^2 R^2}\int \mathrm{d}k\, P\, \frac{9(\sin x - \mathrm{Si}\, x)^2}{x^4}.$$

(1) Insert $\tilde{W}_{\rm MR} = 9(\mathrm{Si}\, x - \sin x)/x^3$.
(2) $k^2/x^6 = 1/(R^2 x^4)$ since $x = kR$; $81/9 = 9$; the square removes the sign.

So the formula they quote describes averaging the ratios u_r/r; the fit they ran on the haloes was the least-squares slope, whose window is the parabola.

What we compute. The CAMB linear spectrum for their cosmology, normalised to $\sigma_8 = 0.80$, and (11.104) with both windows and $f = 0.27^{0.55} = 0.487$.

Side by side.

$r_{\rm max}$ [h^{-1}Mpc]	50	75	150
Wojtak et al., linear theory (their eq. 3)	3.5%	2.2%	0.9%
ours, same formula (mean-of-ratios window)	3.55%	2.28%	0.97%
ours, least-squares window	3.17%	2.01%	0.83%
Wojtak et al., simulation, observers at random points	3.3%	2.1%	0.9%

Why they differ. Our evaluation of their formula agrees with their linear row to within the last digit they quote; the remaining few per cent are what a different transfer function or a rounding of their table would produce. The least-squares window, which is the estimator actually applied to their haloes, gives values 11–14% lower. Their simulation lies between

the two: at 150 h^{-1}Mpc, where linear theory should be good, it is 0.9% against our 0.83%; at 50 h^{-1}Mpc non-linear growth adds variance, and the authors note that voids, which fill most of the volume, push the mean of $H_{\rm loc}$ above H_0 there.

The lesson. "The cosmic variance of H_0 within R" is a property of an estimator, not of the sphere: the same tracers give a 12–17% larger scatter when their ratios are averaged than when a slope is fitted, because the two weight the density near us differently.

11.17.5 Reproduction: Marra et al. (2013)

Their question. In 2013 the local value was 73.8 ± 2.4 km/s/Mpc and the first Planck release gave 67.8 ± 0.8, a gap of $(73.8 - 67.8)/\sqrt{2.4^2 + 0.8^2} = 6.0/2.53 = 2.4$ standard deviations (the variance of a difference of independent measurements is the sum of the variances). Today's values, 73.04 ± 1.04 and Planck's final 67.36 ± 0.54, leave a gap of about the same size in km/s/Mpc but a much smaller error, so the same gap is 4.8 standard deviations (Section 11.20). How much of it can the local gravitational potential absorb, and what systematic error should every local measurement carry for it [223]?

Their setup. A Hubble bubble: a top hat, so that their eq. (1) is $\delta H/H = -\frac{1}{3} f\,\delta$ (in the linear regime, where their non-linear correction Θ equals one), which is (11.100). The contrast inside a sphere of radius R is Gaussian with the top-hat variance σ_R^2 (their eqs. 2–3). The supernovae lie at redshifts between $z_{\rm min}$ and 0.1, and each redshift z is assigned the sphere of comoving radius $R(z)$. The resulting variances are averaged over the redshift distribution $W_{\rm SN}(z)$ of the supernovae:

$$\sigma^2_{H_0} = \int_{z_{\rm min}}^{z_{\rm max}} {\rm d}z\; W_{\rm SN}(z) \left(\frac{f}{3}\right)^2 \sigma^2_{R(z)} \qquad \text{(their eq. 5)}.$$

Their Table I gives 2.1% for $z_{\rm min} = 0.010$ (case I) and 1.2% for $z_{\rm min} = 0.023$ (case III).

Their equation, derived. σ_R^2 is (11.104) without the $(f/3)^2$ and with $\tilde{W}_{\rm TH}$; eq. (5) is the variance of $\delta H/H$ averaged over the redshifts of the supernovae, each probing the sphere out to its own distance.

What we compute. The one input not given in the paper is $W_{\rm SN}(z)$. They state its medians: 0.025 for $z_{\rm min} = 0.010$ and 0.033 for $z_{\rm min} = 0.023$. A lognormal distribution in z, truncated to $[z_{\rm min}, 0.1]$, has two parameters, and the two medians fix them: median 0.0245 and logarithmic width 0.50 before truncation. We use the Planck 2018 spectrum rather than their Planck 2013 one; the matter densities differ by 2%.

Side by side. Case I: 2.13% against their 2.1%. Case III: 1.25% against 1.2%. With the least-squares window instead of the top hat the same averages would be 2.57% and 1.54%.

Why they differ. At the quoted precision they do not; our $W_{\rm SN}$ is a reconstruction, and a different shape with the same medians would move the results by a few hundredths of a per cent.

The lesson. A two-line linear-theory calculation, with the supernova distribution rebuilt from two quoted medians, reproduces the published systematic floor; the floor is about 1% once the nearest supernovae are excluded.

How this is used in real research

The Gaussian boxes *verify* (11.104): they check an analytic result in the regime where it should hold exactly. Wojtak et al.'s N-body simulation is the *research instrument*. It answers what no formula can: the scatter when observers live in haloes rather than at random points (lower $H_{\rm loc}$, because haloes sit in infall regions), when velocities are measured relative to the halo rather than the CMB, and when non-linear voids dominate the small spheres. The

same division of labour runs through the book: closed forms where they exist, checked by simulation; simulation alone where they do not (Chapter 6).

11.17.6 Could we live in a hole?

The ladder value 73.04 exceeds Planck's 67.36 by 8.4%. To produce that by (11.103), the density averaged over the ladder's window would need $\delta_W = -3 \times 0.084/f = -0.48$: a region half empty out to hundreds of megaparsecs, as Section T2.12 estimated. How unlikely is that? The ladder uses supernovae between $z = 0.023$ and 0.15. With Marra's distribution extended to $z_{\max} = 0.15$, the averaged scatter is 1.25% for the top hat and 1.54% for the least-squares window, so the gap is 5.5 standard deviations of the larger one. For a Gaussian, a fluctuation of more than five standard deviations in one direction has probability below 3×10^{-7}. A lognormal density field makes deep voids somewhat more probable than a Gaussian, as Marra et al. show, and observers at the centres of the ten largest voids in Wojtak et al.'s simulation see $H_{\rm loc}$ about 5% high out to $100\,h^{-1}$Mpc, falling to 1% at $200\,h^{-1}$Mpc; but at the ladder's distances both effects fall far short. Cosmic variance is a real systematic error of order 1% and should be in every local error budget [100, Sec. IV.F]; it is not the explanation of the Hubble tension.

11.18 Where is a galaxy whose distance we measured? Malmquist bias

A distance indicator such as the Tully–Fisher relation is calibrated so that it is right on average: take many galaxies at the same true distance r, measure them, and the logarithms of their inferred distances average to $\ln r$. The plain claim that follows seems harmless: *an unbiased indicator gives unbiased distances.* The everyday question it answers is: *if I take all the galaxies that my indicator places at distance d, are they on average at distance d?*

The question contains a hidden assumption. "Unbiased" was established by averaging over galaxies at a fixed *true* distance. The question averages over galaxies at a fixed *inferred* distance. Those are two different sampling rules, and they select two different sets of galaxies. The galaxies that end up labelled d came from a range of true distances, and how many came from each depends on how many galaxies there were at each true distance to begin with. In a uniform universe there are more galaxies at larger distances, simply because a shell of larger radius has more volume, so more of them scatter *in* to d from beyond than from in front. Near a cluster, where the number of galaxies changes rapidly along the line of sight, the effect is larger and changes sign from one side of the cluster to the other. Read as peculiar velocities, the mislabelled distances produce flows that do not exist. We met the first sign of this in Section 11.16.3, where poor distances weakened the fitted infall towards Virgo.

This is the **inhomogeneous Malmquist bias**. It is a cousin of the classical Malmquist bias of Section T2.13, where a flux limit selected the unusually bright objects; here no selection is needed at all.

The question.

1. Given an inferred distance d, what is the probability distribution of the true distance r?
2. What is the mean true distance $E(r \mid d)$ in a uniform universe, and near a density gradient?
3. Does a simulated line of sight through a cluster reproduce the bias found by Strauss and Willick?

4. What does the bias do to inferred peculiar velocities, and how should a peculiar velocity be estimated from a lognormal distance?

11.18.1 The distribution of the true distance

Inputs.

(M1) *Physical: lognormal errors.* For a galaxy at true distance r, the inferred distance is $d = re^{\Delta\eta}$ with $\eta \sim \mathcal{N}(0,1)$. A magnitude error σ in a distance modulus is a fractional distance error $\Delta = (\ln 10/5)\sigma \approx 0.46\sigma$, so 0.35 mag gives $\Delta = 0.161$.

(M2) *Physical: galaxies along the line of sight.* In a narrow cone around the line of sight, the number of galaxies between r and $r + \mathrm{d}r$ is proportional to $r^2 n(r)\,\mathrm{d}r$, with $n(r)$ their number density.

(M3) *Selection does not depend on the true distance.* Galaxies enter the sample through observed quantities (an apparent size, a line width) whose selection is the same at every true distance. Strauss and Willick show that the selection then cancels from what follows [224, Sec. 6.5.2]; when it does not, the classical Malmquist bias of Section T2.13 appears on top.

The event. Our indicator says "d". *What could have produced it?* Any true distance r: a galaxy at r produces the label d if its error happened to be $\eta = \ln(d/r)/\Delta$. *How probable was the label under each candidate?* By (M1), the density of d given r is lognormal, $p(d \mid r) = \exp\left[-\ln^2(d/r)/2\Delta^2\right]/(\sqrt{2\pi}\,\Delta\, d)$. *Only then the prior*: how many galaxies were at r to begin with, $r^2 n(r)$ by (M2). Bayes' theorem (5.5) puts them together:

$$p(r \mid d) = \frac{r^2 n(r)\, \exp\left[-\ln^2(r/d)/2\Delta^2\right]}{\int_0^\infty \mathrm{d}r'\, r'^2 n(r')\, \exp\left[-\ln^2(r'/d)/2\Delta^2\right]}, \qquad E(r \mid d) = \int_0^\infty r\, p(r \mid d)\, \mathrm{d}r. \tag{11.106}$$

The factor $1/d$ and the constants of the lognormal cancel between numerator and denominator, and the square of $\ln(d/r)$ equals that of $\ln(r/d)$. This is eq. (182) of Strauss and Willick, and the mean is their eq. (183). It depends on the density all along the line of sight, wherever the lognormal reaches: the bias at d is not a local property of the point d.

11.18.2 A uniform universe, and a slowly varying one

Uniform density. Let n be constant and change variable to $y = \ln r$, so $\mathrm{d}r = r\,\mathrm{d}y$ and the prior $r^2\mathrm{d}r$ becomes $r^3\mathrm{d}y = e^{3y}\mathrm{d}y$. Then

$$p(y \mid d) \overset{(1)}{=\!\propto} e^{3y} \exp\left[-\frac{(y - \ln d)^2}{2\Delta^2}\right] \overset{(2)}{=\!\propto} \exp\left[-\frac{\left(y - \ln d - 3\Delta^2\right)^2}{2\Delta^2}\right],$$
$$E(r \mid d) \overset{(3)}{=} E\left(e^y \mid d\right) \overset{(4)}{=} \exp\left(\ln d + 3\Delta^2 + \frac{\Delta^2}{2}\right) = d\, e^{7\Delta^2/2}. \tag{11.107}$$

(1) (11.106) with n constant, written in y; $\ln(r/d) = y - \ln d$.

(2) Complete the square: $3y - \frac{(y-\ln d)^2}{2\Delta^2} = -\frac{(y-\ln d-3\Delta^2)^2}{2\Delta^2} + \text{const}$. So y is Gaussian with mean $\ln d + 3\Delta^2$ and variance Δ^2.

(3) $r = e^y$.

(4) For a Gaussian y with mean m and variance s^2, $E(e^y) = e^{m+s^2/2}$, the lognormal mean of (3.121).

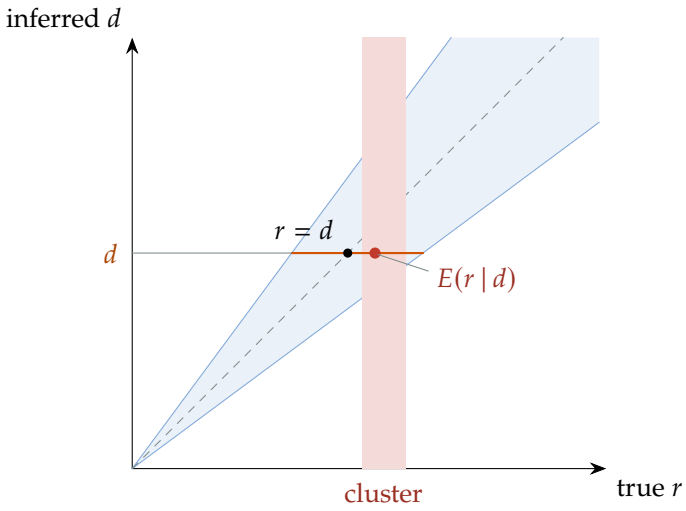

Figure 11.46: Conditioning on the inferred distance. Galaxies at true distance r are scattered vertically into the blue band of inferred distances. Fixing the label d keeps only the horizontal orange segment: the galaxies that could have produced that label. Where the segment crosses the cluster (red strip), there are many more galaxies than elsewhere, so the mean true distance of the galaxies labelled d is pulled towards the cluster.

This is eq. (184) of Strauss and Willick, first derived for galaxy distances by Lynden-Bell et al. [221]. For $\Delta = 0.161$ the factor is 1.095: galaxies labelled d are on average 9.5% farther away. Of the 7/2, three halves come from the volume factor and one half from the asymmetry of the lognormal.

A slowly varying density. If n changes little over the width of the lognormal, approximate it near $r = d$ by a power law, $n(r) \approx n(d)(r/d)^{\gamma}$, with the local logarithmic slope $\gamma(d) = \mathrm{d}\ln n/\mathrm{d}\ln r$ at $r = d$. The prior becomes $e^{(3+\gamma)y}$, the same chain runs with 3 replaced by $3 + \gamma$, and

$$E(r \mid d) \approx d\, e^{(7/2+\gamma)\Delta^2} \approx d\left[1 + \left(\frac{7}{2} + \gamma(d)\right)\Delta^2\right], \tag{11.108}$$

the second form for small Δ^2: Strauss and Willick's eq. (185). In front of a cluster the density rises with distance, $\gamma > 0$, and the bias is larger; behind it, $\gamma < 0$, and the bias is reduced or reversed.

When the approximation fails. A power law must hold across the whole lognormal, from $de^{-\Delta}$ to de^{Δ}, about ±16% of d. A cluster of width 500 km/s at 5000 km/s varies over 10% of its distance, and its $|\gamma|$ reaches 18: (11.108) then predicts corrections of order $\gamma\Delta^2 \approx 0.5$, absurdly large, and the full integral is needed.

11.18.3 Reproduction: Strauss and Willick's line of sight through a cluster

Their question. How large is the Malmquist bias near a realistic density peak, how good is the slowly varying approximation, and does the exact formula (11.106) predict it? [224, Sec. 6.5.2, Fig. 15]

Their setup. One line of sight. A uniform background density plus a Gaussian peak centred at 5000 km/s (distances in velocity units, $H_0 r$), of full width about 1200 km/s and maximum contrast 25. Galaxies follow pure Hubble flow: no true peculiar velocities at all. Distances come from a Tully–Fisher relation with 0.35 mag of scatter. They bin the galaxies in 150 km/s bins of inferred distance and plot the mean true distance in each bin.

Their equations. (11.106), (11.107) and (11.108), derived above, are their eqs. (183)–(185).

What we compute. We read "full width" as the full width at half maximum, which gives a Gaussian of standard deviation 510 km/s, and draw true distances with density $\propto r^2 n(r)$ so that the peak holds about 800 galaxies per 200 km/s bin, as in their upper panel; that makes 13446 galaxies in all. Each is given $d = re^{\Delta\eta}$. The exact curve is (11.106) integrated numerically:

Listing 11.16: The exact mean true distance at given inferred distance (code/ch11/12_malmquist.py)

```
45 def exact_mean(d, rr=np.linspace(RLO, RHI, 20000)):
46     """E(r|d) from the posterior p(r|d) ~ r^2 n(r) p(d|r), p(d|r) lognormal around r."""
47     out = []
48     for dd in np.atleast_1d(d):
49         lik = np.exp(-0.5 * (np.log(dd / rr) / DELTA) ** 2) / dd
50         w = rr ** 2 * n_of_r(rr) * lik
51         out.append(np.trapezoid(rr * w, rr) / np.trapezoid(w, rr))
52     return np.array(out)
```

Line 49 is the lognormal $p(d \mid r)$ on a grid of true distances, line 50 multiplies by the number of galaxies at each r, and line 51 takes the ratio of the first moment to the normalisation.

Side by side. Figure 11.47 has the two panels of their figure, with a third added. The simulated bins follow the exact curve: over the 44 bins with at least five galaxies, $\chi^2 = 66$, where a correct curve gives 44 ± 9. Some realisations give a value on the high side, and that is expected: each error bar is itself estimated from the few galaxies in its bin, and an error bar that comes out too small adds a lot to χ^2. Far from the peak they follow the uniform-density line $de^{7\Delta^2/2}$. In front of the peak, galaxies scattered out of the cluster pile up at smaller inferred distances, so the mean true distance at given d is too large; the excess over the uniform prediction reaches 655 km/s at $d \approx 3256$. Behind the peak the sign reverses, -1185 km/s at $d \approx 6583$. The slowly varying approximation oscillates wildly in between, exactly as theirs does. In their figure the amplitude of the effect is "500–1000 km/s"; ours is in that range in front and slightly larger behind.

Why they differ. Three things are not specified exactly: the width (we assumed FWHM), the number of background galaxies (their sample had a diameter limit, which thins the far background and so their high-d bins), and the scatter of a single realisation. None changes the shape: an S-shaped departure from the uniform-density line, centred on the peak.

The spurious flow. The galaxies have no peculiar velocities. An observer who takes the inferred distance at face value computes $v_{\rm pec} = cz - H_0 d = H_0(r - d)$, and the bottom panel shows what they find: galaxies in front of the peak appear to recede faster than the Hubble flow, galaxies behind it appear to approach. That is exactly the signature of infall onto a mass concentration, the S-shape of Figure 11.43, and its amplitude, hundreds of km/s, is that of a real infall. Uncorrected, the bias makes a peak look more massive than it is, and inflates the infall it is meant to measure. Every velocity analysis must either correct the distances with (11.106), which needs the density field along each line of sight, or work in redshift space, where the flow is modelled and the distances are the noisy data.

The lesson. An indicator that is unbiased at fixed true distance is biased at fixed inferred distance, because conditioning on what we measured reweights the possible true distances by how many galaxies were there.

11.18.4 A peculiar velocity from a lognormal distance

There is a second, smaller trap in $v_{\rm pec} = cz - H_0 d$, even for one galaxy at a known true distance. Take a galaxy in pure Hubble flow at r, so $cz = H_0 r$. Then $v_{\rm pec} = H_0 r\left(1 - e^{\Delta\eta}\right)$, a nonlinear

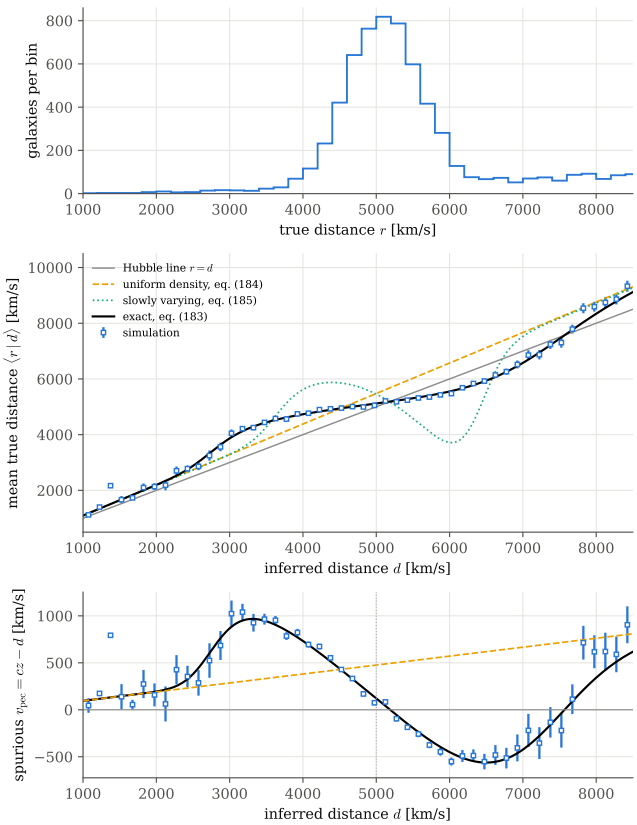

Figure 11.47: A line of sight through a density peak, after Strauss and Willick's Fig. 15. Top: the number of galaxies per 200 km/s bin of true distance. Middle: the mean true distance in 150 km/s bins of inferred distance (squares), with the Hubble line $r = d$, the uniform-density bias, the slowly varying approximation and the exact integral. Bottom: the same as an apparent peculiar velocity $cz - d$ for galaxies that in truth have none; the dotted line marks the peak.

function of the Gaussian η. Its mean is $H_0 r\left(1 - e^{\Delta^2/2}\right) < 0$ and its distribution has a long tail to negative values: at $r = 5000\,\mathrm{km/s}$ the mean is $-64\,\mathrm{km/s}$ and the skewness -0.49. The fix is to estimate the velocity from the logarithm,

$$\hat{v}_{\rm pec} = cz\,\ln\frac{cz}{H_0 d} \;=\; H_0 r\,\ln\frac{r}{d} = -H_0 r\,\Delta\eta,$$

which is linear in η: Gaussian, with mean zero (our simulation gives 2 km/s and skewness 0.00). For small velocities it agrees with $cz - H_0 d$ to first order, since $\ln(1+\epsilon) \approx \epsilon$. This is the estimator of Watkins and Feldman [225], used for the Cosmicflows-4 peculiar velocities [226]. It keeps the noise Gaussian, which is what a likelihood with Gaussian errors assumes; it does nothing about the Malmquist bias, which is a property of the population, not of the estimator.

11.19 Cosmic chronometers: the expansion rate from the ages of galaxies

Every method so far measured a distance. Hubble's slope was wrong because his distance scale was, and (11.93) showed that no fit can see a common error of scale. The modern ladder fixes the scale with geometry, rung by rung (Section T2.12), and the local flows and Malmquist bias of the last three sections are corrections to distances. A completely different route needs no distance at all, only a clock. The Universe expands as it ages, so if we could read the cosmic

time at two nearby redshifts, the rate at which redshift changes with time would give the expansion rate directly. Galaxies that stopped forming stars long ago are such clocks: their stars age passively, and their spectra change in a predictable way as they do.

Where we have met H_0 before. The chronometers first appeared in Section 3.17.6, as 30 mock points spread uniformly over $0.07 < z < 2$, made with $H_0 = 70$ and $\Omega_{m0} = 0.3$, each with an independent 8% error. The weighted ratio (3.139) found H_0 to 1.0 km/s/Mpc at fixed Ω_{m0}, and to about three times worse with Ω_{m0} profiled. The estimator and the profile are the same here; the data are not. The 32 real measurements of Moresco et al. lie mostly below $z = 1$, their errors run from about 5% to over 60% instead of a uniform 8%, and the stellar-population models they share add an error common to all of them, so the covariance is no longer diagonal and the weighted ratio becomes generalised least squares. No truth is supplied: the question is no longer whether the estimator recovers 70 but where the real H_0 lies relative to the ladder's 73.04 ± 1.04 and the CMB's 67.36 ± 0.54, 4.8σ apart (Section T2.12.3). Unlike the ladder, which borrows M (Section 3.17.4), or the CMB (Section 10.6.3) and the inverse ladder (Section T2.15), which borrow a sound horizon, a chronometer borrows only the rate at which a spectrum ages. The error at fixed Ω_{m0} comes out 1.6 rather than 1.0 because, weighted together, the 32 real points carry the information of about a dozen mock points with 8% errors, and the shared model error then adds a floor that no number of points removes.

The question.

1. Why does an age difference measure $H(z)$, and what sets the error of one measurement?
2. With a covariance between the points, what are the estimator of H_0 and its error, and what does a systematic error shared by all the points cost?
3. What do the 32 published measurements give for H_0 in flat ΛCDM, and how does it compare with the CMB and with the ladder?

11.19.1 A clock instead of a ruler

Why ages measure the expansion rate. The redshift of light emitted at cosmic time t and received today is $1 + z = 1/a(t)$, with a the scale factor normalised to one today, and the expansion rate is $H = \dot{a}/a$ (see the cosmology notes). Then

$$\frac{\mathrm{d}z}{\mathrm{d}t} \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{a}\right) \overset{(2)}{=} -\frac{\dot{a}}{a^2} \overset{(3)}{=} -\frac{1}{a}\,\frac{\dot{a}}{a} = -(1+z)\,H(z), \qquad \text{so} \qquad H(z) = -\frac{1}{1+z}\,\frac{\mathrm{d}z}{\mathrm{d}t}. \tag{11.109}$$

(1) $z = 1/a - 1$, and the constant drops out of the derivative.
(2) The chain rule.
(3) Split a^2 and use $1/a = 1 + z$.

This is the starting point of Jimenez and Loeb [227, eq. (2)], and (3.138). Redshift is measured to a part in a thousand or better; the whole difficulty is $\mathrm{d}t$.

What is measured. Take two samples of the most massive galaxies that stopped forming stars early, one at redshift z_1 and one at a slightly larger z_2. If both formed their stars at the same early time, the difference of their stellar ages, Δt, is the cosmic time that elapsed between z_2 and z_1. With $\Delta z = z_2 - z_1$, (11.109) becomes $H(\bar{z}) \approx \Delta z / \left[(1+\bar{z})\,\Delta t\right]$ at the mean redshift $\bar{z}$. Two inputs are hidden in "the difference of their ages is the elapsed time": that the galaxies' clocks started together, and that no new stars were added since. A selection that admits younger galaxies at low redshift breaks the first (the progenitor bias), and a small young component breaks the second; both are checked against the data rather than assumed [228, Sec. 3.1.4].

Why a difference. The absolute age of a stellar population depends on the models used to interpret its spectrum, and different models disagree by a large fraction of a gigayear. An error that shifts both ages by the same amount cancels in Δt. That is the whole point of the differential method: Jimenez and Loeb proposed relative ages precisely because they are far more robust than absolute ones.

Example: the size of the clock signal. At $\bar{z} = 0.4$ in a flat universe with $H_0 = 68$ and $\Omega_{m0} = 0.315$, $H = 68\,E(0.4) \approx 85\,\mathrm{km/s/Mpc}$. The Hubble time $1/H$ is $977.8/85 \approx 11.6\,\mathrm{Gyr}$ ($977.8\,\mathrm{Gyr}$ is $1/(1\,\mathrm{km\,s^{-1}Mpc^{-1}})$). For $\Delta z = 0.1$, $\Delta t = \Delta z/[(1+\bar{z})H] = 0.1/1.4 \times 11.6 \approx 0.83\,\mathrm{Gyr}$. An error of 0.1 Gyr on the age difference is a 12% error on H. Two populations several gigayears old must be dated relative to each other to about a hundred million years.

The ratio, again. H is inversely proportional to Δt, and Δt is the noisy quantity. The inverse of a noisy number is biased: for a fractional error ε, $1/(1+\varepsilon) \approx 1 - \varepsilon + \varepsilon^2$, so the mean of $1/\Delta t$ is high by the fractional variance, 1.5% for a 12% error (Section 3.6.4). The published analyses work with the ages directly; the $H(z_i)$ and their errors that come out are treated as Gaussian, which is what we do too.

A spectral clock. In practice the age is not measured directly. Moresco and collaborators use the strength of the break in the spectrum at 4000 Å, which grows linearly with age for these galaxies, $D_n4000 = A \cdot \mathrm{age} + B$ [229, eq. (2.1)]. Then $\mathrm{d}t = \mathrm{d}D_n4000/A$ and $H = -A\,(1+z)^{-1}\,\mathrm{d}z/\mathrm{d}D_n4000$. The slope A comes from stellar population synthesis models. An error in A multiplies every $H(z)$ measured with the same models by the same factor. Unlike a common shift of the ages, a common error of the slope does not cancel in a difference. It is a scale error, exactly like Hubble's.

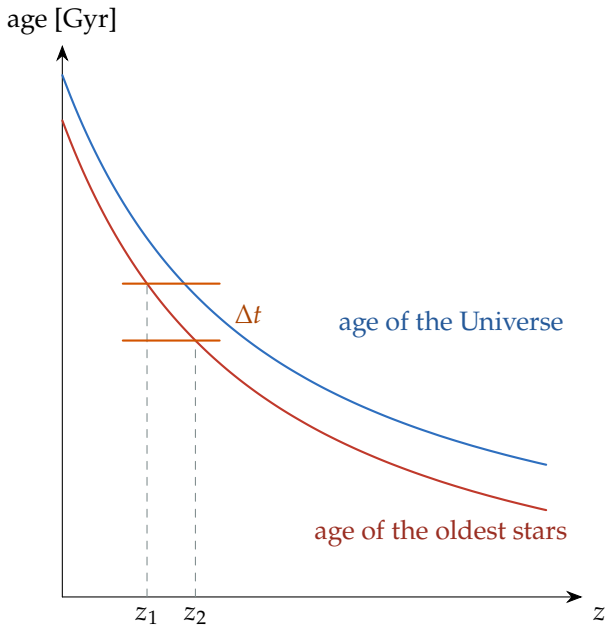

Figure 11.48: The differential-age idea, schematically. Passive galaxies formed their stars soon after the Big Bang, so the age of their oldest stars (red) runs parallel to the age of the Universe (blue). The difference Δt between the ages at two nearby redshifts z_1, z_2 is the cosmic time between them, and $\Delta z/\Delta t$ gives the expansion rate. A model error that shifts both ages by the same amount cancels; an error in the rate at which the spectra age does not.

11.19.2 The estimator with a covariance

A compilation delivers N redshifts z_i, measured rates H_i and a covariance matrix C. In flat ΛCDM the prediction is $H_0 E_i$, with $E_i = E(z_i;\Omega_{m0}) = \sqrt{\Omega_{m0}(1+z_i)^3 + 1 - \Omega_{m0}}$. For Gaussian errors the likelihood is $-2\ln\mathcal{L} = \chi^2 + \text{const}$, with $\chi^2 = (\boldsymbol{H} - H_0\boldsymbol{E})^{\mathsf{T}} C^{-1} (\boldsymbol{H} - H_0\boldsymbol{E})$ (Section 3.10.5). At fixed Ω_{m0}, H_0 enters linearly, so

$$\chi^2(H_0) \overset{(1)}{=} \boldsymbol{H}^{\mathsf{T}} C^{-1} \boldsymbol{H} - 2H_0\, \boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{H} + H_0^2\, \boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{E},$$
$$\hat{H}_0 \overset{(2)}{=} \frac{\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{H}}{\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{E}}, \qquad \operatorname{Var} \hat{H}_0 \overset{(3)}{=} \frac{1}{\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{E}}. \tag{11.110}$$

(1) Expand the quadratic form. The two cross terms are equal because C^{-1} is symmetric: $\boldsymbol{H}^{\mathsf{T}} C^{-1} \boldsymbol{E} = \boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{H}$.
(2) Set $\mathrm{d}\chi^2/\mathrm{d}H_0 = 0$.
(3) $\hat{H}_0$ is a fixed linear combination $\boldsymbol{c}^{\mathsf{T}}\boldsymbol{H}$ with $\boldsymbol{c} = C^{-1}\boldsymbol{E}/(\boldsymbol{E}^{\mathsf{T}} C^{-1}\boldsymbol{E})$, so its variance is $\boldsymbol{c}^{\mathsf{T}} C \boldsymbol{c} = \boldsymbol{E}^{\mathsf{T}} C^{-1} C C^{-1} \boldsymbol{E} / (\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{E})^2$.

For a diagonal C this is the weighted ratio (3.139) and its variance (3.140). It is the same generalised least squares as the distance ladder (T2.106), with one parameter.

A systematic error that every point shares. Suppose the stellar-population slope A is uncertain by a fraction η. Then every rate is off by the same fraction: on top of independent errors with covariance $D = \operatorname{diag}(\sigma_i^2)$ there is a fully correlated part,

$$C = D + \eta^2\, \boldsymbol{m}\boldsymbol{m}^{\mathsf{T}}, \qquad m_i = H_0 E_i,$$

because a common fractional shift $\eta\xi$ (with ξ a standard Gaussian) moves point i by $\eta\xi\, m_i$, and the covariance of two such shifts is $\eta^2 m_i m_j$. What does it cost?

Inverting a matrix plus a rank-one term. For an invertible D and a vector $\boldsymbol{m}$,

$$\left(D + \eta^2 \boldsymbol{m}\boldsymbol{m}^{\mathsf{T}}\right)^{-1} = D^{-1} - \frac{\eta^2\, D^{-1}\boldsymbol{m}\boldsymbol{m}^{\mathsf{T}} D^{-1}}{1 + \eta^2\, \boldsymbol{m}^{\mathsf{T}} D^{-1} \boldsymbol{m}},$$

the Sherman–Morrison formula. To check it, multiply by $D + \eta^2\boldsymbol{m}\boldsymbol{m}^{\mathsf{T}}$ and write $s = \boldsymbol{m}^{\mathsf{T}} D^{-1}\boldsymbol{m}$: the product is $\mathbb{1} + \eta^2\boldsymbol{m}\boldsymbol{m}^{\mathsf{T}} D^{-1} - \eta^2 \boldsymbol{m}\boldsymbol{m}^{\mathsf{T}} D^{-1}(1+\eta^2 s)/(1+\eta^2 s) = \mathbb{1}$. Now let $S = \boldsymbol{E}^{\mathsf{T}} D^{-1} \boldsymbol{E}$, the Fisher information without the systematic. Since $\boldsymbol{m} = H_0 \boldsymbol{E}$,

$$\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{E} \overset{(1)}{=} S - \frac{\eta^2\, (\boldsymbol{E}^{\mathsf{T}} D^{-1} \boldsymbol{m})^2}{1 + \eta^2\, \boldsymbol{m}^{\mathsf{T}} D^{-1} \boldsymbol{m}} \overset{(2)}{=} S - \frac{\eta^2 H_0^2 S^2}{1 + \eta^2 H_0^2 S} \overset{(3)}{=} \frac{S}{1 + \eta^2 H_0^2 S},$$
$$\operatorname{Var} \hat{H}_0 \overset{(4)}{=} \frac{1}{S} + \eta^2 H_0^2. \tag{11.111}$$

(1) Sandwich the Sherman–Morrison formula between $\boldsymbol{E}^{\mathsf{T}}$ and $\boldsymbol{E}$.
(2) $\boldsymbol{E}^{\mathsf{T}} D^{-1} \boldsymbol{m} = H_0 S$ and $\boldsymbol{m}^{\mathsf{T}} D^{-1} \boldsymbol{m} = H_0^2 S$.
(3) Common denominator: $S(1 + \eta^2 H_0^2 S) - \eta^2 H_0^2 S^2 = S$.
(4) Invert and use (11.110).

The same steps applied to $\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{H}$ divide it by the same factor $1 + \eta^2 H_0^2 S$, so the estimate $\hat{H}_0$ itself does not change.

Key idea: A shared fractional error does not average down

If every measurement shares a common fractional error η, the variance of $\hat{H}_0$ is the statistical variance plus $(\eta H_0)^2$. Adding points shrinks the first term as $1/N$ and leaves the second untouched. It is the error of Hubble's distance scale, written as a covariance.

11.19.3 The data, and H_0 from them

Moresco et al. compile 32 measurements of $H(z)$ from cosmic chronometers between $z = 0.07$ and 1.97, obtained with three ways of reading the ages: fitting the full spectrum, Lick absorption indices, and the calibrated 4000 Å break [228, Table 1]. Their errors are the diagonal part of the covariance; the correlated part from the stellar-population models must be added. For that part we use one fully correlated fraction, $\eta = 4.5\%$, the average size of the stellar-population-model term found by Moresco et al. [230]; their recipe gives a separate, redshift-dependent value for each component, which we do not attempt.

Table 11.5: The cosmic-chronometer compilation of Moresco et al. (2022), Table 1: redshift, $H(z)$ and its error in km/s/Mpc.

Script `code/ch11/13_chronometers.py` types in the table and evaluates (11.110) directly:

Listing 11.17: The generalised least-squares estimate of H_0 at fixed Ω_{m0} (`code/ch11/13_chronometers.py`)

```
62 def gls(Hd, om, eta=0.0, H0ref=70.0):
63     """Closed-form GLS estimate of H0 at fixed Om; returns (H0_hat, sigma, chi2_min)."""
64     e = E(z, om)
65     for _ in range(3 if eta > 0 else 1):              # m depends weakly on H0: iterate
66         Ci = np.linalg.inv(cov(om, H0ref, eta))
67         S = e @ Ci @ e
68         h = (e @ Ci @ Hd) / S
69         H0ref = h
70     r = Hd - h * e
71     return h, 1 / np.sqrt(S), r @ Ci @ r
```

Lines 67–68 are (11.110). With the systematic switched on, the vector $\boldsymbol{m}$ in the covariance needs H_0, so lines 65–69 iterate: start from 70, compute $\hat{H}_0$, put it back into $\boldsymbol{m}$. Line 71 returns the estimate, its error $1/\sqrt{\boldsymbol{E}^{\mathsf{T}} C^{-1} \boldsymbol{E}}$ and $\chi^2_{\min}$.

At fixed matter density. With $\Omega_{m0} = 0.315$, $\hat{H}_0 = 68.3 \pm 1.6$ km/s/Mpc from the diagonal errors. With the correlated 4.5%, the estimate stays at 68.3 and the error grows to 3.5, exactly $\sqrt{1.6^2 + (0.045 \times 68.3)^2} = 3.5$ as (11.111) says. The systematic floor, 3.1 km/s/Mpc, is twice the statistical error: more chronometers of the same kind would not help.

Profiling the matter density. Ω_{m0} is not known in advance. At each value on a grid the closed form gives $\hat{H}_0(\Omega_{m0})$ and its $\chi^2_{\min}$, and the profile over Ω_{m0} (Section 3.14) gives $H_0 = 68.1$ with the $\Delta\chi^2 = 1$ interval $[65.1, 71.2]$, and $\Omega_{m0} = 0.32$ in $[0.26, 0.38]$. The interval on H_0 is twice as wide as at fixed Ω_{m0}: the data reach $z \approx 2$, where a higher matter density raises $E(z)$, and a lower H_0 compensates. With the correlated systematic the interval becomes $[63.9, 72.6]$ (Figure 11.49).

The χ^2 is too small. At the best fit, $\chi^2 = 14.6$ for 30 degrees of freedom. If the quoted errors were right and independent, would a χ^2 this small, or even smaller, be something we would reasonably expect? The χ^2_{30} distribution puts only 0.008 of its probability below 14.6 (a lower-tail test of the kind in Chapter 4). The points scatter about the curve by only 0.70 of their error bars. The likely reason is in the errors themselves: the published diagonal errors already include systematic contributions (metallicity, star-formation history), and those are not random from point to point. An honest reading is that the diagonal errors overstate the statistical scatter, and that the H_0 intervals above are, if anything, conservative.

Checking the error bars on mock compilations. The script draws 4000 compilations from $H_0 = 70$, $\Omega_{m0} = 0.315$ with the same redshifts and errors. Without the systematic, the estimates average 69.94 and scatter by 1.58, against 1.57 from (11.110). With a common fractional shift drawn once per compilation, they scatter by 3.48, against 3.52 from (11.111).

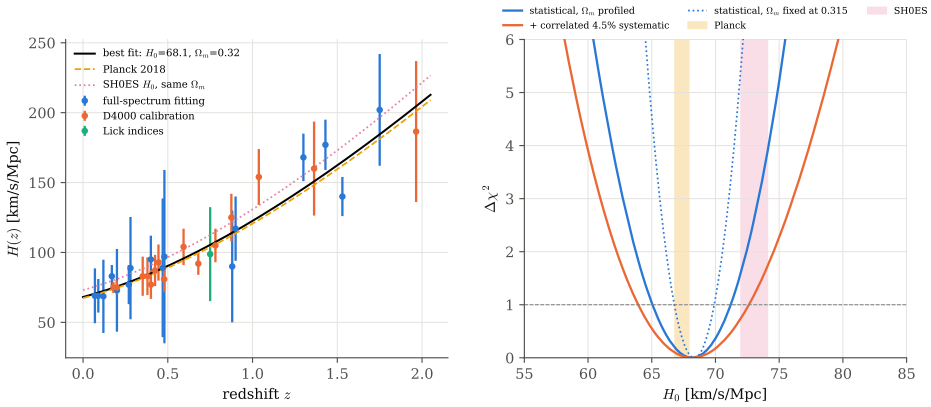

Figure 11.49: Left: the 32 chronometer measurements, coloured by how the ages were read, with the best fit of flat ΛCDM, the Planck 2018 expansion history, and the same history with the SH0ES value of H_0. Right: $\Delta\chi^2$ as a function of H_0 with Ω_{m0} fixed (dotted), profiled (blue), and profiled with the correlated systematic (orange); the bands are Planck and SH0ES at 68%.

Against the CMB and the ladder. Treat the chronometer interval as Gaussian with half-width 3.1 (statistical) or 4.3 (with the systematic). It differs from Planck's 67.36 ± 0.54 by 0.2 standard deviations of the difference and from SH0ES's 73.04 ± 1.04 by 1.5 (1.1 with the systematic), the variance of a difference of independent estimates being the sum of the variances. The chronometers side with the CMB, but at less than two standard deviations from the ladder: on their own they cannot decide the tension, as their compilers note [228, Sec. 3.1.5.1]. What they offer is independence: no distance ladder, and no early-Universe physics.

Three estimators, one structure. The supernova estimator of Section 3.17, Hubble's slope and the chronometer estimator are the same calculation. In each, the parameter enters the model linearly (as a shift of magnitudes, a multiplier of distances, a multiplier of $E(z)$), the

maximum-likelihood estimate is a weighted mean or ratio in closed form, and it sits on the Cramér–Rao bound. And in each, something else enters as a common factor that the fit cannot see: the absolute magnitude of the supernovae (Section 3.17.4), Hubble's distance scale, the stellar-population slope A. The statistics delivers H_0 only in units of a calibration that must come from outside the data.

The lesson. Chronometers measure $H(z)$ with a clock instead of a ruler and give $H_0 = 68.1 \pm 3.1$ km/s/Mpc in flat ΛCDM (±4.3 with the shared model error); their precision is limited not by the number of galaxies but by a shared model error, which a covariance carries and a weighted mean alone would hide.

11.20 One constant, many routes

The Hubble constant has come up in this book as 465, as 70, as 73.04, as 67.36, as 68.1 and as 69.9. Hubble's own slope, Section 11.14, was off from today's by a factor of 6.6, and nobody speaks of a tension about it. The ladder and the CMB differ by 8%, and the disagreement is called a crisis. What separates the two cases? Not the size of the gap. In Hubble's case the error bar was about 10% and the distance scale was unknown; in the modern case the error bars are 1.4% and 0.8%.

So a list of numbers cannot settle anything. For each number we need two answers. First, *what was actually observed, and what had to be brought in from outside to turn it into a value of H_0?* Second, *given the errors, would two such numbers be expected to differ by this much if they measured the same quantity?* The first is physics, and decides which routes can disagree for a reason. The second is statistics, and decides how surprised to be. We take them in that order.

11.20.1 What each route observes, and what it must borrow

H_0 is a velocity per length, km/s per Mpc. A redshift gives the velocity (at low redshift, $v = cz$, up to the peculiar velocities of Section 11.15). The length is never read off the sky. Every route observes something that is not H_0 and combines it with one quantity borrowed from outside the data. Four examples show the pattern, one for each way a length or a time enters.

A brightness, and the true brightness of the candle. The supernovae of Section 3.17.4 observe the apparent magnitude m at redshift z. At low redshift the luminosity distance is $D_L = cz/H_0$, and the distance modulus relates it to the absolute magnitude M of the candle, with D_L in Mpc. Call $\alpha \equiv m - 5\log_{10}(cz)$ the quantity the Hubble-flow supernovae determine:

$$\alpha \overset{(1)}{=} M + 5\log_{10} D_L + 25 - 5\log_{10}(cz) \overset{(2)}{=} M + 25 - 5\log_{10} H_0,$$
$$H_0 \overset{(3)}{=} 10^{(M+25-\alpha)/5}, \qquad \frac{\delta H_0}{H_0} \overset{(4)}{=} \frac{\ln 10}{5}\,\delta M. \tag{11.112}$$

(1) The distance modulus $m = M + 5\log_{10} D_L + 25$, subtracting $5\log_{10}(cz)$ from both sides.
(2) Put $D_L = cz/H_0$: the $5\log_{10}(cz)$ cancels, leaving $-5\log_{10} H_0$.
(3) Solve for H_0, with the observed α fixed.
(4) With α fixed, $\delta \ln H_0 = \ln 10\ \delta \log_{10} H_0 = \ln 10\, \delta M/5$, since $\log_{10} H_0 = (M + 25 - \alpha)/5$.

The data fix the combination $M - 5\log_{10} H_0$ and nothing else, the degeneracy of Section 3.17.4. The absolute magnitude M is the borrowed quantity. It comes from Cepheids anchored by geometry (Section T2.12). A shift of $\delta M = 0.18$ mag moves H_0 by about 8%, the size of the

Hubble tension. Hubble's 465 is the same equation with a wrong M: the distances he assumed, from the brightest stars of each nebula, were short by a factor 6.6 (Section 11.14.5), and $K = sH_0$ for a distance scale off by a factor s.

An angle, and the length of a ruler. A feature of known comoving length r (the sound horizon r_d for baryon acoustic oscillations, r_s at recombination for the CMB peaks) at comoving distance D_M subtends the angle $\theta = r/D_M$. In a flat universe $D_M = c\int_0^z \mathrm{d}z'/H(z') = (c/H_0)\,I(z)$, where $I(z) = \int_0^z \mathrm{d}z'/E(z')$ is a number once the shape of $E(z) = H(z)/H_0$ is fixed. Then

$$\theta \overset{(1)}{=} \frac{r}{D_M} \overset{(2)}{=} \frac{rH_0}{c\,I(z)}, \qquad H_0 \overset{(3)}{=} \frac{c\,I(z)\,\theta}{r}, \qquad \frac{\delta H_0}{H_0} \overset{(4)}{=} -\frac{\delta r}{r}. \tag{11.113}$$

(1) The definition of the subtended angle of a ruler of length r at distance D_M.
(2) Substitute $D_M = cI/H_0$.
(3) Solve for H_0.
(4) Hold the observed θ and the integral I fixed: $\ln H_0 = \ln(cI\theta) - \ln r$.

The borrowed quantity is the ruler r, a length computed from the physics before recombination (Section T2.15). The inverse ladder of Section T2.15 is this equation with $r_d = 147.09\,\mathrm{Mpc}$. For the CMB the integral I also depends on H_0 through $\Omega_{m0} = \omega_m/h^2$ (Section 10.6.3), so H_0 is found by solving $\theta_{\mathrm{MC}} = r_s/D_M$ rather than by rearranging it; the lever on the ruler remains. The CMB borrows a second thing: to carry the result from $z \approx 1100$ to today it assumes the flat ΛCDM expansion history.

A redshift step, and a time step. Chronometers observe the difference Δz between two passively ageing galaxy populations and the difference Δt of their ages, and give $H(z) = -\Delta z/[(1+z)\Delta t]$ (Section 3.17.6); $H_0 = H(z)/E(z)$ then needs the shape of E. The borrowed quantity is the age scale: stellar-population models turn a spectrum into an age, and their error is a common fractional factor $\eta \approx 4.5\%$ (Section 11.19.2). There is no distance in it at all.

A velocity profile, and the flow we are caught in. A fit of velocity against distance in our own neighbourhood needs, besides H_0, the peculiar flow. The joint fit of Section 11.16 recovers H_0 together with the infall speed, which is the borrowed quantity here; the same sample fitted without the infall comes out low. The finite volume adds a random error on top, the cosmic variance of Section 11.17.

The shape they share. Write any route as $H_0 = O/X$, the observable O divided by a borrowed quantity X. Take logarithms: $\ln H_0 = \ln O - \ln X$. If the errors of O and X are independent and small, their variances add:

$$\left(\frac{\sigma_{H_0}}{H_0}\right)^2 = \left(\frac{\sigma_O}{O}\right)^2 + \left(\frac{\sigma_X}{X}\right)^2. \tag{11.114}$$

Observing more supernovae, more galaxies or more acoustic peaks shrinks the first term as $1/N$. The second term is the error on one number that every measurement in the route shares, and it does not shrink at all, as in the shared factor η of Section 11.19.2. The routes differ in which number they borrow, and each route's borrowed number is a different physical quantity with its own independent error. Table 11.6 lists them; Table 11.7 gives the values obtained in the book and in the literature.

Route	Observed	Borrowed from outside	Derived in
Toy Hubble diagram, Hubble 1929	velocities and brightnesses of galaxies	the absolute brightness of the candle (the distance scale)	Sections 3.17 and 11.14
Distance ladder	magnitudes of Cepheids and of Hubble-flow supernovae	M from geometric anchors, one common value across rungs	Sections T2.12 and 3.17.4
CMB	angles and heights of the acoustic peaks	r_s from early-Universe physics, and flat ΛCDM from $z \approx 1100$ to now	Section 10.6.3
BAO, inverse ladder	angle and redshift extent of the baryon feature in galaxy catalogues	r_d, from the CMB or from nucleosynthesis, and the shape of $E(z)$	Sections T2.15 and 11.4.6
Cosmic chronometers	redshift steps and age steps of old galaxies	stellar-population models for the ages ($\eta \approx 4.5\%$)	Sections 3.17.6 and 11.19
Local infall	velocities and distances in our neighbourhood	the infall pattern $v_{\rm inf}\, g(\boldsymbol{x})$	Section 11.16
Local cosmic variance	the density contrast in the volume used	an error floor, not a route	Section 11.17
Combining a chain with a prior on H_0	a posterior sample and a new Gaussian measurement	reweighting, valid only if the two overlap	Section 9.23.1

Table 11.6: The routes to H_0 in the book: what each observes and what it must bring in from outside to become a Hubble constant.

Route	The book's own value	Published value
Toy Hubble diagram, supernovae mock	mock truth 70, recovered at the Cramér–Rao bound	–
Hubble 1929, 24 nebulae	465 ± 56	465 ± 50 (his table, solar-motion solution)
Local infall, mock sample	69.9 ± 0.3 with the infall, 65.5 without	–
Distance ladder	mock truth 73, fit 73.90 ± 1.10	SH0ES: 73.04 ± 1.04
CCHP TRGB ladder	–	69.8 ± 1.7
CMB	Fisher forecast $\sigma = 0.53$ (TT,TE,EE+lowE)	Planck 2018: 67.36 ± 0.54 (0.60 without lensing)
BAO, inverse ladder	69.2 ± 0.9 with the CMB r_d	DESI: 69.29 ± 0.87 (CMB r_d), 68.53 ± 0.80 (BBN r_d)
Cosmic chronometers	68.1 ± 3.1 (±4.3 with η)	–
Chain of Section 9.23.1	67.06 ± 0.93	–

Table 11.7: The values of H_0 in km/s/Mpc. A mock value is a number the script was told to find and then found, not a measurement. The BAO and CMB values share the sound horizon when the CMB r_d is used, and are not independent.

11.20.2 Is the gap too big? The same gap in three sets of error bars

Two routes give $H_A \pm \sigma_A$ and $H_B \pm \sigma_B$, and the errors are independent. Suppose both measure the same constant. Then $D = H_A - H_B$ has mean zero. The variance of a difference of independent variables is the sum of their variances, so D has standard deviation $\sigma_D = \sqrt{\sigma_A^2 + \sigma_B^2}$, and the surprise is $|D|/\sigma_D$ standard deviations. For the ladder and the CMB:

$$\frac{|D|}{\sigma_D} \overset{(1)}{=} \frac{73.04 - 67.36}{\sqrt{1.04^2 + 0.54^2}} \overset{(2)}{=} \frac{5.68}{\sqrt{1.082 + 0.292}} \overset{(3)}{=} \frac{5.68}{1.172} = 4.8. \tag{11.115}$$

(1) SH0ES against Planck, with their quoted errors.
(2) The squares of the errors.
(3) Their sum has square root 1.172.

For a Gaussian, a difference this many standard deviations from zero in either direction has probability of order 10^{-6}. This is the value we use for the Hubble tension throughout. Other places in the book get different numbers, with the same gap and different errors:

Pair	Gap [km/s/Mpc]	σ_D	$\lvert D\rvert/\sigma_D$	Where
SH0ES 73.04 ± 1.04 against Planck 67.36 ± 0.54	5.68	1.17	4.8	Section T2.12.3
SH0ES against the book's chain 67.06 ± 0.93	5.98	1.40	4.3	Section 9.23.1
Riess 2011 73.8 ± 2.4 against Planck 2013 67.8 ± 0.8	6.0	2.53	2.4	Section 11.17.5

Table 11.8: One gap of about 6 km/s/Mpc, three significances. The gap has barely moved in a decade. The error has shrunk from 2.5 to 1.2.

The 4.3 differs from 4.8 only because our chain, fitted to one simulated temperature spectrum, is wider than Planck's final result (0.93 against 0.54): a larger σ_D under the same gap. The 2.4 is the same arithmetic on the numbers of 2013: the ladder then had an error of 2.4 and Planck 0.8. A gap of 6 which was 2.4 standard deviations in 2013 has become 4.8 as the error bars shrank, while the gap stayed. That is the sense in which the tension is a statement about precision.

The other routes, against both camps. The same arithmetic gives where each independent route sits relative to the two:

Route	H_0	against SH0ES	against Planck
CCHP TRGB	69.8 ± 1.7	1.6σ	1.4σ
BAO with BBN r_d (DESI)	68.53 ± 0.80	3.4σ	1.2σ
Chronometers, ours (statistical)	68.1 ± 3.1	1.5σ	0.2σ
Chronometers, ours (with η)	68.1 ± 4.3	1.1σ	0.2σ

Table 11.9: Significance of each route's difference from the ladder and from the CMB, each with the rule $|D|/\sqrt{\sigma_A^2 + \sigma_B^2}$.

For instance, BAO with a big-bang-nucleosynthesis ruler against the ladder is $(73.04 - 68.53)/\sqrt{1.04^2 + 0.80^2} = 4.51/1.31 = 3.4$. The chronometers are consistent with everyone, and so decide nothing. The independent BAO value, which uses neither the CMB peaks nor the ladder, sits with the CMB.

11.20.3 Two calibrations, not two expansion rates

The expansion rate today is one number. What the tension compares is two chains of inference, each ending in that number, each with its own borrowed quantity. The late route, the ladder, borrows the absolute magnitude M and a flow model, and assumes that supernovae are the same kind of candle in Cepheid hosts and in the Hubble flow. The early route borrows the sound horizon r and the history of expansion from $z \approx 1100$. If the two disagree, by (11.112) and (11.113) some borrowed quantity is off:

$$\delta M \overset{(1)}{=} \frac{5}{\ln 10} \ln \frac{73.04}{67.36} = 2.171 \times 0.0810 = 0.18 \text{ mag},$$
$$r_d \overset{(2)}{=} 147.09 \times \frac{69.29}{73.04} = 139.5 \text{ Mpc} \quad \text{(a 5.1\% shorter ruler)}. \tag{11.116}$$

(1) Invert (11.112): $\delta H_0/H_0 = \ln(73.04/67.36) = 0.0810$ must come from a shift of M; this is $5 \log_{10}(73.04/67.36) = 0.18$ in magnitudes.

(2) By (11.113), $H_0 \propto 1/r_d$ with θ fixed, so a ruler of $147.09 \times 69.29/73.04$ would turn the inverse ladder's 69.29 into 73.04.

Either a candle 0.18 mag brighter than assumed, or a ruler 5% shorter. These are the two sizes of the problem. Neither can be tested on the ladder or on the CMB alone, because each calibration is a single number that all its data share (Eq. (11.114)). That is why the way forward is a third route with a different borrowed quantity: chronometers borrow neither, BAO borrows r_d but from nucleosynthesis, and the tip of the red-giant branch borrows a different candle. They sit between, closer to the CMB, with errors still too large to say that the ladder is wrong.

What local cosmic variance can explain. The ladder's volume is finite, and a density contrast averaged over it changes the expansion seen from inside (Eq. (11.100)). For the ladder's supernovae out to $z = 0.15$ the spread of that effect is 1.25 to 1.5% (Section 11.17.6), about 1.1 km/s/Mpc, the size of the ladder's own error. Suppose none of it were in the ladder's quoted 1.04. Then the variances add: $\sqrt{1.04^2 + 1.12^2} = 1.53$, and

$$\frac{5.68}{\sqrt{1.53^2 + 0.54^2}} = \frac{5.68}{1.62} = 3.5.$$

The tension would fall from 4.8 to 3.5 standard deviations. What cosmic variance cannot do is produce the gap itself: 8.4% is 5.5 times the spread, which would need the ladder's volume to be half empty, a fluctuation whose Gaussian probability is below 10^{-7}. Nor does it touch the CMB, the BAO ruler or the chronometers at z up to 2, which use volumes far larger. Local effects bite hardest on the nearest samples: in the mock sample of Section 11.16, within 30 Mpc, ignoring a 200 km/s infall moved H_0 from 69.9 to 65.5, 6%, as large as the tension, but the ladder's supernovae lie beyond $z = 0.023$, where the same 200 km/s is a few per cent of each redshift, and are corrected with a flow model (Section 11.21.3).

The one-line lesson. Every route to H_0 is an observable divided by a borrowed calibration, the calibration does not average down, and the Hubble tension is the statement that two calibrations, a luminosity and a ruler, disagree by 0.18 mag, or 5%, at 4.8 standard deviations.

11.21 How the local Universe is measured in research

The Cosmicflows-4 catalogue lists 55,877 galaxies gathered into 38,065 groups [226]. Each line holds a position on the sky, a redshift in the frame of the cosmic microwave background, a distance with its error, and a peculiar velocity. Every idea we have met since Hubble's diagram is somewhere behind those columns: Hubble's fit of velocity against distance (Section 11.14), the velocity field that structure induces (Section 11.15), our own fall towards Virgo and our motion through the microwave background (Section 11.16), the scatter of a locally measured H_0 (Section 11.17) and the bias of a distance read off a noisy indicator (Section 11.18). The SH0ES distance ladder and the chronometer compilation use the same ideas. Our scripts ran each of them once, on Hubble's 24 nebulae, on a few hundred simulated galaxies, or on a table of 32 measurements. The question, in words:

> *At each step from a catalogue of distances, redshifts or ages to a published H_0 or velocity field, what does a research analysis do that our scripts left out, and which part of its error can more data shrink?*

Figure 11.50 shows the three routes. The top row is the distance ladder: geometry calibrates nearby stars, nearby stars calibrate brighter indicators, and those reach the Hubble flow. The middle row is the map of galaxies that predicts velocities, which the ladder uses to clean its redshifts. The bottom row is the chronometer route, which uses no distances at all.

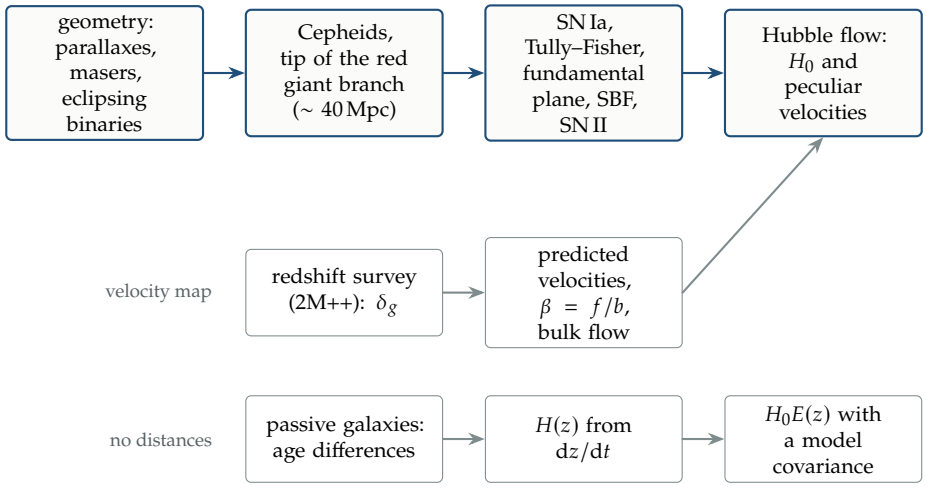

Figure 11.50: Three routes to the local expansion. Top: the distance ladder, each rung calibrating the next. Middle: a map of galaxy positions predicts peculiar velocities, which are subtracted from the redshifts of the Hubble-flow objects. Bottom: cosmic chronometers turn age differences of passive galaxies into $H(z)$ without any distance.

11.21.1 Tens of thousands of distances: Cosmicflows-4

Cosmicflows-4 combines eight ways of measuring a distance [226, Sec. 1]. Most galaxies have a distance from the Tully–Fisher relation [the luminosity of a spiral galaxy predicted from its rotation speed] or the fundamental plane [the same idea for an elliptical galaxy, using its velocity dispersion and surface brightness]; each such distance is uncertain by 20–25%. Type Ia supernovae give about 7% out to $z = 0.1$, type II supernovae about 15%, surface-brightness fluctuations about 5% out to $z \approx 0.03$. Cepheids and the tip of the red giant branch give about 5% but only within about 20 Mpc; masers give six geometric distances.

Putting eight methods on one scale. Every subsample s (one Tully–Fisher survey, say) measures distance moduli with a zero point of its own. Call $\mathrm{DM}_n^{(s)}$ the modulus of object n (a group or a single galaxy) in subsample s, $\Delta\mu_s$ an offset added to every modulus of that subsample, and $\langle \mathrm{DM} \rangle_n$ the weighted mean of the adjusted moduli $\mathrm{DM}_n^{(s)} + \Delta\mu_s$ over all subsamples that contain object n. With independent Gaussian errors $\sigma_{n,s}$ on each difference, the log-likelihood of the offsets is [226, eqs. (1)–(2)]

$$-2 \ln \mathcal{L}(\Delta\boldsymbol{\mu}) = \sum_n \sum_{s \ni n} \frac{\left(\mathrm{DM}_n^{(s)} + \Delta\mu_s - \langle \mathrm{DM} \rangle_n\right)^2}{\sigma_{n,s}^2} + \text{const.} \tag{11.117}$$

For given offsets it asks how plausible the fluctuations are that must be added to the adjusted moduli to make every object have one distance, the likelihood of Chapter 3. With a flat prior the posterior is this likelihood, and the Cosmicflows team samples it with `emcee`, 128 walkers of 10^4 steps.

Two things follow from what we already know. First, each offset enters (11.117) linearly, and so does $\langle \mathrm{DM} \rangle_n$, which is a weighted mean of terms linear in the offsets. The exponent is therefore quadratic in $\Delta\boldsymbol{\mu}$, the posterior is exactly Gaussian, and its mean and covariance follow from one linear solve, as for every linear model since Section 3.17; the chain is a check of that solve. Second, the overlaps cannot fix the overall zero point. Add the same constant c to every offset. With weights $w_{n,s}$,

$$\langle \mathrm{DM} \rangle_n(\Delta\boldsymbol{\mu} + c) \overset{(1)}{=} \frac{\sum_s w_{n,s}\left(\mathrm{DM}_n^{(s)} + \Delta\mu_s + c\right)}{\sum_s w_{n,s}} \overset{(2)}{=} \langle \mathrm{DM} \rangle_n(\Delta\boldsymbol{\mu}) + c,$$

$$\mathrm{DM}_n^{(s)} + \Delta\mu_s + c - \langle \mathrm{DM} \rangle_n(\Delta\boldsymbol{\mu} + c) \overset{(3)}{=} \mathrm{DM}_n^{(s)} + \Delta\mu_s - \langle \mathrm{DM} \rangle_n(\Delta\boldsymbol{\mu}). \tag{11.118}$$

(1) The definition of the weighted mean, with every offset shifted by c.
(2) Split the sum: the c terms give $c \sum_s w_{n,s} / \sum_s w_{n,s} = c$.
(3) Subtract the first line: the two c's cancel.

Every residual, and so the likelihood, is unchanged: one direction in the space of offsets is flat. Cosmicflows fixes it by setting the offset of its own Tully–Fisher sample to zero. This is the third time the same thing has happened. Hubble's slope could not see a common factor in his distances, (11.93), and a supernova Hubble diagram cannot see the absolute magnitude (Section 3.17.4). The absolute scale has to come from outside: 542 calibrator galaxies with distances from the tip of the red giant branch, Cepheids or masers [226, Sec. 10].

Example: how small is the statistical error on H_0? Each group i gives a Hubble parameter $H_i = f_i V_i / d_i$, its recession velocity V_i in the microwave background frame over its distance d_i, with f_i a small correction to the low-redshift Hubble law. Beyond 4000 km/s, where a peculiar velocity of 300 km/s is less than 8% of V_i, the mean of $\log_{10} H_i$ over about 35,000 groups is 1.8725, that is $H_0 = 74.6$ km/s/Mpc, and the scatter is 0.091 in $\log_{10} H$ [226, Sec. 13]. How well does the mean pin down H_0 if the groups are independent?

$$\sigma_{\log H_0} \overset{(1)}{=} \frac{0.091}{\sqrt{35\,000}} = 4.9 \times 10^{-4},$$

$$\frac{\sigma_{H_0}}{H_0} \overset{(2)}{=} \ln 10 \; \sigma_{\log H_0}, \qquad \sigma_{H_0} = 74.6 \times 2.303 \times 4.9 \times 10^{-4} = 0.08 \text{ km/s/Mpc}. \tag{11.119}$$

(1) The error of a mean of N independent values is the scatter over $\sqrt{N}$.
(2) $\log_{10} H = \ln H / \ln 10$, so $\mathrm{d} \log_{10} H = \mathrm{d}H / (H \ln 10)$.

A scatter of 0.091 in $\log_{10} H$ is $\ln 10 \times 0.091 = 21\%$ per group, yet the mean is fixed to about a thousandth. Cosmicflows quotes ±0.2, more than twice the naive figure; groups that fall together in one flow are not independent (Section 11.15.4), so the naive figure is a floor. Either way the number is small beside the ±0.8 of the zero-point calibration and the possible systematic of about 3 km/s/Mpc that the authors themselves state.

The calibration route decides the answer. The value 74.6 comes from merging all eight methods onto one scale and tying that scale to 121 calibrator galaxies. Tying only the supernovae, through the 44 supernova hosts with Cepheid, red-giant or maser distances, gives 72.1, close to the SH0ES value [226, Sec. 14]. The two routes use largely the same data, and they differ by 2.5 km/s/Mpc, three times the statistical error. Hubble's lesson of Section 11.14.5 survives ninety years and a factor of two thousand in the number of galaxies: the fit delivers the expansion rate in units of a calibration, and the error of the calibration does not average down.

Peculiar velocities from the catalogue. The velocities in the catalogue use the difference $cz - H_0 d$ nearby and change over, by 3000 km/s, to the logarithmic estimator of Watkins and Feldman [225], the one we derived in Section 11.18.4 to keep the noise Gaussian [226, eqs. (9)–(11)]. For groups whose modulus is known to 0.10 mag or better, the velocities have a roughly Gaussian distribution with standard deviation 300 km/s. Linear theory with the Planck spectrum gave $\sigma_{v,1\mathrm{D}} = 308$ km/s in Section 11.15.3. The two numbers are not a like-for-like comparison: a modulus error of 0.10 mag is a distance error of $(\ln 10/5) \times 0.10 = 4.6\%$, which at 4000 km/s is 184 km/s of velocity noise, so the measured width contains both the motions and the errors. What the agreement in size does say is that the galaxies move at the speeds linear theory predicts. Cosmicflows also finds larger Hubble parameters in one part of the sky and smaller ones in the opposite part, the dipole pattern of a bulk motion of the sample that we met in Section 11.16.4.

11.21.2 Velocities predicted from a map of galaxies

A distance catalogue measures velocities and asks what mass moves them. The reverse route needs no distances: take a redshift survey, which maps where the galaxies are, and predict the velocities they must have. Carrick et al. did this with the 2M++ compilation, a redshift survey that maps the galaxy density out to 200 h^{-1}Mpc [231].

The prediction. The linear velocity field of Section 11.15.2 is $\boldsymbol{u}(\boldsymbol{x}) = \frac{aHf}{4\pi} \int \mathrm{d}^3x'\, \delta(\boldsymbol{x}')\, (\boldsymbol{x}' - \boldsymbol{x})/|\boldsymbol{x}' - \boldsymbol{x}|^3$, equation (11.95), where δ is the matter density contrast and f the growth rate. A survey sees galaxies, not matter. With the linear bias of Section 11.5.2, $\delta_g = b\,\delta$, the galaxy contrast is b times the matter contrast. Today $a = 1$ and $H = H_0$, so

$$\boldsymbol{u}(\boldsymbol{x}) \overset{(1)}{=} \frac{H_0 f}{4\pi} \int \mathrm{d}^3x'\, \frac{\delta_g(\boldsymbol{x}')}{b}\, \frac{\boldsymbol{x}' - \boldsymbol{x}}{|\boldsymbol{x}' - \boldsymbol{x}|^3} \overset{(2)}{=} \beta\, \frac{H_0}{4\pi} \int \mathrm{d}^3x'\, \delta_g(\boldsymbol{x}')\, \frac{\boldsymbol{x}' - \boldsymbol{x}}{|\boldsymbol{x}' - \boldsymbol{x}|^3}, \qquad \beta \equiv \frac{f}{b}. \tag{11.120}$$

(1) (11.95) at $a = 1$, $H = H_0$, with $\delta = \delta_g/b$.
(2) A constant comes out of the integral; name the ratio f/b.

The map of galaxies predicts the whole velocity field up to one number, β. Call p_i the line-of-sight component of the integral at galaxy i, the velocity it would have if β were one.

The fit is Hubble's fit again. A measured peculiar velocity u_i with error σ_i (the distance error turned into velocity, plus a small-scale dispersion that linear theory does not describe) is

modelled as $u_i = \beta p_i$+noise. Which β makes the required noise most plausible?

$$\chi^2(\beta) \overset{(1)}{=} \sum_i \frac{(u_i - \beta p_i)^2}{\sigma_i^2}, \qquad \frac{\mathrm{d}\chi^2}{\mathrm{d}\beta} \overset{(2)}{=} -2\sum_i \frac{p_i\,(u_i - \beta p_i)}{\sigma_i^2} = 0,$$
$$\hat\beta \overset{(3)}{=} \frac{\sum_i p_i u_i/\sigma_i^2}{\sum_i p_i^2/\sigma_i^2}, \qquad \operatorname{Var}\hat\beta \overset{(4)}{=} \Big(\sum_i \frac{p_i^2}{\sigma_i^2}\Big)^{-1}. \tag{11.121}$$

(1) Gaussian noise: $-2\ln\mathcal{L}$ is the χ^2 up to a constant.
(2) Differentiate each square; the chain rule brings down $-p_i$.
(3) Solve the linear equation for β.
(4) The second derivative is $2\sum p_i^2/\sigma_i^2$; the variance of a maximum-likelihood estimate in a linear-Gaussian model is the inverse of half of it (Chapter 3).

This is Hubble's slope (11.91) with $r_i \to p_i$, and the chronometer estimator (11.110) with $E_i \to p_i$: a parameter that multiplies a known template is estimated by a weighted ratio. Carrick et al. add a uniform velocity $\boldsymbol{V}_{\text{ext}}$, a **bulk flow** [a velocity shared by the whole mapped volume, caused by mass outside it], so that $u_i = \beta p_i + \boldsymbol{V}_{\text{ext}}\cdot\hat{\boldsymbol{r}}_i$. The model is still linear, now in four parameters, and the estimate is still one matrix solve. Comparing with Tully–Fisher and supernova velocities they find $\beta^* = 0.431 \pm 0.021$ for their reference galaxies, which translates into $f\sigma_8 = 0.401 \pm 0.024$, the same combination that redshift-space distortions measure (Section 11.5.4), and a bulk flow of 159 ± 23 km/s, preferred at 5.1 standard deviations [231].

Example: does the map explain our motion? The 2M++ volume alone predicts a Local Group velocity of 540 km/s towards galactic $(l, b) = (268^\circ, 38^\circ)$; the external bulk flow is 159 km/s towards $(304^\circ, 6^\circ)$. The motion through the microwave background found in Section 11.16.4 is 620 km/s towards $(272^\circ, 30^\circ)$. Velocities add as vectors, so we need the angle between the two directions. A direction (l, b) is the unit vector $(\cos b\cos l, \cos b\sin l, \sin b)$, and

$$\cos\theta \overset{(1)}{=} \sin b_1\sin b_2 + \cos b_1\cos b_2\cos(l_1 - l_2) = 0.698, \qquad \theta = 46^\circ,$$
$$|\boldsymbol{v}_1 + \boldsymbol{v}_2|^2 \overset{(2)}{=} v_1^2 + v_2^2 + 2v_1v_2\cos\theta = 540^2 + 159^2 + 2\times 540\times 159\times 0.698,$$
$$|\boldsymbol{v}_1 + \boldsymbol{v}_2| = 661 \text{ km/s}. \tag{11.122}$$

(1) The dot product of the two unit vectors; the $\cos b_1\cos b_2$ terms combine through $\cos l_1\cos l_2 + \sin l_1\sin l_2 = \cos(l_1 - l_2)$.
(2) $|\boldsymbol{v}_1 + \boldsymbol{v}_2|^2 = (\boldsymbol{v}_1 + \boldsymbol{v}_2)\cdot(\boldsymbol{v}_1 + \boldsymbol{v}_2)$, expanded.

The sum points to $(278^\circ, 32^\circ)$, 5° from the dipole direction, and its size is within 7% of the measured 620 ± 15 km/s. Most of our motion is pulled by structure within 200 h^{-1}Mpc; the rest, a bulk flow of 159 km/s, comes from farther away.

11.21.3 Flow corrections in the supernova ladder

The third rung of the SH0ES ladder is 277 supernovae with $0.0233 < z < 0.15$ [24]. Each one's redshift contains a peculiar velocity, which the Hubble law reads as a wrong distance.

How far does an unknown velocity move one supernova? The distance modulus of a source at luminosity distance d is $\mu = 5\log_{10}(d/10\,\text{pc})$; at low redshift the predicted distance is $d = cz/H_0$. By (11.94), the observed cz is $H_0 r + u_r$, the Hubble flow plus the line-of-sight

peculiar velocity u_r. Treating u_r as a small change of cz,

$$\mu \overset{(1)}{=} 5\log_{10}\frac{cz}{H_0 \cdot 1\,\mathrm{Mpc}} + 25, \qquad \delta\mu \overset{(2)}{=} \frac{5}{\ln 10}\frac{\delta(cz)}{cz} \overset{(3)}{=} \frac{5}{\ln 10}\frac{u_r}{cz},$$
$$\sigma_\mu \overset{(4)}{=} \frac{5}{\ln 10}\frac{\sigma_v}{cz} \approx 2.17\,\frac{\sigma_v}{cz}. \tag{11.123}$$

(1) d in Mpc: $5\log_{10}(d \times 10^6\,\mathrm{pc}/10\,\mathrm{pc}) = 5\log_{10} d + 25$.
(2) $\mathrm{d}\log_{10} x = \mathrm{d}x/(x \ln 10)$, the same identity as in (11.119).
(3) The change of cz is the peculiar velocity.
(4) A velocity scatter σ_v gives a scatter in μ larger by the same factor.

For $\sigma_v = 250\,\mathrm{km/s}$ this is 0.181 mag at $z = 0.01$, 0.078 mag at $z = 0.0233$ and 0.012 mag at $z = 0.15$ (Figure 11.51, left). After standardisation, nearby supernovae scatter about the Hubble line by 0.16–0.17 mag all told, velocities included [232]. At $z = 0.01$ a velocity of the typical size is as large as that whole scatter; at $z = 0.0233$ it is half of it in magnitudes, a quarter in variance. The lower cut keeps the supernovae whose distances the velocities barely disturb; the upper cut, $z = 0.15$, keeps the Hubble law nearly independent of the matter density. Pantheon+ puts the remaining velocity scatter into each supernova's error as a term $\sigma_{v_{\mathrm{pec}}}$, computed from 240 km/s and converted to magnitudes as in (11.123) [26, eq. (3), Sec. 3.1.3].

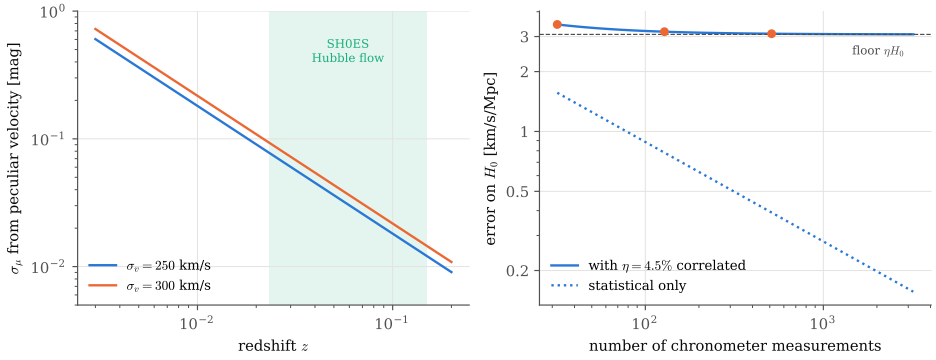

Figure 11.51: Left: the scatter in a supernova's distance modulus caused by an unmodelled peculiar velocity, for two velocity dispersions; the shaded band is the redshift range of the SH0ES Hubble-flow sample. Right: the error on H_0 from cosmic chronometers as the compilation grows, with only statistical errors (dotted) and with a 4.5% error shared by all points (solid), which levels off at ηH_0; the dots are the full generalised least-squares fit to 1, 4 and 16 stacked copies of the data.

Correcting the redshifts. Pantheon+ corrects the redshifts in two steps [232]. A supernova in a group gets the group's mean redshift, which removes the orbital motion inside the group. Then the velocity predicted from the 2M++ map, (11.120), is subtracted. Together the corrections reduce the scatter of 584 nearby supernovae about the Hubble line from 0.167 to 0.157 mag and raise H_0 by about 0.4 km/s/Mpc; the choice among velocity maps leaves a systematic uncertainty of only 0.06–0.11 km/s/Mpc in H_0. In the SH0ES fit, dropping the corrections lowers H_0 by 0.5, and dropping every supernova below $z = 0.06$ raises it by 0.3 [24, Secs. 6.8, 6.12]. As the SH0ES team notes, both changes go the wrong way for the idea that we sit in an underdense region that raises the local H_0 (Section 11.17.6): in such a hole, removing the nearest supernovae would lower H_0, and so would correcting for the outflow. What the corrections cannot remove is the part of the scatter in H_0 that comes from structure beyond the map, the cosmic variance of Section 11.17; for this redshift range it is estimated at 0.5–1% [100, Sec. IV.F].

Example: why not use the Cepheid hosts' own redshifts? The 37 galaxies with Cepheids have a mean cz of about 2000 km/s [24, Sec. 6.12]. If their redshifts were used directly, a velocity of 250 km/s would be 250/2000 = 12.5% of each one's Hubble velocity. For 37 independent velocities the mean would be uncertain by $12.5\%/\sqrt{37} = 2.1\%$. The velocities are not independent: galaxies within a few tens of megaparsecs share most of their motion (Section 11.15.4). The SH0ES team, using the spatial covariance of the flows, finds that this two-rung route is limited to 3–4%. If the velocities alone set that number, the 37 hosts are worth about $(12.5/3.5)^2 \approx 13$ independent ones. A third rung reaching $z > 0.023$ is what makes a 1% measurement possible.

11.21.4 Chronometers: what the error budget is made of

A cosmic chronometer (Section 11.19) reads $H(z) = -(1+z)^{-1}\mathrm{d}z/\mathrm{d}t$ from the age difference $\mathrm{d}t$ of passively evolving galaxies at nearby redshifts. The ages come from spectral features, such as the 4000 Å break, through slopes computed with **stellar population synthesis** models [models that predict the spectrum of a population of stars from its age, metallicity and history]. Moresco et al. split the covariance of the $H(z)$ points into a statistical part and four systematic ones [228, Sec. 3.1.4, eqs. (19)–(21)]:

$$C = C^{\mathrm{stat}} + C^{\mathrm{met}} + C^{\mathrm{young}} + C^{\mathrm{model}}, \qquad C^{\mathrm{model}} = C^{\mathrm{SFH}} + C^{\mathrm{IMF}} + C^{\mathrm{lib}} + C^{\mathrm{SPS}}. \tag{11.124}$$

Each term answers a question about the galaxies. *Is the metallicity right?* A 10% error in the stellar metallicity gives about a 10% error in H; it belongs to each spectrum separately, so it is diagonal. *Did the stars form in one burst?* Assuming so when the star formation lasted up to 0.3 Gyr costs 2–3%, again diagonal. *Is there a young component hiding in an old galaxy?* If 10% (1%) of the light came from young stars, H would be off by 5% (0.5%); in the samples used so far the contamination is below detection and the effect below 0.5%. *Is the population model right?* Changing the synthesis model shifts H by about 4.5%, the initial mass function by less than 0.4%, the stellar library by somewhat more [230]. These shifts move every point the same way, so they are treated as fully correlated across redshift. The three diagonal terms are already inside the published errors of Table 11.5. Errors that include a conservative systematic allowance do not show up as scatter, which is the reading we gave of the small χ^2 in Section 11.19.3. The correlated model term must be added by the user; we added it as a single $\eta = 4.5\%$.

More galaxies do not help. Section 11.19.2 showed that a fully correlated fractional error η adds in quadrature, $\sigma^2_{H_0} = \sigma^2_{\mathrm{stat}} + (\eta H_0)^2$, equation (11.111). Suppose we had k compilations of the same quality instead of one. The statistical variance falls as $1/k$; the shared model error is the same in every copy:

$$\sigma^2_{H_0}(k) \overset{(1)}{=} \frac{\sigma^2_{\mathrm{stat}}}{k} + (\eta H_0)^2 \xrightarrow{k\to\infty} (\eta H_0)^2. \tag{11.125}$$

(1) (11.111) with $\boldsymbol{E}^{\mathsf{T}} D^{-1} \boldsymbol{E}$ multiplied by k, since k independent copies add their Fisher information.

With $\sigma_{\mathrm{stat}} = 1.57$ and $\eta H_0 = 3.08$ km/s/Mpc, the error is 3.45 for the present data, 3.17 with four times as many and 3.10 with sixteen times as many; the generalised least-squares fit on stacked copies gives the same numbers (Figure 11.51, right). The floor is 4.5% of H_0. Moresco et al. reach the same conclusion by simulation: with the current data they find $H_0 = 66.5 \pm 5.4$ in flat ΛCDM, and their optimistic forecast reaches 69.0 ± 2.1 only if the synthesis-model term is resolved, leaving the initial-mass-function term [228, Sec. 3.1.6, Table 2]. In (11.125) a 0.4% floor is 0.27 km/s/Mpc, below the statistical error, so the data would again be limited

by their number. Their current interval is wider than ours (±4.3): their covariance contains the stellar-library term and a redshift-dependent synthesis-model term on top of our single constant. The centres, 66.5 and 68.1, differ by a third of either error.

A bias the differential method avoids. At high redshift, a selection for old passive galaxies may pick objects that are the ancestors of a different population from the one selected nearby, and so flatten the age–redshift relation. Comparing only galaxies at nearly the same redshift limits this **progenitor bias**; Moresco et al. estimate it at about 1% in H, small beside the model term.

11.21.5 What our shortcuts cost

Table 11.10 lists, for each calculation, what a research analysis does instead and what our reduction costs. The reductions are of two kinds. Some only cost precision and would shrink with computing time or data. Others leave out a physical ingredient, and no amount of computing inside our model brings it back.

section	research	ours	what it costs
Hubble 1929	5.6×10^4 galaxies, eight methods, zero points by MCMC, 542 calibrators	Hubble's 24 nebulae, one velocity scatter, solar motion fitted	nothing for the lesson; H_0 itself was off by a factor 6.6 in 1929
velocities	N-body and constrained simulations, nonlinear motions, galaxy bias	linear theory from CAMB; 4 Gaussian boxes of 1000 h^{-1}Mpc	no motions inside groups and clusters; matter only
local flow	velocity field from 2M++ with β and a bulk flow; Cosmicflows velocities	one spherical attractor, power-law profile, 400 simulated galaxies	no external bulk flow (the 159 km/s of [231]); one attractor only
local H_0	N-body box of 6 h^{-1}Gpc, observers in haloes and voids, the real supernova sky	linear $P(k)$, three windows, Gaussian boxes of 1500 h^{-1}Mpc	no observer selection, no nonlinear density; linear rows agree within 0.1 percentage point
Malmquist	joint likelihood of distances and a 3-D density map over the sky	one line of sight through one cluster, lognormal errors	no selection function, no sky coverage; the mechanism only
chronometers	full covariance (11.124), redshift-dependent terms, sampled posteriors	diagonal errors plus one constant 4.5%, grid profile over Ω_{m0}	interval ±4.3 instead of ±5.4 km/s/Mpc

Table 11.10: Each section's analysis at research scale and in the scripts, with the cost of the reduction.

The row that matters most is the local flow. Our Virgo model has one attractor; the real local Universe has the Great Attractor, Perseus–Pisces, the Shapley concentration and a bulk flow from beyond them all. Everything statistical we derived (the linear velocity field, the joint linear fit, the dilution by distance errors, the Malmquist correction) carries over unchanged to a three-dimensional map; what does not carry over is the claim that one parameter, $v_{\rm inf}$, describes the flow. Research replaces it with (11.120) evaluated on a real galaxy map, plus a bulk flow.

How this is used in real research: Checks, and instruments

Four calculations on the local Universe checked an analytic result by simulation: the velocity dispersion from $P(k)$ against Gaussian boxes (298±5 against 298 km/s), the window variance of a local H_0 against observers in boxes (1.48% against 1.45% at 100 h^{-1}Mpc), the Malmquist

factor against a simulated catalogue (1.096 against 1.095), and the chronometer errors against 4000 mock compilations (3.48 against 3.52). Each time the simulation verified a formula we already had. Research uses the same tools where no formula exists: Wojtak et al. needed an N-body simulation because observers sitting in haloes see a nonlinear density; Moresco et al. sized the synthesis-model error by simulating spectra with one model and analysing them with the others; Pantheon+ measures the effect of its velocity model by refitting with an alternative map, because no formula relates two maps.

The lesson. Every local measurement of the expansion is a weighted ratio of a measured quantity to a template, whose statistical error falls as $1/\sqrt{N}$, multiplied by a calibration that does not fall at all; the work of research is in the calibration and in the correlated errors, which is where Hubble's 500 km/s/Mpc went wrong and where the present tension will be decided.

Recap

- Hubble's 24 nebulae, refitted with a solar motion, give his $K = 465 \pm 56$. The slope of a fit through the origin is $\sum v_i r_i / \sum r_i^2$; distance errors add $K^2\Delta^2 r_i^2$ to the variance; a common factor in all distances is invisible to the fit, which is why 465 became 70 (Section 11.14).
- A redshift gives $u_r = c(z_{\rm obs} - z_c)/(1+z_c)$. Linear theory gives $\boldsymbol{u} = \frac{aHf}{4\pi} \int \delta\,(\boldsymbol{x}'-\boldsymbol{x})/|\boldsymbol{x}'-\boldsymbol{x}|^3$, a velocity dispersion $\sigma_{v,1\mathrm{D}} = 308\,\mathrm{km/s}$ from $P(k)/k^2$, and velocities correlated over $\sim 100\,h^{-1}$Mpc (Section 11.15).
- Infall towards a spherical overdensity is $-\frac{1}{3} aHf\,\bar{\delta}(<R)R$; a joint linear fit recovers H_0 and the infall speed, and ignoring the infall biases H_0. The Local Group moves at 620 km/s through the microwave background (Section 11.16).
- A local least-squares H_0 sees the density through the window $15 j_2(kR)/(kR)^2$, with $\delta H/H = -f\,\delta_W/3$; its scatter is about 1% at $150\,h^{-1}$Mpc, reproducing Wojtak et al. and Marra et al., and far too small to explain the 8.4% tension (Section 11.17).
- A distance measured with lognormal error Δ in a density $n(r)$ has $E(r \mid d) \approx d[1 + (7/2 + \gamma)\Delta^2]$: inhomogeneous Malmquist bias, which makes spurious outflows around clusters; the logarithmic velocity estimator keeps the noise Gaussian (Section 11.18).
- Chronometers give $H(z) = -(1+z)^{-1}\mathrm{d}z/\mathrm{d}t$; the generalised least-squares estimate is $\boldsymbol{E}^{\mathsf{T}}C^{-1}\boldsymbol{H}/\boldsymbol{E}^{\mathsf{T}}C^{-1}\boldsymbol{E}$, and a shared 4.5% model error sets a floor $\eta H_0 = 3.08\,\mathrm{km/s/Mpc}$; flat ΛCDM gives $H_0 = 68.1$ with $[63.9, 72.6]$ (Section 11.19).
- Research adds tens of thousands of distances on one zero point, velocity maps with $\beta = f/b$, flow-corrected redshifts beyond $z = 0.023$ where $\sigma_\mu = 2.17\,\sigma_v/cz$ is small, and full systematic covariances (Section 11.21).

Reading the literature

- **Statistics of the fits.** Cowan, *Statistical Data Analysis*, Chapters 6 and 7 on maximum likelihood and least squares [Cowan Chs. 6–7]; Hobson et al., *Bayesian Methods in Cosmology*, on survey design and forecasts [HobsonBMC §5.3].
- **Galaxies as points, and two-point estimators.** Peebles on the large-scale structure of the Universe [190]; Peebles and Hauser, Davis and Peebles, Hamilton, Landy and Szalay and Kerscher et al. on correlation-function estimators [191–195]; Feldman, Kaiser and Peacock on the power spectrum [196]; Xavier et al. on lognormal fields [55].

Chapter summary

A galaxy survey is a list of points, and no theory predicts any one of them. What a model predicts is how the points cluster, so every number a survey yields comes from asking one question about a list: if the points are a random sample of a smooth field, what is the sampling distribution of a summary of their positions, and how does the survey distort it? Poisson sampling adds the shot noise $1/\bar{n}$; a random catalogue cancels the survey's edges in the Landy–Szalay estimator; a weight $1/(1+\bar{n}P)$ minimises the variance of the power spectrum; a dilation of a template measures the acoustic ruler; the motions of galaxies squash the pattern by $(b+f\mu^2)^2$ and so measure the growth rate. The two-point function does not see everything: fields with the same $P(k)$ can look entirely different, and haloes, their abundance, their profiles, and the voids between them carry the rest. In the local Universe the velocities are measured directly, and the same estimators return in their simplest form: Hubble's slope, the infall speed, β and the chronometer H_0 are all weighted ratios, each multiplied by a calibration the data cannot see. In the pipeline

$$\text{physical model} \rightarrow \boxed{\text{field or data} \rightarrow \text{summary } S \rightarrow P(S \mid \theta)} \rightarrow \text{infer physics},$$

galaxy clustering works the middle arrows for points rather than maps: how a sample of a field becomes a summary, and what sampling, masks and motions do to its distribution. Chapter 12 takes the structures the two-point function misses into topological summaries, Chapter 13 turns to the Planck data that set the early-Universe side of the H_0 comparison, and Chapter 14 collects the ways in which an estimator and its calibration part company.

Clustering of galaxies

concept	operational meaning	used later in
Cox process, shot noise	Poisson given $\bar{n}(1+\delta_g)$; counts-in-cells variance $\langle N\rangle + \langle N\rangle^2\sigma_R^2$; power $P(k) + 1/\bar{n}$	Chapters 12 and 14
lognormal field	$1+\delta = e^{G-\sigma_G^2/2}$: a positive density with a chosen spectrum, for mocks	Chapter 12
Landy–Szalay	$(DD - 2DR + RR)/RR$ against a random catalogue; edge terms cancel to first order	Chapter 14
integral constraint	$\hat{\bar{\xi}}$ is low by the mean of ξ over the survey	Chapter 14
FKP estimator	weighted data-minus-randoms field, $w = 1/(1+\bar{n}P)$; information counted by V_{eff}	Chapter 14
BAO dilation α	template fitted at αr; α measures D_V/r_d; significance $\sqrt{\Delta\chi^2}$ peak against no peak	Chapters 13 and 14
Kaiser formula	$P_s(k,\mu) = (b + f\mu^2)^2 P(k)$; multipoles P_0, P_2, P_4	Chapter 14
$f\sigma_8$	the growth rate times the amplitude, measured by the quadrupole-to-monopole ratio	Chapters 13 and 14
fingers of God	small-scale velocities stretch clusters along the line of sight; a damping of P_s	Chapter 14
mocks	a thousand simulated surveys for the covariance; error bars only as good as the mocks	Chapter 14

Beyond two points: haloes and voids

concept	operational meaning	used later in
same $P(k)$, different field	two fields with identical spectra and different phases; the difference is in higher-order statistics	Chapter 12
halo mass function	number of haloes per unit mass and volume, from the fraction of the smoothed field that has collapsed	Chapter 14
halo bias	how much more strongly haloes of a given mass cluster than matter	Chapter 14
halo profile	the density around a halo centre and its Fourier transform $u(k\,\vert\,m)$	Chapter 14
halo model	$P(k)$ as a one-halo (pairs in one halo) plus a two-halo (pairs in two haloes) term	Chapter 14
halo occupation	the mean number of galaxies in a halo of mass m, central and satellites	Chapter 14
voids	large underdense regions; their abundance, profiles and shapes as summaries	Chapters 12 and 14

The local Universe

concept	operational meaning	used later in
fit through the origin	$\hat{K} = \sum v_i r_i / \sum r_i^2$; distance errors add $K^2\Delta^2 r_i^2$ to the variance	Chapter 14
invisible calibration	a common factor in all distances, all magnitudes or all zero points leaves χ^2 unchanged	Chapters 13 and 14
peculiar velocity	$u_r = c(z_{\rm obs} - z_c)/(1+z_c)$; linear theory $\boldsymbol{u} \propto f \int \delta\,(\boldsymbol{x}' - \boldsymbol{x})/\lvert\boldsymbol{x}' - \boldsymbol{x}\rvert^3$	Chapter 14
velocity statistics	$\sigma_v^2 = (aHf)^2 \int P\,{\rm d}k/2\pi^2$; correlations $\psi_\parallel, \psi_\perp$	Chapter 14
infall and dipole	joint linear fit of H_0 and $v_{\rm inf}$; the Local Group moves at 620 km/s	Chapter 13
local H_0 variance	$\delta H/H = -f\delta_W/3$, window $15 j_2(kR)/(kR)^2$; ~1% at 150 h^{-1}Mpc	Chapters 13 and 14
Malmquist bias	$E(r \mid d) \approx d[1 + (7/2 + \gamma)\Delta^2]$; use logarithmic velocities	Chapter 14
$\beta = f/b$	velocities predicted from a galaxy map up to one factor, fitted as a weighted ratio	Chapter 14
flow corrections	$\sigma_\mu = 2.17\,\sigma_v/cz$; group redshifts and a velocity map; $z > 0.023$	Chapter 13
cosmic chronometers	$H = -(1+z)^{-1}{\rm d}z/{\rm d}t$; $\hat{H}_0 = \boldsymbol{E}^{\rm T}C^{-1}\boldsymbol{H}/\boldsymbol{E}^{\rm T}C^{-1}\boldsymbol{E}$; floor ηH_0	Chapters 13 and 14
borrowed calibration	every route is $H_0 = O/X$, an observable over a quantity from outside (M, a sound horizon r_d, an age scale, a distance scale); $\delta H_0/H_0 = (\ln 10/5)\,\delta M$ or $-\delta r_d/r_d$; it does not average down	Section 11.20 and Chapters 13 and 14
significance of a gap	$\lvert H_A - H_B\rvert/\sqrt{\sigma_A^2 + \sigma_B^2}$ for independent routes: ladder against Planck 4.8, the same gap in 2013 errors 2.4	Section 11.20 and Chapter 13

Part IV

Beyond Two-Point Statistics, and Real Data

Chapter 12

Topological Data Analysis: The Shape of a Field as Data

Where this chapter is going

A theory of the early universe does not predict the temperature map we observe. It predicts the statistics of maps like it, and the sky gives us one of them, seen through a beam, with noise, behind a mask, after the light has been bent by every galaxy cluster it passed. Until now we compressed such a map into its power spectrum (Chapters 7 and 8) and fed that summary to likelihoods, Markov chains and Fisher matrices (Chapters 9 and 10). The power spectrum keeps the amount of fluctuation on each scale and throws away everything else: in Section 7.7 two fields with identical spectra looked nothing alike, one made of blobs and the other of rings. So the question of this chapter is a question about what to measure. A physical process, or an instrument, changes the detailed values of the field in ways we do not care about. *Is there information about the shape and structure of the field that those changes cannot easily erase, and how do we turn it into numbers we can do statistics with?*

The answer starts from a simple construction. Pick a threshold and colour every point where the field is above it. The coloured region, the excursion set, is a genuine geometric object: it has separate pieces, and the pieces can have holes. Counting pieces and holes gives the Betti numbers, and pieces minus holes gives the Euler characteristic. These counts do not change when the region is stretched or bent without tearing, which is exactly the kind of change a smooth remapping of the sky produces. On a pixel grid the counting needs a convention for which pixels touch, and the convention for the region and for its complement have to fit together. For a Gaussian field the average Euler characteristic at each threshold can be computed exactly by counting maxima, saddles and minima, and the answer depends on the power spectrum through a single number, the variance of the gradient. That has two consequences: for a Gaussian sky the Euler characteristic adds nothing to the power spectrum, and a measured curve that departs from the formula is a direct sign that the sky is not Gaussian. We check the formula by Monte Carlo on the plane, in three dimensions and on the sphere, and reproduce the classic curves of Hamilton, Gott and Weinberg, of Schmalzing and Górski, of Matsubara and of the *Planck* team (Figure 12.1).

A single threshold is an arbitrary choice. Part 12b follows every piece and every hole as the threshold sweeps through all values, which gives persistent homology: birth and death of each feature, persistence diagrams, and the distances between them. Part 12w runs the whole pipeline on weak-lensing mass maps, from shear to topology. Part 12c closes the loop: a topological summary is a random observable like any other, with a sampling distribution obtained by simulation, a covariance, a likelihood, a Fisher forecast and a posterior, and it can tell apart fields that the power spectrum cannot.

In the pipeline of the book (physical model → field or data set → choose what information matters → construct a summary → derive its sampling distribution → infer physics), this chapter lives on the third and fourth arrows. The earlier chapters answered *how* to do inference once a summary is chosen; this one asks *which* summary is worth choosing, and builds it.

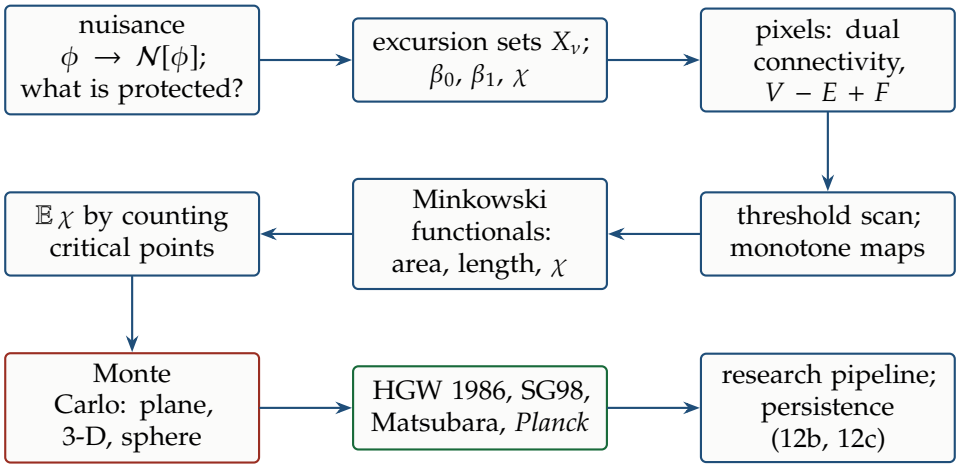

Figure 12.1: The route through the ideas. A nuisance transformation motivates looking for protected quantities; the excursion set turns a field into a shape whose pieces and holes can be counted; pixels force a counting convention; scanning the threshold and the three Minkowski functionals organise the counts; the expected Euler characteristic of a Gaussian field follows from counting critical points. The red box is the numerical test of that formula, the green box the reproduction of the published results.

12.1 What survives a nuisance transformation?

Take one temperature map of the microwave sky. Before it reached us, the light was deflected by the matter it passed, so every hot spot is displaced by a few arcminutes and slightly stretched. The telescope then blurred it with its beam and the detectors added noise. Each of these steps changes the numbers in the map. If we summarise the map by its power spectrum, each of them also changes the summary: lensing moves power between scales and turns some E-mode polarization into B modes (Chapter T1), the beam suppresses the high multipoles (Section 7.6.4), and the noise adds a bias (Section 8.3). In Chapter 8 we handled this the honest way: model each step and simulate it. There is a second strategy, and this chapter is about it. Instead of modelling a nuisance, look for a quantity it cannot change.

The question. Suppose a physical theory produces a field $\phi(\boldsymbol{x})$ and an experiment gives us one imperfect realisation of it. The values of the field are altered by processes we regard as nuisance: perturbations along the way, noise, smoothing, propagation. Is there information about the *shape and structure* of the data that these alterations leave intact?

12.1.1 A nuisance is an operator; a protected statistic ignores it

Write the effect of the nuisance as an operator acting on the whole field,

$$\phi \longrightarrow \phi' = \mathcal{N}[\phi]. \tag{12.1}$$

Here ϕ is the field as the physics made it, ϕ' the field we receive, and $\mathcal{N}$ the **nuisance operator**: lensing, a beam, a monotone change of units, added noise, or a combination. A summary

statistic T is a rule that turns a whole field into a number (or a short list of numbers), like the variance, the power at one wavenumber, or the count of hot spots. The ideal situation is a statistic that does not notice the nuisance,

$$T\big[\mathcal{N}[\phi]\big] = T[\phi] \qquad \text{for every field } \phi \text{ the theory can produce.} \tag{12.2}$$

We call such a T **protected** against $\mathcal{N}$. Read in words: we may measure T on the field we received and interpret it as if we had measured it on the field the physics made, without ever modelling the nuisance. That is a physical reason to care about T, not just one more way of compressing data.

The power spectrum is not protected against any of the nuisances above, as we just saw. What could be? Think about what lensing actually does. It does not change the temperature of a photon; it changes the direction from which the photon seems to arrive. To first order the observed map is the true map evaluated at a displaced point,

$$\phi'(\boldsymbol{x}) = \phi\big(\boldsymbol{x} + \boldsymbol{s}(\boldsymbol{x})\big), \tag{12.3}$$

with $\boldsymbol{s}$ a small, smooth displacement field (the lensing deflection; Chapter T1 and Section T3.4). Every value present in ϕ is still present in ϕ'; only its location has moved. A hot region is carried along, stretched or squeezed, but if the displacement is smooth and never folds the sky onto itself, the region is not torn into two and no two regions are glued together. So any statistic that counts *how regions are connected*, rather than how large or how long they are, has a chance to be protected.

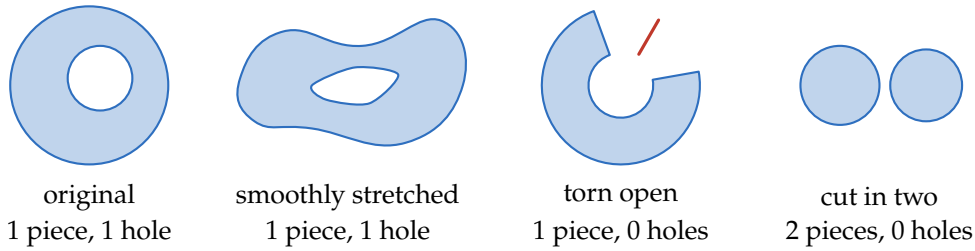

Figure 12.2: What a smooth one-to-one deformation can and cannot do. Stretching the ring (second panel) changes its area and the length of its boundary, but it is still one piece with one hole. Only an operation that tears (third panel, the red cut) or cuts the region (fourth panel) changes these counts.

Figure 12.2 makes the distinction concrete. The number of pieces and the number of holes of a region survive any deformation that neither tears nor glues. Mathematicians call such counts **topological invariants**; the precise statement, and why the counts are well defined, is in the topology notes. For us the working content is short: *a count of pieces and holes can change only at an event where something is torn or glued*.

12.1.2 The protection is conditional

Equation (12.2) is an ideal, and the honest version of it always comes with a condition. A topological count is protected against a stated *class* of transformations, the smooth one-to-one ones, and against nothing else. Noise is not in that class: it adds new small hot and cold spots everywhere, which creates pieces and holes out of nothing. A beam is not in it either: it averages neighbouring values, so two nearby hot spots can merge into one. A remapping that is too strong can fold, sending two different points to the same place, and then regions can be glued. Even a perfect remapping of the full sky becomes imperfect on a masked sky, because a region can slide across the edge of the mask. Finding out exactly what is protected, and how well, is part of the physics problem, not a detail to be waved away.

Example: four nuisances on one map. The script `code/ch12/01_nuisance.py` makes one Gaussian random field on a periodic 256×256 grid with the recipe of Section 7.4 (white noise smoothed on 6 pixels, then scaled to zero mean and unit variance) and colours the pixels where the field exceeds one standard deviation. It then applies four nuisance operators and recounts. (i) A smooth remapping (12.3) whose displacement has an r.m.s. of 14 pixels and varies on a scale of about 45 pixels; the smallest value of the Jacobian $\det(\mathbb{1} + \nabla \boldsymbol{s})$ over the map is 0.33, positive, so the map never folds. (ii) A monotone change of the values, $\phi \to e^{\phi} + \phi^3$, with the threshold moved along with it (Section 12.3.2). (iii) White noise of r.m.s. 0.3 added to every pixel. (iv) Extra smoothing by a Gaussian of 6 pixels. The numbers are:

	area [%]	boundary length [pix]	pieces β_0	holes β_1	$\beta_0 - \beta_1$
original	15.2	2136	37	0	37
smooth remapping	12.5	1957	37	0	37
monotone values	15.2	2136	37	0	37
added noise	16.5	11241	493	450	43
extra smoothing	15.9	1648	17	0	17

The remapping changed the area by 2.8 percentage points and the boundary length by about 8 per cent, but not a single piece or hole was created or destroyed. The monotone change left everything identical, pixel for pixel (the script checks that the two coloured sets coincide: yes). The noise multiplied the number of pieces by more than 13, because it sprinkled tiny one- and two-pixel islands and lakes over the map (Figure 12.3). The extra smoothing merged and erased the smallest hot spots and lost 54% of the pieces. So the counts are protected against exactly the first two operators, and badly broken by the last two, as the argument above predicted.

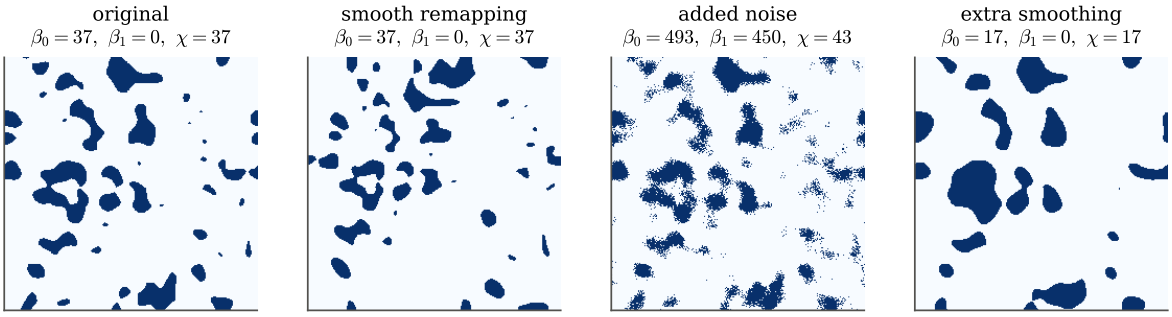

Figure 12.3: The pixels above one standard deviation (dark) for the original field and three of the transformed ones. The smoothly remapped set looks distorted but has the same pieces and holes. Added noise covers the map with tiny spurious pieces; extra smoothing merges or removes the small ones.

Example: lensing of the microwave sky. Section T3.4 carried out this experiment with real lensing deflections on flat patches of the simulated CMB sky. When the deflection was applied as a pure remapping, the Euler characteristic (the pieces minus the holes, defined properly in Section 12.2) changed only at the level of pixel ambiguities; when the beam was applied after the lensing, the change grew to a few tenths of a per cent. That is the same pattern as the table above, with the real nuisance in place of a toy one: the remapping is harmless, the smoothing that follows it is not.

Example: polarization singularities. The polarization of the microwave background has points where it vanishes and its direction is undefined, and around each the direction turns by a

definite half-integer number of turns, its index (Section T3.3). A smooth one-to-one remapping can move such a point and distort its surroundings, but it cannot change its index continuously, so the index is protected [1, 2]. It fails exactly where the conditions fail: when two singularities of opposite index annihilate, when one crosses the edge of the region, or when noise and finite resolution blur it [3]. The method of thought is the same in every example: *identify the nuisance first, then look for information it cannot easily erase*.

12.1.3 Two different questions: what survives, and what changes

The invariance argument is easy to misuse. Topology is unchanged by smooth one-to-one deformations of a *region*. That does not mean the topology of a physical field is unchanged by the *dynamics* that evolves it. Gravitational collapse is not a remapping of the initial density: matter flows together, peaks merge, filaments form and voids empty. The connectivity of the overdense regions at late times is genuinely different from that at early times, and simulations of structure formation track exactly this change with the counts of pieces, loops and voids and their persistence [4, 5]. There the change *is* the signal.

So topology answers two different questions, and an analysis must say which one it asks. For a nuisance that acts like a smooth remapping, the question is *what survives*, and the protected counts are the answer. For a physical process that creates, destroys or reconnects structures, the question is *what changes because of the physics*, and the same counts are the record of it. In both cases the counts are summaries of the data that the power spectrum does not expose: two fields can have identical spectra and very different connectivity, like the rings and their phase-randomised twin of Section 7.7. That is the question behind the last row of the taxonomy of summaries in Section 7.7.1: is there physically meaningful information in the way regions of the field are connected that the statistic we are already using does not expose?

12.2 The topology of a field: excursion sets and what we count in them

A weather map shows the temperature over a country. Ask a forecaster for "the topology of the temperature field" and the question has no answer: the country has a shape, and the field puts a number at every place in it, but a list of numbers has no pieces or holes. Ask instead "which regions are warmer than 25°C?" and the answer is a set of regions you can colour on the map. That coloured set has a shape, and the shape can be counted: three warm regions, one of them with a cooler lake inside. This is the whole trick. We do not assign a topology to the field; we use the field to cut out regions, and we count the topology of the regions.

12.2.1 Excursion sets

Let the field be a map $\phi : \mathcal{M} \to \mathbb{R}$ from a domain $\mathcal{M}$ (a square patch, a periodic box, the sky) to the real numbers. Throughout, ϕ is measured in units of its own standard deviation σ, so a threshold $\nu = 1$ means one standard deviation above the mean.

Working definition 12.1 (excursion set, Betti numbers, Euler characteristic)

The **excursion set** at threshold ν is

$$X_\nu = \{\boldsymbol{x} \in \mathcal{M} : \ \phi(\boldsymbol{x}) > \nu\}, \tag{12.4}$$

the part of the domain where the field exceeds ν [on a CMB map, the directions hotter than the threshold]. In two dimensions $\beta_0(X_\nu)$, the zeroth **Betti number**, is the number of connected pieces of X_ν [pieces that cannot be joined by a path staying inside X_ν], and

$\beta_1(X_\nu)$ is the number of its holes [bounded regions of the complement, each fully enclosed by X_ν]. The **Euler characteristic** of a set in the plane is

$$\chi(X_\nu) = \beta_0(X_\nu) - \beta_1(X_\nu). \tag{12.5}$$

Operationally: colour the pixels above ν, count the coloured pieces, count the uncoloured regions that do not reach the edge, subtract.

Read (12.4) as a machine. The input is a field, which carries a number at every point; the output is a set, which carries a shape. Everything in this chapter measures that set. For a CMB map $T(\hat{\boldsymbol{n}})$ on the sphere, X_ν is literally the set of directions $\hat{\boldsymbol{n}}$ with $T(\hat{\boldsymbol{n}}) > \nu\sigma$, the hot spots at that threshold. "Studying the topology of a field" means studying the topology of its excursion sets, threshold by threshold.

Why pieces minus holes? Each Betti number on its own is a perfectly good count, and parts 12b and 12c use them separately. The combination (12.5) is singled out for two reasons. First, it can be computed by purely local bookkeeping, counting corners, edges and squares, with no need to find which pixels are connected to which (Section 12.2.3). Second, its average over a Gaussian random field can be calculated exactly (Section 12.5), which neither β_0 nor β_1 alone allows. In three dimensions a solid region can also enclose sealed cavities, counted by β_2, and the Euler characteristic becomes $\beta_0 - \beta_1 + \beta_2$ (Section T3.6.2).

Example: three shapes. A disc has one piece and no hole: $\chi = 1 - 0 = 1$. The ring of Figure 12.2 has one piece and one hole: $\chi = 1 - 1 = 0$. A slice of Swiss cheese with three holes has $\chi = 1 - 3 = -2$. Three separate discs have $\chi = 3$. So χ is positive when the set is made of isolated islands and negative when it is a connected sea full of lakes. A threshold scan will move between these two extremes (Section 12.3).

Why the counts survive deformations. A continuous deformation that neither tears nor glues sends paths to paths, so two points that could be joined inside the set can still be joined afterwards, and two points that could not still cannot; the number of pieces is unchanged. A hole is a piece of the complement fully surrounded by the set, and the same argument applied to the complement keeps the number of holes. In fact more is true: the counts are unchanged even by continuous shrinkings, such as squeezing a ring down to a thin circle, as long as nothing is cut (homotopy invariance; see the topology notes). That is why the counts are robust to the smooth remapping of Section 12.1.1, and why they are blind to how big or how elongated the pieces are.

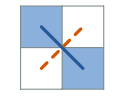
12.2.2 Pixels: which pixels touch?

A real map is a grid of pixels, and the excursion set is a set of coloured squares. To count pieces we must decide when two coloured squares belong to the same piece. Two squares that share an edge clearly touch. Two squares that meet only at a corner are the problem. Under the **4-neighbour** rule only the four squares sharing an edge are neighbours; under the **8-neighbour** rule the four diagonal squares are neighbours too.

Does the choice matter? Look at the smallest troublesome pattern, a 2×2 block coloured like a chessboard (Figure 12.4, left). Under the 8-neighbour rule the two dark squares form one piece, connected through their shared corner. If we also used the 8-neighbour rule for the light squares, they too would form one piece, through the very same corner. Two paths, one dark and one light, would cross at a point without either being interrupted. That cannot happen for regions in the plane: a closed curve always separates its inside from its outside (the Jordan curve theorem; see the topology notes). So if the dark set is 8-connected, its complement must

be 4-connected, and vice versa. With this **dual** convention every dark corner contact cuts the light squares apart there, and the counts of pieces and of holes are consistent with each other.

There is a natural way to see which pairing we are using. Take each coloured pixel to be a *closed* unit square, edges and corners included. Two diagonal squares then share a corner point, so the union is 8-connected. The uncoloured part of the plane is what is left, the union of *open* squares minus every point that belongs to a coloured square; two uncoloured diagonal squares are separated by the coloured corner between them, so the complement is 4-connected. Throughout this chapter the excursion set is the union of closed squares of the pixels above threshold: 8-neighbours for the set, 4-neighbours for the complement. The opposite choice, 4 for the set and 8 for the complement, is equally consistent; the two choices give different counts only where the field crosses the threshold at a saddle inside a single 2×2 block, which becomes rare when the field is smooth on the scale of a pixel (the last example of Section 12.2.3 measures how rare).



8 for both:
paths cross

2	2	2	0	0

0	0	0	1	0
1	0	0	0	0

$\nu = 0.5$

2	2	2	0	0
2	0	2	0	1
2	2	3	0	0
0	0	0	1	0
1	0	0	0	0

$\nu = 1.5$

2	2	2	0	0
2	0	2	0	1
2	2	3	0	0
0	0	0	1	0
1	0	0	0	0

$\nu = 2.5$

Figure 12.4: Left: the chessboard pattern. If dark squares touching at a corner were connected and light ones too, the dark path (solid) and the light path (dashed) would cross without either being broken; so the complement of an 8-connected set must be 4-connected. Right: the 5×5 hand example. Each pixel shows its field value; the pixels above the threshold are shaded.

Example: a 5×5 field by hand. Take the field values of Figure 12.4 (right), with row 1 at the top. At $\nu = 0.5$ the coloured pixels are the seven 2s and the 3 that together surround the central 0, and three 1s. Count the pieces with 8-neighbours. The ring of 2s and the 3 is one piece. The 1 in row 4, column 4 touches the 3 at a corner, so it joins the ring. The 1 at the right end of row 2 has no coloured neighbour at all, nor does the 1 at the bottom left. So $\beta_0 = 3$. Count the holes with 4-neighbours for the uncoloured pixels: the central 0 of the ring is surrounded on all four sides and cannot reach the edge, so it is a hole; every other uncoloured pixel reaches the edge. So $\beta_1 = 1$ and $\chi = 3 - 1 = 2$. With the opposite convention, the 1 that touched the 3 only at a corner is a separate piece, $\beta_0 = 4$, while the hole remains, so $\chi = 3$: the one diagonal contact is where the two conventions disagree. At $\nu = 1.5$ only the ring of 2s and the 3 survive: one piece with one hole, $\chi = 0$ under both conventions. At $\nu = 2.5$ only the single 3 survives, $\chi = 1$. The script `code/ch12/02_grid_counting.py` repeats these counts in code and finds 3, 1, 2 (and 3 with the opposite convention) at $\nu = 0.5$, 0 at 1.5 and 1 at 2.5.

Counting pieces and holes in code. Counting the pieces of a binary image is a standard task, connected-component labelling, and `scipy.ndimage.label` does it for either neighbour rule. For the holes we use the definition directly: a hole is a piece of the complement that does not reach the outside. Surround the image with a one-pixel frame of uncoloured pixels, so that everything outside the image becomes one single uncoloured piece; then label the uncoloured pixels with the dual rule and subtract that one outside piece:

Listing 12.1: Betti numbers of a pixel set in the plane (`code/ch12/lib_topo.py`)

```
def betti_plane(mask, conn: int = 8):
    """(beta0, beta1) of a pixel set in the plane.
```

```
    beta0: components of the set with 'conn'-connectivity.
    beta1: holes = components of the complement that cannot reach the outside, counted
           with the DUAL connectivity (4 if conn == 8, else 8).  Padding the image with a
           frame of background makes everything outside the grid one single component, so
           beta1 = (components of the padded complement) - 1.
    """
    mask = np.asarray(mask, dtype=bool)
    b0 = n_components(mask, conn)
    comp = ~np.pad(mask, 1, constant_values=False)
    b1 = n_components(comp, 4 if conn == 8 else 8) - 1
    return b0, b1
```

That a hole of a region in the plane is the same thing as a bounded piece of its complement is a special property of the plane (and of the sphere), known as Alexander duality (see the topology notes). In three dimensions holes are tunnels, and they cannot be found this way.

12.2.3 The Euler characteristic as vertices minus edges plus faces

There is a second way to compute χ that never asks which pixels are connected. Think of the union of closed squares as built from three kinds of cells: the lattice points at the corners of coloured pixels (vertices, V of them), the unit segments on the sides of coloured pixels (edges, E), and the coloured pixels themselves (faces, F). Each vertex and each edge is counted once, however many coloured pixels share it. Then

$$\chi = V - E + F. \tag{12.6}$$

This is the formula Euler found for polyhedra, and it holds for any set built of cells (see the topology notes for the general statement). We can see why it agrees with $\beta_0 - \beta_1$ for pixel sets by building the set one pixel at a time and checking that both sides change by the same amount at every step.

One square on its own has $V = 4$, $E = 4$, $F = 1$: $\chi = 4 - 4 + 1 = 1$, one piece and no hole.

Adding one more square. Suppose the set is already built and we add one coloured square. The new square brings one face. Some of its four vertices and four edges may already be present, namely those where it touches the existing set. Call the part of its boundary where it touches the set the *contact*. The contact is made of c separate arcs, each a path along the square's boundary made of k_i edges and $k_i + 1$ vertices (an arc can be a single corner, $k_i = 0$). Then

$$\begin{aligned} \Delta\chi &\overset{(1)}{=} \Delta V - \Delta E + 1 \\ &\overset{(2)}{=} \Big[4 - \sum_{i=1}^{c} (k_i + 1)\Big] - \Big[4 - \sum_{i=1}^{c} k_i\Big] + 1 \\ &\overset{(3)}{=} 1 - c. \end{aligned} \tag{12.7}$$

(1) One new face; ΔV and ΔE are the vertices and edges of the new square that were not there before.

(2) The square has 4 vertices and 4 edges; the arcs of the contact already contain $k_i + 1$ vertices and k_i edges each.

(3) The 4s cancel and each arc contributes $-(k_i + 1) + k_i = -1$.

Now check $\beta_0 - \beta_1$ in each case. If $c = 0$ the square is isolated: a new piece, $\Delta\beta_0 = +1$, and (12.7) gives $+1$. If $c = 1$ the square is glued to one piece along one arc, which changes neither the number of pieces nor the number of holes, and (12.7) gives 0. If $c = 2$ the square touches the set

in two separate places. Either those two places belonged to different pieces, which the square now joins ($\Delta\beta_0 = -1$), or to the same piece, in which case the square closes a loop around some uncoloured region and creates a hole ($\Delta\beta_1 = +1$). Either way $\Delta(\beta_0 - \beta_1) = -1 = 1 - c$. Each further arc merges one more piece or closes one more hole, and costs one more unit. The last case is a square whose whole boundary is already present, a one-pixel hole being filled: then the contact is a closed loop with 4 vertices and 4 edges, $\Delta V = \Delta E = 0$, $\Delta\chi = +1$, and indeed one hole disappears, $\Delta\beta_1 = -1$. Since both sides start at 0 for the empty set and change identically at every step, $V - E + F = \beta_0 - \beta_1$ for every pixel set.

Example: the ring by cells. The 3×3 block of the hand example without its centre has the $4 \times 4 = 16$ lattice points as vertices, 12 horizontal and 12 vertical unit edges (every side of the central hole is also a side of a coloured neighbour), and 8 faces: $\chi = 16 - 24 + 8 = 0$, one piece and one hole, as counted by hand.

The cell count is a sum of local terms, so it vectorises in a few lines of `numpy`. A lattice vertex is present if any of the four pixels around it is coloured, an edge if either of the two pixels beside it is:

Listing 12.2: Euler characteristic as $V - E + F$ of the pixel complex (`code/ch12/lib_topo.py`)

```
def euler_cubical(mask, conn: int = 8, periodic: bool = False) -> int:
    """chi = V - E + F of the cubical complex of a binary image.

    conn = 8: union of closed pixel squares (pixels are faces).  A lattice vertex or edge
              belongs to the set if ANY pixel touching it does.
    conn = 4: the dual construction (pixels are vertices).  An edge joins two 4-neighbour
              pixels that are both in the set, a face fills a 2x2 block that is entirely in.
    periodic: the grid is a torus (opposite sides glued), as for an FFT-generated field.
    """
    m = np.asarray(mask, dtype=bool)
    if conn == 8:
        if periodic:
            r0 = np.roll(m, 1, 0)
            r1 = np.roll(m, 1, 1)
            V = (m | r0 | r1 | np.roll(r0, 1, 1)).sum()
            E = (m | r0).sum() + (m | r1).sum()
        else:
            P = np.pad(m, 1)
            V = (P[:-1, :-1] | P[1:, :-1] | P[:-1, 1:] | P[1:, 1:]).sum()
            E = (P[:-1, 1:-1] | P[1:, 1:-1]).sum() + (P[1:-1, :-1] | P[1:-1, 1:]).sum()
        F = m.sum()
    else:
        if periodic:
            r0 = np.roll(m, -1, 0)
            r1 = np.roll(m, -1, 1)
            E = (m & r0).sum() + (m & r1).sum()
            F = (m & r0 & r1 & np.roll(r0, -1, 1)).sum()
        else:
            E = (m[:-1, :] & m[1:, :]).sum() + (m[:, :-1] & m[:, 1:]).sum()
            F = (m[:-1, :-1] & m[1:, :-1] & m[:-1, 1:] & m[1:, 1:]).sum()
        V = m.sum()
    return int(V) - int(E) + int(F)
```

The other branch builds the dual complex (4-neighbour convention), in which pixels are vertices, edges join two coloured 4-neighbours and a face fills a fully coloured 2×2 block. The `periodic` option treats the grid as a torus, which is how a field made with the fast Fourier transform really lives (Section 7.4.1). On a torus a set could in principle wrap all the way around and have holes that are not bounded lakes; at the thresholds and smoothing scales used here this never happens, and $\beta_1 = \beta_0 - \chi$.

Example: three methods on many fields. The script `code/ch12/02_grid_counting.py` draws 200 Gaussian fields on a 128×128 grid, smoothed on 4 pixels, and at each of 9 thresholds between -2 and 2 computes χ four ways: by labelling ($\beta_0 - \beta_1$), by cells ($V - E + F$), by `skimage.measure.euler_number` with 8-connectivity, and by the Betti numbers that the cubical-complex code of `gudhi` assigns to the same union of closed squares. In all 1800 cases the four answers agree exactly: 0, 0 and 0 mismatches. The cell count takes 0.1 ms per image, labelling 0.29 ms; `gudhi` takes 17.51 ms per field, but for that price it computes the counts at *every* threshold at once, which is what persistence will need in part 12b. Figure 12.5 shows what is being counted on one small map.

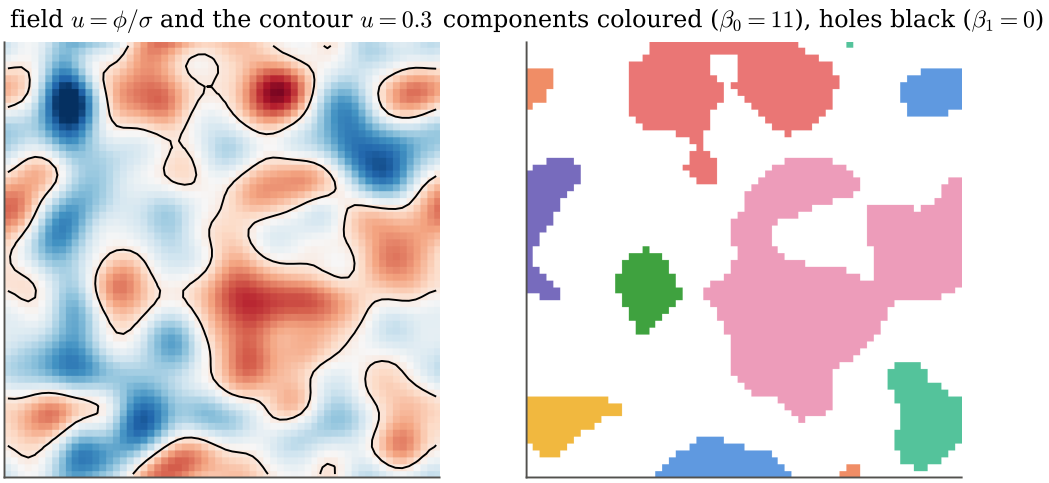

Figure 12.5: One 64×64 Gaussian field (left) with its contour at $\nu = 0.3$, and the excursion set above that contour (right). Each 8-connected piece has its own colour ($\beta_0 = 11$); an uncoloured region that cannot reach the edge is drawn black; this field has $\beta_1 = 0$ of them, so $\chi = 11$.

Example: when does the convention matter? The same script compares the two conventions on fields smoothed on $R = 1$, 2, 4 and 8 pixels. The average difference $|\chi_8 - \chi_4|$, as a fraction of the average $|\chi_8|$, is 15.7%, 4.1%, 1% and 0.1%. A field that changes from pixel to pixel produces many diagonal contacts and the convention matters a great deal; a field smoothed over several pixels produces few, and the two conventions converge. The practical rule: smooth the map on a scale of a few pixels or more before counting, and always state the convention.

Watch out: A count without a convention is not a measurement

The same pixels give different Betti numbers under the 4- and the 8-neighbour rules, and an analysis that uses 8-neighbours for both the set and its complement (or 4 for both) can report a hole count that is inconsistent with its piece count. Fix the pairing (8 for the set, 4 for the complement, or the reverse), use the same one for data and simulations, and smooth on several pixels so that the residual dependence is small.

12.3 Scanning the threshold

Imagine flooding a hilly landscape. With the water level very low, only the deepest valleys are lakes and the dry land is one continent full of holes. As the water rises the lakes grow and join, the continent breaks into islands, and finally only a few mountain tops stick out. The dry land is the excursion set X_ν of the height field, and the water level is the threshold ν, lowered or

raised. A single threshold catches one moment of this story; scanning the threshold tells the whole of it.

12.3.1 One map, all thresholds

The script `code/ch12/03_threshold_scan.py` makes one Gaussian field on a 256×256 grid, smoothed on 4 pixels (the recipe of Section 7.4), scales it to zero mean and unit variance, and computes β_0, β_1 and χ of the excursion set at thresholds from -2.5 to 2.5 in steps of 0.25, with the functions of Section 12.2.2. Three rows of its output:

threshold ν	pieces β_0	holes β_1	$\chi = \beta_0 - \beta_1$
-1	5	65	-60
0	26	21	5
1	77	0	77

At $\nu = -1$ about 84% of the map is above threshold (a standard normal value exceeds -1 with probability 0.84). It forms one large connected sea with a few small islands beside it, and the cold spots below -1 are its holes: χ is large and negative. At $\nu = 0$ half the map is coloured and the set is a tangle of large pieces and holes that nearly cancel. At $\nu = 1$ only 16% is coloured, in separate islands around the hot spots, almost none of them with a hole: χ is large and positive. The full scan is Figure 12.6. The number of pieces rises to a maximum of 78 near $\nu \approx 1$ and then falls, because at still higher thresholds the islands shrink and disappear one by one. The number of holes does the mirror image at negative thresholds.

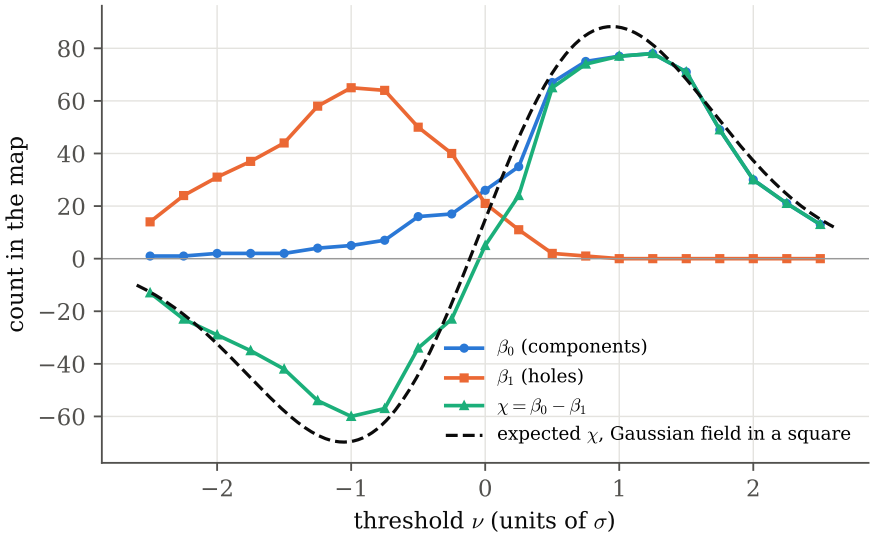

Figure 12.6: Pieces, holes and their difference for one 256×256 Gaussian map as the threshold is scanned. Holes dominate at negative thresholds and pieces at positive ones; χ swings from negative to positive. The dashed curve is the expected χ for a Gaussian field in a square, derived in Sections 12.5 and 12.5.5.

Example: the mirror symmetry. The holes at $\nu = -1$ (65 of them) and the pieces at $\nu = +1$ (77) are similar numbers. That is not a coincidence. A hole of X_{-1} is a bounded region where $\phi < -1$, which is a piece of the excursion set of the field $-\phi$ above $+1$. A Gaussian field with zero mean is exactly as probable as its negative, so the cold spots of ϕ below -1 are statistically identical to the hot spots of ϕ above $+1$. On average, then, $\beta_1(-\nu)$ equals $\beta_0(+\nu)$ and $\chi(-\nu) = -\chi(\nu)$ (up

to small corrections from the edges of the map, which Section 12.5.5 computes). On one map the two counts differ by the realisation's own fluctuations. A field whose hot spots and cold spots differ, for example one with a skewed distribution of values, breaks this symmetry, and the asymmetry of the χ curve is one of the simplest tests of Gaussianity.

These numbers belong to one random map. They are not yet a measurement of anything: another map from the same theory gives other numbers. They become a statistic only when we know how they scatter from map to map, which is what the Monte Carlo of Section 12.6 and the whole of part 12c are about. The scan raises a second question too: if one threshold is an arbitrary choice, why not keep track of every piece and every hole as the threshold moves, recording at which level each appears and at which it disappears? That bookkeeping is persistent homology, the subject of part 12b.

12.3.2 A change of the values that changes nothing

Suppose the field we observe is not ϕ but a pointwise, increasing function of it,

$$\phi'(\boldsymbol{x}) = f\big(\phi(\boldsymbol{x})\big), \qquad f'(\phi) > 0. \tag{12.8}$$

A change of units is such a function; so is the map from the initial density to a lognormal model of the evolved density, $\phi' = e^{a\phi}$; so is the response of a detector that saturates smoothly. The function changes every value but moves no point. *What does it do to the excursion sets?* Move the threshold along with the values:

$$\boldsymbol{x} \in X'_{f(\nu)} \overset{(1)}{\iff} f\big(\phi(\boldsymbol{x})\big) > f(\nu) \overset{(2)}{\iff} \phi(\boldsymbol{x}) > \nu \overset{(3)}{\iff} \boldsymbol{x} \in X_\nu. \tag{12.9}$$

(1) The definition (12.4) of the excursion set of ϕ' at threshold $f(\nu)$.
(2) A strictly increasing function preserves order in both directions: $a > b$ if and only if $f(a) > f(b)$.
(3) The definition of the excursion set of ϕ at threshold ν.

So $X'_{f(\nu)}$ and X_ν are the same subset of the domain, point for point. Their pieces, holes, area and boundary are identical. A monotone change of the values is a nuisance against which *every* property of the excursion sets is protected, provided the threshold is relabelled.

But we do not know f. In practice nobody tells us the function; we only see ϕ'. If we threshold ϕ' in units of its own standard deviation, as we did for ϕ, the thresholds no longer correspond and the curves look different. There is one label that every monotone f respects: the *fraction of the area* above threshold. By (12.9) the set $X'_{f(\nu)}$ has the same area as X_ν. So instead of labelling a threshold by its value, label it by the area it encloses, and convert that area back to a Gaussian-equivalent threshold ν_A through

$$\Psi(\nu_A) = \text{fraction of the map above the threshold}, \qquad \Psi(\nu) \equiv \int_\nu^\infty \frac{e^{-t^2/2}}{\sqrt{2\pi}}\,\mathrm{d}t, \tag{12.10}$$

the probability that a standard normal variable exceeds ν. For a Gaussian field $\nu_A = \nu$ on average, because the expected area fraction above ν is exactly $\Psi(\nu)$ (Section 12.4). For any monotone function of a Gaussian field the excursion set at area-fraction threshold ν_A is the same set as the Gaussian one at ν_A. In code, the threshold with a given area fraction is a quantile of the map's values:

Listing 12.3: The threshold that encloses a given area fraction (`code/ch12/03_threshold_scan.py`)

```
1 def thresh_area(x, nua):
```

```
    """Threshold t with area fraction P(x > t) equal to the Gaussian tail Psi(nua)."""
    frac = 0.5 * (1 - erf(np.asarray(nua) / np.sqrt(2)))
    return np.quantile(x, 1 - frac)
```

Example: a lognormal field. The same script takes 60 Gaussian maps ϕ and their lognormal versions $e^{0.8\phi}$, each standardised to zero mean and unit variance. Thresholded in units of their own standard deviation (Figure 12.7, left), the two χ curves disagree badly. At $\nu = -1$ the Gaussian maps give a mean χ of -80.4, the lognormal ones -9.6. The reason is simple once found: the lognormal field is positive and skewed, so its standardised values cannot go below about -1.06, and at $\nu = -1$ almost the whole map is above threshold, with very few holes. Relabelled by area fraction (right panel), the two curves are identical; the script checks that the two excursion sets coincide pixel for pixel at every threshold of every map: yes.

Example: a field that is not a monotone function of a Gaussian one. Now take two independent Gaussian fields ϕ and ψ with the same spectrum and form $\phi^2 + \psi^2$, a χ^2 field with two degrees of freedom, standardised. Its values are skewed like the lognormal's, but it is not a pointwise function of a single Gaussian field: its value at a point depends on two independent fields, and its lowest values sit only near the isolated points where both happen to vanish. Relabelling by area fraction cannot undo that. At $\nu_A = 1$ its mean χ is 139.4 against the Gaussian 80.4, and at $\nu_A = -1$ it is -196.2 against -80.4. The remaining difference is information about how the field is arranged in space, which no change of units can create or remove.

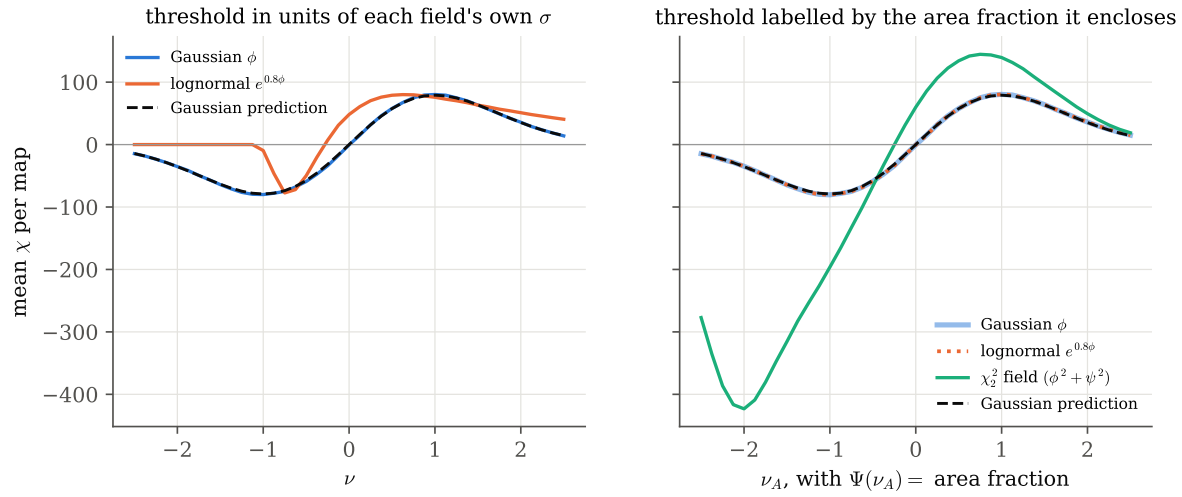

Figure 12.7: Mean χ per 256×256 map. Left: thresholds in units of each field's standard deviation; the lognormal field (orange) looks very different from the Gaussian one (blue). Right: thresholds labelled by the area fraction they enclose; the lognormal and Gaussian curves now lie exactly on top of each other, while the χ^2 field (green), which is not a monotone function of one Gaussian field, still differs.

Section T3.2.2 reached the same conclusion from the other side, for the slightly skewed skies of weakly non-Gaussian models: the part of the change in the Minkowski functionals that comes from a pointwise distortion of the values is only a sideways shift of the curves, and it disappears at fixed area fraction. What the two examples here add is the exact, non-perturbative version: for *any* increasing function, however strongly non-Gaussian the values, the curves at fixed area fraction are untouched. Two lessons follow. First, labelling by area fraction separates the information carried by the one-point distribution of values (which a histogram of the map already gives) from the information about spatial arrangement, which is what topology is

for. Second, the same argument marks the limit of the invariance discussed in Section 12.1.3: gravitational evolution is not a pointwise function of the initial density, because it moves matter, so its effect on the excursion sets does not disappear under relabelling. That is why the topology of the evolved density field carries information about the dynamics.

12.4 Area, boundary length and Euler characteristic

The microwave-sky chapter already measured the shapes of hot spots with three numbers (Section T3.1): the area fraction of the excursion set, a quarter of its boundary length per steradian, and its Euler characteristic per steradian, called v_0, v_1 and v_2. There we derived the expected area fraction and boundary length of a Gaussian sky, (T3.2) and (T3.6), and stated the expected Euler characteristic (T3.7) without proof, promising the derivation for this chapter. Two things are different now. The field lives on a flat square grid, so lengths are in pixels and there is no curvature of the domain to worry about until Section 12.5.6. And we need the Euler characteristic not as a number to be quoted but as a quantity we can compute, which means writing it in a form that the counting argument of Section 12.5 can attack.

12.4.1 Three numbers per threshold

Why exactly these three? Suppose we want a number $S(X)$ that describes the shape of a region X of the plane and has three properties. It is *additive*: for two regions, $S(X \cup Y) = S(X) + S(Y) - S(X \cap Y)$, so the shape number of a set of separate islands is the sum over the islands. It is *motion invariant*: moving or rotating the region does not change it, which is what we want on a statistically homogeneous and isotropic sky. And it changes *continuously* when the region is changed a little. Hadwiger's theorem says that every such S is a linear combination of three numbers: the area A, the boundary length L, and the Euler characteristic χ [105]. In this sense the three are a complete set of shape measures of this kind; any other such measure contains no new information. They are the **Minkowski functionals** of the region.

Working definition 12.2 (Minkowski functionals of an excursion set)

For a field $u = \phi/\sigma$ on a region of area A_{tot}, and a threshold ν:

- area fraction $a(\nu) = \text{area}(X_\nu)/A_{\text{tot}}$ [the share of pixels above ν];
- boundary length per unit area $\ell(\nu) = \text{length}(\partial X_\nu)/A_{\text{tot}}$ [the total length of the contour $u = \nu$ per unit area];
- Euler characteristic per unit area $c(\nu) = \chi(X_\nu)/A_{\text{tot}}$ [pieces minus holes per unit area].

On the sky, $v_0 = a$, $v_1 = \ell/4$ and $v_2 = c$ (with the sphere's own curvature removed, Section 12.5.6).

The area fraction and the boundary length are the "metric" functionals: a smooth remapping changes them (Section 12.1.1). The Euler characteristic is the topological one. Yet Hadwiger's theorem puts it on the same footing, as the third member of a family. To see how a count of pieces can be a functional of the same kind as a length, we need one more way of writing it.

12.4.2 The Euler characteristic as the total turning of the boundary

Walk once around the boundary of a disc, keeping the disc on your left. Your direction of travel turns steadily, and by the time you are back at the start it has turned through one full circle, 2π.

Now walk around a lake inside an island, again keeping the land on your left: you go around the lake clockwise, and your direction turns through -2π. Deform the island and the lake however you like: the walk can wiggle, turning left and right, but every left turn that is not undone by a right turn would leave you facing a new direction at the end, and you must end facing the way you started, having gone once around. So the total turning of a closed boundary curve without self-crossings is exactly $\pm 2\pi$, whatever its shape (the turning-tangent theorem; see the topology notes).

The rate of turning per unit length is the **curvature** of the boundary, κ: on a circle of radius r it is $1/r$, so the total turning is $\kappa\times$length $= (1/r)(2\pi r) = 2\pi$. Add up the total turning over all the boundary curves of a region, each walked with the region on the left. Each piece has one outer boundary and contributes $+2\pi$; each hole has one boundary walked clockwise and contributes -2π. Therefore

$$\frac{1}{2\pi}\oint_{\partial X} \kappa \, \mathrm{d}l = \beta_0(X) - \beta_1(X) = \chi(X). \tag{12.11}$$

This is the bridge. The Euler characteristic is the integral, along the boundary, of a local geometric quantity, the curvature, exactly as the boundary length is the integral of 1 along the boundary. That is why it belongs with the area and the length, and why it is the quantity V_2 of [105] (their eq. 6, $V_2 = \frac{1}{2\pi}\int \kappa \, \mathrm{d}l$).

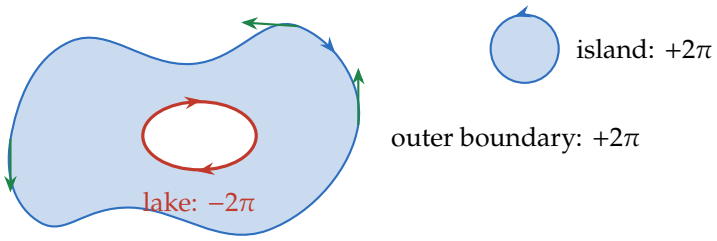

Figure 12.8: Walking each boundary with the set (blue) on the left. The outer boundary of a piece turns in total by $+2\pi$, however wiggly it is; the shore of a lake is walked clockwise and turns by -2π. The total turning divided by 2π is pieces minus holes, here $2 - 1 = 1$. The green arrows show the direction of travel at three places.

Example: a disc and a ring. A disc of radius r: curvature $1/r$ along a length $2\pi r$, so (12.11) gives $\frac{1}{2\pi}\cdot 2\pi = 1$. A ring with radii $r_1 < r_2$: the outer circle gives $+1$, the inner circle, walked clockwise, has curvature $-1/r_1$ along $2\pi r_1$ and gives -1; total 0. Neither result depends on the radii, as it must not.

Example: a cap on the sphere. On a curved surface the walk also turns because the surface itself curves, and (12.11) acquires a term from the area. Take the polar cap of angular radius θ on the unit sphere, the set of points within angle θ of the north pole. Its boundary is a circle of latitude of length $2\pi\sin\theta$, whose curvature measured within the sphere (the geodesic curvature) is $\cot\theta$. The surface has Gaussian curvature $K = 1$, and the cap has area $2\pi(1-\cos\theta)$. The Gauss–Bonnet theorem (see the topology notes) adds the integrated surface curvature to the turning of the boundary:

$$\begin{aligned}\chi(\text{cap}) &\overset{(1)}{=} \frac{1}{2\pi}\Big[\oint \kappa_g \, \mathrm{d}l + \int_{\text{cap}} K \, \mathrm{d}A\Big] \\ &\overset{(2)}{=} \frac{1}{2\pi}\Big[\cot\theta \cdot 2\pi\sin\theta + 2\pi(1-\cos\theta)\Big] \\ &\overset{(3)}{=} \cos\theta + 1 - \cos\theta = 1.\end{aligned} \tag{12.12}$$

(1) Gauss–Bonnet for a region of a curved surface: boundary turning plus enclosed curvature, over 2π.
(2) Geodesic curvature $\cot\theta$ times the length $2\pi\sin\theta$ of the circle; $K = 1$ times the area of the cap.
(3) $\cot\theta\sin\theta = \cos\theta$.

The cap is one piece without holes at every size, and the two terms trade off exactly as θ grows. When $\theta \to \pi$ the boundary shrinks to a point near the south pole and the area term alone gives $\frac{1}{2\pi}\cdot 4\pi = 2$, the Euler characteristic of the whole sphere. This is the origin of the extra term in the full-sky formula of [105] (their eq. 7), $\chi = V_2 + V_0/(2\pi R^2)$ on a sphere of radius R, which Section 12.5.6 needs.

12.4.3 Area and length of a Gaussian field, recalled in the plane

Let $u = \phi/\sigma$ be a statistically homogeneous and isotropic Gaussian field with zero mean and unit variance in the plane. The quantity that sets the scale of everything below is the variance of one component of its gradient,

$$\lambda \equiv \big\langle (\partial_x u)^2 \big\rangle = \tfrac{1}{2}\big\langle |\nabla u|^2 \big\rangle = \frac{\sigma_1^2}{2\sigma_0^2}, \tag{12.13}$$

where σ_0^2 is the variance of ϕ and $\sigma_1^2 = \langle|\nabla\phi|^2\rangle$ the variance of its gradient, the spectral moments of (7.35). The two components contribute equally by isotropy, hence the $\frac{1}{2}$. On the sky, (T3.5) defined the correlation angle $\theta_c = \sigma_0/\sigma_1$, so $\lambda = 1/(2\theta_c^2)$. A large λ means a field that changes quickly, with many small spots.

The area. The expected fraction of the plane above ν is the probability that the field at one point exceeds ν (the plane average equals the ensemble average at a point, by homogeneity and ergodicity, Section 7.5):

$$\mathbb{E}[a(\nu)] = \mathrm{P}(u > \nu) = \Psi(\nu), \tag{12.14}$$

with Ψ the Gaussian tail of (12.10).

The length. Thicken the contour $u = \nu$ into the thin band $\nu < u < \nu + \mathrm{d}\nu$. Where the gradient is $|\nabla u|$, the band has width $\mathrm{d}\nu/|\nabla u|$, so its area is the contour length times $\mathrm{d}\nu/|\nabla u|$, averaged along the contour. Turned around, the length per unit area is the area fraction of the band, weighted by $|\nabla u|$ and divided by $\mathrm{d}\nu$, which is the expectation of $|\nabla u|\,\delta(u-\nu)$:

$$\mathbb{E}[\ell(\nu)] \overset{(1)}{=} \mathbb{E}\left[|\nabla u|\,\delta(u-\nu)\right] \overset{(2)}{=} \frac{e^{-\nu^2/2}}{\sqrt{2\pi}}\,\mathbb{E}\,|\nabla u| \overset{(3)}{=} \frac{e^{-\nu^2/2}}{\sqrt{2\pi}}\sqrt{\frac{\pi\lambda}{2}} \overset{(4)}{=} \frac{\sqrt{\lambda}}{2}\,e^{-\nu^2/2}. \tag{12.15}$$

(1) The band argument above (the coarea formula).
(2) At one point u and ∇u are uncorrelated, $\langle u\,\partial_i u\rangle = \frac{1}{2}\partial_i\langle u^2\rangle = 0$ for a homogeneous field, and uncorrelated jointly Gaussian variables are independent; the average of $\delta(u-\nu)$ is the standard normal density at ν.
(3) $|\nabla u|$ is the length of a two-component vector with independent $\mathcal{N}(0,\lambda)$ components, a Rayleigh variable with mean $\sqrt{\lambda}\sqrt{\pi/2}$ (Section T3.1.2).
(4) $\frac{1}{\sqrt{2\pi}}\sqrt{\frac{\pi}{2}} = \frac{1}{2}$.

On the sky (T3.6) is the same result with $v_1 = \ell/4$ and $\lambda = 1/(2\theta_c^2)$: $\frac{1}{4}\cdot\frac{1}{2\sqrt{2}\,\theta_c} = \frac{1}{8\sqrt{2}\,\theta_c}$. The Euler characteristic is the one functional that needs the second derivatives of the field, because curvature is a second derivative. Its derivation is the next section.

Example: the numbers on simulated maps. The library function `mfs_flat` measures all three on a periodic map: the area fraction by counting pixels, the length from (12.15) with the delta function replaced by a narrow top hat of width 0.1 and the gradient computed exactly by the fast Fourier transform, and χ by $V - E + F$. Over 400 maps of 512×512 pixels with $\lambda = 0.01391$ per pixel^2 (Section 12.6), the mean area fraction at $\nu = 1$ is 0.1589 against $\Psi(1) = 0.1587$, and the mean length per unit area at $\nu = 0$ is 0.059 against 0.059 per pixel from (12.15), a difference of 0.01% (Figure 12.9).

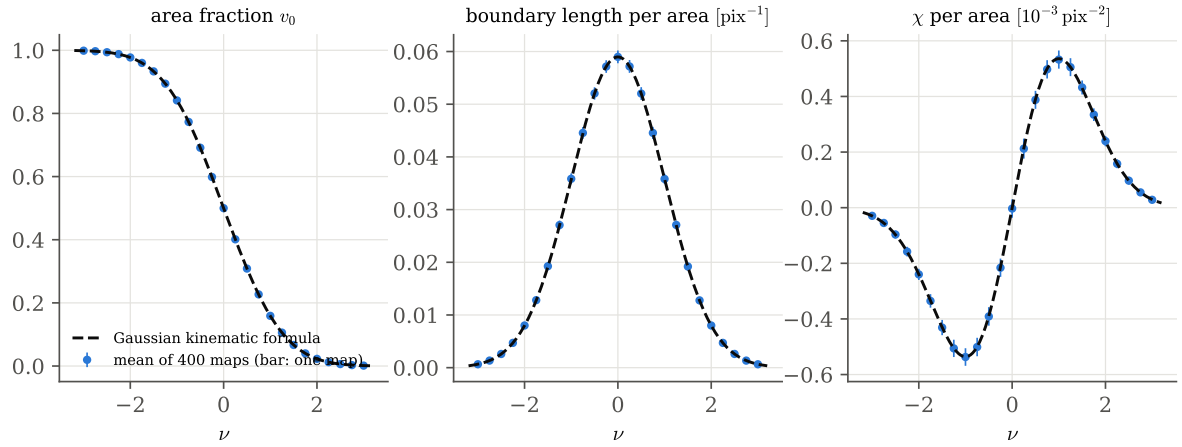

Figure 12.9: The three Minkowski functionals of the excursion sets of 400 Gaussian maps (512×512 pixels, white noise smoothed on 6 pixels). Points: the mean over the maps; bars: the scatter of a single map. Dashed: the Gaussian predictions (12.14), (12.15) and, for χ, (12.23).

12.5 The expected Euler characteristic of a Gaussian field

Counting pieces needs the whole map: to know whether two hot pixels at opposite ends of a long filament belong to one piece we must follow the filament. An average over random fields of such a global count looks hopeless. Yet for a Gaussian field the average Euler characteristic at every threshold has a short closed formula. The trick that makes it possible is to trade the global count for a sum of local events, each of which happens at a single point, and then to ask how often such points occur. That is a question about derivatives of the field at one point, and for a Gaussian field the joint distribution of the value and the derivatives at one point is known exactly. Once the formula is in hand, it tells us what $\chi(\nu)$ can and cannot know about the power spectrum.

The question. For a homogeneous, isotropic Gaussian field u with zero mean and unit variance, what is the expected Euler characteristic of $X_\nu = \{u > \nu\}$ per unit area?

12.5.1 From a global count to local events

Go back to the flooding picture of Section 12.3, and lower the water level ν from far above the highest peak. The dry land X_ν changes its pieces and holes only at particular levels, and each change happens at one point. Which points? A point where the land is sloped is boring: lowering the water a little just moves the shore there. Something can happen only where the ground is flat, at a **critical point** of the height, where the gradient vanishes. In two dimensions there are three kinds, told apart by the second derivatives (the Hessian matrix $H_{ij} = \partial_i \partial_j u$):

- *A peak* (both eigenvalues of H negative). When the water drops below it, a new island appears: β_0 goes up by one, so χ goes up by one.
- *A saddle* (one eigenvalue of each sign), a mountain pass. When the water drops below it, the land on its two sides joins through the pass. Either the two sides were different islands, which merge (β_0 down by one), or they were already connected the long way round, and the new connection closes a ring around a lake (β_1 up by one). Either way χ goes down by one.
- *A pit* (both eigenvalues positive), the bottom of a lake. When the water drops below it, the lake dries up: β_1 goes down by one and χ goes up by one.

Starting from the empty set ($\chi = 0$) at very high water and adding up the changes,

$$\chi(X_\nu) = \#\{\text{peaks above } \nu\} - \#\{\text{saddles above } \nu\} + \#\{\text{pits above } \nu\}, \tag{12.16}$$

for a field on a domain without edges (a periodic box; edges are added in Section 12.5.5). This is the counting rule of Morse theory, and it is the second definition of the Euler characteristic quoted by [110] (their eq. 7). Its sign pattern can be written with the Hessian alone: the determinant $\det H$ is positive at peaks and pits (two eigenvalues of the same sign) and negative at saddles. So

$$\chi(X_\nu) = \sum_{\text{critical points } \boldsymbol{x}_c \text{ with } u(\boldsymbol{x}_c)>\nu} \operatorname{sign} \det H(\boldsymbol{x}_c). \tag{12.17}$$

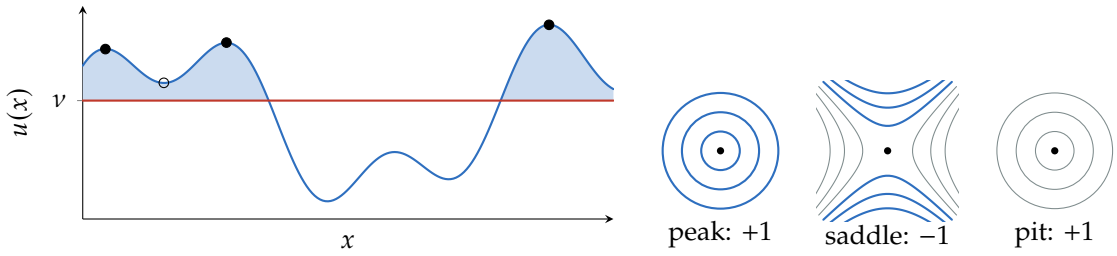

Figure 12.10: Left: in one dimension the excursion set above ν (red line) is a union of intervals (shaded). Each interval contains one more peak (filled dots) than pits (open dot) above the level: two peaks and one pit in the first, one peak in the second. Right: the three kinds of critical point in two dimensions, drawn as contour lines (blue rising towards the centre, grey falling). Lowering the threshold past each changes χ by the amount shown.

12.5.2 The simplest case first: a line

On a line the excursion set is a union of intervals, and its Euler characteristic is the number of intervals. Lowering the level, a new interval appears at a peak and two intervals merge at a pit, so the counting rule reads $\chi = \#\{\text{peaks above } \nu\} - \#\{\text{pits above } \nu\}$ (Figure 12.10, left). On a long line each interval begins where the field crosses ν going up, so the number of intervals per unit length is also the rate of *up-crossings* of the level. We compute it both ways; the agreement is the first check of the method.

The ingredients. At one point x we need the joint distribution of the value u, the slope u' and the curvature u''. They are jointly Gaussian with zero mean (derivatives of a Gaussian field are linear combinations of its values, so they are Gaussian too). Write $\lambda = \langle u'^2 \rangle$, the one-dimensional version of (12.13). Every covariance we need follows from one identity. For a homogeneous field the average of any product of the field and its derivatives is the same at every point, so its derivative vanishes: $\frac{\mathrm{d}}{\mathrm{d}x}\langle f g \rangle = 0$, hence

$$\langle f' g \rangle = -\langle f g' \rangle \qquad \text{(moving a derivative costs a sign).} \tag{12.18}$$

With $f = g = u$ it gives $\langle u'u\rangle = -\langle uu'\rangle$, so $\langle uu'\rangle = 0$. With $f = u'$, $g = u'$ it gives $\langle u''u'\rangle = 0$. With $f = u'$, $g = u$ it gives $\langle u''u\rangle = -\langle u'u'\rangle = -\lambda$. So the slope is uncorrelated with both the value and the curvature, and being jointly Gaussian it is independent of them; the value and the curvature are correlated, with covariance $-\lambda$.

How many up-crossings in a short step $\mathrm{d}x$*?* An up-crossing happens between x and $x + \mathrm{d}x$ if the field starts below the level and ends above it, $u < v < u + u'\mathrm{d}x$, which needs $u' > 0$ and $v - u'\mathrm{d}x < u < v$. The probability of that is

$$\begin{aligned}\mathrm{P}(\text{up-crossing in } \mathrm{d}x) &\overset{(1)}{=} \int_0^\infty \mathrm{d}u' \int_{v-u'\mathrm{d}x}^{v} p(u,u')\,\mathrm{d}u \overset{(2)}{=} \mathrm{d}x \int_0^\infty u'\,p(v,u')\,\mathrm{d}u' \\ &\overset{(3)}{=} \mathrm{d}x\,\frac{e^{-v^2/2}}{\sqrt{2\pi}} \int_0^\infty u'\,\frac{e^{-u'^2/2\lambda}}{\sqrt{2\pi\lambda}}\,\mathrm{d}u' \overset{(4)}{=} \mathrm{d}x\,\frac{e^{-v^2/2}}{\sqrt{2\pi}}\sqrt{\frac{\lambda}{2\pi}} = \mathrm{d}x\,\frac{\sqrt{\lambda}}{2\pi}\,e^{-v^2/2}.\end{aligned} \tag{12.19}$$

(1) Integrate the joint density of value and slope over the region just described.
(2) The inner range has length $u'\mathrm{d}x$, so for small $\mathrm{d}x$ the inner integral is the integrand at $u = v$ times $u'\mathrm{d}x$.
(3) The value and the slope are independent, so the joint density factorises into two Gaussians, of variance 1 and λ.
(4) $\int_0^\infty s\,e^{-s^2/2\lambda}\mathrm{d}s = \lambda$, divided by $\sqrt{2\pi\lambda}$.

This is Rice's formula for the rate of level crossings [237]: the expected number of intervals of $\{u > v\}$ per unit length is $\frac{\sqrt{\lambda}}{2\pi}e^{-v^2/2}$.

The same number by counting critical points. Now use the counting rule instead. A critical point is a zero of the slope u'. Near a zero x_c the slope is $u'(x) \approx u''(x_c)(x - x_c)$, so the delta function $\delta(u'(x))$ integrated over a small neighbourhood gives $1/|u''(x_c)|$; multiplied by $|u''|$ it counts the zero exactly once. Peaks have $u'' < 0$ and pits $u'' > 0$, so $\delta(u')\,(-u'')$ counts peaks as $+1$ and pits as -1, which is exactly the sign rule. Averaging:

$$\begin{aligned}\frac{\mathbb{E}[\chi]}{\text{length}} &\overset{(1)}{=} \mathbb{E}\left[\delta(u')\,(-u'')\,\mathbb{1}\{u > v\}\right] \overset{(2)}{=} p_{u'}(0)\;\mathbb{E}\left[(-u'')\,\mathbb{1}\{u > v\}\right] \\ &\overset{(3)}{=} \frac{1}{\sqrt{2\pi\lambda}}\int_v^\infty \lambda u\,\frac{e^{-u^2/2}}{\sqrt{2\pi}}\,\mathrm{d}u \overset{(4)}{=} \frac{\lambda}{\sqrt{2\pi\lambda}}\,\frac{e^{-v^2/2}}{\sqrt{2\pi}} = \frac{\sqrt{\lambda}}{2\pi}\,e^{-v^2/2}.\end{aligned} \tag{12.20}$$

(1) The counting rule, with each critical point counted by $\delta(u')|u''|$ and signed by $-\operatorname{sign} u''$; the indicator $\mathbb{1}\{u > v\}$ keeps only critical points above the level. On a homogeneous line the average per unit length is the average at one point.
(2) The slope is independent of the value and the curvature, so the average splits; the average of $\delta(u')$ is the density of u' at zero.
(3) The density of u' at zero is $1/\sqrt{2\pi\lambda}$. For the curvature we only need its average at a given value u. For jointly Gaussian variables with zero mean the conditional mean is linear, $\mathbb{E}[Y \mid X] = \frac{\mathrm{Cov}(X,Y)}{\mathrm{Var}\,X}X$ (Chapter 2); with $\mathrm{Cov}(u, u'') = -\lambda$ and $\mathrm{Var}\,u = 1$, $\mathbb{E}[-u'' \mid u] = \lambda u$.
(4) $\int_v^\infty u\,e^{-u^2/2}\mathrm{d}u = e^{-v^2/2}$.

The two routes agree. The second one is the one that generalises, because it never needed to know what an interval is, only how to recognise and sign a critical point.

12.5.3 The plane

Counting critical points in two dimensions. The critical points are the zeros of the gradient ∇u, a map from the plane to the plane. Near a zero, $\nabla u(\boldsymbol{x}) \approx H(\boldsymbol{x}_c)(\boldsymbol{x} - \boldsymbol{x}_c)$, and the two-dimensional

delta function $\delta^2(\nabla u)$ integrated over a neighbourhood gives $1/|\det H|$, the inverse Jacobian of that linear map. So $\delta^2(\nabla u)\,|\det H|$ counts each critical point once, and $\delta^2(\nabla u)\det H$ counts it with the sign of (12.17). Averaging over the field, per unit area,

$$\mathbb{E}[c(\nu)] = \mathbb{E}\left[\delta^2(\nabla u)\,\det H\,\mathbb{1}\{u > \nu\}\right]. \tag{12.21}$$

This is the two-dimensional version of the first line of (12.20), the Kac–Rice counting formula. The absolute value that would make the average of $|\det H|$ hard has disappeared, because the sign rule wants $\det H$ itself, a polynomial in the second derivatives.

The ingredients. The identity (12.18) holds for derivatives in any direction. It gives, exactly as on the line:

- $\langle u\,\partial_i u\rangle = 0$ and $\langle \partial_i u\,\partial_j\partial_k u\rangle = 0$: the gradient is independent of the value and of the Hessian at the same point.
- $\langle u\,\partial_i\partial_j u\rangle = -\langle \partial_i u\,\partial_j u\rangle = -\lambda\delta_{ij}$: by isotropy the two gradient components have the same variance λ and are uncorrelated.
- $\langle \partial_x^2 u\,\partial_y^2 u\rangle = -\langle \partial_x u\,\partial_x\partial_y^2 u\rangle = \langle \partial_x\partial_y u\,\partial_x\partial_y u\rangle$: moving one ∂_x across and then one ∂_y back. Call this common value m.

The last line is the one non-obvious fact, and the whole calculation turns on it.

The average determinant at a given value. Write $u_{xx} = \partial_x^2 u$ and so on. Given the value u, the conditional means are $\mathbb{E}[u_{xx}\,|\,u] = \mathbb{E}[u_{yy}\,|\,u] = -\lambda u$ and $\mathbb{E}[u_{xy}\,|\,u] = 0$ (the linear rule of Section 12.5.2 with the covariances just listed). The conditional covariances are the unconditional ones minus the part explained by u: $\mathrm{Cov}(u_{xx}, u_{yy}\,|\,u) = m - \lambda^2$ and $\mathrm{Var}(u_{xy}\,|\,u) = m - 0^2 = m$. Then

$$\begin{aligned}
\mathbb{E}[\det H\,|\,u] &\overset{(1)}{=} \mathbb{E}[u_{xx}u_{yy}\,|\,u] - \mathbb{E}[u_{xy}^2\,|\,u] \\
&\overset{(2)}{=} \left[(-\lambda u)^2 + m - \lambda^2\right] - \left[0^2 + m\right] \\
&\overset{(3)}{=} \lambda^2(u^2 - 1).
\end{aligned} \tag{12.22}$$

(1) $\det H = u_{xx}u_{yy} - u_{xy}^2$.
(2) For any two variables, $\mathbb{E}[YZ\,|\,u] = \mathbb{E}[Y\,|\,u]\,\mathbb{E}[Z\,|\,u] + \mathrm{Cov}(Y, Z\,|\,u)$.
(3) The unknown fourth moment m cancels, by the identity $\langle u_{xx}u_{yy}\rangle = \langle u_{xy}^2\rangle$.

Everything about the spectrum beyond λ has dropped out.

Putting it together.

$$\begin{aligned}
\mathbb{E}[c(\nu)] &\overset{(1)}{=} p_{\nabla u}(\mathbf{0})\;\mathbb{E}\left[\,\det H\;\mathbb{1}\{u > \nu\}\right] \overset{(2)}{=} \frac{1}{2\pi\lambda}\int_\nu^\infty \lambda^2(u^2-1)\,\frac{e^{-u^2/2}}{\sqrt{2\pi}}\,\mathrm{d}u \\
&\overset{(3)}{=} \frac{\lambda}{2\pi}\,\frac{\nu\,e^{-\nu^2/2}}{\sqrt{2\pi}} = \frac{\lambda}{(2\pi)^{3/2}}\,\nu\,e^{-\nu^2/2}.
\end{aligned} \tag{12.23}$$

(1) The gradient is independent of the value and the Hessian, so the average of $\delta^2(\nabla u)$ factors out as the density of ∇u at zero.
(2) That density is $(2\pi\lambda)^{-1}$, two independent $\mathcal{N}(0,\lambda)$ components at zero; then average $\det H$ first at fixed u with (12.22) and integrate over u above ν.
(3) $\frac{\mathrm{d}}{\mathrm{d}u}\left[-u\,e^{-u^2/2}\right] = (u^2-1)e^{-u^2/2}$, so the integral is $\nu e^{-\nu^2/2}$.

Key idea: Expected Euler characteristic of a Gaussian excursion set

For a homogeneous, isotropic Gaussian field in units of its standard deviation, with $\lambda = \langle(\partial_x u)^2\rangle = \sigma_1^2/2\sigma_0^2$, the expected Euler characteristic of $\{u > v\}$ per unit area is

$$\mathbb{E}[c(v)] = \frac{\lambda}{(2\pi)^{3/2}}\, v\, e^{-v^2/2}.$$

The shape $ve^{-v^2/2}$ is the same for every spectrum; the spectrum enters only through the single number λ.

What the formula knows about the spectrum. The whole power spectrum $P(k)$ enters through one number. Write $\sigma_j^2 = \int \frac{\mathrm{d}^2k}{(2\pi)^2} k^{2j} P(k)$ for the spectral moments of (7.35); then $\lambda = \sigma_1^2/(2\sigma_0^2)$, half the mean of k^2 weighted by the power. Two spectra with the same λ give the same expected χ curve, however different they look. For example, the family $P \propto k^n e^{-k^2R^2}$ has

$$\lambda \overset{(1)}{=} \frac{1}{2}\frac{\int_0^\infty k^{3+n} e^{-k^2R^2}\mathrm{d}k}{\int_0^\infty k^{1+n} e^{-k^2R^2}\mathrm{d}k} \overset{(2)}{=} \frac{1}{2R^2}\frac{\Gamma\left(\frac{n}{2}+2\right)}{\Gamma\left(\frac{n}{2}+1\right)} \overset{(3)}{=} \frac{n+2}{4R^2}. \tag{12.24}$$

(1) $\mathrm{d}^2k = 2\pi k\,\mathrm{d}k$ for an isotropic integrand; the 2π's cancel in the ratio.
(2) Substitute $t = k^2R^2$: $\int_0^\infty k^{2s-1}e^{-k^2R^2}\mathrm{d}k = \Gamma(s)/(2R^{2s})$, with $s = \frac{n}{2}+2$ and $s = \frac{n}{2}+1$.
(3) $\Gamma(s+1) = s\,\Gamma(s)$.

So $n = 0$ with $R = 6$, $n = -1$ with $R = \sqrt{18}$ and $n = 2$ with $R = \sqrt{72}$ all have $\lambda = 1/72$ and the same expected χ curve, although the first is smooth blobs, the second has much more small-scale structure, and the third has a missing long-wavelength part (Section 12.6 tests this).

Two consequences follow, and they are the reason the formula matters for the rest of the chapter. For a Gaussian field, the Euler characteristic curve carries no information beyond the power spectrum: it is fixed by one of its moments. And the *shape* of the curve is universal, $ve^{-v^2/2}$, so any measured departure from that shape is a model-independent sign that the field is not Gaussian. Topology is therefore most useful exactly where the power spectrum is not the whole story, which is the situation of Section 7.7 and of part 12c.

Example: a 512×512 map. With $\lambda = 1/72$ per pixel^2 and $512^2 = 262144$ pixels, the expected χ at $v = 1$ is

$$262144 \times \frac{1/72}{(2\pi)^{3/2}} \times 1 \times e^{-1/2} = 262144 \times \frac{0.01389}{15.75} \times 0.6065 \approx 140.$$

The map has about 140 more pieces than holes at one standard deviation. At $v = 0$ the expectation is zero: pieces and holes balance exactly, on average, at the median.

12.5.4 Three dimensions

In a box the excursion set is a solid region. Lowering the level through a critical point now changes χ by $+1$ at a peak (three negative eigenvalues, a new piece), by -1 at a saddle with two negative eigenvalues (two pieces merge, or a loop closes around a tunnel), by $+1$ at a saddle with one negative eigenvalue (a tunnel is closed off or a cavity is sealed), and by -1 at a pit (a cavity fills). In each case the change is $-\operatorname{sign}\det H$, because $\det H$ is the product of three eigenvalues. So $\mathbb{E}[c_3(v)] = \mathbb{E}[\delta^3(\nabla u)(-\det H)\mathbb{1}\{u > v\}]$ per unit volume, with $\lambda = \langle(\partial_x u)^2\rangle = \sigma_1^2/3\sigma_0^2$ now a third of the mean of k^2.

The average determinant. Given u, write $H = -\lambda u\,\mathbb{1} + Z$, with Z the fluctuating part of the Hessian, which has zero conditional mean. The determinant of $a\mathbb{1} + Z$ expands as $a^3 + a^2 \operatorname{tr} Z + a\, M_2(Z) + \det Z$, where M_2 is the sum of the three principal 2×2 minors $Z_{xx}Z_{yy} - Z_{xy}^2$ and so on. Then

$$\mathbb{E}[\det H \mid u] \overset{(1)}{=} a^3 + a\ \mathbb{E}[M_2(Z) \mid u] \overset{(2)}{=} a^3 + 3a\big[(m - \lambda^2) - m\big] \overset{(3)}{=} -\lambda^3 u^3 + 3\lambda^3 u = -\lambda^3(u^3 - 3u). \tag{12.25}$$

(1) $\mathbb{E}[\operatorname{tr} Z \mid u] = 0$, and $\mathbb{E}[\det Z \mid u] = 0$ because $\det Z$ is a sum of products of three zero-mean jointly Gaussian variables, whose average vanishes.
(2) Each of the three minors averages to $\operatorname{Cov}(u_{xx}, u_{yy} \mid u) - \operatorname{Var}(u_{xy} \mid u)$, exactly as in (12.22).
(3) $a = -\lambda u$.

In two dimensions the same expansion, $\det(a\mathbb{1} + Z) = a^2 + a \operatorname{tr} Z + \det Z$, reproduces (12.22). Now

$$\mathbb{E}[c_3(\nu)] \overset{(1)}{=} \frac{1}{(2\pi\lambda)^{3/2}} \int_\nu^\infty \lambda^3(u^3 - 3u)\frac{e^{-u^2/2}}{\sqrt{2\pi}}\,\mathrm{d}u \overset{(2)}{=} \frac{\lambda^{3/2}}{(2\pi)^2}\,(\nu^2 - 1)\,e^{-\nu^2/2}. \tag{12.26}$$

(1) The density of the three gradient components at zero, and $\mathbb{E}[-\det H \mid u]$ from (12.25).
(2) $\frac{\mathrm{d}}{\mathrm{d}u}\big[-(u^2-1)e^{-u^2/2}\big] = (u^3 - 3u)e^{-u^2/2}$.

At the median, $\nu = 0$, the Euler characteristic is negative: a Gaussian field in three dimensions is a sponge, with more tunnels than pieces, the property that Section T3.6.1 recalled and Section 12.7.1 reproduces.

12.5.5 Edges

A real map is a square with edges, not a torus. The counting rule still works if we count the critical points of the field restricted to the closed square, and these include points on the edges. Take the bottom edge, with the square above it, and let x run along the edge. A point of the edge behaves like a peak of the field on the closed square if the field has a maximum *along* the edge there ($u_x = 0$, $u_{xx} < 0$) and decreases *into* the square ($u_y < 0$): lowering the water past it creates a new piece that touches the edge, +1. If instead it is a minimum along the edge and decreases into the square, it behaves like a saddle, −1. Points where the field increases into the square are not critical points of the restricted field. So the edge contributes, per unit length,

$$\mathbb{E}\left[\delta(u_x)(-u_{xx})\,\mathbb{1}\{u_y < 0\}\,\mathbb{1}\{u > \nu\}\right] \overset{(1)}{=} \mathrm{P}(u_y < 0)\ \mathbb{E}\left[\delta(u_x)(-u_{xx})\,\mathbb{1}\{u > \nu\}\right] \overset{(2)}{=} \frac{1}{2}\,\frac{\sqrt{\lambda}}{2\pi}\,e^{-\nu^2/2}. \tag{12.27}$$

(1) The normal derivative u_y is uncorrelated with u, u_x and u_{xx} (by (12.18) and isotropy), hence independent of them.
(2) u_y is symmetric about zero; the remaining average is the one-dimensional count (12.20).

A corner is a critical point of the restricted field when the field decreases into the square along both edges, which happens with probability $\frac{1}{4}$, and it then counts +1 if it is above ν. For an $L \times L$ square, with four edges and four corners,

$$\mathbb{E}[\chi_{\text{square}}(\nu)] = L^2\,\frac{\lambda\,\nu\,e^{-\nu^2/2}}{(2\pi)^{3/2}} + 4L \cdot \frac{1}{2}\,\frac{\sqrt{\lambda}\,e^{-\nu^2/2}}{2\pi} + 4 \cdot \frac{1}{4}\,\Psi(\nu). \tag{12.28}$$

The edge term is largest at $\nu = 0$, where the area term vanishes. It is the reason the threshold scan of Figure 12.6 does not pass through zero at $\nu = 0$, and it is why masks matter: every edge of a mask adds such a term, and a mask with a long, ragged boundary adds a lot.

12.5.6 The sphere, and the general formula

On the full sky there are no edges, but the domain is curved. The Gauss–Bonnet form of χ from Section 12.4.2 splits the count into two parts: the turning of the boundary of X_ν, and the curvature of the sphere enclosed by X_ν, $\chi = \frac{1}{2\pi}\big[\oint \kappa_g \,\mathrm{d}l + \int_{X_\nu} K \,\mathrm{d}A\big]$, with $K = 1/R^2$. The first part is a sum of local contributions along the contours and has, per unit area, the same expectation $\lambda\nu e^{-\nu^2/2}/(2\pi)^{3/2}$ as in the plane, with λ now measured per steradian. The second part is $\frac{1}{2\pi R^2}$ times the area of X_ν, whose expectation is $4\pi R^2\Psi(\nu)$. So, on the unit sphere,

$$\mathbb{E}[\chi_{\mathrm{sky}}(\nu)] = 4\pi\,\frac{\lambda\,\nu\,e^{-\nu^2/2}}{(2\pi)^{3/2}} + 2\,\Psi(\nu), \qquad \lambda = \frac{\sum_\ell (2\ell+1)C_\ell\,\ell(\ell+1)/2}{\sum_\ell (2\ell+1)C_\ell}, \tag{12.29}$$

where $\lambda = \sigma_1^2/2\sigma_0^2$ follows from the sums (T3.3) and (T3.4). At very low thresholds the excursion set covers the whole sky and $\chi \to 2$, the Euler characteristic of a sphere; that is the 2Ψ term. That the plane density carries over exactly to the sphere, with no correction from the curvature of the sky, is a theorem [238]; Section 12.7.2 checks it numerically.

The formulas (12.14), (12.20), (12.23), (12.26), (12.28) and (12.29) are all instances of a single statement, the **Gaussian kinematic formula** [238, 239]:

$$\mathbb{E}[\chi(X_\nu \cap \mathcal{M})] = \sum_{j=0}^{d} \mathcal{L}_j(\mathcal{M})\,\rho_j(\nu), \qquad \begin{aligned} \rho_0 &= \Psi(\nu), & \rho_1 &= \tfrac{\lambda^{1/2}}{2\pi} e^{-\nu^2/2}, \\ \rho_2 &= \tfrac{\lambda}{(2\pi)^{3/2}}\,\nu\,e^{-\nu^2/2}, & \rho_3 &= \tfrac{\lambda^{3/2}}{(2\pi)^2}(\nu^2-1)e^{-\nu^2/2}. \end{aligned} \tag{12.30}$$

The densities ρ_j come from the field: ρ_j is the expected χ per unit j-dimensional volume, computed by the counting argument in j dimensions. The numbers $\mathcal{L}_j(\mathcal{M})$ come from the domain alone (they are its Lipschitz–Killing curvatures): $\mathcal{L}_0$ is its Euler characteristic, $\mathcal{L}_1$ half its boundary length (in two dimensions), $\mathcal{L}_2$ its area. For a square of side L, $(\mathcal{L}_0, \mathcal{L}_1, \mathcal{L}_2) = (1, 2L, L^2)$, which is (12.28); for the unit sphere $(2, 0, 4\pi)$, which is (12.29); for a torus $(0, 0, A)$. A mask enters only through the $\mathcal{L}_j$ of the unmasked region. The same structure, with the ρ_j replaced by other Hermite polynomials, gives the expected area and boundary length; [240] derived all the Minkowski functionals of Gaussian fields in any dimension, and Section 12.7.3 matches our results to Matsubara's general expression.

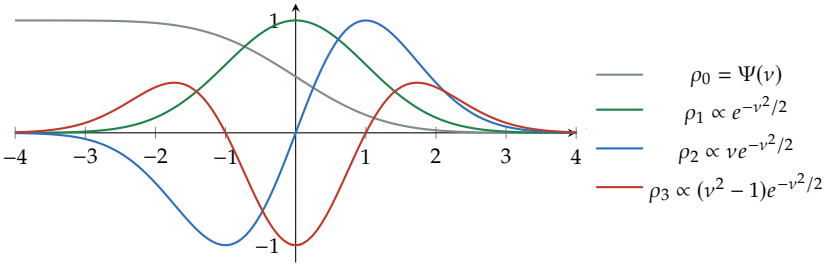

Figure 12.11: The shapes of the four Euler-characteristic densities, each scaled to a maximum of one in absolute value. In one dimension χ counts intervals, positive everywhere; in two dimensions it changes sign at the median; in three it is negative (sponge-like) between $\nu = -1$ and $\nu = 1$. (Ψ is drawn with a standard smooth approximation to the normal tail.)

12.6 Testing the formula on simulated maps

The derivation of Section 12.5 made several moves that deserve to be checked: the counting rule that turned a global count into critical points, the independence of the gradient from everything else, the cancellation of the fourth moment m, and the claim that nothing but λ

survives. A formula derived by hand and code written by hand can both be wrong; when they agree on thousands of simulated maps, both are probably right. And the simulations give something the formula does not: how much χ scatters from one map to the next, which is what any measurement on a single sky needs.

The experiment. The script `code/ch12/04_gkf_plane.py` draws 400 periodic Gaussian maps of 512×512 pixels for each of the three spectra $P \propto k^n e^{-k^2R^2}$ of (12.24) with $n = 0, -1, 2$ and $R = 6, \sqrt{18}, \sqrt{72}$ pixels, which all have $\lambda = 1/72 = 0.01389$ per pixel^2 in the continuum. On the finite grid the sums over the box modes give slightly different values, 0.01391, 0.01441 and 0.01389 (the $n = -1$ spectrum has the most power near the grid scale, where the lattice sum departs most from the integral), and the script uses these exact lattice values in the predictions. For each map it computes the three Minkowski functionals at 25 thresholds from -3 to 3, with χ from $V - E + F$ on the torus, and the same maps are also treated as squares with edges. The run takes a few minutes and is cached in `data/ch12/`.

The mean. For $n = 0$ the mean of χ at $\nu = 1$ over the 400 maps is 139.6, with a Monte Carlo error of 0.4, against 140.5 from (12.23). At $\nu = -1$ the maps give -140.8 against -140.5, and at $\nu = 0$ they give -0.82 ± 0.43 against exactly zero. Over all 25 thresholds the largest deviation of the mean from the formula is 2.49 times its Monte Carlo error, what one expects from chance among 25 comparisons. The area and length agree equally well (Figure 12.9).

One number from the spectrum. Figure 12.12 shows small corners of one map of each spectrum, which look clearly different: the $n = -1$ map is rough, the $n = 2$ map is dominated by a single scale. Yet their mean χ curves lie on the same line. At $\nu = 1$ the $n = -1$ maps give 144.9 (prediction 145.5 with its lattice λ), the $n = 2$ maps give 140.1 (prediction 140.2). This is the content of the key idea of Section 12.5.3 seen on data: the mean Euler characteristic of a Gaussian field cannot tell these three spectra apart.

But not the same scatter. The standard deviation of χ at $\nu = 1$ for a single map is 8.6 for $n = 0$, 11 for $n = -1$ and 7 for $n = 2$. The means are equal, the spreads are not. The variance of a count of critical points depends on how critical points are correlated with one another, which involves the whole correlation function and not only its curvature at the origin. So for a Gaussian field the mean χ curve carries one number of the spectrum, while its covariance carries more. Part 12c, which builds likelihoods for topological summaries, has to take the covariance from simulations for exactly this reason: no formula as simple as (12.23) exists for it.

Example: what the edges add. The same $n = 0$ maps, cut open into 512×512 squares (no periodic gluing), have more pieces than the torus: pieces that wrapped across the seam are now counted twice, and pieces touching an edge are no longer balanced by holes. The edge term of (12.28), $2L\sqrt{\lambda}\, e^{-\nu^2/2}/2\pi$, is 19.2 at $\nu = 0$, and the full square formula predicts 19.7; the squares give 18.9 ± 0.5. At $\nu = 1$ the prediction is 152.3 and the squares give 151.2 (Figure 12.13, left). The deficit at $\nu = 0$, about one unit or one and a half Monte Carlo errors, is of the size expected from the pixel grid along the edges, where the counting convention matters most; we do not pursue it further. The lesson is quantitative: on a 512×512 map the edges contribute as much to χ at the median as all the topology inside, and a masked sky, with its long mask boundary, is affected even more.

Example: the sampling distribution of χ. The right panel of Figure 12.13 is the histogram of χ at $\nu = 1$ over the 400 torus maps. It is centred on the formula and close to a Gaussian

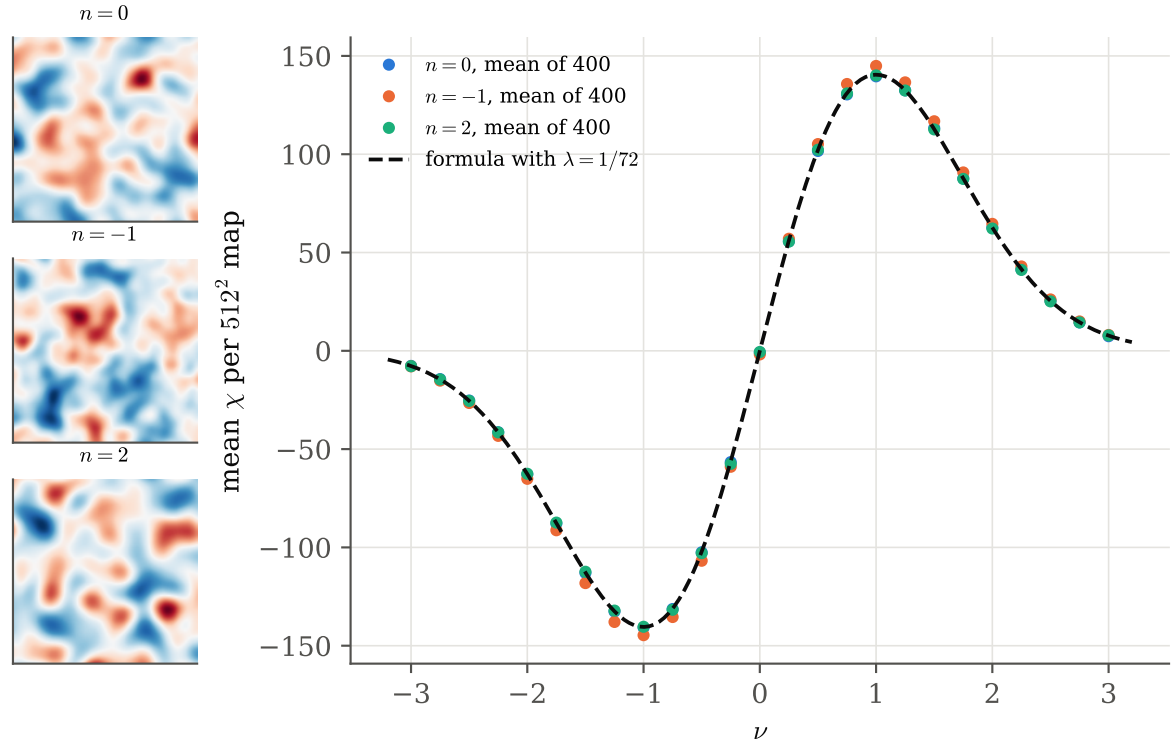

Figure 12.12: Three Gaussian fields with different spectra, $P \propto k^n e^{-k^2R^2}$ with $n = 0, -1, 2$, chosen to have the same λ. Left: a 128×128 corner of one map of each. Right: their mean χ over 400 maps of 512×512 pixels, all on the single prediction (dashed).

with standard deviation 8.6, about 6% of the mean. That is the sampling distribution of the statistic, the thing a likelihood needs (Chapter 3): a single 512×512 map measures $\chi(1)$ to about 6%, and a measured value 25 units away from the Gaussian expectation would be a three-standard-deviation departure. The near-Gaussian shape is no accident: χ is a sum of signed counts over many weakly correlated regions of the map, and the central limit theorem (Chapter 2) applies to such sums.

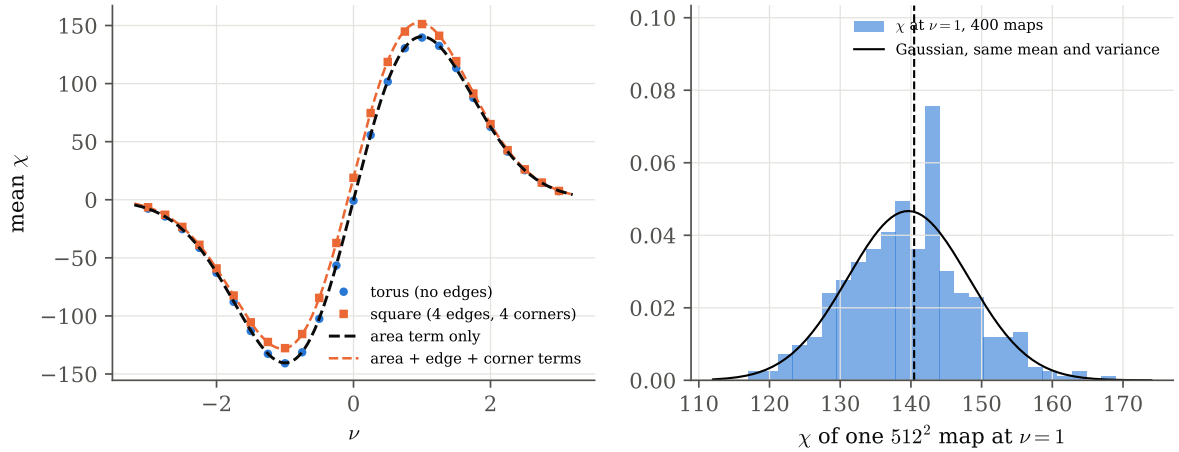

Figure 12.13: Left: mean χ of the same maps on a torus (circles) and cut into squares with four edges and four corners (squares); the black dashed line is the area term alone, the orange dashed line adds the edge and corner terms of (12.28). Right: the distribution of χ at $\nu = 1$ over 400 maps on the torus, with a Gaussian of the same mean and variance and the predicted mean (dashed).

How this is used in real research: Verification here, research instrument elsewhere

Everything in this section is a *verification*: the expected Euler characteristic of a Gaussian field is known exactly, and the simulations test the derivation and the code against it. The same machinery becomes the research instrument wherever no formula exists. The covariance of χ at different thresholds, the effect of a real mask with point-source holes, of anisotropic noise, of a non-Gaussian model, of lensing followed by a beam: none has a closed form, and analyses such as *Planck*'s compare the data with large sets of simulated skies processed by exactly the same pipeline [109]. In that use the formula (12.30) is still valuable, as the check that the pipeline reproduces the Gaussian limit before it is trusted on anything else.

12.7 Reproducing the classic results

The Gaussian formula for the Euler characteristic has been derived, tested and used for forty years, in three dimensions for the galaxy distribution, on the sphere for the microwave sky, and in a general form that also handles weak non-Gaussianity. Four papers mark the way. Each asked a different question, set its problem up in its own notation, and checked the answer against its own simulations. Each can be redone with the machinery of Section 12.5 and our own code. Their conventions (which variance, which normalisation, which units for the threshold) differ from paper to paper, and are the main source of confusion when numbers are compared, so each derivation below ends by mapping their symbols to ours.

12.7.1 Hamilton, Gott and Weinberg (1986): is the universe a sponge?

Their question. In the mid-1980s the first redshift surveys showed bubbles and walls, and three pictures of the large-scale structure competed: isolated clusters in an empty background ("meatballs"), empty bubbles in a connected background ("Swiss cheese"), or a "sponge" in which high- and low-density regions are both connected and interlock. A Gaussian random field, the prediction of inflation, is symmetric between overdense and underdense regions, so at the median density it must be a sponge. Hamilton, Gott and Weinberg proposed to measure this with the curvature of the surfaces of constant density, and derived what a Gaussian field predicts [110].

Their setup. They smooth the density contrast $\delta(\boldsymbol{r})$ with a window and take the surface $\delta = \nu\,\xi(0)^{1/2}$, where $\xi(0)$ is the variance of the smoothed field. On that surface they integrate the Gaussian curvature $K = 1/(a_1 a_2)$, with a_1, a_2 the two principal radii of curvature at a point. By the Gauss–Bonnet theorem the integral over one closed surface of genus g (the number of handles) is $\int K\,\mathrm{d}A = 4\pi(1-g)$ (their eq. 2), so a ball contributes $+4\pi$ and a doughnut 0. Their statistic is $C(\nu)$, the total curvature of all the surfaces per unit volume. They test it on eight simulations, each 5×32^3 points laid at random in a periodic box of 32^3 cells (so pure shot noise with no clustering), smoothed with $W(r) = e^{-r^2/r_0^2}$ with r_0 twice the cell size, and they measure the curvature by tiling space with cubes, the same idea as our voxel counting.

Their equation, derived. Two facts connect C to our Euler characteristic. Gauss–Bonnet for a closed surface reads $\int K\,\mathrm{d}A = 2\pi\chi(\text{surface})$, and the surface bounding a solid region has twice the Euler characteristic of the solid, $\chi(\partial X) = 2\chi(X)$ (a ball: $\chi = 1$, its sphere $\chi = 2$; see the

topology notes). With $\mathbb{E}[c_3(\nu)]$ from (12.26),

$$C(\nu) \overset{(1)}{=} \frac{2\pi\,\chi(\partial X_\nu)}{V} \overset{(2)}{=} 4\pi\,\frac{\chi(X_\nu)}{V} \overset{(3)}{=} 4\pi\,\frac{\lambda^{3/2}}{(2\pi)^2}(\nu^2-1)e^{-\nu^2/2} \overset{(4)}{=} -\frac{1}{\pi}\left[\frac{-\xi''(0)}{\xi(0)}\right]^{3/2}(1-\nu^2)e^{-\nu^2/2}. \tag{12.31}$$

(1) Gauss–Bonnet, summed over all the surfaces in the volume V.
(2) The boundary of a solid has twice its Euler characteristic.
(3) Take the expectation with (12.26).
(4) $4\pi/(4\pi^2) = 1/\pi$; and for an isotropic field $-\xi''(0)/\xi(0) = \langle k^2\rangle/3 = \lambda$, the variance of one gradient component in units of the field variance (their eq. 4).

This is their eq. (3). Symbol map: their $\xi(0)$ is our σ_0^2, their $-\xi''(0)$ our $\sigma_0^2\lambda$ in three dimensions, their genus per unit volume is $-\chi/V$. The minimum of C is at $\nu = 0$, where $C = -\lambda^{3/2}/\pi$: a sponge. In their Fig. 4 they plot C in units with $\lambda = 1$, so the curve is $-\pi^{-1}(1-\nu^2)e^{-\nu^2/2}$, with minimum -0.3183 and maxima 0.142 at $\nu = \pm\sqrt{3}$.

What we compute. The script `code/ch12/05_hgw3d.py` reproduces their setup with Poisson counts of mean 5 in each of the 32^3 cells (equivalent, for this purpose, to 5×32^3 points dropped at random), subtracts the mean, smooths with the Fourier transform of their window, and counts $\chi = V-E+F-C$ of the union of closed voxels above each threshold, the three-dimensional version of (12.6); on one non-periodic block the count agrees with `skimage.measure.euler_number` (*yes*). The result is divided by $\lambda^{3/2}$ computed from the lattice modes, $\lambda = 0.251$ (the continuum value is $1/r_0^2 = 0.25$):

Listing 12.4: Hamilton, Gott and Weinberg's simulation, redone (`code/ch12/05_hgw3d.py`)

```
def smoothed_poisson(N, r0, mean_per_cell=5.0):
    """HGW's field: Poisson counts in cells, smoothed with exp(-r^2/r0^2) (FT: exp(-k^2 r0^2/4))."""
    n = rng.poisson(mean_per_cell, size=(N, N, N)).astype(float)
    kx, ky, kz = kvec(N)
    W = np.exp(-(kx ** 2 + ky ** 2 + kz ** 2) * r0 ** 2 / 4)
    return np.fft.irfftn(np.fft.rfftn(n - n.mean()) * W, s=(N, N, N), axes=(0, 1, 2))

def lam3(N, r0):
    """<k^2>/3 of the smoothed white-noise field on the lattice: sum k^2 W^2 / (3 sum W^2)."""
    k = 2 * np.pi * np.fft.fftfreq(N)
    kx, ky, kz = np.meshgrid(k, k, k, indexing="ij")
    k2 = kx ** 2 + ky ** 2 + kz ** 2
    w2 = np.exp(-k2 * r0 ** 2 / 2)
    w2.flat[0] = 0.0
    return (k2 * w2).sum() / (3 * w2.sum())

def run(N, r0, nsim):
    C = np.zeros((nsim, len(nus)))
    for s in range(nsim):
        f = smoothed_poisson(N, r0)
        u = (f - f.mean()) / f.std()
        C[s] = [4 * np.pi * euler_cubical_3d(u > nu, periodic=True) / N ** 3 for nu in nus]
    return C / lam3(N, r0) ** 1.5          # HGW's normalisation: -xi''(0)/xi(0) = <k^2>/3 = 1
```

It runs their eight simulations, then 400 more with the same setup, then 200 boxes of 64^3 cells with $r_0 = 4$ cells, which resolve the smoothing scale twice as finely.

Side by side. Figure 12.14 overlays the three runs on their curve, and the table compares the numbers that can be read off their figure.

	formula (12.31)	HGW Fig. 4 (read)	ours, 8 sims	ours, 400 sims
$C(0)$	-0.3183	-0.32	-0.308 ± 0.006	-0.3208 ± 0.0016
$C(+1.75)$	0.142	0.15	0.127	0.1303 ± 0.0008
$C(-1.75)$	0.142	0.14		0.1475 ± 0.0008

Their eight simulations and ours agree with the formula, and with each other, within the scatter of eight boxes. Their error bars are the scatter of a single box, about 0.045 at $\nu = 0$; with eight boxes the mean is known to about 0.016, and our eight boxes give an error of the mean of 0.006.

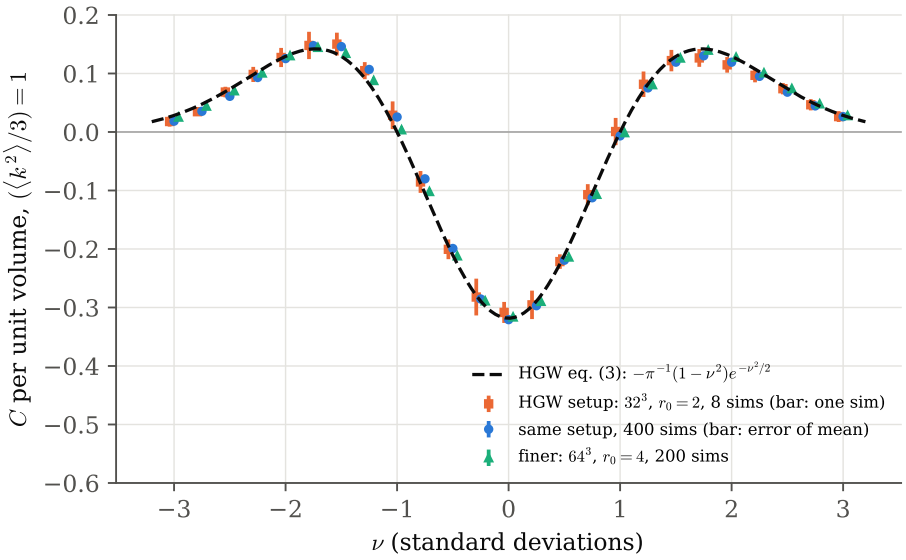

Figure 12.14: The total curvature of isodensity surfaces per unit volume, in units with $\lambda = 1$. Dashed: the Gaussian prediction (12.31). Squares: our redo of the eight simulations of Hamilton, Gott and Weinberg (bars: scatter of one simulation, as in their Fig. 4). Circles: 400 simulations of the same setup (bars: error of the mean). Triangles: 200 finer simulations.

Why they differ. With 400 boxes the statistical error is small enough to look for two effects that eight boxes hide. Hamilton, Gott and Weinberg estimated that tiling with cubes half the smoothing length biases $C(0)$ by about 1%. At the median our coarse boxes differ from the formula by 0.8% (a positive number means more negative), 1.6 standard errors; the finer boxes differ by -0.7%, 1.1 standard errors. A standard error here is about half a per cent, so a 1% bias sits at the edge of what 400 boxes can see: our runs are consistent with their estimate, but they cannot prove that the tiling is the cause. The residual non-Gaussianity of shot noise shows elsewhere, at $\nu = \pm 1.75$: the coarse boxes give 0.1303 at +1.75 and 0.1475 at −1.75, against 0.142 for both. Shot noise is skewed (a Poisson count has a long tail to high values), so its high peaks are fewer and broader than a Gaussian field's and its low troughs more numerous; the curve is distorted asymmetrically. In the finer boxes each smoothing volume holds about eight times more points, the field is closer to Gaussian, and the asymmetry shrinks to 0.1398 and 0.1446. The size and sign of this distortion is what Matsubara's formula of Section 12.7.3 predicts from the skewness.

Lesson. Eight simulations were enough in 1986 to show that a Gaussian field is a sponge; four hundred show that "Gaussian" smoothed shot noise is not quite Gaussian, and that the

genus curve is sensitive enough to notice.

12.7.2 Schmalzing and Górski (1998): Minkowski functionals on the sky

Their question. The COBE satellite had mapped the microwave sky with a 7° beam, and the question was whether the fluctuations were Gaussian. Schmalzing and Górski set out to measure all three Minkowski functionals on the sphere, directly from pixelised maps, and asked whether their estimators reproduce the Gaussian expectations on simulated skies [105].

Their setup. The sky is the unit sphere, the field is the temperature u in mK, and the excursion set is $Q_\nu = \{u > \nu\}$ with the threshold ν in mK, not in units of σ. Their power spectrum is built to look like COBE's:

ingredient	value (their eqs. 17–20)
primordial spectrum	Harrison–Zel'dovich, $n = 1$: $C_\ell \propto 1/\ell(\ell+1)$, with $C_{10} = (7\,\mu\mathrm{K})^2$
beam	Gaussian, 7° FWHM: $g_\ell = e^{-\sigma_b^2 \ell(\ell+1)/2}$, $\sigma_b = 7^\circ/\sqrt{8\ln 2}$
noise	white, $C_\ell^{\mathrm{noise}} = (3\,\mu\mathrm{K})^2$
extra smoothing	Gaussian, $e^{-\omega^2\ell(\ell+1)/2}$ with $\omega = 3^\circ$
simulations	1000 skies on the 6144 pixels of the COBE map

They call the width of the extra smoothing "3°" without saying whether it is ω or a FWHM. Their Fig. 1 settles it: the smoothed noise spectrum $\ell(\ell+1)(3\,\mu\mathrm{K})^2 e^{-\omega^2\ell(\ell+1)}$ peaks where $\ell(\ell+1) = 1/\omega^2$, at height $(3\,\mu\mathrm{K})^2/(e\,\omega^2)$. For $\omega = 3^\circ = 0.0524$ rad this is $\ell \approx 18.6$ and $1.2 \times 10^{-3}\,\mathrm{mK}^2$, which is where their dotted curve peaks.

Their equation, derived. Their eq. (14) gives the expected functionals in terms of three numbers measured from the map: the mean μ, the variance (which they call σ, not σ^2) and $\tau = \frac{1}{2}\langle u_{;i} u_{;i}\rangle$, half the mean squared gradient. In our language τ/σ is exactly $\lambda = \sigma_1^2/2\sigma_0^2$, and their threshold in standard units is $x = (\nu-\mu)/\sqrt{\sigma}$. Their Euler-characteristic density is

$$v_2(\nu) \overset{(1)}{=} \frac{\tau}{2\pi^{3/2}\sigma}\,\frac{\nu-\mu}{\sqrt{2\sigma}}\,\exp\Big(-\frac{(\nu-\mu)^2}{2\sigma}\Big) \overset{(2)}{=} \frac{\lambda}{2^{3/2}\pi^{3/2}}\,x\,e^{-x^2/2} \overset{(3)}{=} \frac{\lambda}{(2\pi)^{3/2}}\,x\,e^{-x^2/2}, \tag{12.32}$$

(1) Their eq. (14), third line.
(2) $\tau/\sigma = \lambda$ and $(\nu-\mu)/\sqrt{2\sigma} = x/\sqrt{2}$.
(3) $2^{3/2}\pi^{3/2} = (2\pi)^{3/2}$.

which is our (12.23). Their $v_1 = \frac{\sqrt{\tau}}{8\sqrt{\sigma}}e^{-x^2/2} = \frac{\sqrt{\lambda}}{8}e^{-x^2/2}$ is a quarter of our length density (12.15), and v_0 is $\Psi(x)$. Their eq. (7), $\chi = V_2 + V_0/(2\pi R^2)$, is the Gauss–Bonnet split of Section 12.4.2: on the unit sphere with $v_j = V_j/4\pi$, $\chi = 4\pi v_2 + 2v_0$, which is (12.29).

A misprint. Their eq. (16) gives $\sigma = \sum_\ell (2\ell+1)C_\ell$ and $\tau = \sum_\ell (2\ell+1)C_\ell\,\ell(\ell+1)/2$. Both sums lack the factor $1/4\pi$ of the addition theorem: the variance of a map is $\sum_\ell \frac{2\ell+1}{4\pi}C_\ell$ (T3.3). The slip cancels in $\lambda = \tau/\sigma$, so the shapes and heights of v_1, v_2 and χ are unaffected. But it makes the standard deviation $\sqrt{4\pi} \approx 3.5$ times too large (145.3 instead of 41 μK for their spectrum) and would stretch every curve plotted against the threshold in mK by that factor. Their Fig. 2 runs from -0.25 to $+0.25$ mK and its curves have died out by about ± 0.13 mK, three times 41 μK: they used the correct variance and only the printed equation is wrong.

What we compute. The script `code/ch12/06_sphere_sg98.py` builds their spectrum,

Listing 12.5: The COBE-like spectrum of Schmalzing and Górski (`code/ch12/06_sphere_sg98.py`)

```
# ------------------------------------------------------------------ SG98's spectrum, eqs. (17)-(20), in mK^2
ell = np.arange(LMAX + 1)
cl_hz = np.zeros(LMAX + 1)

```

draws 1000 skies at HEALPix $N_{\mathrm{side}} = 128$ (196608 pixels of 0.46°) and again at $N_{\mathrm{side}} = 32$ (12288 pixels of 1.8°, close to the 2.6° COBE pixels), and measures the functionals with the library `lib_sphere.py`: area by counting pixels; length by the band argument of (12.15) with the gradient computed from the $a_{\ell m}$; χ by $V - E + F$ of the HEALPix pixel mesh (which pixels share each corner and each edge is worked out once from the pixel corners). As a check, χ is also computed as pieces of the hot set (pixels touching at an edge or a corner) minus pieces of the cold set (pixels sharing an edge) plus one, the spherical form of Alexander duality: β_1 of the hot set is the number of cold pieces minus one, because on the sphere one cold piece is the "outside". In 4100 comparisons the two counts disagree 0 times. For this spectrum $\lambda = 51.4\,\mathrm{sr}^{-1}$, a correlation angle $\theta_c = 1/\sqrt{2\lambda} = 5.65°$.

Side by side.

	formula	SG98 Fig. 2 (read)	ours, $N_{\mathrm{side}} = 128$
peak of v_1 (at $\nu = 0$)	0.896	≈ 0.9	0.899
peak of v_2 [sr^{-1}]	1.98	≈ 2.1	2
χ at its peak ($\nu \approx \sigma$)	25.1	≈ 26	25.5 ± 5.9 (one sky)
threshold of the χ peak [mK]	0.041	≈ 0.04	0.043
χ at $\nu = -3\sigma$	0.63	$\to 2$ at low ν	0.64

Figure 12.15 is our version of their Fig. 2. The mean curves of our skies lie on the formula, the values read from their figure sit on top of both, and the full-sky χ rises to the sphere's own value 2 at low thresholds, the $2v_0$ term without which the curve would go to zero (dotted).

Why they differ. Three effects, each small. First, pixel size: at $N_{\mathrm{side}} = 32$ the pixels are a third of the correlation angle, and counting χ on them loses $4.5 \pm 0.2\%$ at the peak (24.3 instead of 25.5, on the same skies), because small spots and narrow necks are not resolved. Schmalzing and Górski avoided this by not counting at all: their estimator integrates the curvature formula of their eq. (12) over pixels, using derivatives of the field, which does not care whether a spot is resolved by the grid. Second, our thresholds are in units of each sky's own mean and standard deviation, as theirs are (their eq. 15). Those two numbers fluctuate from sky to sky, because

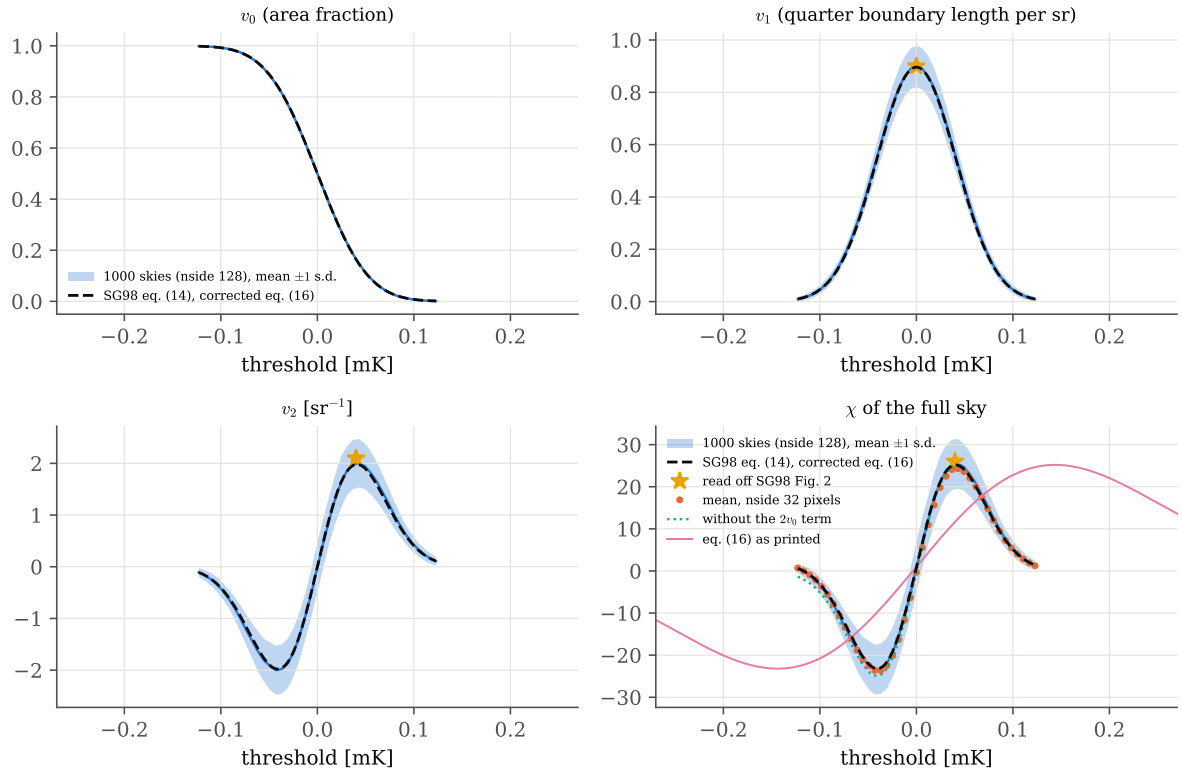

Figure 12.15: The Minkowski functionals of 1000 COBE-like Gaussian skies against threshold in mK, as in Schmalzing and Górski's Fig. 2. Band: mean ± one standard deviation of a single sky ($N_{\text{side}} = 128$). Dashed: their eq. (14) with the variance computed correctly. Stars: values read off their figure. In the χ panel, orange dots are the mean at $N_{\text{side}} = 32$, the dotted line omits the $2v_0$ term, and the pink line shows what the printed eq. (16) would give.

a sky with a 5.65° correlation angle has only a few hundred independent spots. Each sky's threshold scale is therefore shifted and stretched a little at random, and averaging the curve over those random rescalings bends it slightly where it is most curved. The largest deviation of our 1000-sky mean from the formula is 6.5 Monte Carlo errors, but only 0.79 in χ, at $\nu = 1.8$, against a scatter of several units for one sky; it would disappear with thresholds fixed in units of the ensemble standard deviation, which a real sky does not offer. Third, the numbers read from their figure are good to about five per cent.

Lesson. The formula carries over to the sphere with one extra term, the sphere's own Euler characteristic times the area fraction; and a misprinted normalisation that cancels in every shape still matters as soon as a curve is plotted against a physical threshold.

12.7.3 Matsubara (2003): one formula for every functional

His question. The Gaussian predictions are only the starting point: the late universe is not Gaussian, and the question is how the Minkowski functionals change when it departs slightly. Matsubara derived the Gaussian functionals and their first non-Gaussian corrections, in any dimension and for every functional, in a single expression [108].

His equation, and ours. For a field with variance σ_0^2 and gradient variance σ_1^2 in d dimensions, his eq. (3.54) reads, at zeroth order in the non-Gaussianity,

$$V_k^{(d)}(\nu) = \frac{1}{(2\pi)^{(k+1)/2}} \frac{\omega_d}{\omega_{d-k}\,\omega_k} \left(\frac{\sigma_1}{\sqrt{d}\,\sigma_0}\right)^k e^{-\nu^2/2} H_{k-1}(\nu), \qquad \omega_k = \frac{\pi^{k/2}}{\Gamma(k/2+1)}, \tag{12.33}$$

where ω_k is the volume of the unit ball in k dimensions ($\omega_0 = 1$, $\omega_1 = 2$, $\omega_2 = \pi$, $\omega_3 = 4\pi/3$) and H_n are the Hermite polynomials $H_0 = 1$, $H_1 = \nu$, $H_2 = \nu^2 - 1$, with $e^{-\nu^2/2} H_{-1}(\nu) = \int_\nu^\infty e^{-t^2/2} \mathrm{d}t$. Symbol map: $\sigma_1/(\sqrt{d}\,\sigma_0) = \sqrt{\lambda}$, because σ_1^2/σ_0^2 is the sum of the d equal gradient-component variances. Then, in the plane,

$$V_2^{(2)} \overset{(1)}{=} \frac{1}{(2\pi)^{3/2}} \frac{\pi}{\omega_0\,\pi} \lambda\, e^{-\nu^2/2} \nu = \frac{\lambda}{(2\pi)^{3/2}} \nu e^{-\nu^2/2}, \qquad V_1^{(2)} \overset{(2)}{=} \frac{1}{2\pi} \frac{\pi}{2\cdot 2} \sqrt{\lambda}\, e^{-\nu^2/2} = \frac{\sqrt{\lambda}}{8} e^{-\nu^2/2},$$
$$V_0^{(2)} \overset{(3)}{=} \frac{1}{\sqrt{2\pi}} \frac{\pi}{\pi\cdot 1} \int_\nu^\infty e^{-t^2/2} \mathrm{d}t = \Psi(\nu), \qquad V_3^{(3)} \overset{(4)}{=} \frac{1}{(2\pi)^2} \frac{4\pi/3}{1\cdot 4\pi/3} \lambda^{3/2} e^{-\nu^2/2} (\nu^2 - 1). \tag{12.34}$$

(1) $k = d = 2$: $\omega_2/(\omega_0\omega_2) = 1$, $H_1 = \nu$. This is the Euler characteristic density (12.23); his eq. (3.18) for the two-dimensional genus is the same expression.
(2) $k = 1$, $d = 2$: $\omega_2/(\omega_1\omega_1) = \pi/4$, $H_0 = 1$. This is a quarter of the length density (12.15), the normalisation used for v_1 on the sky.
(3) $k = 0$: the area fraction (12.14).
(4) $k = d = 3$: the three-dimensional Euler characteristic density (12.26), ρ_3 of (12.30); minus it is his three-dimensional genus.

Every Gaussian result of this part is one line of (12.33), and every Monte Carlo of Sections 12.6, 12.7.1 and 12.7.2 is therefore also a check of it: in two dimensions to a few tenths of a per cent (Section 12.6), in three to about one per cent (Section 12.7.1), on the sphere to the accuracy of the pixel counting (Section 12.7.2).

The non-Gaussian part. Matsubara's formula continues with a term proportional to σ_0 and to three skewness parameters $S^{(0)}, S^{(1)}, S^{(2)}$, averages of u^3, $u^2\nabla^2 u$ and $|\nabla u|^2\nabla^2 u$ [108]; Section T3.2.1 wrote it out for the sky and tested it on skewed maps. Two features matter here. The correction is built from the Hermite polynomials H_{k+2}, H_k and H_{k-2}, which are odd where the Gaussian term is even and vice versa, so it distorts the curves asymmetrically, as the shot noise did in Section 12.7.1. And when the threshold is labelled by area fraction (Section 12.3.2) the term with $S^{(0)}$, the one-point skewness, disappears and only the differences $S^{(1)} - S^{(0)}$ and $S^{(2)} - S^{(0)}$ survive (his eq. 3.54 in the variable ν_A). That is the perturbative version of the exact statement of Section 12.3.2: relabelling removes what is in the histogram of the values and keeps what is in their arrangement.

Lesson. The four Gaussian densities are one formula. What the field contributes is a single number per dimension, $\lambda^{k/2}$; everything else is geometry (ω_k) and the Hermite polynomials.

12.7.4 *Planck* 2018: are the microwave sky's shapes Gaussian?

Their question. Section T3.5.1 described how the *Planck* collaboration used the three functionals, at many resolutions, to test whether the temperature and polarization maps are consistent with Gaussian, isotropic skies [109]. Here we reproduce the Gaussian side of that test, the curves against which the data are compared (their Fig. 10), and work out in which normalisation those curves are drawn.

Their setup. The four component-separated maps are degraded to a chosen $N_{\rm side}$ and smoothed with a Gaussian beam whose FWHM grows with the pixel size (40′ at $N_{\rm side}=256$, their Table 1). A common mask leaves 75% of the sky. The thresholds are 12 values from -3 to 3 in units of the map's own standard deviation σ_0. At each threshold they compute the area fraction, the boundary length and the genus (their eqs. 13–15), divide out the part of each that depends on the power spectrum to get what they call "normalised" functionals, and compare the 36 numbers with 999 FFP10 simulations, which contain the CMB, the noise and the component-separation pipeline, through a χ^2 with the simulation covariance (their eqs. 20–22).

Their equations, derived. Their eqs. (16)–(19) are (12.33) with $d=2$: $V_k = A_k v_k$, with $v_k = e^{-\nu^2/2}H_{k-1}(\nu)$ and $A_k = \frac{1}{(2\pi)^{(k+1)/2}}\frac{\omega_2}{\omega_{2-k}\omega_k}\left(\frac{\sigma_1}{\sqrt{2}\sigma_0}\right)^k$. All the dependence on the spectrum is in the factor $(\sigma_1/\sigma_0)^k$. Its value for their maps follows from the sums (T3.3) and (T3.4) with the fiducial spectrum, the 40′ beam and the $N_{\rm side}=256$ pixel window: $\sigma_1/\sigma_0 = 108.4$ per radian, a correlation angle $\theta_c = 31.7'$, compared with a pixel of 13.7′. The genus amplitude per steradian is then $\lambda/(2\pi)^{3/2} \approx 108.4^2/(2\times 15.75) \approx 370$.

The normalisation of their figure. Their Fig. 10 shows the boundary length peaking at about 0.081 and the genus between about -0.020 and $+0.021$, at every resolution from $N_{\rm side}=32$ to 1024. These cannot be the functionals per steradian (the genus amplitude above is in the hundreds and grows with resolution), nor the normalised v_k of their eq. (17) (which peak at 1 and $e^{-1/2}=0.61$). They are reproduced exactly by $V_k/(\sigma_1/\sigma_0)^k$, the Gaussian functionals with the spectral factor divided out but the numerical prefactors of A_k kept:

$$\frac{V_1}{\sigma_1/\sigma_0} \overset{(1)}{=} \frac{1}{2\pi}\,\frac{\pi}{2\cdot 2}\,\frac{1}{\sqrt{2}}\,e^{-\nu^2/2} = \frac{e^{-\nu^2/2}}{8\sqrt{2}} \quad\Rightarrow\quad \text{peak } 0.0884,$$
$$\frac{V_2}{(\sigma_1/\sigma_0)^2} \overset{(2)}{=} \frac{1}{(2\pi)^{3/2}}\,\frac{1}{2}\,\nu\,e^{-\nu^2/2} \quad\Rightarrow\quad \text{extremes } \pm\frac{e^{-1/2}}{2(2\pi)^{3/2}} = \pm 0.0193. \tag{12.35}$$

(1) A_1 with σ_1/σ_0 set to one: $\omega_2/(\omega_1\omega_1) = \pi/4$ and $(1/\sqrt{2})^1$.
(2) A_2 with σ_1/σ_0 set to one: $\omega_2/(\omega_0\omega_2) = 1$ and $(1/\sqrt{2})^2 = \frac{1}{2}$; $\nu e^{-\nu^2/2}$ is extreme at $\nu=\pm 1$.

At their nearest thresholds to the extremes, $\nu = \pm 0.27$ for the length and ± 0.82 for the genus, these give 0.0852 and ± 0.0186. Why divide out only $(\sigma_1/\sigma_0)^k$? Because it is the one factor that changes with resolution (the beam sets σ_1) and from map to map (cosmic variance); dividing it out makes the curves at different $N_{\rm side}$ comparable and removes most of the fluctuation of the overall amplitude, leaving the shape, which is where non-Gaussianity would show. Their eq. (15), read literally, would add a further $1/2\pi$ to the genus; the plotted curves do not have it.

What we compute. The script `code/ch12/07_planck_mf.py` draws 300 full-sky Gaussian maps with the fiducial spectrum (Chapter T1), the 40′ beam and the pixel window at $N_{\rm side}=256$, $\ell \le 767$. For each map it measures σ_0 and σ_1 (from the exact derivative maps) and the functionals at their 12 thresholds and on a finer grid:

Listing 12.6: Planck-style normalised functionals of one map (`code/ch12/07_planck_mf.py`)

```
def measure(alm, nside, nus, msh, lmax, dnu=0.1):
    """V0, V1/(s1/s0), V2/(s1/s0)^2 per steradian, and s1/s0 of the map (rad^-1)."""
    t, dth, dph = hp.alm2map_der1(alm, nside, lmax=lmax)
    t = t - t.mean()
    s0 = t.std()
    g = np.hypot(dth, dph)
    r = np.sqrt((g ** 2).mean()) / s0                # sigma1 / sigma0, measured on this
    map
```

```
    u, gu = t / s0, g / s0
    v0 = np.array([(u > nu).mean() for nu in nus])
    v1 = np.array([0.25 * (gu * (np.abs(u - nu) < dnu / 2)).mean() / dnu for nu in nus])
    chi = np.array([chi_sphere(u > nu, msh) for nu in nus])
    v2 = (chi - 2 * v0) / (4 * np.pi)                    # remove the sphere's own curvature
    term
    return v0, v1 / r, v2 / r ** 2, r
```

The measured σ_1/σ_0 is 108.1 ± 2.9 per radian against 108.4 from the spectrum. Then, as *Planck* does, it forms the 36-number vector of each map, estimates the covariance from the other $300-1$ maps (with the Hartlap factor 0.876 [6]), and computes each map's χ^2.

Side by side.

	formula (12.35)	*Planck* Fig. 10 (read)	ours, mean	ours, one map
length at $\nu = 0.27$	0.0852	0.081	0.0851	$\pm 8.000 \times 10^{-4}$
genus at $\nu = 0.82$	0.0186	0.021	0.0173	$\pm 4.000 \times 10^{-4}$
$\chi^2/N_{\rm dof}$, Gaussian sky	1	peak near 1	1.01 (median 0.97)	

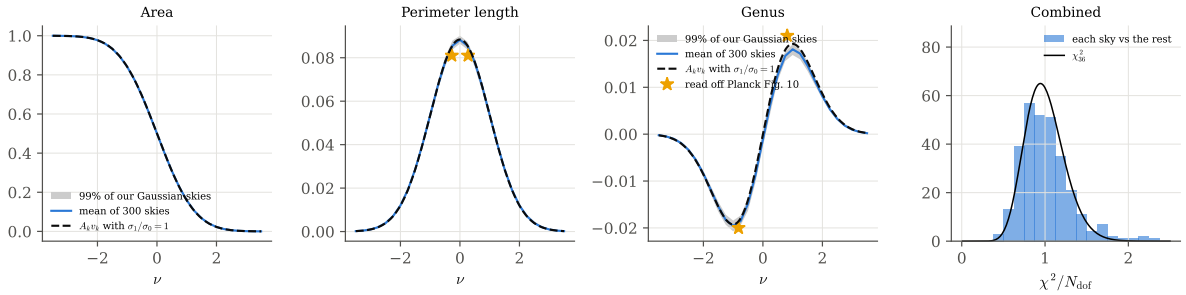

Figure 12.16: Our version of the $N_{\rm side} = 256$ row of *Planck*'s Fig. 10. Grey: the central 99% of 300 Gaussian skies; blue: their mean; dashed: (12.35); stars: values read off the published figure. Right: $\chi^2/N_{\rm dof}$ of each sky against the other skies, using all 36 numbers, with the χ^2_{36} distribution.

Why they differ. The length agrees with the formula to the third digit and with the published curve to within the accuracy of reading it. The genus of our maps is 0.0173, about 7% below the formula. That is the pixel effect of Section 12.2.2, now large because the correlation angle is only 2.3 pixels. Its signature is clearest at the median: the full-sky χ at $\nu = 0$ should be $2\Psi(0) = 1$, and our skies give -172 ± 6. Near $\nu = 0$ the expected χ rises with slope $4\pi\lambda/(2\pi)^{3/2} = 4688$ per unit of ν, so this is the whole curve shifted by 0.037 standard deviations towards higher thresholds. The 8-neighbour rule joins hot pixels that touch at a corner, which makes the hot set behave as if the threshold were slightly lower at every saddle that falls inside a 2×2 block of pixels; the effect is as large as the fraction of saddles that are not resolved by the grid. The same skies sampled at $N_{\rm side} = 512$ give a genus of 0.0183 instead of 0.0174 at $\nu = 0.82$, a deficit of 4.8% that finer pixels mostly remove. The published curve, read at ≈ 0.021, lies about 10% above the formula. We cannot settle the reason from the paper: their genus is computed from counts of hot and cold spots on the masked sky with their own pixel treatment, and the reading of a small figure is uncertain at this level. It does not matter for their test, and this is the point of their method: data and simulations pass through the identical estimator, so any such offset is common to both and cancels in the comparison. Finally, the χ^2 of Gaussian skies against Gaussian skies follows the χ^2_{36} distribution, mean 1.01 per degree of freedom, which is what the histograms of their right-hand column show for the FFP10 simulations.

Lesson. A published curve is only reproducible once its normalisation is reverse-engineered; here the curves are the Gaussian functionals with σ_1/σ_0 divided out. And the reason the *Planck* test is robust to such details is that it never compares the data with a formula, only with simulations processed the same way.

12.8 How it is done in research

The calculations so far used clean, full-sky or periodic Gaussian maps, because that is where the answer is known and the code can be checked. A real analysis of the microwave sky starts from maps that have been through an instrument and a foreground-cleaning pipeline, covers only part of the sky, and asks whether the measured curves are consistent with a model whose only complete description is a set of simulations. The pipeline of the *Planck* temperature and polarization analysis [109] runs as follows, each step with its purpose.

The data products. Four maps of the CMB, each produced by a different component-separation method (Commander, NILC, SEVEM, SMICA), at $N_{\rm side} = 2048$; for each, a common mask of the Galaxy and point sources; and 999 FFP10 simulations, which are Gaussian CMB skies from the best-fit spectrum, lensed, observed with the real scanning, beams and noise, and passed through the same component separation. The simulations are the null hypothesis: a sky that is Gaussian and isotropic apart from everything the instrument and the pipeline do to it.

The pipeline.

1. *Choose a resolution.* Degrade each map to $N_{\rm side}$ between 16 and 2048 and smooth it with a Gaussian beam whose FWHM is about three pixels (their Table 1). The smoothing makes the field smooth on the pixel scale, which the counting needs (Section 12.2.2), and fixes σ_1/σ_0. Each resolution probes a different range of scales.
2. *Apply the mask.* Only unmasked pixels enter. The mask's boundary adds pieces to the excursion set and changes χ (Section 12.5.5); because the simulations are masked identically, the effect is carried by the null distribution rather than modelled.
3. *Set the thresholds.* Twelve thresholds from -3 to 3, in units of the standard deviation measured on the unmasked part of the map itself.
4. *Measure.* The area fraction by counting pixels, the boundary length from the contour lengths, the genus from the numbers of hot and cold spots; then divide by $(\sigma_1/\sigma_0)^k$ (Section 12.7.4).
5. *Repeat on every simulation*, with the identical code, to obtain the sampling distribution of the 36 numbers.
6. *Compare.* Form the χ^2 of the data vector with the mean and covariance of the simulations; the p-value is the fraction of simulations with a larger χ^2 (their Table 5). Repeat for each resolution, for each component-separation method, and for E-mode polarization.

The checks. Each step has a failure mode, and a real analysis tests for it before looking at the data. The Gaussian limit: on Gaussian simulations without mask the pipeline must reproduce the formulas of Section 12.5, which is what Sections 12.6, 12.7.2 and 12.7.4 did. Convergence: the covariance of 36 numbers from 999 simulations is well determined, but its inverse is biased by the factor $(n-p-2)/(n-1)$ [6], 0.96 for $n = 999$ and $p = 36$; with fewer simulations, or more thresholds, the correction grows quickly. Resolution and convention: the counts must be stable

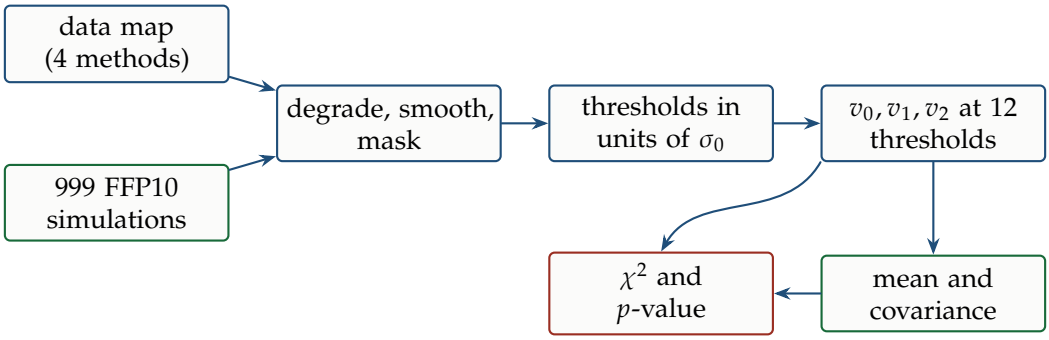

Figure 12.17: The Minkowski-functional test of a sky map. Data and simulations follow the same path; the simulations (green) provide the mean and covariance of the 36 numbers, against which the data vector is compared through a χ^2 (red).

when the pixel size is halved at fixed smoothing (our genus moved by 4.8% at $N_{\rm side} = 256$, Section 12.7.4), and the connectivity convention must be the same for data and simulations. The mask: the counts near the mask boundary are the most fragile, and their effect is checked by changing the mask. Agreement between the four component-separation methods is itself a test of foreground residuals.

12.8.1 What a mask does, and how the formula absorbs it

The general formula (12.30) says that a mask enters only through three numbers of the unmasked region: its Euler characteristic $\mathcal{L}_0$, half its boundary length $\mathcal{L}_1$ and its area $\mathcal{L}_2$. A tempting shortcut, "the masked sky is a fraction $f_{\rm sky}$ of the full sky, so multiply the full-sky prediction by $f_{\rm sky}$", misses the boundary term entirely. How much does that matter?

Example: a Galactic band. The script `code/ch12/08_mask_gkf.py` masks the band $|b| < 20°$ around the Galactic equator, leaving two polar caps of angular radius 70° ($f_{\rm sky} = 65.8\%$). For two caps, $\mathcal{L}_0 = 2$ (two discs), $\mathcal{L}_1$ is half of the two boundary circles, $\frac{1}{2} \cdot 2 \cdot 2\pi \sin 70° = 5.9$, and $\mathcal{L}_2$ is their area, $2 \cdot 2\pi(1 - \cos 70°) = 8.27\,\mathrm{sr}$. On 300 Gaussian skies with the fiducial spectrum, a 160′ beam and $N_{\rm side} = 256$ ($\lambda = 306\,\mathrm{sr}^{-1}$, a correlation angle of about nine pixels, so that the pixel shift found in Section 12.7.4 is negligible), standardised on the unmasked pixels, the mean χ of the unmasked excursion set at $\nu = 0$ is 14.5 ± 0.9. The formula with the three $\mathcal{L}_j$ predicts 17.4, of which the boundary term $\mathcal{L}_1\rho_1(0)$ is 16.4; the $f_{\rm sky}$ shortcut predicts 0.66. At $\nu = 1$ the skies give 109, the formula 108, the shortcut 97 (Figure 12.18). The largest deviation of the simulated mean from the formula, over all thresholds, is 3.7 Monte Carlo errors, a few per cent of the peak value of χ: the residual of the pixel counting and of standardising each sky on its own unmasked pixels. So the boundary of a simple mask adds a known, sizeable amount to χ, and the formula accounts for it exactly; a real mask, with hundreds of point-source holes each adding its own boundary, makes $\mathcal{L}_1$ large and is one reason real analyses rely on simulations masked in the same way.

Laptop scale, and what it costs. Every computation in this part was reduced to run in minutes on a laptop. Each reduction, and what the full analysis does instead:

- *Planck* analyses maps up to $N_{\rm side} = 2048$ with 999 end-to-end simulations including noise, lensing and component separation; we used 300 Gaussian skies at $N_{\rm side} = 256$ without noise, which reproduces the Gaussian curves and the χ^2 distribution but cannot test foreground residuals or noise inhomogeneity.

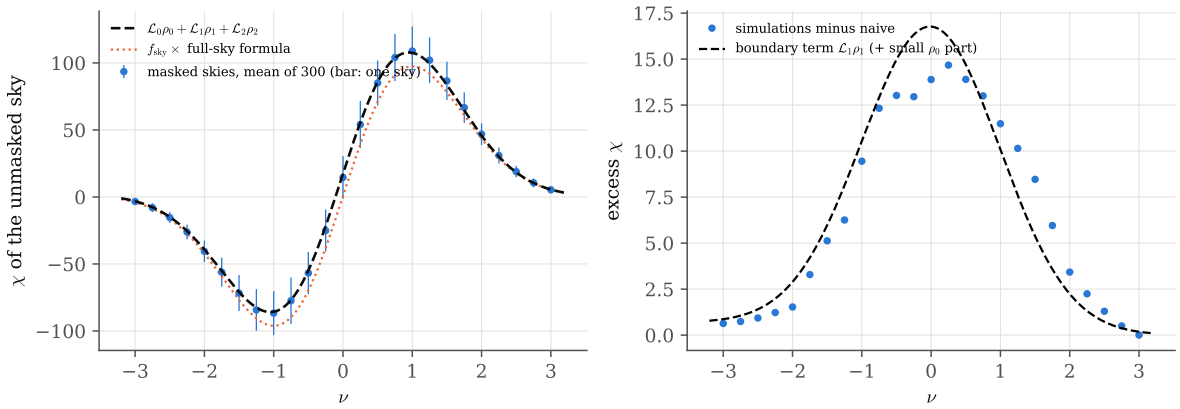

Figure 12.18: Euler characteristic of the sky outside a $|b| < 20°$ band. Left: the mean over 300 Gaussian skies (bars: one sky), the formula with the Lipschitz–Killing numbers of the two caps (dashed) and the full-sky formula scaled by $f_{\rm sky}$ (dotted). Right: the difference between the simulations and the $f_{\rm sky}$ shortcut is the boundary term.

- *Planck* masks 25% of the sky with a mask full of point-source holes; we used the full sky for the reproduction and a simple band for the mask test, which shows the boundary term but understates its size for a real mask.
- Our flat maps are 512×512 pixels with 400 realisations per spectrum; this resolves the mean χ to about 0.3%, enough to see the edge term and the lattice value of λ, not enough to study the far tails beyond $|\nu| \approx 3$.
- Our three-dimensional boxes are 32^3 and 64^3 cells, where cosmic-web studies use 512^3 or more; the small boxes reproduce the Gaussian genus curve but resolve only a few correlation lengths per side, so the residual shot-noise skewness is larger than in a large survey.

Recap

- A nuisance is an operator $\phi \to \mathcal{N}[\phi]$; a statistic T is protected if $T[\mathcal{N}[\phi]] = T[\phi]$. Counts of pieces and holes are protected against smooth one-to-one remappings (lensing, to first order) and monotone changes of the values; not against noise, smoothing, tearing, or a feature crossing a mask edge.
- The topology of a field is the topology of its excursion sets $X_\nu = \{\phi > \nu\}$. In two dimensions β_0 counts pieces, β_1 holes, and $\chi = \beta_0 - \beta_1$.
- On pixels, use dual connectivity (8 for the set, 4 for its complement, or the reverse); $\chi = V - E + F$ of the closed-pixel complex equals $\beta_0 - \beta_1$; labelling, cell counting, `scikit-image` and `gudhi` agree exactly.
- Under a monotone transform the excursion sets are the same sets with relabelled thresholds; labelling thresholds by area fraction removes all pointwise (one-point) non-Gaussianity and keeps only spatial information.
- The Minkowski functionals (area, length, χ) are the complete set of additive, motion-invariant shape measures; χ is the total turning of the boundary over 2π, plus enclosed curvature on a curved sky.
- Counting critical points with the sign of $\det H$ gives, for a Gaussian field, $\mathbb{E}[\chi]/A = \lambda\nu e^{-\nu^2/2}/(2\pi)^{3/2}$ with $\lambda = \sigma_1^2/2\sigma_0^2$; in 3-D $\lambda^{3/2}(\nu^2-1)e^{-\nu^2/2}/(2\pi)^2$; edges, masks and the sphere enter through $\mathbb{E}\,\chi = \sum_j \mathcal{L}_j\rho_j$.

- For a Gaussian field the mean χ curve knows only λ; its covariance knows more. A departure from the shape $\nu e^{-\nu^2/2}$ is a model-independent sign of non-Gaussianity.
- Reproduced: Hamilton–Gott–Weinberg's sponge (to 1%), Schmalzing–Górski's sky functionals (and their misprinted eq. 16), Matsubara's general formula, and *Planck*'s Gaussian curves, whose plotted normalisation is $V_k/(\sigma_1/\sigma_0)^k$.

12.9 One threshold is not enough: births, deaths and persistence

The threshold scan of Section 12.3 counted the pieces and holes of the excursion set of one Gaussian map at one threshold after another. At $\nu = 1$ it found a certain number of pieces, and that number is all the scan remembers about $\nu = 1$. But the pieces are not all alike. One may be the top of a broad mountain that stands far above the water; another may be a pebble that pokes out by a hair and would be gone at $\nu = 1.05$. The count gives both the same weight, and a physical conclusion drawn from it can change when we move the threshold by a small amount that nobody could defend as special. The cure is to stop treating the thresholds one at a time. We follow every piece and every hole through all thresholds, and record the level at which it appears and the level at which it disappears. A pebble then shows up as something that lived over a tiny range of levels, and a mountain as something that lived over a wide range, and the difference is no longer hidden.

The picture to keep in mind is the flooded landscape of Section 12.3, run in one direction only. The field $\phi(\boldsymbol{x})$ is the height of the ground at the point $\boldsymbol{x}$, measured as before in units of its standard deviation. The water level is ν. The dry land at level ν is the set of points with height at least ν,

$$X_\nu = \{\boldsymbol{x} : \ \phi(\boldsymbol{x}) \geq \nu\}, \tag{12.36}$$

the excursion set of Eq. (12.4) with the boundary points included (for a continuous field the two versions differ only at levels equal to the height of some pixel, and that changes no count we will make). We start with the water above the highest summit, so nothing is dry, and we let the water drain slowly away. The dry land only ever grows: if a point is dry at level ν, it is dry at every lower level, so $X_\nu \subseteq X_{\nu'}$ whenever $\nu \geq \nu'$.

The question. As the water level drops from above the highest peak to below the deepest valley, at which level does each island first appear, and at which level does it stop being a separate island? At which level does each lake (a pool of water completely surrounded by land) appear, and at which level does it drain away?

12.9.1 The simplest landscape: a line

Take a one-dimensional landscape, nine heights at equally spaced points joined by straight lines,

$$(h_0, \ldots, h_8) = (0.2,\ 1.8,\ 0.9,\ 2.6,\ 0.5,\ 1.4,\ 1.1,\ 2.0,\ 0.3), \tag{12.37}$$

drawn in Figure 12.19. It has four summits, at heights 2.6 (call it A), 2.0 (D), 1.8 (B) and 1.4 (C), and three valleys between them, at 0.9, 0.5 and 1.1. In one dimension a piece of dry land is an interval, and nothing can enclose a lake, so islands are the only things to follow. We lower the water and stop at every level where something happens.

Level 2.6. The top of A breaks the surface. One island exists, born at 2.6.

Level 2.0. The top of D breaks the surface, far from A. A second island is born, at 2.0.

Level 1.8 *and level* 1.4. The same happens at B and at C. Four islands are now dry: A, D, B and C, born at 2.6, 2.0, 1.8 and 1.4.

Level 1.1. The water drops to the bottom of the valley between C and D (the point with height 1.1). Below this level the two islands are joined by dry ground. Two islands have become one. Which one stopped existing? Neither has disappeared physically; they have merged. But the number of islands has dropped by one, so for the record we must decide which island ends here and which continues.

The elder rule. The rule we adopt is that the island that was born later, the one with the lower summit, dies at the merger, and the older one carries on with the merged land. Here C (born at 1.4) is younger than D (born at 2.0), so C dies at 1.1, and its record is the pair $(1.4,\ 1.1)$. Mountaineers know this number: the height of a summit above the highest pass on any route from it to higher ground (the pass the best route crosses) is its *prominence*, and C's prominence is $1.4 - 1.1 = 0.3$. The rule is not arbitrary. Suppose the older island died instead. The highest summit of the whole map, which is the oldest island there is, would then die at the first pass where it meets any other island, and the diagram would say that the tallest mountain lives only as long as the smallest pebble beside it. With the elder rule the older island carries on, a summit dies at the first pass, going down from the summit, that reaches higher ground, and every summit except the highest is paired with exactly one pass, whatever order the pixels are visited in (equal heights are ties, broken in any fixed order, which changes no persistence).

Level 0.9. The valley between B and A floods dry. B (born at 1.8) is younger than A (born at 2.6), so B dies: the pair $(1.8,\ 0.9)$.

Level 0.5. The valley between A and the merged C–D island dries. That island carries the birth level of D, 2.0, which is younger than A's 2.6, so it dies: the pair $(2.0,\ 0.5)$.

Below 0.5. Nothing else merges. The edges at 0.2 and 0.3 join A as the water sinks further. A never dies; we give it the death level $-\infty$, the pair $(2.6,\ -\infty)$.

The whole history of the landscape is therefore four pairs,

$$\{(2.6, -\infty),\ (2.0, 0.5),\ (1.8, 0.9),\ (1.4, 1.1)\}, \tag{12.38}$$

one for each summit. The differences between birth and death, ∞, 1.5, 0.9 and 0.3, are the prominences, and they rank the summits by how much of the water's descent each survives as a separate island.

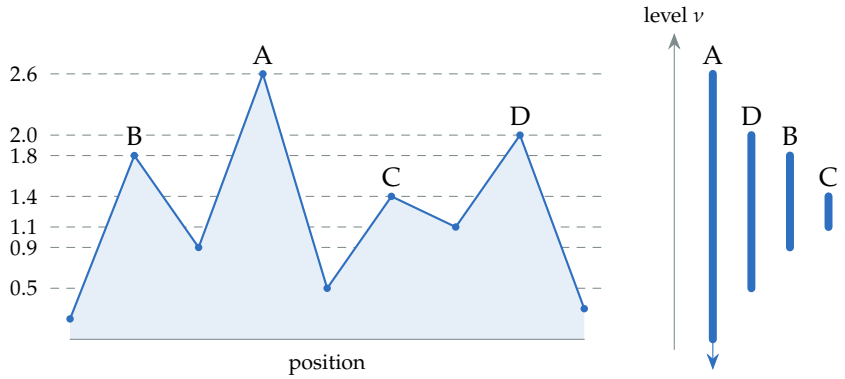

Figure 12.19: The landscape (12.37) and its barcode. The dashed lines are the water levels at which something happens. On the right each island is a vertical bar drawn against the same height axis: it starts at the height of its summit, where the island appears, and ends at the height of the pass where it merges into an older island. The bar of A, the highest summit, never ends.

Working definition 12.3 (filtration, persistence pair, diagram, barcode)

A **filtration** is a family of sets X_ν that only grows as the parameter moves in one direction [here the dry land (12.36), which grows as the level ν drops]. A feature (an island, a lake, a void) is **born** at the level b where it first appears and **dies** at the level d where it merges into an older feature or fills up [for superlevel sets $b \geq d$, because the level decreases]. The pair (b, d) is a **persistence pair** and $b - d$ is its **persistence**. The **persistence diagram** is the set of all pairs, drawn as points in the (b, d) plane, one diagram for islands (H_0) and one for lakes (H_1) [H_k is the standard name for the k-dimensional features: $k = 0$ pieces, $k = 1$ loops, $k = 2$ enclosed voids]. The **barcode** draws the same pairs as intervals. *Operationally:* sort the pixels by height, lower the level through them, and write down a pair whenever a feature dies.

The name of the subject comes from the H_k: they are the homology groups of algebraic topology, whose dimensions are the Betti numbers β_k of Section 12.2. Following them through a filtration is **persistent homology** [241]. We need no more of the algebra than the counts (see the topology notes for the groups themselves), but one fact explains why the record is trustworthy. Inside a computer the dry land is built from cells: the corners, edges and squares of the pixels. Adding one cell changes exactly one Betti number, by exactly one. A new corner is a new island. A new edge either joins two different islands, so one island dies, or joins two corners of the same island, which closes a loop around some water, so a lake is born. A new square either fills a loop, so a lake dies, or changes nothing. (A dry pixel brings its square together with any of its edges and corners that are not yet dry, all at the same level, so several such events can share one level.) Every change of a Betti number is therefore a single event that either creates a feature or destroys one. Pairing each destruction with the creation it undoes, by the elder rule, is what makes the history a list of non-overlapping lifetimes rather than a tangle [241, 242].

12.9.2 A grid by hand: islands and a lake

In two dimensions dry land can enclose water, and a second kind of feature appears. Take the 5×5 grid of heights

$$\phi = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 9 & 4 & 8 & 0 \\ 0 & 5 & 1 & 6 & 0 \\ 0 & 3 & 7 & 2 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \tag{12.39}$$

row 0 at the top. As in Section 12.2.2, a pixel is dry when its height is at least the water level, dry pixels that touch along an edge or at a corner belong to the same island (8-neighbours), and wet pixels belong to the same body of water only if they share an edge (4-neighbours). A body of water that does not reach the edge of the map is a lake. We lower the level through the distinct heights $9, 8, 7, \ldots$ and watch (Figure 12.20).

Level 9. The pixel in row 1, column 1 dries: island A is born at 9.

Level 8. The pixel $(1, 3)$ dries. Its eight neighbours are all still wet, so it is a new island, B, born at 8.

Level 7. The pixel $(3, 2)$ dries. Its neighbours $(2, 1)$, $(2, 2)$, $(2, 3)$ have heights 5, 1, 6, all still wet. A third island, C, is born at 7.

Level 6. The pixel $(2, 3)$ dries. It touches B at $(1, 3)$ through an edge and C at $(3, 2)$ through a corner, so B and C merge. C is younger (born at 7 against 8), so C dies: the pair $(7, 6)$.

Level 5. The pixel $(2, 1)$ dries. It touches A at $(1, 1)$ through an edge and the B–C island at $(3, 2)$ through a corner. B is younger than A, so B dies: the pair $(8, 5)$. All the dry land is now

one island.

Level 4. The pixel $(1,2)$ dries and joins the island. Nothing merges, but look at the centre pixel $(2,2)$, height 1, still wet. Its four edge-neighbours $(1,2)$, $(2,1)$, $(2,3)$, $(3,2)$ are now all dry, so the water at the centre is cut off from the open water outside: a lake is born at 4.

Levels 3 and 2. The pixels $(3,1)$ and $(3,3)$ dry and join the island. The lake is unchanged.

Level 1. The centre itself dries. The lake has drained: it dies at 1, the pair $(4,1)$.

Level 0. The border dries and joins the island. A never dies: $(9,-\infty)$.

The diagrams are

$$\text{islands } (H_0):\ \{(9,-\infty),\ (8,5),\ (7,6)\}, \qquad \text{lakes } (H_1):\ \{(4,1)\}. \tag{12.40}$$

A lake is born at the pass where the ring of land around it closes, and dies at the bottom of the lake, the lowest point it contains; it is the island story turned upside down, which Section 12.11.2 turns into an algorithm. Figure 12.21 shows the same history as a barcode and as a persistence diagram.

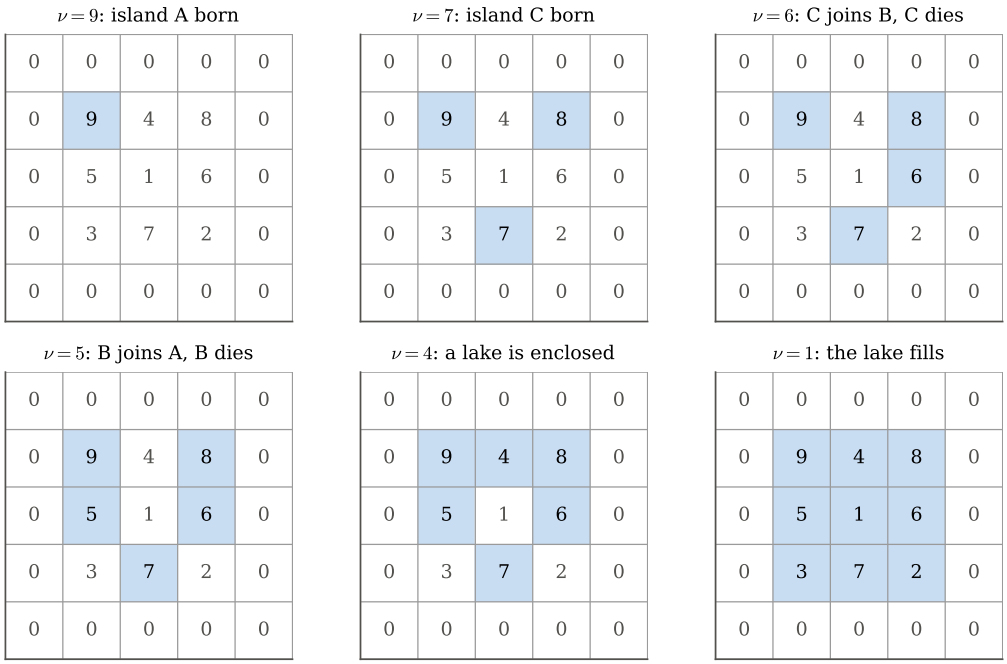

Figure 12.20: The 5×5 landscape (12.39) at six water levels; dry pixels are shaded. Island A appears at 9, B at 8 (not shown) and C at 7; C merges into B at 6 and B into A at 5. At 4 the ring of land around the centre closes and the centre becomes a lake, which drains when the level reaches the centre's height 1.

12.9.3 From the diagram back to the counts

The diagram contains every threshold count of Section 12.3. *How many islands are dry at level ν?* An island is present at level ν when it has been born and has not yet died. It is born at b and the level is decreasing, so it has been born if $\nu \le b$; it dies at d, so it is still alive if $\nu > d$. Counting the pairs that pass both tests gives the **Betti curve**

$$\beta_k(\nu) = \#\{(b,d) \in \mathrm{Dgm}_k :\ d < \nu \le b\}, \tag{12.41}$$

where Dgm_k is the diagram of the k-dimensional features. In the diagram plane the condition $d < \nu \le b$ picks out the points to the right of the vertical line $b = \nu$ and below the horizontal line $d = \nu$: a quadrant with its corner on the diagonal at (ν,ν) [5].

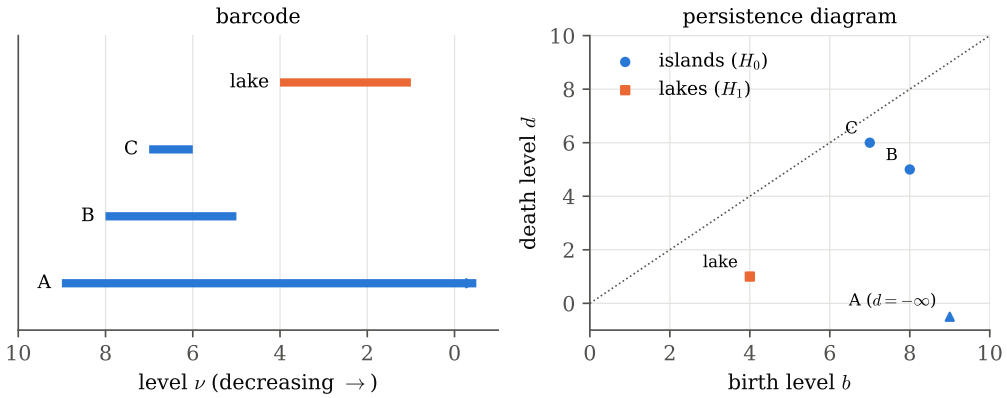

Figure 12.21: The history of Figure 12.20 in the two standard forms. Left: the barcode, one bar per feature, from its birth level to its death level, with the level decreasing to the right. Right: the persistence diagram, one point (b, d) per feature; the dotted line is $d = b$. Island A, which never dies, is drawn as a triangle at the bottom of the panel. The farther a point lies below the diagonal, the longer the feature lived.

Example: the line at $\nu = 1$. With the pairs (12.38),

$$\beta_0(1.0) \overset{(1)}{=} \#\{(2.6, -\infty), (2.0, 0.5), (1.8, 0.9), (1.4, 1.1) \ : \ d < 1.0 \le b\}$$
$$\overset{(2)}{=} \#\{(2.6, -\infty), (2.0, 0.5), (1.8, 0.9)\} = 3.$$

(1) Definition (12.41) applied to the four pairs of the line.
(2) All four births are at least 1.0. The deaths $-\infty$, 0.5 and 0.9 are below 1.0; the death 1.1 is not, because C has already merged into D when the water is at 1.0.

Directly from (12.37): the heights at least 1.0 are $h_1 = 1.8$, $h_3 = 2.6$ and the run $h_5, h_6, h_7 = 1.4, 1.1, 2.0$, which form three separate intervals. The two counts agree, as they must.

Example: the grid at $\nu = 4.5$ and $\nu = 3$. From (12.40), at $\nu = 4.5$ only the island pair $(9, -\infty)$ satisfies $d < 4.5 \le b$: the pairs $(8, 5)$ and $(7, 6)$ have deaths 5 and 6, not below 4.5, so B and C have already merged into A. Hence $\beta_0(4.5) = 1$. The lake pair $(4, 1)$ fails $4.5 \le b = 4$, so $\beta_1(4.5) = 0$: the ring has not closed yet. At $\nu = 3$ the lake pair satisfies $1 < 3 \le 4$, so $\beta_1(3) = 1$, and still $\beta_0(3) = 1$. The Euler characteristic $\chi = \beta_0 - \beta_1$ of Eq. (12.5) is 1 at $\nu = 4.5$ and 0 at $\nu = 3$, the values of a disc and of a ring.

Example: the diagram knows more than the curve. Two different landscapes can have the same Betti curve. Take one with island pairs $\{(3, 1), (2, 0)\}$ and another with $\{(3, 0), (2, 1)\}$, each with one immortal island besides. In both, β_0 counts one extra island for $2 < \nu \le 3$, two for $1 < \nu \le 2$, and one for $0 < \nu \le 1$, so the curves are identical. The diagrams are not. In the first, the island born at 3 merges at 1, and in the second the island born at 3 survives down to 0 while the one born at 2 merges at 1. The curve counts how many islands are present at each level; the diagram also says which island is which, so it knows how long each one lived. That is why research analyses that use Betti curves [4, 5] also look at the diagrams themselves.

12.9.4 Persistence measures robustness to the choice of threshold

A feature with pair (b, d) is present in X_ν for every level in the interval $d < \nu \le b$, an interval of width

$$\Delta\nu = b - d. \tag{12.42}$$

This is the sense in which persistence answers the complaint at the start of the section. Any analysis that picks one threshold inside that interval sees the feature; any threshold outside it misses it. A feature with large $\Delta\nu$ is seen by a wide range of reasonable choices, and conclusions drawn from it do not hang on one of them. A feature with tiny $\Delta\nu$ is seen only in a narrow window of levels, and whether it is counted at all depends on where the threshold happens to fall. In the diagram, long-lived features are points far below the diagonal $d = b$, and short-lived ones crowd along it.

Key idea: Persistence

Lowering the threshold through every level turns the excursion sets into a filtration. Each island, lake or void has a birth level and a death level; the pairs form the persistence diagram, and the number of pairs alive at any level is the Betti number there (12.41). The persistence $b - d$ is the range of thresholds over which a feature exists: points far from the diagonal are structures that no reasonable choice of threshold can miss.

Whether a short bar is noise or a small real structure is a different question, the question of stability: if the field is known only up to an error of size ϵ, a feature whose persistence is below about 2ϵ may have been created by the error, while a feature that persists much longer cannot have been.

12.10 Small changes of the field, small changes of the diagram

A measured map is never the field itself. It is the field plus instrumental noise, smoothed by a beam, with the occasional bad pixel. Every wiggle that noise adds to the landscape of Section 12.9 is a tiny summit with a tiny pass beside it, so a noisy map has many more islands than the field under it. If each of them were an equal entry in the persistence diagram, the diagram of the data would have little to do with the diagram of the physics. What saves the method is that the noise-made islands are not equal entries: they are born and die at almost the same level, so they sit right next to the diagonal, while the islands of the underlying field barely move. The statement can be made precise, and checked on simulated maps.

The question. Suppose every value of the field changes by at most ϵ,

$$\|f - g\|_\infty \equiv \max_{\boldsymbol{x}} |f(\boldsymbol{x}) - g(\boldsymbol{x})| \le \epsilon, \tag{12.43}$$

where f is the true field and g the measured one. How far can the persistence diagram of g be from that of f? To answer we need two things: a way to measure the distance between two diagrams, and an argument for why that distance is small.

12.10.1 The simplest case first: a noise wiggle on a slope

Start where nothing should happen. Let f be a field that only rises along a line, $f(x) \le f(x')$ whenever $x < x'$, so its superlevel sets have no features in this stretch: every dry point is joined to the higher ground on its right. Add noise $\eta(x)$ with $|\eta| \le \epsilon$, so $g = f + \eta$. Suppose the noise has made a small summit at x_p, a separate island of g born at $g(x_p)$. To merge into the higher ground on its right it must be joined through the lowest point $x_s > x_p$ between them, the pass,

where it dies at $g(x_s)$. How long can it live?

$$\begin{aligned} g(x_p) - g(x_s) &\overset{(1)}{=} \big[f(x_p) - f(x_s)\big] + \big[\eta(x_p) - \eta(x_s)\big] \\ &\overset{(2)}{\le} 0 + \big[\eta(x_p) - \eta(x_s)\big] \\ &\overset{(3)}{\le} \epsilon + \epsilon = 2\epsilon. \end{aligned} \tag{12.44}$$

(1) Write $g = f + \eta$ at both points and regroup.
(2) The pass lies to the right of the summit, $x_s > x_p$, and f rises to the right, so $f(x_p) \le f(x_s)$.
(3) Each noise value lies between $-\epsilon$ and ϵ, so a difference of two of them is at most 2ϵ.

A feature that the noise creates out of nothing has persistence at most 2ϵ. Its point (b, d) in the diagram therefore lies within a vertical (or horizontal) distance 2ϵ of the diagonal, and within ϵ of the diagonal point $\left(\frac{b+d}{2}, \frac{b+d}{2}\right)$ in each coordinate. The same chain read the other way shows that a genuine island of f is not destroyed by the noise unless its own persistence is below 2ϵ, and that its birth (a summit height) and its death (a pass height) each move by at most ϵ, because every height does.

12.10.2 A distance between diagrams

To compare two diagrams we pair up their points and ask how far the paired points are. Two complications appear at once. The diagrams may have different numbers of points, and a short-lived feature present in one may simply be absent from the other. Both are handled by allowing a point to be paired with the diagonal, which means "this feature has shrunk to zero persistence in the other diagram".

Working definition 12.4 (bottleneck distance)

A **matching** between diagrams D and D' pairs each point of D either with one point of D' or with the diagonal, and likewise each point of D'. The cost of pairing (b, d) with (b', d') is $\max(|b - b'|, |d - d'|)$ [the larger of the shift in birth and the shift in death]; the cost of pairing (b, d) with the diagonal is $(b - d)/2$ [the shift needed to move it onto the diagonal, to the point $((b + d)/2, (b + d)/2)$]. The **bottleneck distance** $d_B(D, D')$ is the smallest possible value of the largest cost in a matching. *Operationally:* try matchings, record the worst pair in each, and keep the matching whose worst pair is best.

Example: a matching by hand. Let $D = \{(3, 0),\ (2, 1.6)\}$ and $D' = \{(2.8, 0.1)\}$ (Figure 12.22). Only two matchings are worth trying. In the first, $(3, 0)$ goes with $(2.8, 0.1)$ and $(2, 1.6)$ goes to the diagonal:

$$\text{worst cost} \overset{(1)}{=} \max\left(\max(|3 - 2.8|, |0 - 0.1|),\ \tfrac{2-1.6}{2}\right) = \max(0.2,\ 0.2) = 0.2.$$

(1) The first entry is the cost of the paired points, the second the cost of sending $(2, 1.6)$ to the diagonal.

In the second, $(2, 1.6)$ goes with $(2.8, 0.1)$ and $(3, 0)$ goes to the diagonal: the costs are $\max(0.8, 1.5) = 1.5$ and $3/2 = 1.5$, so the worst is 1.5. The bottleneck distance is the better of the two, $d_B = 0.2$. In words: the long-lived feature moved by 0.2, and the short one could have been created or destroyed by a change of size 0.2.

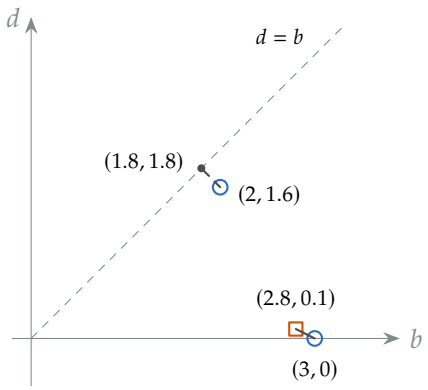

Figure 12.22: The best matching between D (circles) and D' (square). The long-lived point $(3, 0)$ is paired with $(2.8, 0.1)$; the short-lived point $(2, 1.6)$ has no partner and is sent to the nearest point of the diagonal, $(1.8, 1.8)$, at cost 0.2. Both costs are 0.2, so $d_B = 0.2$.

12.10.3 The stability theorem

The wiggle of Section 12.10.1 gave the bound in the simplest case. Cohen-Steiner, Edelsbrunner and Harer proved that it holds in general [243].

Key idea: Stability of persistence diagrams

For two fields f and g on the same domain (continuous, with finitely many critical levels, which covers every pixel map),

$$d_B\big(\mathrm{Dgm}_k(f),\, \mathrm{Dgm}_k(g)\big) \le \|f - g\|_\infty \qquad \text{for every } k.$$

Physically: a perturbation of size ϵ moves every robust feature by at most ϵ in birth and in death, and every feature it creates or destroys has persistence at most 2ϵ, so it sits within the band $b - d \le 2\epsilon$ along the diagonal.

Why it is true, at the physicist's level. Births and deaths are heights of special points, summits, passes and lake bottoms, and (12.43) says that no height moves by more than ϵ. If the special points of g were simply the special points of f, moved a little, every pair would move by at most ϵ in each coordinate and we would be done. The real work in the proof is the case where g has extra special points (the noise wiggles) or fewer (a feature of f washed out); the slope argument (12.44) shows that such points can only belong to pairs of persistence at most 2ϵ, which the matching sends to the diagonal at cost at most ϵ. The general proof organises this bookkeeping for all levels at once [243]. Note what the theorem does *not* say: it does not bound the number of new points, only where they can be. A noisy map can have a hundred times more islands than the clean one and still be within ϵ of it in the bottleneck distance, because all the extra islands are near the diagonal [5].

Testing it. The script `code/ch12/b03_stability.py` makes a smooth Gaussian field f on a 128×128 grid, adds either white noise or noise smoothed over a pixel and a half, at amplitudes from 0.01 to 0.4 standard deviations of f, and computes $\|f - g\|_\infty$ and the bottleneck distance between the island diagrams and between the lake diagrams of f and g (with gudhi's `bottleneck_distance`, checked once against persim; they agree to 0). Over all 60 trials the largest value of $d_B / \|f - g\|_\infty$ is 0.9132: the bound is never broken, and it comes close to being reached (Figure 12.23, left). It cannot be improved in general, as the simplest perturbation shows: add the same constant ϵ to every pixel. Every summit and every pass rises by exactly ϵ,

so every point of the diagram moves by ϵ in birth and in death, no matching does better, and $d_B = \epsilon = \|f - g\|_\infty$.

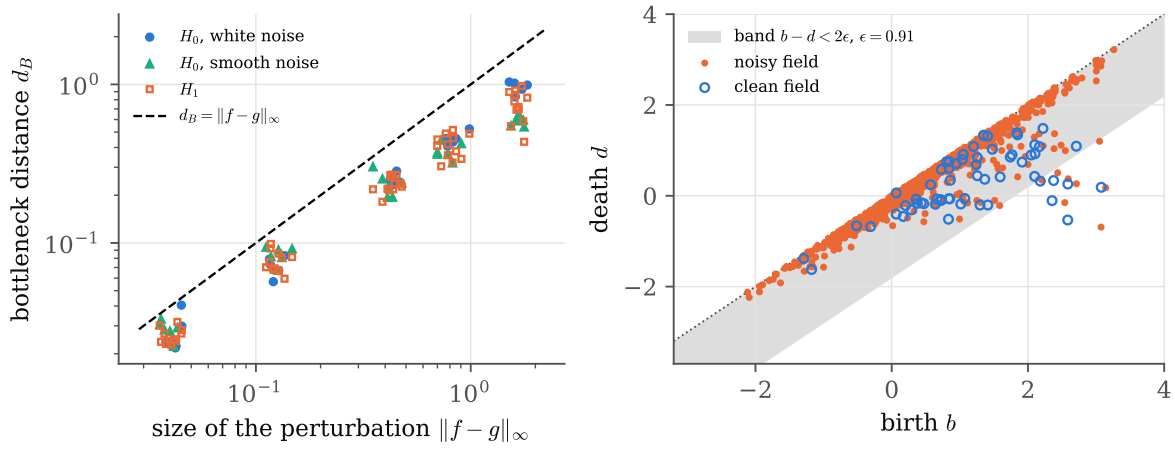

Figure 12.23: Left: bottleneck distance between the diagrams of a clean field and a noisy copy, against the size of the noise, for white and smoothed noise and for islands and lakes. Every point lies below the dashed line $d_B = \|f - g\|_\infty$. Right: the island diagrams of one clean field (open circles) and of the same field with white noise of 0.2 standard deviations added (dots). The grey band is $b - d < 2\epsilon$. The noise adds a crowd of points inside the band; the points of the clean field far from the diagonal have partners close by.

Example: where the noise islands sit. In the right panel of Figure 12.23 the white noise has standard deviation 0.2, but its largest value over the 16 384 pixels is $\epsilon = 0.908$ (the maximum of many Gaussian numbers lies several standard deviations out). The clean field has 60 islands; the noisy one has 871. Of these, 863 have persistence below 2ϵ, inside the band the theorem allows for created features. The most persistent island lives for 3.117 in the clean field and 3.763 in the noisy one; the tenth most persistent, 1.502 and 1.614. Smoothing the noisy map over a pixel and a half brings the count back to 57 islands: the smoothing removes the wiggles that made the short bars, which is the beam of Section 8.2.1 doing, for topology, what it does for the power spectrum.

What the bound costs us. The theorem controls the worst pixel, not the typical one. For Gaussian noise the worst pixel of a map of 10^4 to 10^6 pixels lies about 4 to 5 standard deviations out, so the band of 2ϵ is wide, and many genuine but small features of the field lie inside it, where the theorem cannot tell them from noise. Worse, one bad pixel (a cosmic-ray hit, an unmasked point source) makes ϵ large on its own. In practice we do not rely on the worst-case band. We simulate the noise, pass the simulations through the same pipeline, and read off where noise features actually fall in the diagram; that is the Monte Carlo of part 12c. The theorem's job is the qualitative guarantee: features far from the diagonal are safe, and the diagram is a continuous function of the data, so it is a sensible input to a statistical analysis.

Watch out: Bottleneck is not the only distance

The bottleneck distance looks only at the worst-matched pair and ignores everything else. The p-**Wasserstein distance** instead adds up the costs, $W_p = \left(\min_{\text{matchings}} \sum \text{cost}^p\right)^{1/p}$, so it feels all the small points near the diagonal too. It is more sensitive to how many noise features there are, and for that reason it is not bounded by $\|f - g\|_\infty$ alone; its stability needs extra conditions on the fields [242]. Use the bottleneck distance when the question is

"did any robust feature move?", and a Wasserstein distance when the whole population of features matters.

12.11 Computing persistence: union–find and the elder rule

The 5×5 landscape of Section 12.9.2 took a page by hand. A 256×256 simulated patch has 65 536 pixels, and a HEALPix map at $N_{\text{side}} = 2048$ has fifty million. The procedure itself does not change: sort the pixels from the highest to the lowest, let them become dry one at a time, and whenever a new dry pixel touches dry neighbours, find out which islands those neighbours belong to and merge them, recording a death by the elder rule. The only hard part is the question "which island does this pixel belong to?", asked again and again. If we answered it by relabelling whole islands at every merger, a big island would be relabelled thousands of times. The standard answer is a data structure called **union–find**, which makes each question cost almost nothing.

The question. How can a program keep track of which island every dry pixel belongs to, merge two islands in one step, and remember the summit height of each island, so that it can apply the elder rule?

12.11.1 Union–find

Store each island as a tree of pointers. Every dry pixel p holds one number, parent[p], the pixel it points to. Following the pointers from any pixel of an island always ends at the same pixel, the **root**, which points to itself. The root is the island's name, and we store the island's summit height at the root. Two operations are needed.

- *Find*: to learn which island p belongs to, follow parent from p until reaching a pixel that points to itself.
- *Union*: to merge two islands, make the root of one point to the root of the other. One pointer changes; nothing else does.

Trees made this way can grow long chains, which would make *find* slow. A one-line repair keeps them shallow: while walking up, make each visited pixel point to its grandparent (**path halving**). With it, a long sequence of operations costs, on average, a small constant number of steps each, so the total work is proportional to the number of pixels, apart from the sort that puts them in order of height [242].

The whole algorithm for the islands of a pixel map is then the function `islands` of `code/ch12/lib_persist.py`:

Listing 12.7: Islands (H_0) of the superlevel sets by union–find (`code/ch12/lib_persist.py`)

```
def islands(f, conn: int = 8):
    """Birth-death pairs of the islands of {f >= nu} as the level nu is lowered
    (union-find)."""
    ny, nx = f.shape
    h = f.ravel()
    order = np.argsort(-h, kind="stable")       # pixels from the highest to the lowest
    parent = np.full(h.size, -1)                # -1 means: still under water
    peak = np.empty(h.size)                     # for the root of each island: its peak
    height
    steps = NEIGH8 if conn == 8 else NEIGH4

```

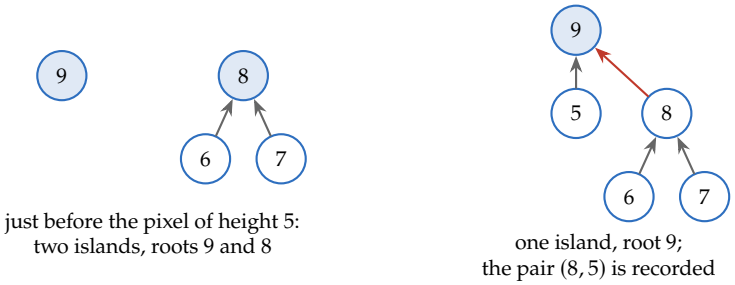

Figure 12.24: Union–find on the island step of the 5×5 example at level 5 (Section 12.9.2). Each circle is a dry pixel labelled by its height, each arrow its parent pointer; the shaded circles are roots, which carry the summit height of their island. When the pixel of height 5 joins both islands, the root of the younger island (summit 8) is made to point to the root of the older one (summit 9, red arrow), and the death of the younger island at level 5 is written down.

```
39      def root(p):                                    # follow parents to the island's root
40          while parent[p] != p:
41              parent[p] = parent[parent[p]]           # path halving keeps the trees shallow
42              p = parent[p]
43          return p
44
45      pairs = []
46      for p in order:                                 # lower the water level pixel by pixel
47          parent[p], peak[p] = p, h[p]                # p emerges as a one-pixel island
48          i, j = divmod(p, nx)
49          for di, dj in steps:
50              a, b = i + di, j + dj
51              if not (0 <= a < ny and 0 <= b < nx) or parent[a * nx + b] < 0:
52                  continue                            # off the grid, or neighbour still under
    water
53              r1, r2 = root(p), root(a * nx + b)
54              if r1 == r2:
55                  continue                            # already the same island
56              if peak[r1] < peak[r2]:
57                  r1, r2 = r2, r1                     # r1: the elder island (higher peak)
58              if peak[r2] > h[p]:                     # the younger one dies at this level
59                  pairs.append((peak[r2], h[p]))
60              parent[r2] = r1                         # ... and becomes part of the elder
61      pairs.append((h[order[0]], -np.inf))            # the highest island never dies
62      return np.array(pairs)
```

Line 34 sorts the pixels from the highest to the lowest: this is the falling water. Lines 35–36 hold the two arrays of union–find, `parent` (with -1 for a pixel still under water) and `peak`, the summit height stored at each root. Lines 39–43 are *find* with path halving. The loop of line 46 makes one pixel dry per step. Line 47 makes it a one-pixel island, its own root, with its own height as summit. Lines 49–52 visit the eight neighbours and skip those off the map or still wet. Line 53 finds the roots of the new pixel and of the neighbour. If they differ, the two islands are merging at the level $h[p]$ of the new pixel. Lines 56–57 apply the elder rule: `r1` becomes the root with the higher summit. Lines 58–59 record the death of the younger island, (its summit, $h[p]$), unless the younger "island" is just the new pixel itself, whose summit equals $h[p]$ and whose pair would have zero persistence. Line 60 is the *union*. When every pixel is dry, line 61 adds the island that never dies.

Example: the code on the hand example. Run on the grid (12.39), `islands` returns the pairs $(7, 6)$, $(8, 5)$ and $(9, -\infty)$, exactly (12.40), in the order in which the deaths happen (`code/ch12/b01_hand_examples.py`). gudhi, given the same grid, returns the same three

pairs.

12.11.2 Lakes from islands: duality in the plane

Lakes need a second idea. A lake of the dry land is a body of water that does not reach the open sea. So instead of watching the land, watch the water. The water at level ν is the set $\{\phi < \nu\}$. As the level falls, the water shrinks; read backwards, with the level rising, the water grows, starting at the lowest points of the map and spreading. That is exactly the island story for the upside-down landscape $-\phi$: its summits are the lake bottoms of ϕ, and its passes are the passes of ϕ.

The translation. Run `islands` on $-\phi$, with two changes. First, water pixels are connected only through edges, 4-neighbours, because the land is 8-connected and the two must be dual (Section 12.2.2). Second, surround the map with a frame of open sea that is always wet, by giving the frame the height $+\infty$ in $-\phi$; the frame then becomes the oldest island of $-\phi$, and any water connected to the edge of the map merges into it. Now take a water body of $-\phi$ born at $-\phi = -m$ and merging at $-\phi = -s$. In the language of the land: the water body has its bottom at height m and joins other water through a pass of height $s > m$. With the level falling, it is part of a larger body while $\nu > s$; when ν drops below s it is cut off from the rest, so if the rest is the sea, a lake is born at s; and it drains when ν drops below its bottom m. So a pair $(-m, -s)$ of $-\phi$ becomes the lake pair (s, m) of ϕ. On the hand example the centre pixel is a water island of $-\phi$ born at -1. In the reversed picture the water rises; the first of its four edge-neighbours to go under is the pixel of height 4, which is already joined to the border, so the centre's water body merges into the sea at -4. The lake pair is $(4, 1)$, as found by hand. That this bookkeeping gives exactly the lakes, the holes of the land, is a case of **Alexander duality** (see the topology notes): in the plane, the holes of a set are the bounded pieces of its complement.

Listing 12.8: Lakes (H_1) by duality: the islands of $-\phi$ with a sea around the map (`code/ch12/lib_persist.py`)

```
65 def lakes(f):
66     """Birth-death pairs of the holes (lakes) of {f >= nu}, by Alexander duality in the
       plane.
67
68     A hole of the land is a piece of the water {f < nu} that does not reach the open sea.
       We
69     surround the map by a frame of sea (+inf in -f), compute the islands of -f with
70     4-neighbours, and translate: a water body born at -f = -m (the lake bottom, height m)
       and
71     merging into another at -f = -s (the pass, height s) is a lake of the land that appears
72     when the level drops to s and fills up when it drops below m.
73     """
74     g = np.pad(-np.asarray(f, float), 1, constant_values=np.inf)
75     p = islands(g, conn=4)
76     p = p[np.isfinite(p[:, 0]) & np.isfinite(p[:, 1])]  # drop the open sea itself
77     return np.column_stack([-p[:, 1], -p[:, 0]])        # (birth, death) = (pass, bottom)
```

Line 74 builds $-\phi$ with the frame of sea, line 75 runs the island code with 4-neighbours, line 76 drops the one immortal water body (the sea), and line 77 translates each pair back.

On the torus the shortcut fails. A periodic map, such as a simulation box, has no edge and so no open sea. Two new things happen. A band of land that wraps around the torus contains a loop that encloses no lake; and the water can also wrap around, so no water body is "outside". The lake count then misses the loops that wind around the torus, and the frame of sea, if we add it, cuts features that should continue across the edges. For periodic maps we therefore use gudhi's `PeriodicCubicalComplex` (Section 12.13), which builds the torus directly.

12.11.3 Checks against the libraries, and timing

`code/ch12/b02_grf_persistence.py` makes one Gaussian field on a 256×256 grid, smoothed on 4 pixels (the recipe of Section 7.4), and runs four independent checks.

- *gudhi.* Its `CubicalComplex`, built from the pixels as squares, computes the persistence of the sublevel sets of $-\phi$, which are our superlevel sets of ϕ with the same 8- and 4-neighbour rules. Both codes find 207 island pairs and 231 lake pairs, and the bottleneck distance between our diagrams and gudhi's (computed by persim) is 0: they are identical.
- *ripser.* Its `lower_star_img` computes the island pairs of an image. The bottleneck distance to ours is 1.115×10^{-7}, the rounding error of the single-precision numbers ripser uses internally.
- *scipy.* At 61 levels from -3 to 3 we count the islands directly with `scipy.ndimage.label` (8-neighbours) and the lakes as the 4-connected water bodies that do not touch the edge. These counts and the Betti curves (12.41) read from our diagrams differ by at most 0 at any level.
- *scikit-image.* `skimage.measure.label` (with `connectivity=2`, its name for 8-neighbours) counts the islands again, and `skimage.measure.euler_number` computes χ of the dry land by counting cells, as in Section 12.2.3. They equal β_0 and $\beta_0 - \beta_1$ from our diagrams at every level.

A fifth check is a physical one. The field $e^{0.8\phi}$ is a strictly increasing function of ϕ, so by the argument of Section 12.3.2 its dry land at level $e^{0.8\nu}$ is the dry land of ϕ at level ν. Its diagram must be the diagram of ϕ with every level relabelled, and it is: taking the logarithm of its pairs and dividing by 0.8 gives back the pairs of ϕ exactly.

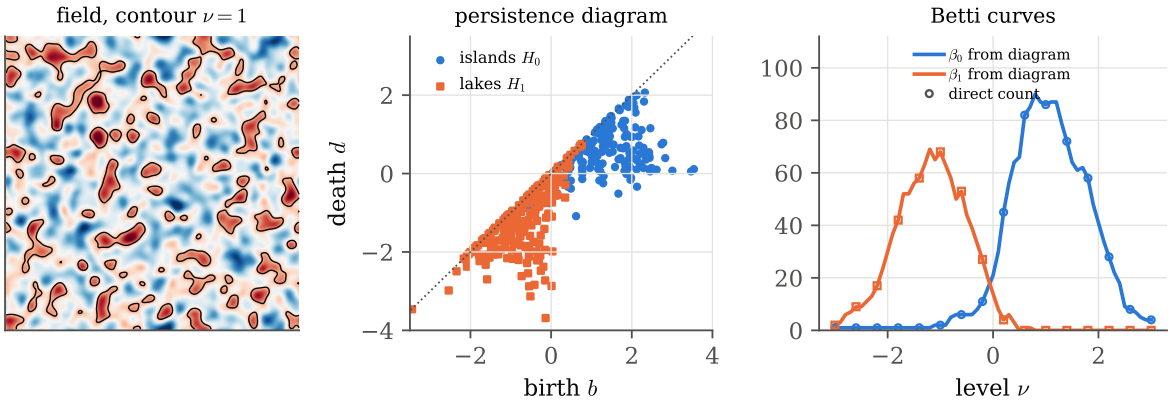

Figure 12.25: One 256×256 Gaussian field and its persistence. Left: the field, with the boundary of the dry land at $\nu = 1$. Middle: the diagrams of islands (circles) and lakes (squares). Islands are born at positive levels, the summits, and lakes die at negative levels, the lake bottoms. Right: the Betti curves read from the diagrams (lines) and counted directly with `scipy.ndimage.label` (open symbols).

Figure 12.25 shows what the diagram of a smooth random field looks like. The islands are born at summits, almost all above $\nu = 0$, and die at passes, spread from about -2 to 2. The lakes are their mirror image: born at passes, dying at lake bottoms, almost all below 0. The mirror symmetry is the one of Section 12.3: a Gaussian field is as likely as its negative, so the lakes of ϕ are statistically the islands of $-\phi$. The longest-lived island lives for 3.427, and a fraction 0.3738 of the islands live for less than 0.25; even without noise, a smooth field has many shallow summits sitting on the shoulders of bigger ones.

Timing. The union–find code is plain Python, one loop over pixels. Its run time grows in proportion to the number of pixels (a fitted power of 1.001), from about a second at 256^2 to 15.83 s for islands and lakes at 1024^2; gudhi, written in C++, takes 1.757 s there (Figure 12.26). Both are fast enough for every map used in this chapter's experiments. Scaled to a full-resolution *Planck* map of fifty million pixels, the measured times become about thirteen minutes for the Python code and about a minute and a half for gudhi (on the sphere the neighbours would come from `healpy.get_all_neighbours` instead of the grid).

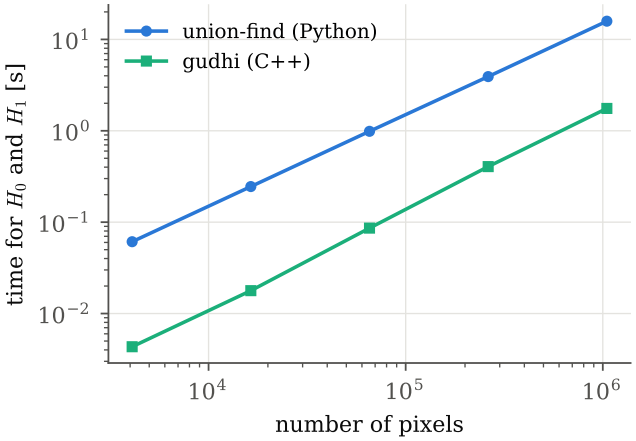

Figure 12.26: Time to compute the island and lake diagrams against the number of pixels, for the union–find code of Section 12.11.1 and for gudhi. Both grow in proportion to the number of pixels; the compiled library is about ten times faster.

How this is used in real research: Persistence software in research

Research codes never write their own union–find. For pixel maps and simulation boxes the standard tools are gudhi's cubical complexes (periodic or not), Cubical Ripser, and DIPHA for maps too large for one machine; for point clouds, ripser and gudhi's Rips and alpha complexes; and for diagrams, persim and gudhi's own distances [242]. Cosmic-web studies compute persistence on a Delaunay tessellation of the particles with the density estimated at each particle, using the PHAT library [4, 5]. The from-scratch code earns its place as a check: on a small map, a disagreement between it and the library almost always means a convention has been mixed up (superlevel against sublevel sets, 4- against 8-neighbours, the sign of the field).

12.12 Point clouds: shapes grown from points

A galaxy survey or an N-body simulation does not hand us a field. It hands us points: positions of galaxies, haloes or dark-matter particles. One way forward is to turn the points into a density field on a grid and use the landscape of the previous sections; Section 12.13 does that. The other is to build shapes directly from the points. Put a small ball around every point and let all the balls grow together. When two balls touch, their points are linked; when three points are pairwise linked, the triangle between them is filled in. At a small radius every point is alone. As the radius grows, close points join into clusters, clusters join each other, rings of points close into loops, and the loops eventually fill in. The radius plays the role the water level played for a field, and the same bookkeeping of births and deaths applies.

The question. For a set of points, at which linking distance does each cluster stop being separate, and at which distances do loops of points appear and fill in? And how do we compute this without drawing balls?

Working definition 12.5 (Vietoris–Rips filtration)

For points $x_1, \dots, x_n$ and a scale $r \geq 0$, the **Vietoris–Rips complex** VR_r contains every point, an edge between x_i and x_j whenever $|x_i - x_j| \leq r$, and a filled triangle (and higher simplices) on every set of points that are pairwise within r [a triangle enters exactly when its longest edge does]. As r grows the complex only gains edges and triangles, so it is a filtration. Every point is born at $r = 0$; a cluster dies at the r where it joins another; a loop is born at the length of the edge that closes it and dies at the length of the edge that completes the triangles filling it.

In this filtration the parameter increases, so births come before deaths, $b \leq d$, and the diagram points lie above the diagonal; this is the convention of every point-cloud library. Figure 12.27 shows the complex of a noisy ring of 40 points with a small clump of 12 beside it at three scales.

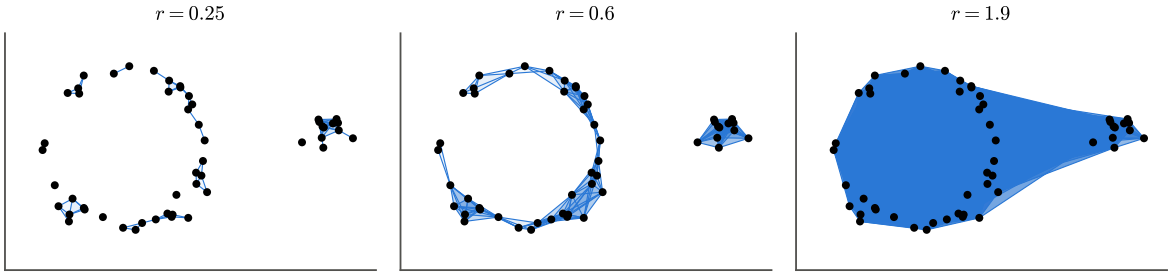

Figure 12.27: The Vietoris–Rips complex of a noisy ring with a clump beside it, at three scales r. At $r = 0.25$ only near neighbours are linked. At $r = 0.6$ the ring is linked all the way round except for one gap on its left, which closes a little later into a loop around an empty middle, and the clump is one cluster. At $r = 1.9$ triangles have filled the middle of the ring and the clump is joined to it: one blob.

12.12.1 Clusters: the minimum spanning tree

Connectivity in VR_r is decided by the edges alone: triangles fill area but join nothing that their edges have not already joined. So to follow the clusters we only need to add the edges in order of length and ask, for each edge, whether it joins two different clusters. That is **Kruskal's algorithm**: sort all $n(n-1)/2$ edges by length; take them one by one; if an edge joins two different clusters, merge them (one dies at that length) and keep the edge; if it joins a cluster to itself, skip it. The kept edges form the **minimum spanning tree**, the shortest network of edges that connects all the points, and their lengths are exactly the deaths of the island diagram of the points. All births are at 0, so the elder rule never has to choose by age; any choice of which cluster dies gives the same pairs.

Example: six points by hand. Take $A = (0,0)$, $B = (1,0)$, $C = (0,1)$, $D = (4,0)$, $E = (5,0)$, $F = (4,2)$ (Figure 12.28). The shortest distances, in order, are $AB = AC = DE = 1$, $BC = \sqrt{2}$, $DF = 2$, $EF = \sqrt{5}$, then $BD = 3$. Kruskal takes AB (one cluster dies at 1), AC (another at 1), DE (another at 1). BC joins B and C, already in one cluster through A, so it is skipped; at the same length the triangle ABC enters (its longest edge is BC), so no loop ever exists there. DF joins F

to the cluster $\{D, E\}$: a death at 2. EF is skipped. $BD = 3$ joins the two clusters: a death at 3. The island diagram is

$$\{(0,1),\ (0,1),\ (0,1),\ (0,2),\ (0,3),\ (0,\infty)\}, \tag{12.45}$$

and the minimum spanning tree has total length $1 + 1 + 1 + 2 + 3 = 8$. Read the bars: three die at 1, the spacing inside the two groups; one at 2, the loose point F; and one bar, from 0 to 3, stands out. It says that there are two groups of points, separate for all scales between 2 (when the second group is complete) and 3 (when they join). The script `b04_point_cloud.py` returns exactly these deaths, and so does ripser.

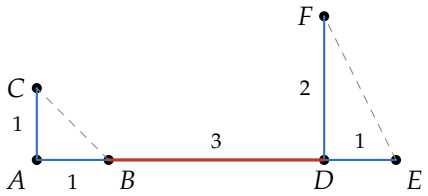

Figure 12.28: The six points of the hand example and their minimum spanning tree. Blue edges join points within a group; the red edge, of length 3, is the last one added and joins the two groups. Dashed edges are skipped by Kruskal's algorithm because their endpoints are already connected.

Two old friends. Hierarchical clustering with "single linkage" joins at each step the two clusters with the closest pair of members; its merge heights are the edge lengths of the minimum spanning tree, and `scipy.cluster.hierarchy.linkage(X, method="single")` returns exactly our deaths. And the friends-of-friends group finder used on N-body simulations, which links any two particles closer than a linking length b and calls each connected group a halo, returns the clusters of VR_b. The island diagram of the particles therefore contains the friends-of-friends catalogue for every linking length at once: the number of haloes at linking length b is the number of bars still alive at $r = b$.

Listing 12.9: Island diagram of a point cloud: Kruskal's minimum spanning tree (`code/ch12/lib_persist.py`)

```
def kruskal_h0(X):
    """H0 of the Vietoris-Rips filtration = the edges of the minimum spanning tree
    (Kruskal).

    All points are born at r = 0; a component dies at the length of the edge that merges it
    into another.  Returns the sorted death values (n - 1 of them; one component never
    dies).
    """
    n = len(X)
    i, j = np.triu_indices(n, k=1)
    length = np.linalg.norm(X[i] - X[j], axis=1)
    parent = list(range(n))

    def root(p):
        while parent[p] != p:
            parent[p] = parent[parent[p]]
            p = parent[p]
        return p

    deaths = []
    for e in np.argsort(length, kind="stable"):  # shortest edges first
        r1, r2 = root(i[e]), root(j[e])
        if r1 != r2:                             # the edge joins two components: one dies
            parent[r1] = r2
            deaths.append(length[e])
```

```
121             if len(deaths) == n - 1:
122                 break
123     return np.array(deaths)
```

Lines 105–106 list every pair of points and its distance. The loop of line 116 takes the edges from the shortest up; `root` is the *find* of Section 12.11.1. Lines 117–120 keep an edge only when it joins two different clusters, and record its length as a death. After $n-1$ deaths a single cluster is left and the loop can stop.

12.12.2 Loops: reducing the boundary matrix

Loops cannot be found with union–find, which only knows who is connected to whom. The general algorithm keeps, for every edge and triangle, the list of its faces, and does linear algebra on these lists [5, 241].

Example: the unit square by hand. Four points at the corners of a unit square, $v_0 = (0,0)$, $v_1 = (1,0)$, $v_2 = (1,1)$, $v_3 = (0,1)$. At $r = 1$ the four sides enter. Every triangle on these points needs a diagonal, of length $\sqrt{2}$, so no triangle enters yet: the four sides enclose an empty loop, and a loop is born at $r = 1$. At $r = \sqrt{2}$ both diagonals enter and with them all four triangles, which cover the square: the loop dies. The loop diagram is $\{(1, \sqrt{2})\}$.

How the algorithm finds this. List the cells in the order they enter: the four points, then the sides $e_{01}, e_{12}, e_{23}, e_{03}$ (length 1), then the diagonals e_{02}, e_{13} and the triangles (length $\sqrt{2}$). Write each cell as the list of its faces, its **boundary**: $\partial e_{01} = \{v_0, v_1\}$, $\partial t_{023} = \{e_{02}, e_{23}, e_{03}\}$, and so on. Lists are added modulo 2: a face present in both lists cancels. Go through the cells in order. For each, look at the latest-entering face in its list, its *lowest* entry. If an earlier cell already owns that lowest entry, add that cell's (already reduced) list to this one and look again. Stop when the lowest entry is new, or the list is empty.

- e_{01}: list $\{v_0, v_1\}$, lowest v_1, new. So e_{01} kills the cluster born at v_1: the pair $(0, 1)$. Likewise e_{12} kills v_2 and e_{23} kills v_3.
- e_{03}: list $\{v_0, v_3\}$. Lowest v_3 is owned by e_{23}: add, $\{v_0, v_3\} + \{v_2, v_3\} = \{v_0, v_2\}$. Lowest v_2 is owned by e_{12}: add, giving $\{v_0, v_1\}$; lowest v_1 is owned by e_{01}: add, giving $\{\}$. The list is empty: e_{03} kills nothing, so it creates something. It is the edge that closes the loop, born at $r = 1$.
- The diagonals reduce to empty lists the same way: each closes a new loop at $\sqrt{2}$.
- The triangle t_{012}, list $\{e_{01}, e_{12}, e_{02}\}$, lowest e_{02}, new: it kills the loop that e_{02} created, the pair $(\sqrt{2}, \sqrt{2})$, of zero persistence. The triangle t_{013} kills the loop of e_{13} the same way.
- The triangle t_{023}, list $\{e_{02}, e_{23}, e_{03}\}$. Lowest e_{02} is owned by t_{012}: add, giving $\{e_{01}, e_{12}, e_{23}, e_{03}\}$, the four sides. Lowest e_{03}, new: t_{023} kills the loop born when e_{03} entered, the pair $(1, \sqrt{2})$.

The reduced list of t_{023} is the boundary of the square: the algorithm has discovered that the two triangles t_{012} and t_{023} together fill the loop of the four sides. Every pair of a persistence diagram, in any dimension, is found this way [241].

Listing 12.10: Persistence of a Rips filtration by reducing the boundary matrix (small clouds) (`code/ch12/lib_persist.py`)

```
126 def rips_bruteforce(X, maxdim: int = 1):
127     """Persistence of the Vietoris-Rips filtration by reducing the boundary matrix over Z_2.
128 
129     Simplices up to dimension maxdim + 1.  Filtration value of a simplex = its longest edge.
```

```
130     Returns {dim: array of (birth, death)}, deaths of essential classes = inf.  Small
        clouds only.
131     """
132     n = len(X)
133     D = np.linalg.norm(X[:, None, :] - X[None, :, :], axis=-1)
134     simplices = []
135     for k in range(1, maxdim + 3):
136         for s in itertools.combinations(range(n), k):
137             val = 0.0 if k == 1 else max(D[a, b] for a, b in itertools.combinations(s, 2))
138             simplices.append((val, k - 1, s))
139     simplices.sort(key=lambda t: (t[0], t[1]))          # by value, faces before cofaces
140     index = {s: c for c, (_, _, s) in enumerate(simplices)}
141     low_of = {}                                         # pivot row -> column that owns it
142     out = {k: [] for k in range(maxdim + 1)}
143     paired = set()
144     for c, (val, dim, s) in enumerate(simplices):
145         col = {index[f] for f in itertools.combinations(s, dim)} if dim > 0 else set()
146         while col and max(col) in low_of:               # add earlier columns until the
        pivot is new
147             col ^= low_of[max(col)][1]
148         if col:
149             r = max(col)                                # simplex r (dim-1) is killed by c
150             low_of[r] = (c, col)
151             paired.update((r, c))
152             b = simplices[r][0]
153             if dim - 1 <= maxdim and val > b:
154                 out[dim - 1].append((b, val))
155     for c, (val, dim, s) in enumerate(simplices):       # unpaired simplices: essential
        classes
156         if c not in paired and dim <= maxdim:
157             # a simplex whose column reduced to zero creates a class; if never killed it is
        essential
158             out[dim].append((val, np.inf))
159     return {k: np.array(v).reshape(-1, 2) for k, v in out.items()}
```

Lines 133–138 build all points, edges and triangles with their entry scale, the longest edge. Line 139 sorts them, faces before the cells they bound at equal scale. In the loop of line 144, line 145 builds the list of faces, lines 146–147 do the additions, and lines 148–154 record a pair when the reduced list is not empty (pairs of zero persistence are dropped). Lines 155–158 add the features that are never killed.

Example: a ring and a clump. For the 52 points of Figure 12.27, the loop diagram has one point far from the diagonal, (0.7001, 1.668): the ring closes at $r \approx 0.7001$, about the largest gap between neighbouring points on it, and fills at $r \approx 1.668$, when triangles can span its middle; the next loop lives for only 0.00431. In the island diagram, the longest finite bar ends at 1.233, the distance at which the clump joins the ring (Figure 12.29). Our reduction, ripser and gudhi's `RipsComplex` give the same loop diagram: the bottleneck distances between them are 2.129×10^{-8} and 2.129×10^{-8}, single-precision rounding again. Our Kruskal deaths equal ripser's island deaths and scipy's single-linkage heights to machine precision.

Cost. The reduction works on every triangle, and there are $n(n-1)(n-2)/6$ of them: already 23478 cells for 52 points, and our pure-Python reduction takes 0.3344 s on them. It is a teaching code. ripser avoids building most of the triangles and reduces cleverly, and handles 1600 points (islands and loops) in 1.394 s; Kruskal alone, for islands only, takes 0.23 s there. For millions of galaxies in three dimensions, research codes replace the Rips complex by the much smaller alpha complex built on the Delaunay tessellation, which gives the same shapes as growing balls without the explosion of cells [5, 242].

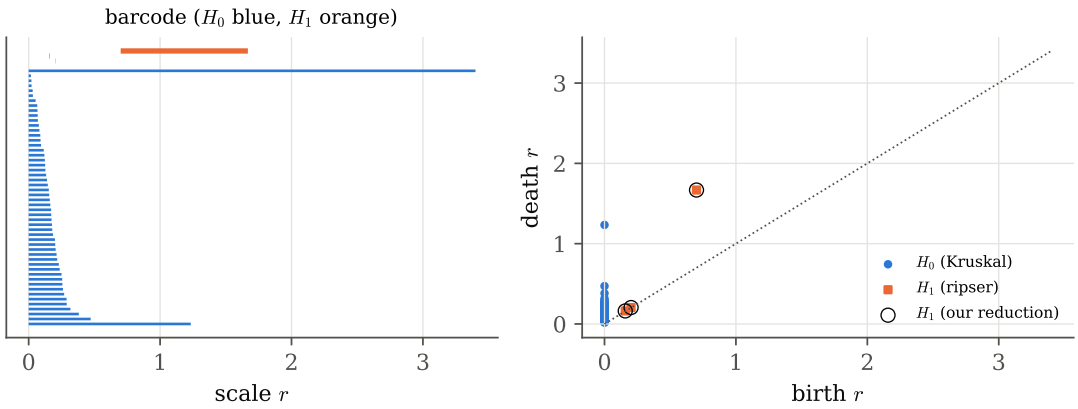

Figure 12.29: Persistence of the ring and clump of Figure 12.27. Left: the barcode; every island bar starts at $r = 0$, and the one long loop bar (orange, top) is the ring. Right: the diagram, with island points on the vertical axis (birth 0) and loop points above the diagonal; the ring's loop, found identically by ripser and by our reduction (open circles), stands far from the diagonal.

12.13 The cosmic web: clusters, tunnels and voids

The matter of the late universe is arranged in a web: dense clusters at the nodes, filaments joining them, thin walls between filaments, and large nearly empty voids (see Chapter T1 for the objects and the cosmology notes for their physics). The same three-dimensional density contrast $\delta(\boldsymbol{x})$ has already been met twice. In Section T3.6 we measured the genus of its excursion sets in simulated Gaussian boxes and found it equal to the Gaussian formula Eq. (T3.16): a Gaussian field is a sponge at the median density. In Section 12.5.4 the expected Euler characteristic of a three-dimensional Gaussian field was derived from its critical points. Both results are about one number per threshold, the alternating sum $\chi = \beta_0 - \beta_1 + \beta_2$. What is new here is to split that sum into its three counts and to follow each feature through the thresholds, as Pranav and collaborators proposed for the cosmic web [5] and Wilding and collaborators carried out for ΛCDM simulations [4].

In three dimensions the dry land $X_\nu = \{\delta \geq \nu\}$ (with δ in units of its standard deviation) has three kinds of features. β_0 counts its separate pieces: *clusters*. β_1 counts independent *tunnels*: loops in the land around which a string could be threaded, the holes of a doughnut, formed for example by a ring of filaments around an empty channel. β_2 counts *voids*: pockets of low density completely sealed inside the land, like the hollow of a ball. A sum with signs can hide its terms; two clusters and one hollow ball have the same $\chi = 2$ (Figure T3.14). The separate counts cannot hide them.

Example: three solids. A solid ball has one piece, no tunnel and no sealed pocket: $(\beta_0, \beta_1, \beta_2) = (1, 0, 0)$, $\chi = 1$. A solid doughnut has one piece and one tunnel, through its hole: $(1, 1, 0)$, $\chi = 0$. A hollow ball, a thick shell around an empty pocket, has one piece and one void: $(1, 0, 1)$, $\chi = 2$. A pretzel with two holes has $(1, 2, 0)$ and $\chi = -1$. In each case $\chi = \beta_0 - \beta_1 + \beta_2$, and only the separate counts say whether a negative χ comes from tunnels or a positive one from clusters rather than voids.

The question. As the density threshold is lowered through a Gaussian random field in three dimensions, at which levels are clusters, tunnels and voids most numerous, and do the three Betti curves, combined with their signs, reproduce the Euler characteristic predicted for a Gaussian field?

12.13.1 Which events create and destroy which features

Section 12.5.1 showed that the topology of the dry land changes only when the level passes the height of a critical point, a point where the gradient of the field vanishes, and that the type of the point fixes the type of change. In three dimensions there are four types, told apart by how many of the three principal curvatures of the field are negative (how many directions the field falls away in). Take them in the order in which the falling level meets them.

- A *maximum* (the field falls in all three directions) is the top of a cluster. Passing it creates a new cluster: β_0 increases by one.
- A *filament saddle* (falls in two directions, rises in one) is the lowest point along the spine of a filament between two higher regions. Passing it adds a bridge of land. If the bridge joins two clusters, one of them dies (β_0 decreases); if it joins a cluster to itself, it closes a ring, and a tunnel is born (β_1 increases).
- A *wall saddle* (falls in one direction, rises in two) is the lowest point of a thin sheet stretched across an opening. Passing it adds a membrane of land. If the membrane spans a ring, the tunnel is closed off and dies (β_1 decreases); if it closes the last opening of a pocket, a void is sealed and born (β_2 increases).
- A *minimum* (the field rises in all directions) is the bottom of a void. Passing it fills the void (β_2 decreases).

Figure 12.30 summarises the list. It explains the order in which the three Betti curves rise and fall: clusters are born at maxima, which are mostly high; tunnels at filament saddles, typical of intermediate levels; voids at wall saddles and they die at minima, mostly low. For a Gaussian field, which is as likely as its negative, the list is symmetric: the voids of δ are the clusters of $-\delta$, so β_2 at level ν should behave on average like β_0 at $-\nu$, and β_1 should be symmetric about $\nu = 0$.

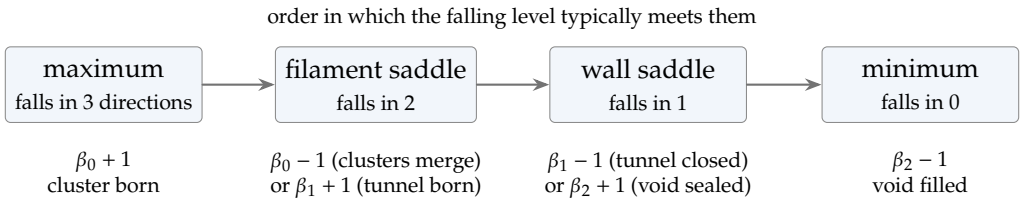

Figure 12.30: The four kinds of critical point of a three-dimensional field and what passing each does to the dry land $\{\delta \geq \nu\}$ as the level falls. Every birth or death in the three persistence diagrams happens at one of them.

12.13.2 Betti curves of Gaussian boxes

`code/ch12/b05_cosmic_web.py` draws 24 periodic Gaussian boxes of 80^3 cells with a power spectrum $P(k) \propto k^{-1.5} e^{-k^2R^2}$, $R = 2.5$ cells (the simulator of Section 7.4 in three dimensions), and computes the persistence of the superlevel sets on the 3-torus with gudhi's `PeriodicCubicalComplex`. The Betti curves are then counted from the diagrams with (12.41). A from-scratch check: on the first box, the number of clusters at $\nu = 1$ and $\nu = 2$ counted by `scipy.ndimage.label` (26 neighbours, the three-dimensional version of 8), with labels glued across the periodic faces, differs from gudhi's by 0.

Figure 12.31 shows the result. The clusters peak at $\nu = 1.7$ with 0.0979 per thousand cells; the tunnels peak at $\nu = 0$, at 0.2345 per thousand cells, more than twice as many as the other two at their peaks; the voids peak at $\nu = -1.6$ with 0.1072. The order is the one Figure 12.30

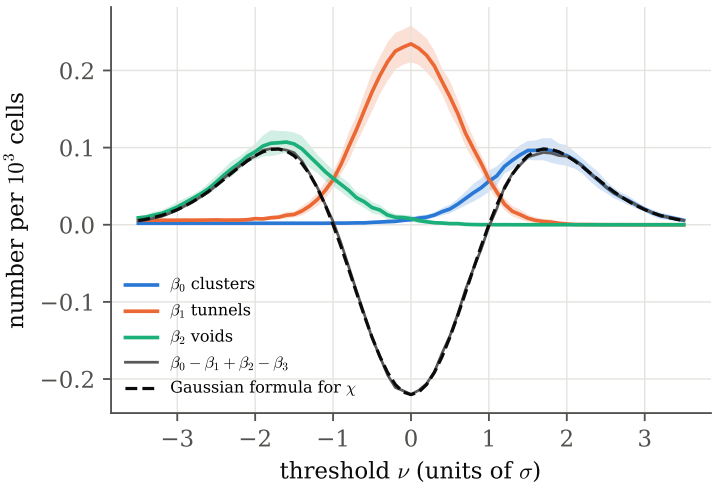

Figure 12.31: Betti curves of three-dimensional Gaussian boxes: clusters (β_0), tunnels (β_1) and voids (β_2) per thousand cells, mean of 24 boxes with the box-to-box scatter shaded. The grey curve is $\beta_0 - \beta_1 + \beta_2 - \beta_3$ (the last term is the single three-dimensional class of the whole torus at the lowest levels) and the dashed curve the Gaussian formula for the Euler characteristic.

predicts, and the symmetry is visible: the void curve is the mirror image of the cluster curve, and the tunnel curve is centred on zero. The alternating sum agrees with the Gaussian formula for χ (Section 12.5.4, Eq. (T3.16)) to within 2.205% of its peak at every threshold, where one Monte Carlo error is up to 2.772%; over all 71 thresholds the largest deviation is 1.8 of its own Monte Carlo errors. At this smoothing the finite cells, which the formula for a continuous field does not know about, leave no visible trace.

Example: what χ hides at the median density. At $\nu = 0$ the Euler characteristic is -0.22 per thousand cells. Read alone, it says "more tunnels than clusters and voids". The Betti curves say how: at $\nu = 0$ there are 0.00651 clusters and 0.007975 voids per thousand cells, almost none, against 0.2345 tunnels. At $\nu = +1.6$, where χ is 0.09082, and at -1.6, where it has the same size, the curves say which side we are on: at +1.6 the positive χ is clusters, at -1.6 it is voids. The Euler characteristic cannot tell these two apart without the sign of ν; for a non-Gaussian field, where the two sides need not mirror each other, only the separate counts can.

Verification and research. The agreement of the alternating sum with the formula verifies the code: it is a known answer reproduced. The Betti curves themselves have no known answer. For Gaussian fields there are no exact expressions for the expected Betti numbers, only approximations and numerical studies [5], and for the non-Gaussian density of the late universe there is nothing analytic at all. Here the Monte Carlo is not a check of a formula but the only instrument we have: the expected curves and their scatter are whatever the simulations say, and part 12c turns exactly these simulated means and covariances into a likelihood.

12.13.3 What gravity does to the diagram

The Gaussian box is the starting point of structure formation, not its result. Section 12.1.3 drew the distinction: a monotone relabelling of the density, such as $\delta \to e^{\delta}$, changes no excursion set and no persistence pair beyond relabelling the levels (we checked this on a map in Section 12.11.3), but gravitational evolution moves matter around, merges structures and empties voids, so the topology itself changes. Wilding and collaborators followed this

in ΛCDM N-body simulations, computing the Betti curves and persistence diagrams of the density estimated on the Delaunay tessellation of the particles at redshifts from 3.8 to 0 [4]. Their diagrams grow sharp apexes, and the apex of the cluster diagram sits at the density at which matter detaches from the expansion and begins to collapse; the features near the apex form a self-similar population that reflects the hierarchical growth of structure. The topology there is not a quantity protected from the physics; it is the record of the physics. Reproducing those diagrams needs N-body simulations and the Delaunay density estimate, far beyond laptop scale; Section 12.15.3 reproduces the simpler reference case that the same group used to learn to read such diagrams, a random scatter of points.

12.14 Polarization singularities: a charge that a remapping cannot change

The CMB polarization at a point is a headless stick: a direction without an arrowhead, described by the Stokes parameters Q and U combined into $P = Q + iU = |P|e^{2i\alpha}$, with α the angle of the stick (Eq. (T3.12); see the cosmology notes for where the polarization comes from). Where $Q = U = 0$ the stick has no direction. Walk once around such a point and the stick turns by half a turn, with the walk or against it: the *index* of the singularity is $+\frac{1}{2}$ or $-\frac{1}{2}$ (Section T3.3.1). Section T3.3.2 counted them on simulated maps and Section T3.4 showed, on lensed patches, that gravitational lensing moves them without changing their indices. Treated as data, the singularities are a catalogue of points with charges $\pm\frac{1}{2}$, and the questions are the statistical ones: what exactly protects the charges, how do we measure them on a pixel map, and when does the protection fail? In the language of Section 12.1, lensing is a nuisance operator $\mathcal{N}$ that acts by remapping the sky, and we want to know precisely which statistics T satisfy $T[\mathcal{N}[P]] = T[P]$ and under which conditions.

The question. If a polarization map is deformed continuously, or remapped by $\boldsymbol{x} \mapsto \boldsymbol{x} + \boldsymbol{d}(\boldsymbol{x})$, which properties of its singularities are guaranteed to survive, which can change, and how do they change?

12.14.1 Why the charge cannot change continuously

Take a closed loop Γ on which the polarization never vanishes, and define the charge inside it as the number of turns of the stick along the loop,

$$q(\Gamma) = \frac{1}{2\pi}\oint_\Gamma \mathrm{d}\alpha = \frac{1}{4\pi}\oint_\Gamma \mathrm{d}\arg P, \tag{12.46}$$

which is the sum of the indices of the singularities inside Γ ([1], their eq. 5). Now let the map change continuously with a parameter t (time, or the strength of a lensing deflection), P_t, and suppose that no singularity crosses Γ while t changes, so $P_t \neq 0$ on Γ throughout.

$$\begin{aligned} q_t(\Gamma) &\overset{(1)}{=} \frac{1}{4\pi} \times (\text{a whole number of turns of } \arg P_t \text{ along } \Gamma) \times 2\pi \in \tfrac{1}{2}\mathbb{Z} \\ &\overset{(2)}{=} \text{a continuous function of } t \\ &\overset{(3)}{=} q_0(\Gamma) \quad \text{for all } t. \end{aligned} \tag{12.47}$$

(1) Going once around Γ brings P_t back to its starting value, so its phase changes by 2π times a whole number, and (12.46) divides by 4π: q is a multiple of $\frac{1}{2}$.

(2) $\arg P_t$ at each point of Γ changes continuously with t because P_t does and never passes through 0 there, so the integral changes continuously.
(3) A continuous function whose values are restricted to the separated numbers $\dots, -\frac{1}{2}, 0, \frac{1}{2}, \dots$ cannot jump from one to another, so it is constant.

So the total charge inside a fixed loop can change only when a singularity crosses the loop. Inside the loop, singularities can move, and a $+\frac{1}{2}$ and a $-\frac{1}{2}$ can be created together or annihilate together, because that leaves the total unchanged; a single charge can never appear or vanish on its own [1].

12.14.2 The index of a zero, and what a remapping does to it

The simplest zero first. Near a zero at the origin, Q and U both vanish linearly, so $Q + iU \approx f(z) = c_1 z + c_2 \bar{z}$, with $z = x + iy$ and complex constants c_1, c_2. The real map $(x, y) \mapsto (Q, U)$ has the Jacobian matrix J with rows ∇Q and ∇U. Its determinant is

$$\begin{aligned} \det J &\overset{(1)}{=} Q_x U_y - Q_y U_x \overset{(2)}{=} \operatorname{Im}\left(\overline{f_x}\, f_y\right) \\ &\overset{(3)}{=} \operatorname{Im}\left((\bar{c}_1 + \bar{c}_2)(ic_1 - ic_2)\right) \\ &\overset{(4)}{=} \operatorname{Re}\left(|c_1|^2 - |c_2|^2 + c_1\bar{c}_2 - \bar{c}_1 c_2\right) \overset{(5)}{=} |c_1|^2 - |c_2|^2. \end{aligned} \tag{12.48}$$

(1) The determinant of the 2×2 matrix with rows (Q_x, Q_y) and (U_x, U_y); subscripts are partial derivatives.
(2) With $f_x = Q_x + iU_x$ and $f_y = Q_y + iU_y$, the product $\overline{f_x} f_y = (Q_x Q_y + U_x U_y) + i(Q_x U_y - U_x Q_y)$.
(3) From $f = c_1(x + iy) + c_2(x - iy)$: $f_x = c_1 + c_2$ and $f_y = ic_1 - ic_2$.
(4) Multiply out and use $\operatorname{Im}(iw) = \operatorname{Re} w$.
(5) $c_1\bar{c}_2 - \bar{c}_1 c_2$ is a number minus its complex conjugate, which is purely imaginary.

Which way does P turn? If $|c_1| > |c_2|$, write $f = c_1 z\,(1 + w)$ with $w = (c_2/c_1)(\bar{z}/z)$. On a circle around the origin $|w| = |c_2/c_1| < 1$, so $1 + w$ stays in a disc around 1 that does not contain 0 and its phase returns to where it started without turning; the phase of f then turns exactly as z does, once, with the loop. The index is $+\frac{1}{2}$. If $|c_2| > |c_1|$, the same argument with $f = c_2\bar{z}(1 + \dots)$ gives one turn against the loop: index $-\frac{1}{2}$. With (12.48) both cases read

$$\text{index of a zero} = \tfrac{1}{2}\,\operatorname{sgn}\det J. \tag{12.49}$$

This is the rule the plaquette finder of Section T3.3.1 applies implicitly: summing the phase steps around a 2×2 block measures the sign of the local Jacobian.

A remapping. The remapped map is $\tilde{P}(\boldsymbol{x}) = P(\boldsymbol{F}(\boldsymbol{x}))$ with $\boldsymbol{F}(\boldsymbol{x}) = \boldsymbol{x} + \boldsymbol{d}(\boldsymbol{x})$, and its zeros are the points $\boldsymbol{x}_0$ with $\boldsymbol{F}(\boldsymbol{x}_0) = \boldsymbol{y}_0$ a zero of P. By the chain rule the Jacobian of $\tilde{P}$ at $\boldsymbol{x}_0$ is $J(\boldsymbol{y}_0)\,\mathsf{A}(\boldsymbol{x}_0)$, where $\mathsf{A} = \mathbb{1} + \partial\boldsymbol{d}$ is the Jacobian of the remapping, the magnification matrix of lensing (Section T3.4.2). Then

$$\begin{aligned} \text{index of } \tilde{P} \text{ at } \boldsymbol{x}_0 &\overset{(1)}{=} \tfrac{1}{2}\,\operatorname{sgn}\det\left(J(\boldsymbol{y}_0)\mathsf{A}(\boldsymbol{x}_0)\right) \overset{(2)}{=} \tfrac{1}{2}\,\operatorname{sgn}\det J(\boldsymbol{y}_0)\ \operatorname{sgn}\det\mathsf{A}(\boldsymbol{x}_0) \\ &\overset{(3)}{=} \operatorname{sgn}\det\mathsf{A}(\boldsymbol{x}_0) \times \left(\text{index of } P \text{ at } \boldsymbol{y}_0\right). \end{aligned} \tag{12.50}$$

(1) The rule (12.49) applied to $\tilde{P}$, whose Jacobian is $J\mathsf{A}$.
(2) The determinant of a product is the product of the determinants.
(3) The rule (12.49) read backwards for P at $\boldsymbol{y}_0$.

Where the remapping keeps orientation, $\det\mathsf{A} > 0$, every zero keeps its index. Where the sky is folded over itself, $\det\mathsf{A} < 0$, the image is a mirror image and the index flips.

Folds create pairs. If $\det \mathsf{A} > 0$ everywhere, the remapping is one-to-one and each zero of P has exactly one image, with the same index. If the displacement is strong enough to fold the sky, a point $\boldsymbol{y}_0$ can have three preimages: one before the fold, one inside it (with $\det \mathsf{A} < 0$), one after it. Their indices are, by (12.50), $+q$, $-q$, $+q$, which add up to q. The one-dimensional cartoon of Figure 12.32 shows why the signs alternate: the curve $F(x)$ must cross the level y_0 going up, then down, then up again. Seen from the remapped sky, a fold has created a pair of opposite charges and kept the total. This is the exact form of the statement that a continuous change can only create or annihilate pairs.

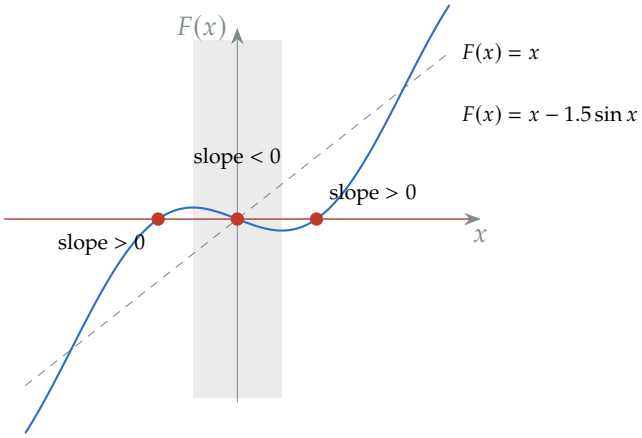

Figure 12.32: A one-dimensional remapping $F(x) = x - 1.5\sin x$ that folds: in the shaded strip its slope is negative. The level $F = 0$ (red line), the position of one singularity of the original map, is reached at three points (dots) with slopes of signs $+, -, +$. The three images carry indices $+q, -q, +q$, which add up to the original q. The dashed line is the identity map, which has a single crossing.

12.14.3 Testing the protection on simulated maps

`code/ch12/b06_pol_remap.py` draws 6 E-mode polarization maps on periodic $10^\circ \times 10^\circ$ patches with 512^2 pixels of 1.172′, smoothed by a 10′ beam, from the fiducial C_ℓ^{EE}; each has about 919 singularities. For each map it draws a smooth random potential, coherent over about a degree, takes $\boldsymbol{d}$ as its gradient, and scales it so that the convergence $\kappa = -\frac{1}{2}\nabla \cdot \boldsymbol{d}$ has a chosen root-mean-square value $\kappa_{\rm rms}$, from 0.03 (the size of real CMB lensing on these scales) up to 0.8. The remapped maps $\tilde{Q}(\boldsymbol{x}) = Q(\boldsymbol{x} + \boldsymbol{d})$ and $\tilde{U}(\boldsymbol{x}) = U(\boldsymbol{x} + \boldsymbol{d})$ are computed by cubic interpolation. (On the curved sky the polarization must also be carried from the displaced point by parallel transport [3], Section T3.4.1; on a flat patch that step is the identity.) For every singularity of the remapped map the code follows $\boldsymbol{d}$ to the point $\boldsymbol{x} + \boldsymbol{d}(\boldsymbol{x})$ and looks there for a singularity of the original map within a pixel and a half; it checks the index rule (12.50) with the sign of $\det \mathsf{A}$ at that point; and for every original singularity it adds up the indices of all its images and compares with its own index.

Example: realistic lensing strength. At $\kappa_{\rm rms} = 0.03$ no point of any map is folded. The remapped maps have the same number of singularities as the originals (the change is −0.07254%); 99.82% of them sit on an original singularity at the far end of their displacement, and 99.66% also carry the index the rule (12.50) predicts. The few exceptions are zeros that fall at the corner shared by two 2×2 blocks, where the pixel finder can put them in either block. This is the result of Section T3.4.4 seen from the other side: the catalogue of charges is unchanged, point by point, up to the resolution of the grid.

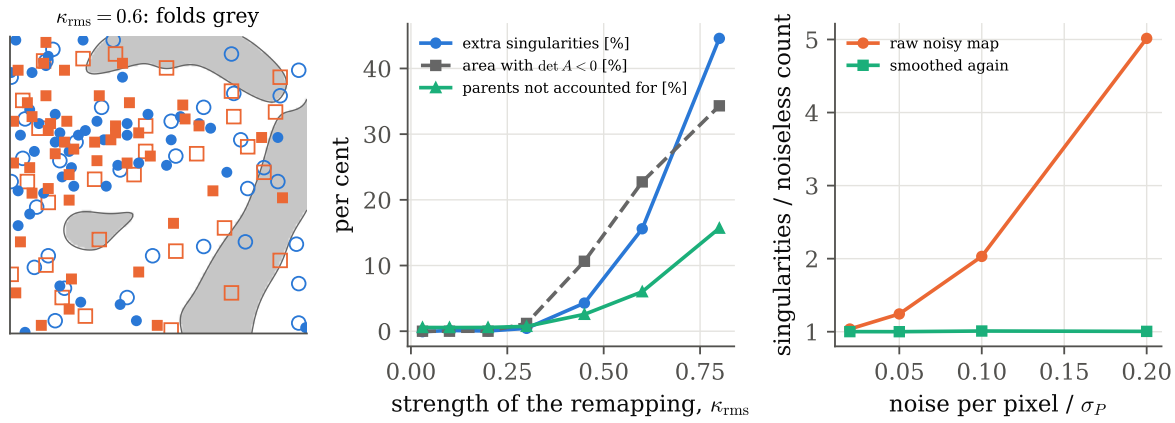

Figure 12.33: Left: a 2.5° × 2.5° corner of one map remapped with $\kappa_{\rm rms} = 0.6$; grey regions are folded ($\det \mathsf{A} < 0$). Open markers: singularities of the original map; filled: of the remapped map (circles $+\frac{1}{2}$, squares $-\frac{1}{2}$). Middle: against the strength of the remapping, the fraction of extra singularities, the folded area, and the fraction of original singularities whose images do not add up to their index. Right: noise is not a remapping; white noise added to the map multiplies the number of singularities (orange), and smoothing the noisy map again removes the extra ones (green).

Example: folding the sky. The first folds appear at $\kappa_{\rm rms} \approx 0.3$ (Figure 12.33, middle). At $\kappa_{\rm rms} = 0.6$, 22.73% of the area is folded and the remapped maps have 15.6% more singularities than the originals, all of them created in pairs, as the left panel shows: inside and beside the grey regions, one original singularity has three images, the middle one with the opposite index. For 93.99% of the original singularities the indices of the images still add up to the original index, and 95.48% of the images obey the sign rule. The failures grow with the folding because the remapped field is squeezed near the fold lines, and some of the created pairs are closer together than a pixel: the grid can no longer resolve them. Real CMB lensing, with a convergence of a few hundredths, is about ten times too weak to fold the sky; the experiment shows what the protection rests on, and where it would end.

Example: noise is not a remapping. White noise added to Q and U in each pixel, at a level of 5% of the polarization amplitude, raises the number of singularities by a factor 1.243; at 20%, by a factor 5.015, and only 37.05% of the singularities of the noisy map lie on one of the original map. The noise creates pairs on the scale of a pixel, wherever the polarization is weak. Smoothing the noisy map over two pixels removes almost all of them: the count returns to 1.005 times that of the equally smoothed clean map, and 94.29% of the singularities match. The order matters, as Section T3.4.3 found for the beam: a smoothing that acts on the remapped, noisy sky is part of the nuisance, and its effect must be measured by simulating it.

12.14.4 What is protected, and what is not

Putting the pieces together, for a map changed by a smooth remapping or any continuous deformation:

- *Protected:* the total charge inside any loop that no singularity crosses (12.47); and, while the remapping is one-to-one, the whole catalogue, singularity by singularity, with its indices (12.50).
- *Not protected:* the positions (they move with the remapping); the number of singularities once folds appear (pairs are created); the charge inside a loop that singularities cross, which

is the situation at the edge of any finite patch or mask; pairs closer than the resolution, which a beam or a pixel grid can merge or hide; and anything that noise touches, because noise is not a deformation of the map but an addition to it.

- *A non-local step breaks it:* the E-mode and B-mode maps are built from Q and U by a non-local filter, so the singularities of an E-only map are not those of the full map and are not protected (Section T3.4.3).

This is the caution of Section 12.1.2 made concrete: a topological statistic is protected only against a named class of transformations, and every analysis must say which class its nuisance belongs to.

12.15 Reproducing the literature

Three papers carry the quantitative claims about persistence and singularities: Huterer and Vachaspati counted the polarization singularities of simulated CMB maps and measured how their charges are arranged [2], testing a prediction of Vachaspati and Lue [1]; and Pranav and collaborators built the reference Betti curves and diagrams against which the cosmic web is read [5]. We redo each of their measurements with our own code, starting from what they asked and what they assumed, deriving the equation behind the number they plot, and then putting their numbers next to ours and tracing every difference to a cause.

12.15.1 How many singularities: Huterer and Vachaspati's counts

Their question. In 2004 the first CMB polarization maps were arriving, and Huterer and Vachaspati asked what the singularities of a polarization map from the standard cosmological model should look like, so that the predictions would be ready when the data were. The first number they report is the simplest: how many singularities a full-sky map has, and how that grows with the angular resolution of the map.

Their setup. They computed the spectra of a flat ΛCDM model with CMBFAST, drew Gaussian E and B coefficients from them up to a maximum multipole $\ell_{\max}$, made HEALPix maps at $N_{\rm side} = 256$ and found the singularities with the winding rule of Section T3.3.1. With no tensor modes and no lensing, $C_\ell^{BB} = 0$, so the maps are pure E. Their parameters, as stated in the paper:

quantity	value	meaning
Ω_m	0.3	matter fraction of the critical density
$\Omega_m h^2$, $\Omega_b h^2$	0.127, 0.021	physical matter and baryon densities ($h = 0.6506$ follows)
n_s	1	primordial spectral index (scale-invariant)
tensors, lensing	none	so $B = 0$
optical depth τ	not stated	sets the large-scale reionization signal in C_ℓ^{EE}

They found about 6000 singularities for $\ell_{\max} = 100$ and about 150 000 for $\ell_{\max} = 500$, growing "roughly as the square of" $\ell_{\max}$.

Their key equation, here. The paper gives no formula; the counts come from the maps. But the expected count follows from the density formula derived in Eq. (T3.13), $n = \sigma_1^2/(4\pi\sigma_0^2)$ per steradian, with $\sigma_0^2 = \langle Q^2\rangle$ and $\sigma_1^2 = \langle |\nabla Q|^2\rangle$. On a flat patch with pure E modes, a Fourier mode $\boldsymbol{\ell}$ of angle $\varphi_{\boldsymbol{\ell}}$ contributes $Q(\boldsymbol{\ell}) = E(\boldsymbol{\ell})\cos 2\varphi_{\boldsymbol{\ell}}$ (see the cosmology notes for this relation),

and a gradient brings down a factor $i\boldsymbol{\ell}$. So

$$\frac{\sigma_1^2}{\sigma_0^2} \overset{(1)}{=} \frac{\int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\, \ell^2\, C_\ell^{EE} \cos^2 2\varphi_{\boldsymbol{\ell}}}{\int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\, C_\ell^{EE} \cos^2 2\varphi_{\boldsymbol{\ell}}} \overset{(2)}{=} \frac{\int_0^{\ell_{\max}} \ell^3 C_\ell^{EE}\, \mathrm{d}\ell}{\int_0^{\ell_{\max}} \ell\, C_\ell^{EE}\, \mathrm{d}\ell} \equiv \langle \ell^2 \rangle_E ,$$

$$N_{\mathrm{sky}} \overset{(3)}{=} 4\pi\, n \overset{(4)}{=} \langle \ell^2 \rangle_E \;\longrightarrow\; \frac{\sum_\ell (2\ell+1)\, \ell(\ell+1)\, C_\ell^{EE}}{\sum_\ell (2\ell+1)\, C_\ell^{EE}} . \tag{12.51}$$

(1) The variance of a Gaussian field is the integral of its spectrum over all modes; for the gradient each mode is weighted by $|i\boldsymbol{\ell}|^2 = \ell^2$.

(2) Write $\mathrm{d}^2\ell = \ell\, \mathrm{d}\ell\, \mathrm{d}\varphi$. The angular integral of $\cos^2 2\varphi$ is π in both numerator and denominator and cancels, as do the $(2\pi)^2$; the spectrum is cut at $\ell_{\max}$.

(3) A full sky is 4π steradians.

(4) Insert $n = \sigma_1^2/(4\pi\sigma_0^2)$. The arrow is the same average written on the sphere, Eq. (T3.14), where a ring of $\mathrm{d}\ell$ in the flat plane, of circumference $2\pi\ell$, becomes the $2\ell+1$ modes of each multipole, and ℓ^2 becomes the eigenvalue $\ell(\ell+1)$ of the Laplacian.

The number of singularities on the sky is the power-weighted average of $\ell(\ell+1)$ below $\ell_{\max}$. Because C_ℓ^{EE} rises with ℓ up to the first acoustic peaks, most of the weight sits near the cut, the average is a fixed fraction of $\ell_{\max}^2$, and that is the "roughly as the square".

What we compute. `code/ch12/b07_hv_counts.py` runs CAMB for their model twice, once with an optical depth $\tau = 0.06$ and once with reionization switched off, since their τ is not given; evaluates (12.51) for $\ell_{\max}$ from 50 to 500; and counts the singularities directly on 12 simulated $30° \times 30°$ periodic patches at each $\ell_{\max}$, with at least four pixels per half wavelength, scaling the counts to the full sky. The grid version of (12.51), the same average over the discrete Fourier modes of the patch, matches the patch counts to 4.663% at every $\ell_{\max}$, at most 2.3 times the Monte Carlo error of 12 patches. The same formula with the fiducial *Planck* spectra (Section 7.11.1) repeats the numbers of Section T3.3.3.

Side by side.

$\ell_{\max}$	H&V 2005	(12.51), $\tau = 0.06$	(12.51), no reionization	our patches	fiducial
100	≈ 6000	5245	6082	6142 ± 127	5311
500	$\approx 150\,000$	138531	139047	137854 ± 513	133373

Why they differ. At $\ell_{\max} = 100$ the formula gives 5245 with $\tau = 0.06$ and 6082 without reionization: the reionization bump of C_ℓ^{EE} at $\ell < 12$ adds variance σ_0^2 but almost no gradient variance σ_1^2, so it lowers the count by 14%. The published 6000 is the no-reionization number. Our patches agree with that number for a different reason: a $30°$ patch cannot hold modes with ℓ below about $360°/30° = 12$, so it does not contain the bump at all (Figure 12.34; at $\ell_{\max} = 50$ the patches follow the orange curve, 1659, far from the 716 of the dashed one). At $\ell_{\max} = 500$ the bump no longer matters and the three numbers for their cosmology (formula with and without reionization, and patches) agree to about one per cent; the published count is 8% above them. We cannot trace that difference from the paper: their value is quoted as a round number, their spectrum came from a different Boltzmann code, and their counting on HEALPix pixels at $N_{\mathrm{side}} = 256$ samples an $\ell_{\max} = 500$ map with only about three pixels per wavelength. The growth from 100 to 500 is a power $\ell_{\max}^{2.123}$ in our formula, close to their "square".

The lesson. Counting singularities measures one moment of the polarization spectrum, $\langle \ell(\ell+1) \rangle$, and that moment is sensitive to whatever adds large-scale variance, here the reionization of the universe, which has nothing to do with the small-scale structure where the singularities live. The count itself carries no information beyond C_ℓ^{EE}; any new information must be in how the charges are arranged, which the charge statistics below probe.

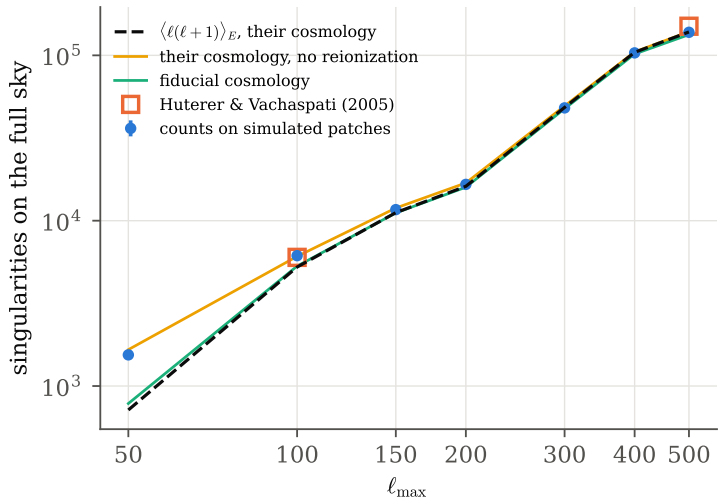

Figure 12.34: Number of polarization singularities on the full sky against the maximum multipole of the map. Dashed: the formula (12.51) for their cosmology with $\tau = 0.06$; orange: the same without reionization; green: the fiducial *Planck* cosmology; dots: direct counts on simulated patches scaled to the full sky; squares: the two numbers of Huterer and Vachaspati. The curves differ only at low $\ell_{\max}$, where the reionization signal at $\ell < 12$ carries a large share of the variance.

12.15.2 How the charges are arranged: Vachaspati and Lue's exponent

Their question. Vachaspati and Lue noticed that a polarization map is a field of headless rods, like the molecules of a nematic liquid crystal, and that the theory of defects in condensed matter predicts how the defects of such a field are arranged [1]. The prediction concerns the net charge inside a large loop: it fluctuates around zero, and its root-mean-square value should grow as the square root of the loop's length. Huterer and Vachaspati measured the exponent on simulated maps [2].

Their key equation, derived. Take a loop Γ of length L, much longer than the correlation length ξ of the stick directions. Cut it into $m = L/\xi$ stretches of length ξ, and let $\delta\alpha_k$ be the change of the stick angle along stretch k. By (12.46) the charge inside is $q = \frac{1}{2\pi}\sum_k \delta\alpha_k$. The increments have zero mean (no direction of turning is preferred), and increments along stretches farther apart than ξ are independent; call their common variance s^2. Then

$$\sigma^2(q) \overset{(1)}{=} \frac{1}{4\pi^2}\,\mathrm{Var}\Big(\sum_{k=1}^{m}\delta\alpha_k\Big) \overset{(2)}{=} \frac{1}{4\pi^2}\sum_{k=1}^{m}\mathrm{Var}(\delta\alpha_k) \overset{(3)}{=} \frac{m\,s^2}{4\pi^2} = \frac{s^2}{4\pi^2}\,\frac{L}{\xi},$$

$$\sigma(q) = \frac{s}{2\pi}\Big(\frac{L}{\xi}\Big)^{1/2} \qquad (\nu = \tfrac{1}{2}). \tag{12.52}$$

(1) The variance of a constant times a random variable is the constant squared times its variance.

(2) The variance of a sum of independent terms is the sum of their variances (the covariances vanish).

(3) All m terms have the same variance s^2, and $m = L/\xi$.

This is [1], their eq. 6, with $\beta = \frac{1}{2}$. *What the exponent means.* Compare a sky on which the singularities were scattered at random with random signs, with density n. The charge inside a circle of circumference L, area $A = L^2/4\pi$, would then be a sum of $\langle N\rangle = nA$ independent charges $\pm\frac{1}{2}$:

$$\sigma^2(q) \overset{(1)}{=} \langle N\rangle\ \mathrm{Var}(\pm\tfrac{1}{2}) \overset{(2)}{=} \frac{nA}{4} \overset{(3)}{=} \frac{n\,L^2}{16\pi}, \qquad \sigma(q) \propto L \quad (\nu = 1). \tag{12.53}$$

(1) For a Poisson number of independent terms with zero mean, the variance of the sum is the mean number times the variance of one term.
(2) A charge $\pm\frac{1}{2}$ with equal probabilities has variance $\frac{1}{4}$.
(3) $A = \pi R^2$ and $L = 2\pi R$ give $A = L^2/4\pi$.

So $\nu = \frac{1}{2}$ is the signature of charges that are not independent: a $+\frac{1}{2}$ almost always has a $-\frac{1}{2}$ nearby, and only the pairs that the loop cuts in two contribute to the net charge. Their number grows with the length of the loop, not with its area. A measured ν near $\frac{1}{2}$ says "the charges are screened"; near 1, "they are not".

Their setup. On a HEALPix map, the pixels of a ring at colatitude θ form a loop of length $L = 2\pi \sin\theta$ around the north pole; the winding of the polarization angle along the ring gives the charge of the polar cap (with a correction of one unit for the pole, where the local axes themselves turn once; it is the same for every map and drops out of the spread). They rotated one map in a hundred random directions, measured $\sigma(q)$ ring by ring, and fit $\sigma \propto L^{\nu}$ over rings plotted at $L = 0.01, 0.03, \ldots, 0.99$; values from 0.01 to 1 in equal steps match $\sin\theta$, the ring length divided by 2π, rather than the length itself, and we read their axis that way. They found $\nu = 0.54$ for $\ell_{\max} = 100$ and $\nu = 0.45$ for $\ell_{\max} = 500$, each with an error of about 0.01. They also measured the distance from each singularity to its nearest neighbour of the same and of the opposite index, with means of 3.24° and 2.69° at $\ell_{\max} = 100$.

What we compute. `code/ch12/b08_charge_stats.py` repeats their ring measurement on 100 independent full-sky maps at $N_{\mathrm{side}} = 256$, their resolution, with their spectrum (without reionization, which matched their counts in Section 12.15.1), at the 50 rings with $\sin\theta = 0.01, 0.03, \ldots, 0.99$. The error on the fitted exponent comes from refitting it many times on maps drawn at random, with repeats, from the 100 (a bootstrap, Section 3.15). On periodic 40° flat patches it also catalogues the singularities themselves, measures the charge inside circles of circumference L with the true indices and with the indices shuffled among the singularities (which turns the catalogue into the random-sign sky of (12.53) at the same positions), and measures nearest-neighbour distances.

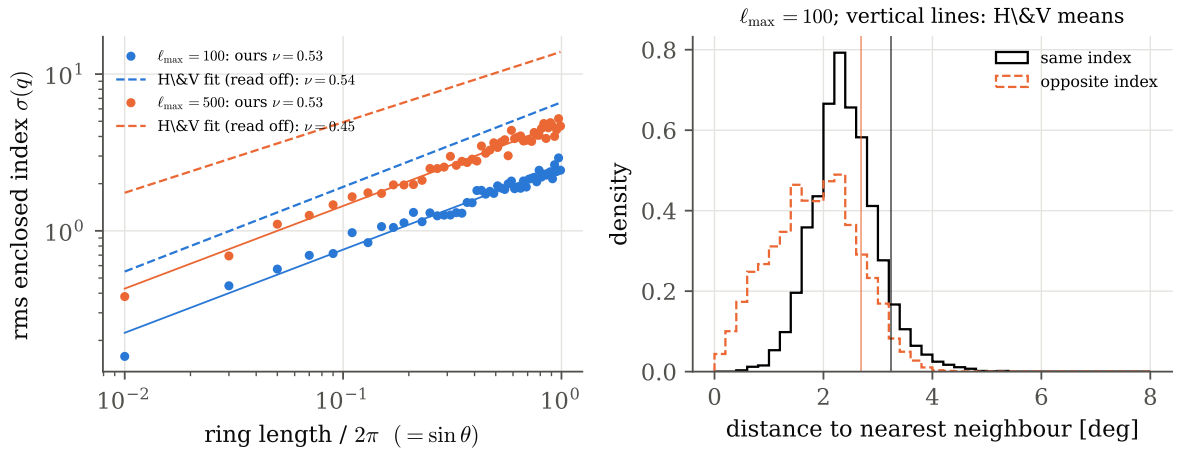

Figure 12.35: Left: root-mean-square charge of the polar caps against the ring length divided by 2π, for maps cut at $\ell_{\max} = 100$ and 500 (dots, with power-law fits), and the fitted laws of Huterer and Vachaspati read off their figure (dashed). The slopes are close; the normalisations differ by a factor of two to three. Right: distance from each singularity to its nearest neighbour of the same index and of the opposite index at $\ell_{\max} = 100$; vertical lines are their two means.

Side by side.

	H&V 2005	ours
ν, $\ell_{\max} = 100$ (rings)	0.54 ± 0.01	0.5305 ± 0.01527
ν, $\ell_{\max} = 500$ (rings)	0.45 ± 0.01	0.5273 ± 0.009313
ν with indices shuffled, $\ell_{\max} = 100$ / 500 (patches)	–	0.8951 / 0.9041
$\sigma(q)$ at $\sin\theta = 1$, $\ell_{\max} = 100$ / 500	≈ 7 / ≈ 14 (read off)	2.436 / 4.656
nearest neighbour, same index	3.24°	2.404°
nearest neighbour, opposite index	2.69°	1.839°
ratio same / opposite	1.20	1.307

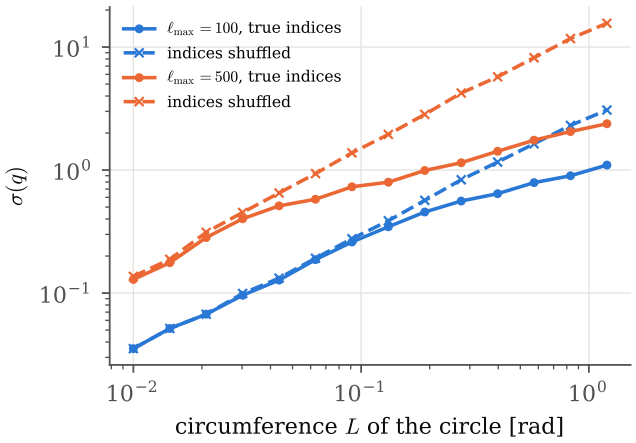

Figure 12.36: Charge inside circles on flat patches, with the true indices (dots) and with the indices shuffled among the same positions (crosses). For small circles, which hold at most one singularity, the two agree. For circles much longer than the distance between a $+\frac{1}{2}$ and its partner, the true charge grows as about $L^{1/2}$ and the shuffled one as about L.

Why they differ. At $\ell_{\max} = 100$ the two exponents differ by 0.5 combined standard errors. At $\ell_{\max} = 500$ ours is 0.08 higher, 5.7 combined standard errors. Two things make the published error bar too small to judge either difference. Their hundred ring sets come from rotations of one map, so they share that map's particular arrangement of charges, and the error of 0.01 does not include the scatter from one sky to another, which ours does. And $\sigma(q)$ is not an exact power of L: on small rings the cap holds at most one singularity, and (12.53) applies, with ν near 1; only on rings much longer than the pair separation does (12.52) take over (Figure 12.36). The fitted slope depends on how much of each regime the fit range contains, and it is noisy: on the patches, where we fit only circles longer than 0.2 radians, the slope from one set of simulations to another scatters by about ± 0.05. The normalisation is a separate matter. On the smallest ring, $\sin\theta = 0.01$, the polar cap has an area of about $\pi \times 10^{-4}$ steradians, and with 6082 singularities on 4π steradians it holds on average $6082 \times 10^{-4}/4 \approx 0.15$ of them, so the charge there, made of independent single charges, has a spread of about $\frac{1}{2}\sqrt{0.15} \approx 0.19$ in units of the fundamental charge $\frac{1}{2}$, by (12.53); we measure 0.1581. Their figure shows about 0.4 there, and the ratio stays between two and three at all lengths, so their plotted charge must be in a different unit, which the paper does not state; a constant unit does not affect the exponent. Finally, their nearest-neighbour distances are both about 1.4 times ours, while the ratio of the two, the measure of attraction against repulsion, is close (1.20 against 1.307). Our distances are consistent with our count: for random points at our density the mean nearest-neighbour distance would be 1.325°, and we find 1.684° to the nearest singularity of either index. Their own text quotes a mean nearest-neighbour distance "slightly above 2°" for about 6000 singularities, where our maps with the same number give 1.684°, so their absolute distances belong to a sparser map than the one described, and cannot be compared with ours; the qualitative result, opposite charges closer than equal ones, is reproduced.

The lesson. The exponent ν is a slope fitted over a range of loop sizes on which the charge spread is not an exact power law; its second decimal place depends on the range and on how many independent skies are used. What is robust is the contrast between $\nu \approx \frac{1}{2}$, screened charges born in pairs, and $\nu \approx 1$, independent charges, and the shuffling test shows that contrast directly.

A third look: the angular correlation function. The charge spread looks at the net charge in a big loop, and the nearest-neighbour distance at one singularity and its closest partner. A third question puts the two together: at a separation θ, are there more singularities, or fewer, than points thrown down at random would give, and does the answer depend on the signs of the two charges? Huterer and Vachaspati answer with the angular correlation function $w(\theta)$, borrowed from the clustering of galaxies. Its definition is a statement about pairs. If the singularities were independent of each other, the chance that a given one has a second within a ring of separations $[\theta_1, \theta_2]$ around it would just be the share of the sky inside the ring, $f = \frac{1}{2}(\cos\theta_1 - \cos\theta_2)$ on a sphere, or $f = \pi(\theta_2^2 - \theta_1^2)/A$ on a flat periodic patch of area A. We then write the true chance as $f\,(1 + w)$: $w = 0$ is random, $w < 0$ is repulsion, $w > 0$ is attraction (their eqs. 4–5). Counting over all pairs,

$$\text{pairs found in the ring} \overset{(1)}{=} \frac{N(N-1)}{2}\, f\,\big(1 + w(\theta)\big),$$
$$w(\theta) \overset{(2)}{=} \frac{DD(\theta)}{RR(\theta)} - 1, \qquad RR \equiv \frac{N(N-1)}{2}\, f. \tag{12.54}$$

(1) There are $N(N-1)/2$ pairs among N singularities, and each lands in the ring with chance $f(1+w)$.

(2) DD is the number of pairs in the data that fall in the ring and RR the number a random scatter would give; solving for w gives the Peebles–Hauser estimator [2] (their eq. 6, where the two numbers of points differ and so a ratio $N_{\text{rand}}/N_{\text{map}}$ appears). For pairs of equal charge the $N(N-1)/2$ is replaced by the number of such pairs, $N_+(N_+-1)/2 + N_-(N_--1)/2$, and for opposite charges by N_+N_-.

With no mask there is no selection function to model, and RR is exact; the estimator needs no random catalogue. `code/ch12/b09_wtheta.py` computes (12.54) on 60 periodic 40° patches at $\ell_{\max} = 100$ in bins of 2.5° (Figure 12.37).

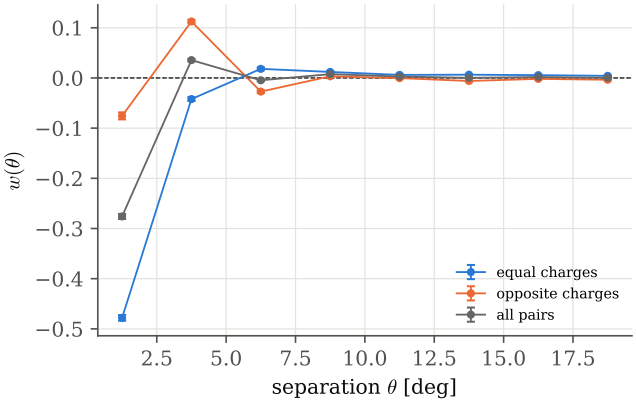

Figure 12.37: Angular correlation function of the singularities of E-mode maps cut at $\ell_{\max} = 100$, mean of 60 flat patches with the error of the mean, for all pairs and for pairs of equal and of opposite charge. Closer than about 5° equal charges are strongly deficient and opposite charges are in excess; beyond about 10° all three curves are flat at zero.

In the first bin, closer than 2.5°, equal charges are almost absent ($w = -0.4781 \pm 0.005635$) and opposite charges are also deficient but much less so (-0.07559 ± 0.007006); in the next bin, 2.5° to 5°, which is where the typical distance to the nearest partner sits, opposite charges are in excess and equal charges are still deficient. Beyond 10° every bin has $|w| \leq 0.006497$: the singularities are placed as if at random. (The tiny positive values there are the counterpart of the deficit at short range, since the pair counts of all bins must add up to $N(N-1)/2$.) This is their result: attraction of opposite and repulsion of equal charges below about 10°, randomness above. Their bins have a half-width of 5°, four times the width of ours, so they cannot resolve the dip below 2.5° that the finer bins show; the two agree on the sign of the effect and on the scale, about 10°, at which it ends. On the physics: the correlation length of the polarization stick at $\ell_{\max} = 100$ is a few degrees, so there is nothing to correlate beyond it. They also repeated all these measurements for maps with a large tensor fraction, a very tilted primordial spectrum ($n_s = 0$ and 2) and strongly skewed, non-Gaussian $a_{\ell m}$, and found ν and $w(\theta)$ unchanged within errors, while the number of singularities changed with the total power; only a grossly anisotropic spectrum altered the statistics [2]. We did not repeat these variations. The pairing of charges is a property of any smooth random headless-vector field, not of a particular cosmology, and that is why these statistics hardly respond to the cosmological model.

12.15.3 Betti curves of shot noise: Pranav and collaborators' baseline

Their question. To read the Betti numbers and persistence diagrams of the real cosmic web one needs reference cases where the answer is understood. Pranav and collaborators built such templates from simple point processes [5]. They point out that even for a Gaussian random field no exact expressions for the Betti numbers or the persistence diagrams exist, so the templates must be computed. The first template is the most featureless one: points scattered uniformly at random, a Poisson process, whose topology is pure shot noise.

Their setup. They put 500 000 particles at random in a periodic box of side $200\,h^{-1}$Mpc, estimated the density at every particle with the Delaunay tessellation field estimator (DTFE, which uses the volume of the tetrahedra around each particle), and computed the persistence of the superlevel sets. They plotted the Betti curves against the density threshold divided by the standard deviation of the density, and reported that β_0 peaks at a normalised level of about 1.8, β_1 at 0.6 and β_2 at 0.3; that the three peaks are well separated, so the topology is dominated in turn by clusters, tunnels and voids; and that for different mean separations of the particles the normalised peak positions coincide.

Their key relation. The Betti number at level ν is the number of diagram points with $b \geq \nu > d$ (their §5.3), which is (12.41); and the order of the peaks follows from Figure 12.30.

What we compute. The Poisson part of `code/ch12/b05_cosmic_web.py` puts particles at random in a periodic box of 64^3 cells with mean separations of 2, 3 and 4 cells (three realisations each), estimates the density on the grid from the distance to the 5th nearest particle, $\rho = 5/(\frac{4}{3}\pi r_5^3)$, which adapts to the local density as the DTFE does, and computes the Betti curves of ρ/σ_ρ with gudhi's periodic cubical complex.

Side by side.

Gaussian field: exact Betti curves	none known	Monte Carlo, Figure 12.31

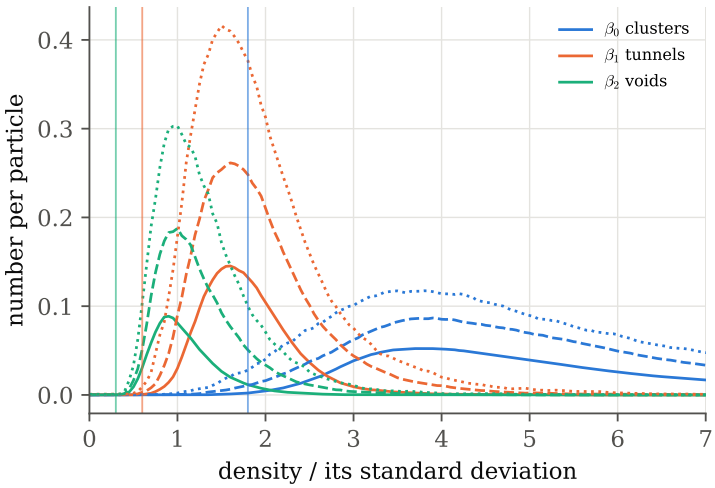

Figure 12.38: Betti curves of the density of randomly placed points, per particle, against the density divided by its standard deviation, for mean separations of 2 (solid), 3 (dashed) and 4 (dotted) cells. Vertical lines: the peak positions reported by Pranav and collaborators for their Delaunay density estimate. The order of the peaks and their coincidence across separations are reproduced; the positions themselves depend on the estimator.

Why they differ. The levels are absolute densities in units of the standard deviation, not deviations from the mean, so the peak positions depend on the ratio of the mean density to its spread, and that ratio belongs to the estimator, not to the points. The DTFE gives very high densities to particles closely surrounded by others and very low ones in empty regions, a broad distribution with a long tail; Pranav and collaborators note its tendency to form spikes at clusters. Our nearest-neighbour estimate on a grid averages over five particles and is much narrower, so in units of its own spread its mean sits higher and all three peaks move up. The order of the peaks and their independence of the particle density do not depend on the estimator, and both are reproduced. The coincidence across separations is not an accident: with the estimator tied to the mean separation, the density field of a Poisson process looks the same in units of that separation, whatever its value.

The lesson. A Betti curve of a point set describes the points and the estimator together. Two analyses can only be compared, or a measurement compared with a model, if the simulated points go through the same density estimate as the data: the same rule as for the beam and the noise in Section 12.10.

12.16 How it is done in research

The Gaussian patches, boxes and random points of the experiments are scaled-down versions of analyses that are run in research. The steps are the same; the data, the sizes and the care taken at each step are not. Figure 12.39 lays out the pipeline as a real analysis runs it. Under each step of the pipeline we say what a real analysis involves, what we did instead, and what the reduction costs.

1. Data products. For CMB polarization the inputs are the component-separated Q and U maps of *Planck* (HEALPix, $N_{\mathrm{side}} = 2048$), or arcminute-resolution maps from ground-based telescopes over part of the sky, together with the mask of the Galaxy and point sources and a large set of end-to-end simulations of the instrument's noise and processing (about a thousand for *Planck*). For the cosmic web the inputs are galaxy catalogues with positions and redshifts,

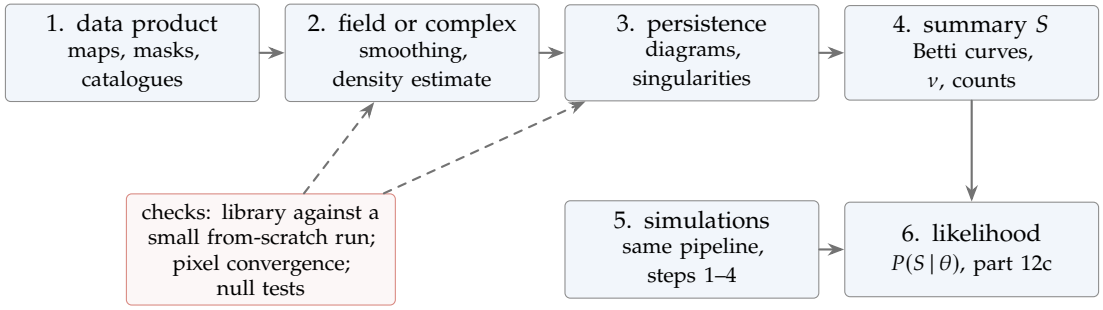

Figure 12.39: The pipeline of a persistence or singularity analysis. The data and every simulation go through exactly the same steps 1–4; the simulations then give the sampling distribution of the summary, which part 12c turns into a likelihood. The checks (red) guard the two steps where conventions are easiest to get wrong.

or particle snapshots of N-body simulations; Wilding and collaborators used five ΛCDM runs, each with 256^3 particles in a box of 300 h^{-1}Mpc, at several redshifts [4]. *Ours:* Gaussian simulations only, flat patches of 10° to 40° and full-sky maps at $N_{\rm side} = 256$, periodic Gaussian boxes of 80^3 cells and Poisson points on a 64^3 grid. *Cost:* no real noise, no mask, no non-Gaussian structure; these are the baselines a real analysis compares against, not the analysis.

2. From data to a field or a complex. Maps are smoothed to a common resolution chosen so that the pixel noise is well below the field on that scale; Section 12.10 showed why: the stability theorem bounds the damage by the largest noise value, and smoothing is what brings that value down. Particles are turned into a density by the Delaunay tessellation field estimator, or the Delaunay tessellation itself becomes the complex (an alpha complex) [5]. *Ours:* Gaussian smoothing on a grid and a nearest-neighbour density. *Cost:* the peak positions of the Betti curves move with the estimator (Section 12.15.3), so our curves are templates of the same kind as the published ones, not the same templates.

3. Persistence and singularities. On the sphere the cubical grid is replaced by HEALPix pixels with their neighbours from `healpy.get_all_neighbours`, and persistence is computed with gudhi or a dedicated cubical code; for N-body data, by the reduction of the Delaunay complex with PHAT [4, 5]. Polarization singularities are found on HEALPix by following the polarization angle around small circuits of neighbouring pixels, with the polarization at neighbouring pixels carried to a common tangent plane by parallel transport before the angles are compared [1], and with the correction at the poles of the coordinate system [2]. The pixel size must resolve the map: Huterer and Vachaspati require $N_{\rm side} > \ell_{\rm max}/4$. *Ours:* flat periodic grids, where none of these geometric corrections arise, and HEALPix rings only for the ring charges. *Cost:* none in the statistics, which are local; but every geometric step we skipped is a place where a real analysis can go wrong.

4. The summary. A diagram is a set of points of varying number, which a likelihood cannot take directly. The standard summaries are the Betti curves on a fixed grid of levels, histograms of the diagram points in birth–death bins (the "intensity maps" of [5]), or smooth versions of them; for singularities, the counts by index, the charge spread $\sigma(q)$ on a grid of loop sizes, nearest-neighbour statistics and the angular correlation function of the singularities [2]. Each is a fixed-length vector S.

5. Simulations through the same pipeline. Every effect we cannot model analytically, the mask cutting features at its edges, the noise creating short bars and pairs of singularities, the

beam merging them, the estimator, is put into the simulations and goes through steps 1–4 unchanged. The simulated summaries give the mean and the covariance of S under each model. *Ours:* a few dozen to a hundred realisations per measurement, each script under ten minutes on a laptop. *Cost:* Monte Carlo errors of a few per cent on means, as quoted with each result, and too few realisations for an accurate covariance of a long summary vector, which part 12c addresses.

Checks. Three checks recur in every serious analysis, and each appeared here. A library run is compared with a from-scratch run on a small map (Section 12.11.3), which catches mixed conventions. The pixel or particle resolution is changed and the summary must not move (the count of singularities against pixel size, Section 12.15.1). And null tests destroy the structure being measured while keeping everything else: shuffling the indices among fixed positions (Figure 12.36) is one; rotating the map, or flipping the sign of a Gaussian field, are others.

Recap

- Lowering a threshold through a field turns its excursion sets into a filtration. Each island, lake, tunnel or void has a birth level and a death level (Section 12.9); with the elder rule the record is unique. The persistence diagram is the set of pairs, the barcode draws them as intervals, and the Betti number at any level is the number of pairs alive there (12.41). Persistence $b - d$ is the range of thresholds over which a feature exists.
- Stability: if the field changes by at most ϵ everywhere, the diagram moves by at most ϵ in the bottleneck distance; features created by the change have persistence at most 2ϵ and sit by the diagonal (Section 12.10). Verified on noisy maps: the ratio never exceeded 0.9132.
- Islands are computed by union–find with the elder rule, lakes by the same code on $-\phi$ with a sea around the map (Alexander duality in the plane, not on the torus); our code and gudhi, ripser, scipy and scikit-image agree exactly (Section 12.11).
- For points, the Vietoris–Rips filtration; its island diagram is the minimum spanning tree (Kruskal, single linkage, friends-of-friends), and loops need the reduction of the boundary matrix (Section 12.12).
- In three dimensions clusters, tunnels and voids are born and die at maxima, filament saddles, wall saddles and minima; for a Gaussian field their curves peak at $\nu \approx 1.7$, 0 and -1.6, and their alternating sum reproduces the Gaussian χ (Section 12.13). Gravity changes this topology; a monotone relabelling does not.
- The index of a polarization singularity is $\frac{1}{2}\operatorname{sgn}\det J$; a remapping multiplies it by $\operatorname{sgn}\det \mathsf{A}$, so a one-to-one remapping keeps every charge, a fold creates pairs, and noise creates pairs on the pixel scale (Section 12.14).
- Reproduced: the singularity counts of Huterer and Vachaspati (the published 6000 at $\ell_{\max} = 100$ is the no-reionization value), the exponent $\nu \approx \frac{1}{2}$ of Vachaspati and Lue and its meaning (screened pairs, against $\nu \approx 1$ for shuffled charges), and the ordering of the Betti peaks of Pranav and collaborators (Section 12.15).

12.17 Weak-lensing maps to practise on: Gaussian and lognormal convergence

Every topological summary of Sections 12.2 and 12.9 was tried so far on fields we could simulate in a fraction of a second: Gaussian maps of the CMB, shot noise, Gaussian boxes. The field this part is about is the weak-lensing convergence κ of Chapter T1: the projected matter between us and a population of distant galaxies, read off from the tiny stretches of their images. The surveys measure it on thousands of square degrees, and the questions are the ones Section T1.7 ended with. How well do the maps measure the amount of matter, Ω_m, and how clumped it is, σ_8? And can the peaks, islands and lakes of the map shorten the long valley along $S_8 = \sigma_8(\Omega_m/0.3)^{0.5}$ that the power spectrum leaves open?

To answer with Monte Carlo, in the way of Chapters 6 and 8, we need many maps whose statistics we trust, and we need them for several cosmologies. The real tools are ray-traced N-body simulations, each of which costs thousands of processor hours (Section 12.21). On a laptop we need a field that can be made from a power spectrum by fast Fourier transforms, as in Section 7.4, and yet looks like lensing where it matters for topology. The Gaussian field of Section 7.2 is the obvious first try. It fails in a way that a single physical fact makes plain.

The question. What is the smallest value the convergence can take, and what kind of random field respects that floor while keeping the power spectrum the survey measures?

12.17.1 The floor: an empty line of sight

Recall from Section T1.6 how the convergence is built. Cut the line of sight to the galaxies into thick slices; then κ is a weighted sum of the density contrast δ_s averaged through each slice, $\kappa = \sum_s w_s \delta_s \, \Delta\chi$, with weight $w_s = \frac{3}{2}(H_0/c)^2 \Omega_m \, g(\chi_s)\chi_s/a(\chi_s)$. Here χ is comoving distance (the universe is flat, so $f_K = \chi$), a the scale factor, and $g(\chi)$ the lensing efficiency of Section T1.6: the fraction of the source light that lies behind χ, weighted by how strongly matter at χ bends it. Every weight is positive.

A density contrast is $\delta = \rho/\bar{\rho} - 1$, and a density cannot be negative, so $\delta \geq -1$, with equality for a slice that is completely empty. A sum of positive weights times numbers that are each at least -1 is at least minus the sum of the weights. So the lowest convergence any line of sight can have is the one with no matter at all along it, an **empty beam**:

$$\kappa \overset{(1)}{=} \sum_s w_s \, \delta_s \, \Delta\chi \overset{(2)}{\geq} -\sum_s w_s \, \Delta\chi \overset{(3)}{=} -\frac{3}{2}\left(\frac{H_0}{c}\right)^2 \Omega_m \int_0^{\chi_{\max}} \mathrm{d}\chi \, \frac{g(\chi)\,\chi}{a(\chi)} \equiv -\lambda. \tag{12.55}$$

(1) The convergence as a sum over independent slices, Section T1.6.
(2) Each $w_s > 0$ and each $\delta_s \geq -1$, so each term is at least $-w_s \Delta\chi$.
(3) Thin slices turn the sum into an integral; we give the result a name, λ, the **shift**.

On the other side there is no ceiling: a line of sight that passes through the core of a cluster has δ of hundreds in a few slices, and κ can reach several tenths. So the distribution of κ is lopsided by construction: a hard wall a little below zero, a long tail above it. A Gaussian has neither.

Example: the size of the floor. `lib_wl.limber_and_shift` evaluates the integral in (12.55) on the same redshift grid as the Limber integral of Section T1.7.3, for the source sample of Section T1.7.2 ($p_z \propto z^2 e^{-(z/0.5)^{1.5}}$, median redshift 0.71) and the Planck cosmology ($\Omega_m = 0.3153$, $\sigma_8 = 0.8111$). It gives $\lambda = 0.0452$. The rms of the convergence in a pixel of 1.5′ is $\sigma_\kappa = 0.0129$ (the square root of the integral of C_ℓ over the modes the pixels carry, (7.13)). The wall therefore sits

$\lambda/\sigma_\kappa = 0.0452/0.0129 \approx 3.5$ standard deviations below the mean. A Gaussian puts a fraction 2.3×10^{-4} of its pixels beyond 3.5σ on each side; it would give about 15 pixels of a 256×256 map a convergence that no arrangement of matter can produce, and, worse, would make the high tail exactly as thin as the low one.

Example: how the floor moves with the cosmology. The shift does not depend on σ_8 at all: (12.55) contains no clumping, only the geometry and the mean density. It does depend on Ω_m. Changing Ω_m by ±5% at fixed h gives $\lambda = 0.0465$ and 0.0437, a logarithmic slope

$$\frac{\mathrm{d}\ln\lambda}{\mathrm{d}\ln\Omega_m} \approx \frac{\ln 0.0465 - \ln 0.0437}{\ln 1.05 - \ln 0.95} = 0.62.$$

The explicit factor Ω_m alone would give 1. The rest comes from the distances: more matter decelerates the expansion more, so the same source redshift lies at a smaller comoving distance, and the integral of $g\chi/a$ over a shorter path is smaller. This small number will matter in Section 12.20: it is a property of the map that responds to Ω_m but not to σ_8, which the power spectrum, responding to both in nearly the same way, cannot provide.

12.17.2 The shifted lognormal field

What is the simplest random field with a floor at $-\lambda$, a mean of zero, and a prescribed power spectrum? State the inputs first, and separate physics from convenience.

- *Physical inputs.* The convergence never goes below $-\lambda$ (12.55); its mean over the sky is zero (lensing conserves the mean, since the matter fluctuations average to zero); its power spectrum is the Limber $C_\ell^{\kappa\kappa}$ of Section T1.6.
- *Mathematical choice.* Build κ from a Gaussian field G by the simplest increasing transformation with a floor: an exponential. This is a choice, not a law. Its only justification is that it is the simplest such map and that it describes simulated matter fields reasonably well [55].

The **shifted lognormal** convergence is then

$$\kappa(\boldsymbol{\theta}) = \lambda\left[e^{\,G(\boldsymbol{\theta})-s^2/2} - 1\right], \qquad G \text{ Gaussian, mean } 0,\ \text{variance } s^2,\ \text{correlation function } \xi_G(\vartheta). \tag{12.56}$$

The exponential is positive, so $\kappa > -\lambda$ automatically. Two questions remain, and each is answered by one property of the Gaussian. Why the $-s^2/2$ in the exponent? And which ξ_G gives the convergence the correlation function we want? (Xavier and collaborators write the same field as $X = e^Z - \lambda$ with a mean μ for Z; their $\alpha = \langle X\rangle + \lambda$ is our λ when $\langle X\rangle = 0$ [55, eqs. 1, 4, 6].)

The one fact we use. For a Gaussian variable Y with mean m and variance v,

$$\langle e^Y\rangle = e^{m+v/2}, \tag{12.57}$$

the moment generating function of the Gaussian at $t = 1$ (complete the square in the exponent of the density, as in Section 7.2). A sum of jointly Gaussian variables is again Gaussian, so the fact applies to any sum $G_1 + G_2$ as well.

The mean. Take $Y = G - s^2/2$, with mean $-s^2/2$ and variance s^2:

$$\langle\kappa\rangle \overset{(1)}{=} \lambda\left[\langle e^{G-s^2/2}\rangle - 1\right] \overset{(2)}{=} \lambda\left[e^{-s^2/2+s^2/2} - 1\right] = 0. \tag{12.58}$$

(1) The average of a sum is the sum of the averages; λ is a constant.

(2) Equation (12.57) with $m = -s^2/2$ and $v = s^2$.

The $-s^2/2$ is exactly what cancels the upward pull of the exponential: e^G alone has mean $e^{s^2/2} > 1$, because the exponential lifts the high values of G more than it lowers the low ones.

The correlation function. Take two directions a separation ϑ apart, write G_1, G_2 for the Gaussian field there and κ_1, κ_2 for the convergence. Their sum $G_1 + G_2$ is Gaussian with mean zero and variance $s^2 + s^2 + 2\xi_G(\vartheta)$. Then

$$\begin{aligned}\xi_\kappa(\vartheta) \equiv \langle \kappa_1 \kappa_2 \rangle &\overset{(1)}{=} \lambda^2 \left\langle \left(e^{G_1 - s^2/2} - 1\right)\left(e^{G_2 - s^2/2} - 1\right)\right\rangle \\ &\overset{(2)}{=} \lambda^2 \left[e^{-s^2}\left\langle e^{G_1+G_2}\right\rangle - 1 - 1 + 1\right] \\ &\overset{(3)}{=} \lambda^2 \left[e^{-s^2}\, e^{s^2 + \xi_G(\vartheta)} - 1\right] = \lambda^2 \left[e^{\xi_G(\vartheta)} - 1\right], \qquad (12.59)\end{aligned}$$

$$\xi_G(\vartheta) \overset{(4)}{=} \ln\left[1 + \frac{\xi_\kappa(\vartheta)}{\lambda^2}\right]. \qquad (12.60)$$

(1) The definition (12.56) at the two points; the mean of κ is zero (12.58), so $\langle \kappa_1 \kappa_2 \rangle$ is the covariance.
(2) Multiply out. The two cross terms are each $\langle e^{G - s^2/2} \rangle = 1$ by (12.58).
(3) Equation (12.57) for $Y = G_1 + G_2$, with $m = 0$ and $v = 2s^2 + 2\xi_G$, so $\langle e^Y \rangle = e^{s^2 + \xi_G}$.
(4) Solve for ξ_G.

Equations (12.59) and (12.60) are eqs. (6) and (7) of [55], in our notation. They are the recipe: from the wanted ξ_κ compute ξ_G point by point, turn it into a power spectrum P_G, and make G by the method of Section 7.4.2. The transformation acts point by point in real space, so the correlation function, not the power spectrum, is the natural place to apply it. At zero separation it fixes the variance of G: $s^2 = \xi_G(0) = \ln(1 + \sigma_\kappa^2/\lambda^2)$.

The skewness. How lopsided is this field? Write $Y = e^{G - s^2/2}$, so $\kappa = \lambda(Y - 1)$ and the skewness of κ is that of Y. By (12.57) with $m = -ns^2/2$ and $v = n^2 s^2$ for the variable $nG - ns^2/2$, $\langle Y^n \rangle = e^{n(n-1)s^2/2}$, that is 1, e^{s^2}, e^{3s^2} for $n = 1, 2, 3$. Call $q \equiv e^{s^2} - 1 = \sigma_\kappa^2/\lambda^2$ (the zero-separation case of (12.59)). Then

$$\begin{aligned}\left\langle (Y-1)^2 \right\rangle &\overset{(1)}{=} e^{s^2} - 2 + 1 = q, \\ \left\langle (Y-1)^3 \right\rangle &\overset{(2)}{=} e^{3s^2} - 3e^{s^2} + 3 - 1 \overset{(3)}{=} (1+q)^3 - 3(1+q) + 2 \overset{(4)}{=} q^2(3+q), \\ \gamma_\kappa \equiv \frac{\langle (Y-1)^3 \rangle}{\langle (Y-1)^2 \rangle^{3/2}} &\overset{(5)}{=} \sqrt{q}\,(3+q) = r\,(3 + r^2), \qquad r \equiv \frac{\sigma_\kappa}{\lambda}. \qquad (12.61)\end{aligned}$$

(1) Expand the square and use $\langle Y \rangle = 1$, $\langle Y^2 \rangle = e^{s^2}$.
(2) Expand the cube, $(Y-1)^3 = Y^3 - 3Y^2 + 3Y - 1$, and use the three moments.
(3) $e^{s^2} = 1 + q$ and $e^{3s^2} = (1+q)^3$.
(4) Multiply out: $1 + 3q + 3q^2 + q^3 - 3 - 3q + 2 = 3q^2 + q^3$.
(5) Divide by $q^{3/2}$; $\sqrt{q} = \sigma_\kappa/\lambda$.

This is eq. (10) of [55] with their $\alpha = \lambda$ and $v = \sigma_\kappa^2$. The whole one-point shape is controlled by one number, the ratio r of the rms to the depth of the floor. A shallow floor (small λ) or a large rms makes a strongly skewed field; when $r \to 0$ the field becomes Gaussian.

Example: the skewness by hand. With $\sigma_\kappa = 0.0129$ and $\lambda = 0.0452$, $r = 0.29$ and $\gamma_\kappa = 0.29 \times (3 + 0.084) \approx 0.89$; the unrounded numbers give 0.88. The skewness of a Gaussian is zero. A map smoothed with a Gaussian of 3′, as the peak and topology analyses will use, has a

smaller rms, 0.0064, so $r \approx 0.0064/0.0452 = 0.14$ and (12.61) suggests $\gamma \approx 0.14 \times 3.02 \approx 0.43$. This last number is only a guide: smoothing averages neighbouring pixels, and an average of lognormal variables is not exactly lognormal.

Example: why the skewness carries what the spectrum does not. The literature often quotes the **reduced skewness**, the third moment divided by the square of the second, $S_3 \equiv \langle\kappa^3\rangle/\langle\kappa^2\rangle^2 = \gamma_\kappa/\sigma_\kappa$. For a weakly skewed lognormal field (12.61) gives $S_3 \approx 3r/\sigma_\kappa = 3/\lambda$. The clumping amplitude has dropped out: σ_8 raises σ_κ but not λ. What remains is $1/\lambda \propto \Omega_m^{-0.62}$. Perturbation theory says the same about the real field: the reduced skewness of the lensing signal is independent of the normalisation of the power spectrum and scales roughly as Ω_m^{-1} [BartelmannSchneider2001 p. 146]. A low-Ω_m, high-σ_8 universe and a high-Ω_m, low-σ_8 one with the same S_8 have nearly the same C_ℓ (Section T1.7.4), but the first has fewer lenses, each more clumped, and so a more lopsided map. The one-point shape is a lever on the valley of Section T1.7.

12.17.3 Making the maps

The patch is 256×256 pixels of 1.5′, a square of 6.4° on a side (24.4 such patches make 1000 deg^2), periodic as every FFT simulation is. `w01_lognormal.py` computes the Limber spectrum with our own integral over CAMB's halofit matter spectrum (the hand-made Limber code of Section T1.7.3, now inside `lib_wl`) and λ for the fiducial cosmology and for Ω_m and σ_8 moved by ±5%, and caches all five for the later scripts. The lognormal recipe is four lines:

Listing 12.11: From the target spectrum to a shifted lognormal map (`code/ch12/lib_wl.py`)

```
127 def lognormal_spectrum(P, lam):
128     """Spectrum P_G of the Gaussian field G such that kappa = lam (e^{G - s^2/2} - 1) has
        spectrum P.
129
130     xi_kappa(x) = ifft2(P)/A_pix on the grid;  xi_G = ln(1 + xi_kappa / lam^2);  P_G =
        A_pix fft2(xi_G).
131     Negative P_G (a few modes at the highest l) are set to zero.
132     """
133     xi = np.fft.ifft2(P).real / A_PIX
134     xig = np.log1p(xi / lam**2)
135     PG = np.fft.fft2(xig).real * A_PIX
136     PG[0, 0] = 0.0
137     return np.clip(PG, 0.0, None), xig[0, 0]
138
139
140 def lognormal_map(PG, lam, white):
141     """Shifted lognormal convergence with zero mean, built from the Gaussian spectrum PG."""
142     G = gaussian_map(PG, white)
143     s2 = G.var()
144     k = lam * (np.exp(G - s2 / 2) - 1.0)
145     return k - k.mean()
```

Line 133 turns the target spectrum on the FFT grid into the correlation function at every pixel separation (the inverse transform of the Wiener–Khinchin relation, Section 7.3.2, with the grid normalisation of (7.19)). Line 134 is (12.60), point by point. Line 135 transforms ξ_G back into the spectrum P_G of the Gaussian field. A spectrum must be non-negative, and nothing guarantees that the transform of $\ln(1 + \xi_\kappa/\lambda^2)$ is; this is the limitation Xavier and collaborators analyse, which bites hardest when several correlated lognormal fields must be made at once [55, §2.2]. For our single map the negative modes are a fraction 0.00% of the grid, and line 137 sets them to zero. Lines 142–145 draw G from white noise, exponentiate as in (12.56), and remove the tiny mean that one finite map has. A Gaussian map with the same spectrum is made from

the same white noise (`gaussian_map`), so the two maps of Figure 12.40 have the same phases and differ only through the transformation.

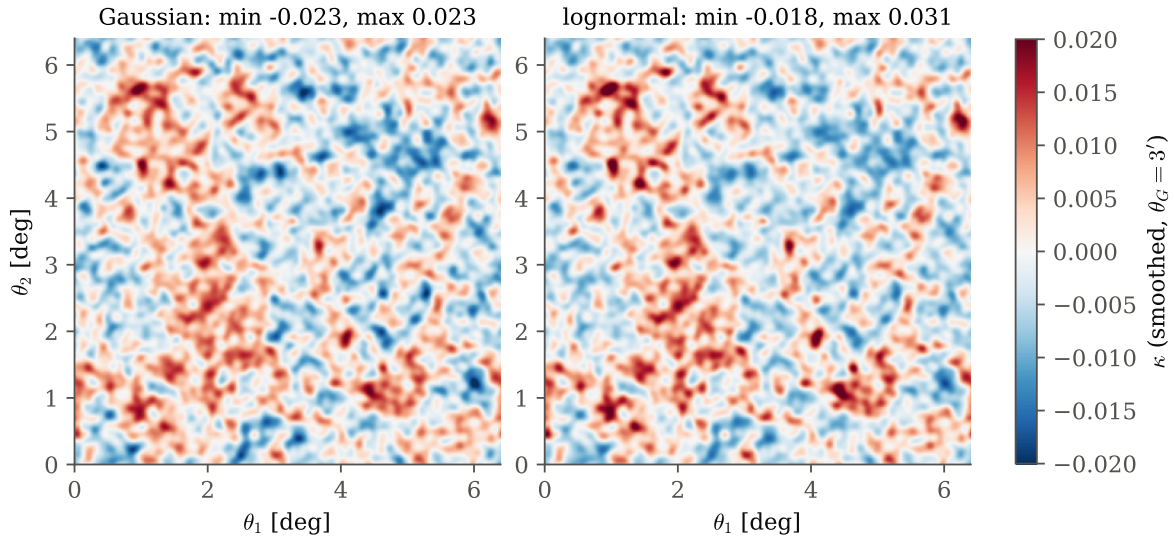

Figure 12.40: A Gaussian convergence map (left) and a shifted lognormal one (right), built from the same white noise and with the same power spectrum, both smoothed with a 3′ Gaussian. The large-scale pattern is identical. The lognormal map has compact, intense red spots, where many lenses line up, and shallow, wide blue regions, because it cannot fall far below zero: compare the minimum and maximum in the titles.

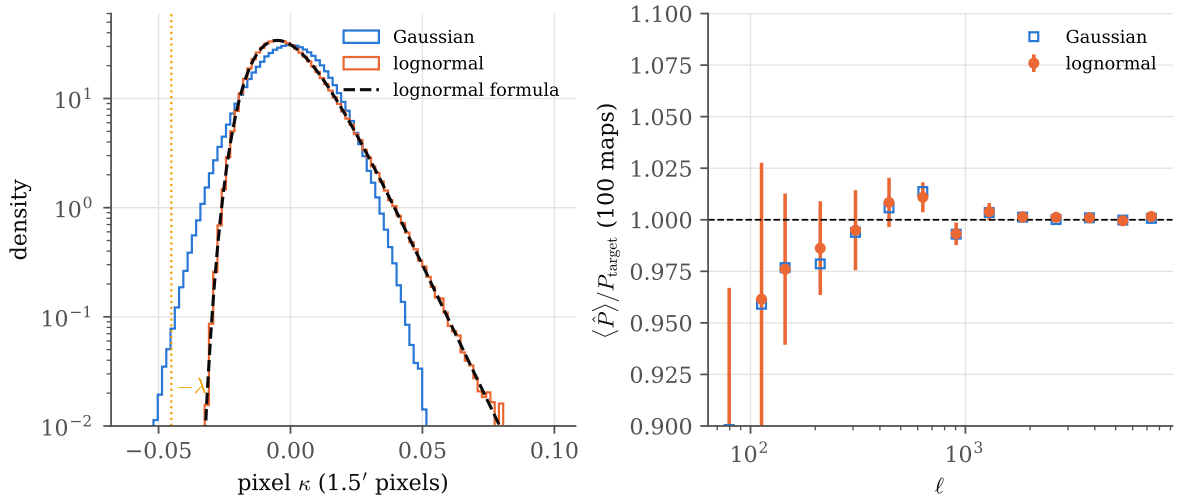

Figure 12.41: Left: the distribution of pixel values in 20 Gaussian and 20 lognormal maps (1.5′ pixels, logarithmic vertical axis), with the lognormal density obtained from (12.56) by a change of variables (dashed). The Gaussian is symmetric; the lognormal stops at the floor $-\lambda$ (dotted line) and has a long tail to high κ. Right: the band powers of 100 maps of each kind divided by the target spectrum. Both reproduce it; the scatter at low ℓ, the same for both since the maps share their white noise, is the sampling variance of the few modes there.

What the maps show. Over 100 maps, the measured skewness of the lognormal pixels is 0.88, against 0.88 from (12.61); the Gaussian maps give 0.001. After 3′ smoothing the lognormal skewness is 0.44 (the guide above said about 0.43) and the Gaussian 0.001. The lowest lognormal pixel in 20 maps is −0.0356, inside the wall at −0.0452. The power spectrum survives the

transformation: for $\ell > 300$ the mean band powers of the lognormal maps differ from the target by at most 1.1%; including the lowest bands the largest deviation is 10.9%, the same as the Gaussian maps' 10.2%, which is the sampling scatter of a handful of modes and not an error of the method (Figure 12.41, right). So the two families of maps share their two-point statistics and differ in everything else. That is exactly the situation in which a summary beyond C_ℓ can win.

What the lognormal model gets wrong. It is a model of the one-point shape with one free number, and the number we chose, the empty-beam shift, is not the best one. Xavier and collaborators made convergence maps the honest way, as sums of correlated lognormal density slices along the line of sight, and asked which shift a lognormal fitted to them needs. For sources at $z = 2.1$ the empty-beam value is 0.2115, while matching the first three moments gives 0.1288 [55, Table 2]. The empty beam overestimates the shift by about 60%, so by $S_3 \approx 3/\lambda$ it underestimates the skewness by a similar factor: our maps are less non-Gaussian than the real sky, and any gain we find from non-Gaussian summaries is, if anything, too small. The reason is physical: a real line of sight is never empty, and the deepest voids have $\delta \approx -0.8$, not -1. A sum of lognormal slices is also not itself lognormal [55, §3.3], and a lognormal field has no haloes, no filaments and no lensing of lensing. For each of these the research analyses use ray-traced N-body maps [51]; we return to the cost in Section 12.21.

12.18 From galaxy shapes to a mass map

A survey never sees the convergence. It sees galaxies, each with a measured ellipticity $\varepsilon \approx \varepsilon^{(0)} + \gamma$: its own random shape $\varepsilon^{(0)}$ plus the shear γ of Section T1.6, a spin-2 quantity, a headless stick. Peaks, islands and lakes are properties of a map of κ, so before any of the summaries of Sections 12.2 and 12.9 can be computed, the convergence must be reconstructed from the sticks. Three things stand between the sticks and the map. The reconstruction itself is non-local: the shear at one point is caused by matter everywhere. The shapes carry noise some thirty times larger than the signal (Section T1.8). And part of every survey is missing, behind bright stars and beyond its edges.

The question. Given the shear on a patch of sky, which convergence produced it? And how faithful is the answer when each galaxy's shape is mostly its own, and when some of the patch is blank?

12.18.1 The inversion, mode by mode

Recall the two second-derivative relations of Section T1.6, in the flat angles θ_1, θ_2 of Figure T1.7: the convergence is half the Laplacian of the lensing potential, $\kappa = \frac{1}{2}(\psi_{,11} + \psi_{,22})$, and the shear is $\gamma \equiv \gamma_1 + i\gamma_2$ with $\gamma_1 = \frac{1}{2}(\psi_{,11} - \psi_{,22})$ and $\gamma_2 = \psi_{,12}$, a comma meaning a derivative. Both are linear in one unknown function, so we should eliminate it. Derivatives become multiplications in Fourier space. Write each field on the patch as a sum of plane waves, $f(\boldsymbol{\theta}) = \int \frac{\mathrm{d}^2\boldsymbol{\ell}}{(2\pi)^2} \hat{f}(\boldsymbol{\ell}) e^{i\boldsymbol{\ell}\cdot\boldsymbol{\theta}}$, with $\boldsymbol{\ell} = (\ell_1, \ell_2) = \ell(\cos\varphi_\ell, \sin\varphi_\ell)$, so that $\partial/\partial\theta_a$ acting on a wave multiplies it by $i\ell_a$. Then, for every $\boldsymbol{\ell} \neq \mathbf{0}$,

$$\begin{aligned} \hat{\kappa} &\overset{(1)}{=} \tfrac{1}{2}\big[(i\ell_1)^2 + (i\ell_2)^2\big]\hat{\psi} = -\tfrac{1}{2}\ell^2\hat{\psi}, \\ \hat{\gamma} \equiv \hat{\gamma}_1 + i\hat{\gamma}_2 &\overset{(2)}{=} \tfrac{1}{2}\big[(i\ell_1)^2 - (i\ell_2)^2\big]\hat{\psi} + i\,(i\ell_1)(i\ell_2)\hat{\psi} = -\tfrac{1}{2}\big(\ell_1^2 - \ell_2^2 + 2i\ell_1\ell_2\big)\hat{\psi} \\ &\overset{(3)}{=} -\tfrac{1}{2}(\ell_1 + i\ell_2)^2\hat{\psi} \overset{(4)}{=} -\tfrac{1}{2}\ell^2 e^{2i\varphi_\ell}\hat{\psi} \overset{(5)}{=} e^{2i\varphi_\ell}\,\hat{\kappa}, \end{aligned} \tag{12.62}$$

$$\hat{\kappa} \overset{(6)}{=} e^{-2i\varphi_\ell}\,\hat{\gamma}. \tag{12.63}$$

(1) The Laplacian of a plane wave: each derivative brings down $i\ell_a$, and $i^2 = -1$.
(2) The two shear components with the same rule, combined into one complex number.
(3) $(\ell_1 + i\ell_2)^2 = \ell_1^2 - \ell_2^2 + 2i\ell_1\ell_2$.
(4) $\ell_1 + i\ell_2 = \ell e^{i\varphi_\ell}$, the polar form of the wavevector.
(5) The first line: $-\frac{1}{2}\ell^2\hat{\psi} = \hat{\kappa}$.
(6) Multiply both sides by $e^{-2i\varphi_\ell}$, which has modulus one.

Equation (12.63) is the **Kaiser–Squires inversion** [46]. In the notation of [BartelmannSchneider2001 p. 88, eqs. 5.2–5.3] it reads $\hat{\kappa} = \pi^{-1}\hat{\mathcal{D}}^*\hat{\gamma}$ with $\hat{\mathcal{D}} = \pi e^{2i\varphi_\ell}$, the row of the table in Section T1.6. In words: a convergence wave of any orientation produces a shear wave of the same wavelength whose sticks are turned by twice the angle of the wavevector, and undoing the turn returns the convergence. Nothing is lost in either direction, because a phase has modulus one.

Two remarks complete the inversion. First, the chain needs $\boldsymbol{\ell} \neq \mathbf{0}$: a uniform convergence κ_0 comes from $\psi = \frac{1}{2}\kappa_0\theta^2$, whose $\psi_{,11} = \psi_{,22}$ and $\psi_{,12} = 0$, so it makes no shear at all. The map is therefore known only up to an added constant, the **mass-sheet degeneracy** [BartelmannSchneider2001 p. 88]. On a periodic simulated patch we fix the constant by requiring zero mean; a peak height or a threshold measured from the mean is unaffected by it. Second, in real space the multiplication by $e^{-2i\varphi_\ell}$ is a convolution with a kernel that falls only as $1/\theta^2$ [BartelmannSchneider2001 eq. 5.4]: the convergence at a point is a weighted sum of the shear over the whole patch. This is why a hole in the data will spoil the map well beyond its edge.

***E* and *B* from any stick field.** Apply (12.63) to a stick field that did *not* come from a convergence, such as one with noise or an error in it. The result is a complex map, and we name its two parts:

$$\kappa_E(\boldsymbol{\theta}) + i\kappa_B(\boldsymbol{\theta}) \equiv \int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\, e^{-2i\varphi_\ell}\,\hat{\gamma}(\boldsymbol{\ell})\, e^{i\boldsymbol{\ell}\cdot\boldsymbol{\theta}}. \tag{12.64}$$

If the sticks came from a real convergence, the integrand is $\hat{\kappa}(\boldsymbol{\ell})$, whose inverse transform is the real map κ, so $\kappa_E = \kappa$ and $\kappa_B = 0$: lensing makes no B, the statement proved in real space in (T1.7). Now turn every stick by 45°. A stick at angle ϕ is $|\gamma|\,e^{2i\phi}$, so the turn multiplies γ by $e^{2i\pi/4} = i$, and by linearity the output becomes $i\kappa$: the same map, moved entirely into κ_B. This is the swirl pattern of Figure T1.6(b). Pure E and pure B are the two ways a stick field can be arranged around each point, and (12.64) sorts any field into them.

Listing 12.12: Shear from convergence and back (`code/ch12/lib_wl.py`)

```
148 def shear_from_kappa(kappa):
149     """gamma_1 + i gamma_2 from kappa: multiply each Fourier mode by e^{2 i phi_l}."""
150     g = np.fft.ifft2(E2IPHI * np.fft.fft2(kappa))
151     return g.real, g.imag
152
153
154 def kaiser_squires(g1, g2):
155     """kappa_E + i kappa_B: multiply each mode of gamma_1 + i gamma_2 by e^{-2 i phi_l}."""
156     k = np.fft.ifft2(np.conj(E2IPHI) * np.fft.fft2(g1 + 1j * g2))
157     return k.real, k.imag
```

The two functions are (12.62) and (12.64) on the FFT grid: `E2IPHI` is the array $e^{2i\varphi_\ell} = (\ell_1 + i\ell_2)^2/\ell^2$ (step 3 of the chain, which avoids computing any angle), set to zero at $\boldsymbol{\ell} = \mathbf{0}$, where the mass sheet lives. Lines 150 and 156 multiply every mode by the phase or its conjugate.

Example: the round trip. Take one lognormal map of Section 12.17.2, make its shear, and invert. `w02_ks.py` finds that the recovered κ_E differs from the input by at most 2.7×10^{-15} of the map's rms, and κ_B is at most 1.8×10^{-15} of it: zero to the precision of double arithmetic. The input map has rms 0.0126 and each shear component 0.0089. Why smaller by $\sqrt{2}$? Because a phase of modulus one keeps the power of every mode, the complex shear has the variance of κ, $\langle|\gamma|^2\rangle = \langle\gamma_1^2\rangle + \langle\gamma_2^2\rangle = \sigma_\kappa^2$, and on an isotropic sky the two components share it equally: $\sigma_{\gamma_1} = \sigma_\kappa/\sqrt{2} = 0.0126/1.414 = 0.0091$.

12.18.2 Shape noise in the mass map

Recall the noise of (T1.11). With $\sigma_e = 0.27$ the rms of one ellipticity component and $\bar{n}$ galaxies per unit solid angle, a pixel of solid angle A holds about $\bar{n}A$ galaxies and its mean ellipticity scatters by $\sigma_e/\sqrt{\bar{n}A}$ in each component, independently from pixel to pixel. For the KiDS-like density $\bar{n} = 6.2\,\mathrm{arcmin}^{-2}$ and our 1.5′ pixels this is $0.27/\sqrt{6.2 \times 2.25} = 0.0723$ per component, against a signal of 0.0089: the per-pixel signal-to-noise ratio is about 1/8. The inversion keeps the power of every mode, so the noise power $\sigma_e^2/\bar{n}$ of each component goes, unchanged in total, into κ_E and κ_B, each receiving $\sigma_e^2/\bar{n}$; fifty pure-noise maps give 1.002 and 0.990 times $\sigma_e^2/\bar{n} = 9.95 \times 10^{-10}$ in E and B. The noise is white, the same at every ℓ, while the signal falls with ℓ; at the pixel scale the map is all noise. Shrinking the pixels makes it worse without limit, the "infinite noise" of a direct inversion [BartelmannSchneider2001 p. 88]. The cure is to smooth.

How much noise survives smoothing? Smooth with a normalised Gaussian of standard deviation θ_G, $W(\boldsymbol{\theta}) = e^{-\theta^2/2\theta_G^2}/(2\pi\theta_G^2)$. White noise $n(\boldsymbol{\theta})$ with power N has the correlation $\langle n(\boldsymbol{\theta})n(\boldsymbol{\theta}')\rangle = N\,\delta^{(2)}(\boldsymbol{\theta} - \boldsymbol{\theta}')$ (a field of independent pixels, Section T1.6). The smoothed noise is $n_s(\boldsymbol{\theta}) = \int \mathrm{d}^2\theta'\, W(\boldsymbol{\theta} - \boldsymbol{\theta}')n(\boldsymbol{\theta}')$, so

$$\sigma^2_{\mathrm{noise}} \equiv \langle n_s^2\rangle \overset{(1)}{=} \int \mathrm{d}^2\theta_1 \int \mathrm{d}^2\theta_2\, W(\boldsymbol{\theta} - \boldsymbol{\theta}_1)W(\boldsymbol{\theta} - \boldsymbol{\theta}_2)\, N\delta^{(2)}(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2) \overset{(2)}{=} N \int \mathrm{d}^2\theta'\, W^2(\boldsymbol{\theta}')$$
$$\overset{(3)}{=} \frac{N}{(2\pi\theta_G^2)^2} \int_0^\infty 2\pi\vartheta\, e^{-\vartheta^2/\theta_G^2}\,\mathrm{d}\vartheta \overset{(4)}{=} \frac{N}{4\pi^2\theta_G^4}\,\pi\theta_G^2 \overset{(5)}{=} \frac{\sigma_e^2}{4\pi\theta_G^2\,\bar{n}}. \tag{12.65}$$

(1) Square the smoothed noise and average; only the noise is random.
(2) The delta function removes one integral; shift the variable.
(3) Insert W^2 and use polar coordinates.
(4) $\int_0^\infty 2\pi\vartheta e^{-\vartheta^2/\theta_G^2}\mathrm{d}\vartheta = \pi\theta_G^2$ (substitute $u = \vartheta^2$).
(5) $N = \sigma_e^2/\bar{n}$ for κ_E.

The smoothing area $4\pi\theta_G^2$ counts the galaxies that the filter effectively averages. For $\theta_G = 3'$ and $\bar{n} = 6.2\,\mathrm{arcmin}^{-2}$, $\sigma^2_{\mathrm{noise}} = 0.0729/(4\pi \times 9 \times 6.2) = 1.04 \times 10^{-4}$, so $\sigma_{\mathrm{noise}} = 0.0102$. On the pixel grid the same quantity is a lattice sum over the modes, and it gives 0.0102; fifty noise maps give 0.0102. The smoothed signal has rms 0.0064 (Section 12.17.3), so even after smoothing each pixel is dominated by noise. Every peak, island and lake of the mass map will be measured in units of this σ_{noise}, the signal-to-noise map $\nu(\boldsymbol{\theta}) \equiv \kappa_{E,s}(\boldsymbol{\theta})/\sigma_{\mathrm{noise}}$.

Example: a published noise level, recovered. Kratochvil and collaborators quote the smoothed noise as $\sigma^2_{\mathrm{noise}} = \langle\sigma_\gamma^2\rangle/(2\pi\theta_G^2 n_{\mathrm{gal}})$ [52, eq. 9], with σ_γ the rms of one shear component. Compared with (12.65) the 4π has become 2π. The two agree if their θ_G is the width in $e^{-\theta^2/\theta_G^2}$, a standard deviation of $\theta_G/\sqrt{2}$: then $4\pi(\theta_G/\sqrt{2})^2 = 2\pi\theta_G^2$. Their own numbers confirm this reading. With $\sigma_\gamma = 0.15 + 0.035z = 0.22$ for sources at $z = 2$, $n_{\mathrm{gal}} = 15\,\mathrm{arcmin}^{-2}$ and $\theta_G = 1'$, the formula gives $\sigma^2_{\mathrm{noise}} = 0.0484/(2\pi \times 15) = 5.1 \times 10^{-4}$, $\sigma_{\mathrm{noise}} = 0.0227$, and their detection

threshold of $4.5\sigma_{\rm noise}$ is 0.102, the value they quote. A smoothing scale is a number with a convention attached, like the σ_e of Section T1.6.2.

12.18.3 Aperture mass: a filtered map without the inversion

Kaiser–Squires builds the convergence at a point from the shear of the whole patch, and then we smooth it. The peak analyses of Dietrich and Hartlap and of Heydenreich and collaborators do not do it in two steps. They compute the **aperture mass**, a filtered convergence obtained straight from the sticks [53, 56]. *Can the filter be put inside the inversion?* Choose a round filter $U(|\boldsymbol{\theta}|)$ and ask for

$$M(\boldsymbol{\theta}_0) \equiv \int \mathrm{d}^2\theta\, U(|\boldsymbol{\theta}-\boldsymbol{\theta}_0|)\,\kappa(\boldsymbol{\theta}), \qquad \int \mathrm{d}^2\theta\, U = 0, \tag{12.66}$$

the convergence averaged around $\boldsymbol{\theta}_0$ with weight U. The second condition makes the filter **compensated**: positive in the middle and negative in a ring, so that its total weight is zero. We express M through the shear. The convolution theorem turns (12.66) into a sum over modes, and (12.63) replaces $\hat\kappa$:

$$\begin{aligned} M(\boldsymbol{\theta}_0) &\overset{(1)}{=} \int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\,\hat U(\ell)\,\hat\kappa(\boldsymbol{\ell})\,e^{i\boldsymbol{\ell}\cdot\boldsymbol{\theta}_0} \overset{(2)}{=} \int \mathrm{d}^2\theta\,\gamma(\boldsymbol{\theta})\,K(\boldsymbol{\theta}_0-\boldsymbol{\theta}),\\ K(\boldsymbol{x}) &\equiv \int \frac{\mathrm{d}^2\ell}{(2\pi)^2}\,\hat U(\ell)\,e^{-2i\varphi_\ell}\,e^{i\boldsymbol{\ell}\cdot\boldsymbol{x}}\\ &\overset{(3)}{=} \int_0^\infty \frac{\ell\,\mathrm{d}\ell}{(2\pi)^2}\,\hat U(\ell)\int_0^{2\pi}\mathrm{d}\varphi_\ell\,e^{-2i\varphi_\ell}\,e^{i\ell|\boldsymbol{x}|\cos(\varphi_\ell-\varphi_x)}\\ &\overset{(4)}{=} -e^{-2i\varphi_x}\,Q(|\boldsymbol{x}|), \qquad Q(\vartheta) \equiv \int_0^\infty \frac{\ell\,\mathrm{d}\ell}{2\pi}\,\hat U(\ell)\,J_2(\ell\vartheta). \end{aligned} \tag{12.67}$$

(1) The transform of a filtered map is the product of the transforms (U is even, so $\hat U$ is real and depends on ℓ only).
(2) Insert $\hat\kappa = e^{-2i\varphi_\ell}\hat\gamma$ and write $\hat\gamma(\boldsymbol{\ell}) = \int \mathrm{d}^2\theta\,\gamma(\boldsymbol{\theta})e^{-i\boldsymbol{\ell}\cdot\boldsymbol{\theta}}$; the $\boldsymbol{\ell}$ integral moves inside and collects into the kernel K.
(3) Polar coordinates in $\boldsymbol{\ell}$, with φ_x the polar angle of $\boldsymbol{x}$, so that $\boldsymbol{\ell}\cdot\boldsymbol{x} = \ell\,|\boldsymbol{x}|\cos(\varphi_\ell-\varphi_x)$.
(4) Shift the angle, $\varphi_\ell = \varphi_x + \alpha$, which pulls out $e^{-2i\varphi_x}$, and use the Bessel integral $\int_0^{2\pi} e^{-2i\alpha}e^{iz\cos\alpha}\mathrm{d}\alpha = 2\pi\, i^{-2}J_{-2}(z) = -2\pi J_2(z)$.

For a map that is pure E the result is real, so we may keep the real part. With $\boldsymbol{x} = \boldsymbol{\theta}_0 - \boldsymbol{\theta}$ the angle φ_x differs from the polar angle φ of $\boldsymbol{\theta}-\boldsymbol{\theta}_0$ by π, which leaves $e^{-2i\varphi_x} = e^{-2i\varphi}$, and

$$M(\boldsymbol{\theta}_0) = \int \mathrm{d}^2\theta\, Q(|\boldsymbol{\theta}-\boldsymbol{\theta}_0|)\,\gamma_t(\boldsymbol{\theta};\boldsymbol{\theta}_0), \qquad \gamma_t(\boldsymbol{\theta};\boldsymbol{\theta}_0) \equiv -\mathrm{Re}\big[\gamma(\boldsymbol{\theta})\,e^{-2i\varphi}\big]. \tag{12.68}$$

The number γ_t is the **tangential shear**: the component of the stick at $\boldsymbol{\theta}$ along the direction that circles $\boldsymbol{\theta}_0$. For a stick tangential to the circle, $\gamma = -|\gamma|\,e^{2i\varphi}$ (the pattern around a lump found in Section T1.6), so $\gamma_t = +|\gamma|$; a radial stick gives $-|\gamma|$. The real-space form of the weight, $Q(\vartheta) = (2/\vartheta^2)\int_0^\vartheta \vartheta' U(\vartheta')\mathrm{d}\vartheta' - U(\vartheta)$, is the one quoted by [56, eq. 2]; the Bessel form above is what falls out of our inversion. Three things follow at once. *No mass sheet.* The compensation condition says $\hat U(0) = \int U\,\mathrm{d}^2\theta = 0$. A constant κ_0 lives only in the mode $\boldsymbol{\ell}=\mathbf{0}$, which $\hat U$ removes, so M is blind to it: the degeneracy of Section 12.18.1 is built out of the observable. *Holes cost only what they hold.* Equation (12.68) is an integral over the sticks that exist. In the estimator below a masked galaxy is a term missing from a sum, and the aperture around a hole is merely less well measured, whereas a Kaiser–Squires map is spoiled over the whole

range of its $1/\theta^2$ kernel (Section 12.18.4). Heydenreich and collaborators discard the pixels for which at least half the aperture is masked [56, §2.2]. *A noise level.* Replace the integral by a sum over the $\bar{n}$ galaxies per unit solid angle, each carrying its measured ellipticity $\varepsilon_{t,i} = \varepsilon^{(0)}_{t,i} + \gamma_t$: $\hat{M} = \bar{n}^{-1} \sum_i Q_i \, \varepsilon_{t,i}$. The intrinsic tangential components are independent with variance σ_e^2, so

$$\sigma_M^2 \overset{(1)}{=} \frac{1}{\bar{n}^2} \bar{n} \int \mathrm{d}^2\theta \, Q^2 \, \sigma_e^2 \overset{(2)}{=} \frac{\sigma_e^2}{\bar{n}} \int \mathrm{d}^2\theta \, Q^2(|\boldsymbol{\theta}|). \tag{12.69}$$

(1) The variance of a sum of independent terms is the sum of the variances, and the number of galaxies in $\mathrm{d}^2\theta$ is $\bar{n}\,\mathrm{d}^2\theta$.
(2) Collect the constants.

This is the shape of (12.65), in which the Gaussian W played the part of Q: smoothed noise is always $\sigma_e^2/\bar{n}$ times the integral of the square of the weight. The aperture-mass **signal-to-noise map** is $\nu = M/\sigma_M$, and it is the map of the three published analyses; Heydenreich and collaborators choose Q as a smooth function shaped like the lensing signal of a typical dark-matter halo, so that the peaks of ν are tuned to haloes [56, §2.2.1]. We use the Gaussian-smoothed Kaiser–Squires map, which is easier to simulate on a periodic grid and has the same noise algebra. The two maps are two different linear filters of the same shear, so the qualitative behaviour of their peaks and islands, which is what the comparisons of Section 12.20.4 rest on, is the same, and the numbers are not.

12.18.4 What a mask does to the map

Real data have holes. Our mask removes 40 discs of radius 3′ to 9′ around imagined bright stars and a strip of 0.4° along one edge, keeping a fraction $f_{\mathrm{obs}} = 0.91$ of the patch. Where there is no galaxy, the measured shear is zero. What does (12.64) do with a shear map that is suddenly zero inside a hole?

A masked shear map is not the shear of any convergence. Inside a hole the true κ is not zero, yet the sticks around it are gone, and the inversion, which builds κ at a point from the sticks everywhere with a $1/\theta^2$ kernel, attributes the missing pattern partly to a different convergence and partly to B. In Fourier language the mask multiplies the shear by a window $W(\boldsymbol{\theta})$, which convolves its transform: the mode $\boldsymbol{\ell}$ of the masked shear is a mixture of modes $\boldsymbol{\ell}'$ of the true one, each carrying the phase $e^{2i\varphi_{\ell'}}$ of its own wavevector. Undoing it with the phase $e^{-2i\varphi_\ell}$ of the new wavevector leaves the factor $e^{2i(\varphi_{\ell'} - \varphi_\ell)}$, whose imaginary part feeds B. The equation is derived in Section 12.19.1. The effect should be strongest next to a hole, where the missing sticks are close, and fade with distance.

Figure 12.42 shows it, and the numbers confirm it. Within 3′ of a masked pixel the error of κ_E has an rms of 0.37 times the rms of the map, and κ_B has 0.36 of it; farther than 30′ from any masked pixel the two fall to 0.023 and 0.018. In power, the masked B map carries 2% of the E power at the lowest band ($\ell \approx 200$) and 0.9% at the highest ($\ell \approx 5000$), and the E power is lowered to 0.90 and 0.90 of its true value, against an observed fraction f_{obs} of the area: most of the loss is simply the missing area. For the topological summaries the lesson is local: features near holes are unreliable, and a research analysis either excludes a margin around the mask or, better, applies the same mask to every simulation, so that the distortion is part of the model; Heydenreich and collaborators handle masked pixels with relative homology for the same reason [56, §2.3.3]. We sidestep the problem for the summaries of Section 12.20 by analysing full periodic patches, and keep the mask for the power spectrum, where Section 12.19.1 shows how to undo it.

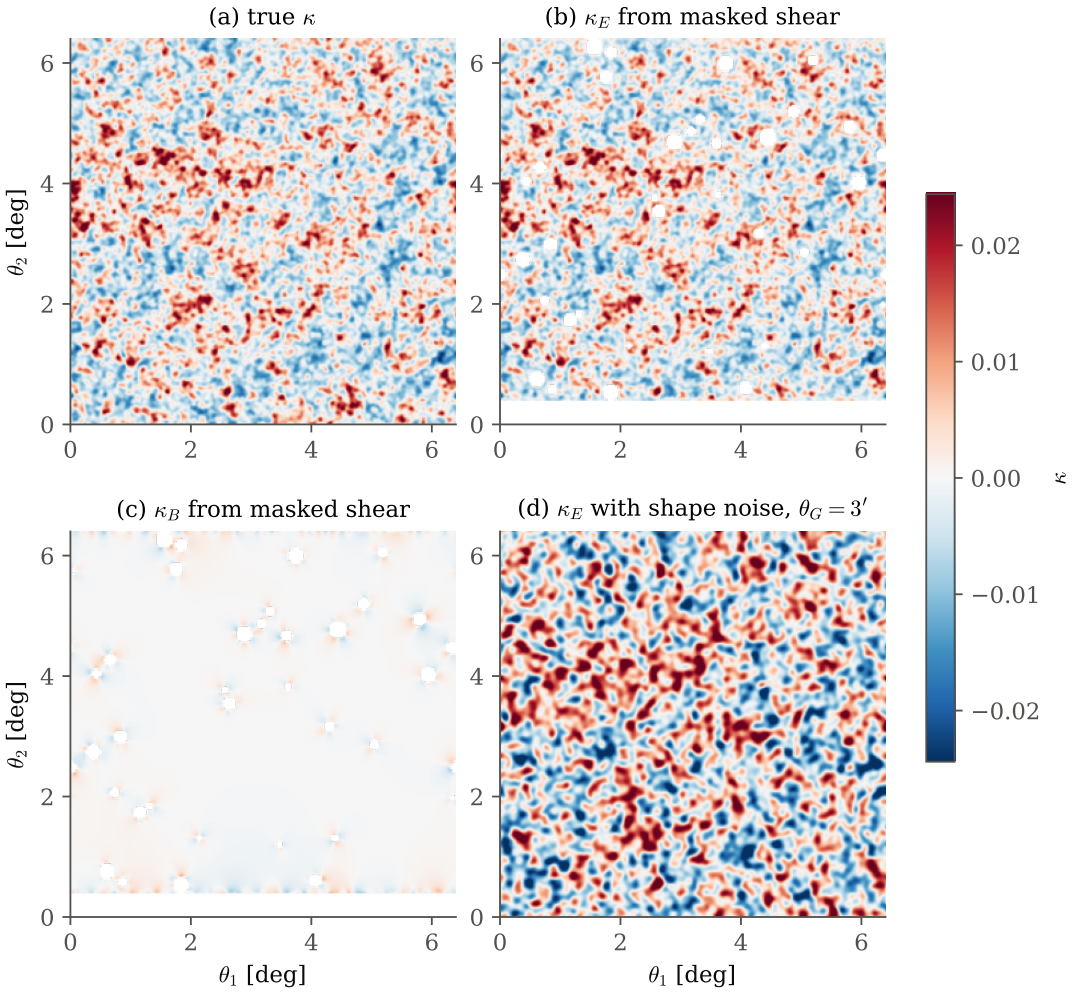

Figure 12.42: (a) A lognormal convergence map (1.5′ smoothing for display). (b) The E map reconstructed from its shear with the mask applied: away from the holes and the edge strip (grey) it is the map of panel (a). (c) The B map of the same masked shear: zero far from the mask, rings around every hole. (d) The E map from the full, unmasked shear with KiDS-like shape noise, smoothed with $\theta_G = 3'$: the strongest peaks of panel (a) survive, the rest of the structure is mixed with noise.

12.18.5 Reproducing a published test: how much to smooth a mass map

Their question. The Dark Energy Survey published mass maps of its Year 3 footprint, 4143 deg^2 of sky. Jeffrey, Gatti and collaborators asked which reconstruction method, and which amount of smoothing, gives the map closest to the truth [54]. The answer matters for anyone who wants to count peaks or voids in the map: too little smoothing and the map is noise; too much and the structures are washed out.

Their setup. A full-sky ray-traced convergence map of [51] played the true sky. They placed the DES Y3 galaxies on it, with the real positions, footprint and weights, $n_{\rm eff} = 5.59$ galaxies per square arcminute, and shape noise drawn by rotating the real ellipticities at random. They reconstructed κ_E by Kaiser–Squires on the sphere at HEALPix $N_{\rm side} = 1024$ (3.44′ pixels), and by three methods with priors, and smoothed the Kaiser–Squires map with Gaussians of standard deviation θ from 0 to 40′.

Their key equation. Their inversion is (12.63); their eq. (22) is its flat-sky form. Their score is the **Pearson correlation coefficient** between the true map κ and the reconstruction $\hat{\kappa}$ [54, eq. 35], the correlation coefficient of Chapter 1 computed over pixels, $r = \langle \kappa\hat{\kappa}\rangle / \sqrt{\langle\kappa^2\rangle\langle\hat{\kappa}^2\rangle}$ (both maps with zero mean). Why should r have a maximum as θ grows? Write the smoothed reconstruction mode by mode as $\hat{\kappa}_\ell = W_\ell(\kappa_\ell + n_\ell)$, with W_ℓ the transform of the smoothing kernel ($e^{-\ell^2\theta^2/2}$ for a Gaussian), C_ℓ the signal power and N the noise power. Different modes are uncorrelated, and the noise is uncorrelated with the signal, so each average is a sum over modes:

$$r \overset{(1)}{=} \frac{\sum_\ell W_\ell C_\ell}{\sqrt{\sum_\ell C_\ell}\,\sqrt{\sum_\ell W_\ell^2 (C_\ell + N)}} \overset{(2)}{=} \frac{\sum_\ell a_\ell b_\ell}{\sqrt{\sum_\ell C_\ell}\,\sqrt{\sum_\ell a_\ell^2}} \overset{(3)}{\le} \left[\frac{\sum_\ell C_\ell^2/(C_\ell + N)}{\sum_\ell C_\ell}\right]^{1/2}, \tag{12.70}$$

(1) Parseval's theorem turns each pixel average into a sum over modes: $\langle\kappa\hat{\kappa}\rangle$ picks up $W_\ell C_\ell$ from each mode, $\langle\hat{\kappa}^2\rangle$ picks up $W_\ell^2(C_\ell + N)$.

(2) Name $a_\ell \equiv W_\ell\sqrt{C_\ell + N}$ and $b_\ell \equiv C_\ell/\sqrt{C_\ell + N}$, so that $a_\ell b_\ell = W_\ell C_\ell$.

(3) The Cauchy–Schwarz inequality, $\sum ab \le \sqrt{\sum a^2}\sqrt{\sum b^2}$, with equality when $a_\ell \propto b_\ell$.

The bound is reached when $W_\ell \propto C_\ell/(C_\ell + N)$: pass a mode in proportion to the fraction of its power that is signal. That filter is the Wiener filter, which is why the Wiener reconstruction of Jeffrey and collaborators beats every smoothed Kaiser–Squires map in their Fig. 6. A Gaussian W_ℓ can only imitate it: it passes everything below $\ell \sim 1/\theta$ and nothing above. If θ is too small, it passes noise-dominated modes, which add to the denominator only; if too large, it removes signal-dominated modes from the numerator. The best θ puts the cut near the multipole where $C_\ell = N$, which moves to higher ℓ, so to smaller θ, as the galaxy density grows. That is the prediction to test.

What we compute. `w02_ks.py` makes 20 lognormal maps, adds the shape noise of three surveys (DES Y3, $n = 5.59$, $\sigma_e = 0.268$; our KiDS-like 6.2 and 0.27; a Stage-IV-like 30 and 0.27), inverts, smooths with θ from 0.75′ to 20′, and computes r against the true map at our 1.5′ resolution and against the true map smoothed to the size of an $N_{\rm side} = 1024$ pixel, which is what they compared with.

Listing 12.13: The Pearson test (`code/ch12/w02_ks.py`)

```
    for i in range(nmap):
        kt = wl.lognormal_map(PG, lam, rng.standard_normal((wl.N, wl.N)))
        t1, t2 = wl.shear_from_kappa(kt)
        # the truth at a HEALPix-like resolution (N_side = 1024 pixels are 3.4 arcmin wide)
        kt_hp = wl.smooth(kt, 3.4 / np.sqrt(12))
        white = rng.standard_normal((2, wl.N, wl.N))
        for name, (n, se) in surveys.items():
            s = wl.sigma_pix(n, se)
            e, _ = wl.kaiser_squires(t1 + s * white[0], t2 + s * white[1])
            for j, th in enumerate(thetas):
                es = wl.smooth(e, th)
                res[name][i, j] = pearson(es, kt)
                res_hp[name][i, j] = pearson(es, kt_hp)
```

Side by side. Figure 12.43 has the predicted shape. For the DES-like density our curve peaks at $\theta = 4'$ with $r = 0.34$; against the pixel-averaged truth at 5′ with $r = 0.44$. The KiDS-like case peaks at 4′ ($r = 0.35$), and the Stage-IV case at 2′ ($r = 0.55$). Jeffrey and collaborators find the Kaiser–Squires r rising from 0.20 unsmoothed to about 0.31 at 10′, nearly flat between 5′ and 15′, and slowly falling beyond [54, Fig. 6].

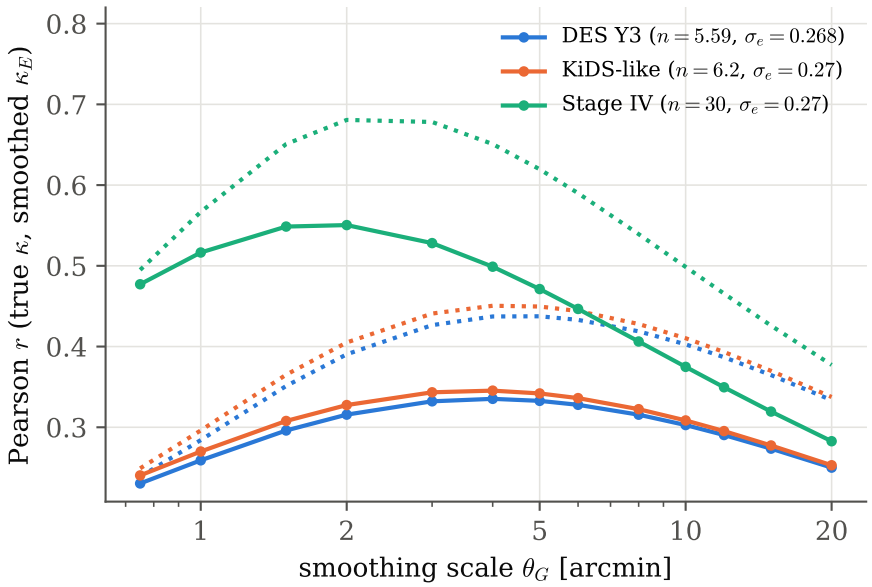

Figure 12.43: Pearson correlation between the true convergence and the smoothed Kaiser–Squires map, as a function of the smoothing scale, for three galaxy densities (solid: truth at our 1.5′ pixels; dotted: truth averaged to the size of a $N_{\rm side} = 1024$ pixel, as in the DES Y3 test). Each curve rises while smoothing removes noise faster than signal and falls once it removes signal; the optimum moves to smaller scales as the galaxy density grows.

Why they differ. The shapes agree and the optimum lies in the same range, a few to ten arcminutes, with ours at the small end and our r a little higher. Three causes push in this direction. Their truth is a ray-traced N-body map, more strongly non-Gaussian than our lognormal one, with more of its signal in compact peaks that smoothing removes. Their footprint has edges and holes everywhere, and Section 12.18.4 showed how a mask lowers the agreement near them; our patch has none. And their effective density varies over the footprint with the depth of the images, while ours is uniform. Their grid of smoothing scales $(0, 5, 10, 15, \dots)$ also cannot resolve a maximum this flat to better than 5′. The galaxy density moves the optimum as (12.70) predicts: from 4′ at $n = 5.59$ to 2′ at $n = 30$.

The lesson. The best smoothing scale is not a property of the method but of the data: it is set by where the signal stops beating the noise, and a mass map from a deeper survey deserves less smoothing. The summaries of Section 12.20 use $\theta_G = 3'$, close to the optimum for our density.

12.19 The two-point analysis: band powers, their errors, and the banana

Every lensing survey so far has drawn its headline number from a two-point statistic: KiDS-1000 from band powers and related statistics, DES Year 3 from the correlation functions $\xi_\pm$, HSC from power spectra (Section T1.7.6). Before asking what the peaks and the topology of the mass map can add, we need the number they must beat, computed in the same setting as everything else: our KiDS-like galaxy density, our source sample, our patches. That calls for three pieces, each met before on the CMB. The band powers must be measured on a patch with holes, which is the pseudo-C_ℓ problem of Section 8.9.3, now for a spin-2 field. Their errors must be known, which is the covariance problem of Section 8.13. And the errors must be turned into errors on (Ω_m, σ_8), which is the Fisher matrix of Section 10.3.

The question. On a KiDS-like survey of 1000 deg^2, can the convergence power spectrum be measured without bias through a mask, and how well does it then measure Ω_m, σ_8 and S_8?

12.19.1 Band powers through a mask: E leaks into B

Recall the pseudo-C_ℓ idea of Section 8.9.3: the power spectrum of a masked map is not the true spectrum, but its *average* is a known linear combination of the true band powers, through a coupling matrix that depends only on the mask; inverting that matrix (MASTER, Section 8.11) removes the bias. For a scalar CMB map the coupling comes from the window alone. Section 12.18.4 found a second effect for shear: the mask also moves power from E to B. We now derive both at once, on the flat periodic patch.

The masked shear, mode by mode. Let the true shear be pure E, $\hat\gamma(\boldsymbol{\ell}) = e^{2i\varphi_\ell}\hat E(\boldsymbol{\ell})$, where $\hat E$ is the transform of the real map κ (12.62). The mask $W(\boldsymbol{\theta})$, one where we see and zero where we do not, multiplies the shear, so its transform $\hat W$ convolves it. On the grid, with $N_{\rm pix}$ pixels, the convolution is a sum over the grid modes $\boldsymbol{\ell}'$. Apply the inversion (12.64) to the masked shear, and call the result $X(\boldsymbol{\ell}) = \hat E_W(\boldsymbol{\ell}) + i\hat B_W(\boldsymbol{\ell})$, where $\hat E_W$ and $\hat B_W$ are the transforms of the two real maps κ_E and κ_B made from the masked shear:

$$
\begin{aligned}
X(\boldsymbol{\ell}) &\overset{(1)}{=} e^{-2i\varphi_\ell}\frac{1}{N_{\rm pix}}\sum_{\boldsymbol{\ell}'}\hat W(\boldsymbol{\ell}-\boldsymbol{\ell}')\,e^{2i\varphi_{\ell'}}\hat E(\boldsymbol{\ell}') = \frac{1}{N_{\rm pix}}\sum_{\boldsymbol{\ell}'}\hat W(\boldsymbol{\ell}-\boldsymbol{\ell}')\,e^{2i(\varphi_{\ell'}-\varphi_\ell)}\hat E(\boldsymbol{\ell}'),\\
\hat E_W(\boldsymbol{\ell}) &\overset{(2)}{=} \tfrac12\big[X(\boldsymbol{\ell}) + X(-\boldsymbol{\ell})^*\big] \overset{(3)}{=} \frac{1}{N_{\rm pix}}\sum_{\boldsymbol{\ell}'}\hat W(\boldsymbol{\ell}-\boldsymbol{\ell}')\cos\big[2(\varphi_{\ell'}-\varphi_\ell)\big]\hat E(\boldsymbol{\ell}'),\\
\hat B_W(\boldsymbol{\ell}) &\overset{(4)}{=} \tfrac{1}{2i}\big[X(\boldsymbol{\ell}) - X(-\boldsymbol{\ell})^*\big] = \frac{1}{N_{\rm pix}}\sum_{\boldsymbol{\ell}'}\hat W(\boldsymbol{\ell}-\boldsymbol{\ell}')\sin\big[2(\varphi_{\ell'}-\varphi_\ell)\big]\hat E(\boldsymbol{\ell}').
\end{aligned}
\tag{12.71}
$$

(1) The transform of a product is the convolution of the transforms (with the $1/N_{\rm pix}$ of the discrete transform); then multiply by the phase of the inversion.

(2) A real map has a transform with $\hat f(-\boldsymbol{\ell}) = \hat f(\boldsymbol{\ell})^*$. X is the transform of the complex map $\kappa_E + i\kappa_B$, and the transform of its real part is the average of $X(\boldsymbol{\ell})$ and $X(-\boldsymbol{\ell})^*$.

(3) In $X(-\boldsymbol{\ell})^*$ rename $\boldsymbol{\ell}' \to -\boldsymbol{\ell}'$ and use $\hat W(-\boldsymbol{q})^* = \hat W(\boldsymbol{q})$ and $\hat E(-\boldsymbol{\ell}')^* = \hat E(\boldsymbol{\ell}')$ (both maps are real), and $\varphi_{-\ell} = \varphi_\ell + \pi$, which leaves $e^{2i\varphi}$ unchanged. It becomes the same sum with $e^{-2i(\varphi_{\ell'}-\varphi_\ell)}$, and $\frac12(e^{ix}+e^{-ix}) = \cos x$.

(4) The imaginary part in the same way, with $\frac{1}{2i}(e^{ix}-e^{-ix}) = \sin x$.

Each true mode $\boldsymbol{\ell}'$ feeds the masked mode $\boldsymbol{\ell}$ with the window's weight $\hat W(\boldsymbol{\ell}-\boldsymbol{\ell}')$, split between E and B by the angle between the two wavevectors. Without a mask $\hat W$ is a spike at zero, only $\boldsymbol{\ell}' = \boldsymbol{\ell}$ contributes, the angle is zero, and everything stays in E. With a mask, nearby wavevectors at an angle leak a fraction $\sin^2$ of their power into B.

The average power. Different true modes are uncorrelated, $\langle \hat E(\boldsymbol{\ell}')\hat E(\boldsymbol{\ell}'')^*\rangle = N_{\rm pix}A_{\rm pix}^{-1}C_{\ell'}\,\delta_{\boldsymbol{\ell}'\boldsymbol{\ell}''}$ on the grid (7.19). Squaring (12.71) and averaging keeps only the diagonal terms:

$$
\langle \tilde C_\ell^E\rangle = \sum_{\boldsymbol{\ell}'} w_2(\boldsymbol{\ell}-\boldsymbol{\ell}')\cos^2\big[2(\varphi_{\ell'}-\varphi_\ell)\big]C_{\ell'}, \qquad \langle \tilde C_\ell^B\rangle = \sum_{\boldsymbol{\ell}'} w_2(\boldsymbol{\ell}-\boldsymbol{\ell}')\sin^2\big[2(\varphi_{\ell'}-\varphi_\ell)\big]C_{\ell'}, \tag{12.72}
$$

with $w_2(\boldsymbol{q}) \equiv \big|\hat W(\boldsymbol{q})\big|^2/N_{\rm pix}^2$ the power of the window. Three checks. Without a mask w_2 is one at $\boldsymbol{q}=\boldsymbol{0}$ and zero elsewhere, and (12.72) returns C_ℓ in E and nothing in B. By Parseval, $\sum_{\boldsymbol{q}} w_2(\boldsymbol{q}) = N_{\rm pix}^{-1}\sum_{\boldsymbol{\theta}} W^2 = f_{\rm obs}$, the observed fraction, so a flat spectrum $C_\ell = N$ put into both E and B (shape noise, Section 12.18.2) comes out as $f_{\rm obs}N$ in each, whatever the angles, since $\cos^2+\sin^2 = 1$: the noise bias of a masked map is simply $f_{\rm obs}N$. And the formula is the flat-sky version of the spin-2 coupling kernels of the MASTER family [140], the scalar case of Eq. (8.60)

with the cosine and sine as the only new ingredient. Binning (12.72) into bands gives four matrices $M^{EE}_{bb'}$, $M^{BE}_{bb'}$ and, by the 45° rotation of Section 12.18.1, $M^{BB} = M^{EE}$ and $M^{EB} = M^{BE}$; the decoupled band powers are the measured pseudo band powers, noise subtracted, multiplied by the inverse of the 2×2 block matrix, as in (8.68).

Listing 12.14: The coupling matrices from the exact average (`code/ch12/w03_twopoint.py`)

```
60 def coupling_exact(mask, P):
61     """The same matrices from the exact expectation (flat-sky MASTER):
62     <p_E(l)> = sum_l' w2(l - l') cos^2[2(phi_l - phi_l')] P(l'),  w2 = |FFT(W)|^2 / N_pix^2,
63     and sin^2 for B; cos^2 = (1 + cos 4 dphi)/2 turns each sum into two FFT convolutions."""

`coupling_exact` evaluates (12.72) without a double sum over modes. The identity $\cos^2 x = \frac{1}{2}(1 + \cos 2x)$ turns the $\cos^2[2\Delta\varphi]$ into $\frac{1}{2}[1 + \mathrm{Re}\, e^{4i(\varphi_{\ell'} - \varphi_\ell)}]$, and each term is a convolution of w_2 with C times a phase, done by FFT in line 70 (the convolution theorem again, now used in reverse). Line 79 is the $e^{4i\varphi}$ term, lines 80–83 add or subtract the two and average over each band. The bands are the eight analysis bands from $\ell = 112$ to 5000 plus one below and one above, since power outside the analysed range also leaks into it. As a check the same matrices are measured by brute force (`coupling`): 100 Gaussian maps with power in one band at a time, masked, inverted, measured. The diagonals agree to 2.4%, the Monte Carlo scatter of 100 maps.

Example: what the coupling matrix says. For our mask ($f_{\rm obs} = 0.907$) the largest off-diagonal entry of M^{EE}, relative to the diagonal, is 2%, and the largest $E \to B$ entry is 1.3% of the diagonal: a mask of small holes couples neighbouring bands only weakly and leaks about one per cent of E into B, the same order as the 2% to 0.9% found from the maps in Section 12.18.4.

Example: the recovered spectrum. `w03_twopoint.py` makes 200 lognormal maps with KiDS-like noise, masks them and measures the band powers three ways (Figure 12.44). The raw masked band powers, noise subtracted, are −18% to −7% off. Dividing by $f_{\rm obs}$, the simplest correction, leaves errors up to 10%. The decoupled band powers deviate by at most 5.4% with a Monte Carlo error of the mean up to 3.1%; over the 8 bands the χ^2 of the mean against the truth is 10.4. The decoupled B band powers give $\chi^2 = 6.9$ for 8 degrees of freedom: consistent with zero, which is the null test of (T1.7) passed on a masked map. The price of the mask is a scatter 1.07 times that of the unmasked patch, close to $1/\sqrt{f_{\rm obs}} = 1.05$: fewer independent modes, as in Section 8.4.2.

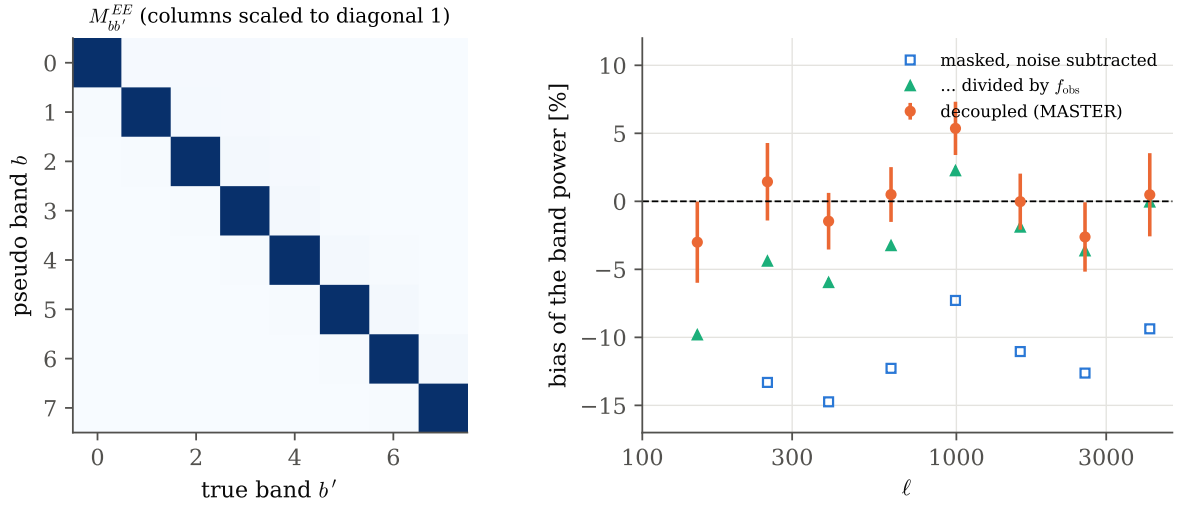

Figure 12.44: Left: the coupling matrix M^{EE} of the masked patch, each column divided by its diagonal entry; it is nearly diagonal. Right: the bias of the band powers over 200 lognormal maps with KiDS-like shape noise. Masked and noise-subtracted (squares): between −18% and −7%, mostly the missing area. Divided by $f_{\rm obs}$ (triangles): up to 10%, varying with ℓ. Decoupled by the inverse coupling matrix (circles, with the Monte Carlo error of the mean): consistent with zero.

12.19.2 How large are the errors? Gaussian formula and simulations

The Gaussian band-power error of (T1.16) assumes that each Fourier mode is a Gaussian variable. On a flat patch of area A it reads as follows. The grid modes form a lattice of spacing $2\pi/L$, with $L^2 = A$, so a ring of radius ℓ and width $\mathrm{d}\ell$ holds $2\pi\ell\,\mathrm{d}\ell/(2\pi/L)^2 = \ell A\,\mathrm{d}\ell/2\pi$ modes. The modes come in pairs $\pm\boldsymbol{\ell}$ with the same power (the map is real), so a band of n_b grid modes has $n_b/2$ independent ones. For a Gaussian mode the measured power $|\hat\kappa|^2$ follows an exponential distribution, whose standard deviation equals its mean $C_\ell + N$ (the χ^2_2 of (7.75), scaled). Averaging $n_b/2$ independent such powers,

$$\mathrm{Var}\,\hat C_b = \frac{(C_b+N)^2}{n_b/2} = \frac{2(C_b+N)^2}{n_b}, \qquad n_b \simeq \frac{A}{2\pi}\int_{\rm band} \ell\,\mathrm{d}\ell. \tag{12.73}$$

On the full sky $A = 4\pi f_{\rm sky}$ and $n_b \simeq \int (2\ell+1) f_{\rm sky}\mathrm{d}\ell$, which is (T1.16) again: the same mode counting in a different coordinate system. Our bands hold from 28 grid modes (the lowest) to 15208 (the highest).

A lognormal field is not Gaussian, and its band powers are not exponential sums: a single bright spot puts power in many modes at once, so the modes are correlated and the variance is larger. `w05_costs.py` compares (12.73) with the scatter of the 1000 lognormal and 600 Gaussian fiducial maps of Section 12.20 (unmasked, with shape noise). For the Gaussian maps the ratio of the simulated to the predicted variance lies between 0.93 and 1.03, within the Monte Carlo error of a variance from 600 maps, $\sqrt{2/(n-1)} = 0.058$; the largest correlation between two bands is 0.11, also noise. For the lognormal maps the ratio runs from 0.98 to 1.04, within their own error of 0.045, and no two bands are correlated by more than 0.08, less than the noise correlation of the Gaussian maps (Figure 12.45): in these maps the excess is too small to see. Shape noise is what rescues the formula: where it dominates $C_b + N$, the noise, which is Gaussian and white, dilutes the non-Gaussian excess of the signal.

This is the situation Section 8.13 described for the CMB, now with a physical cause: the analytic covariance is a good start, and simulations are needed for the part the analytic form leaves out. Research analyses add to the Gaussian term a non-Gaussian term from the

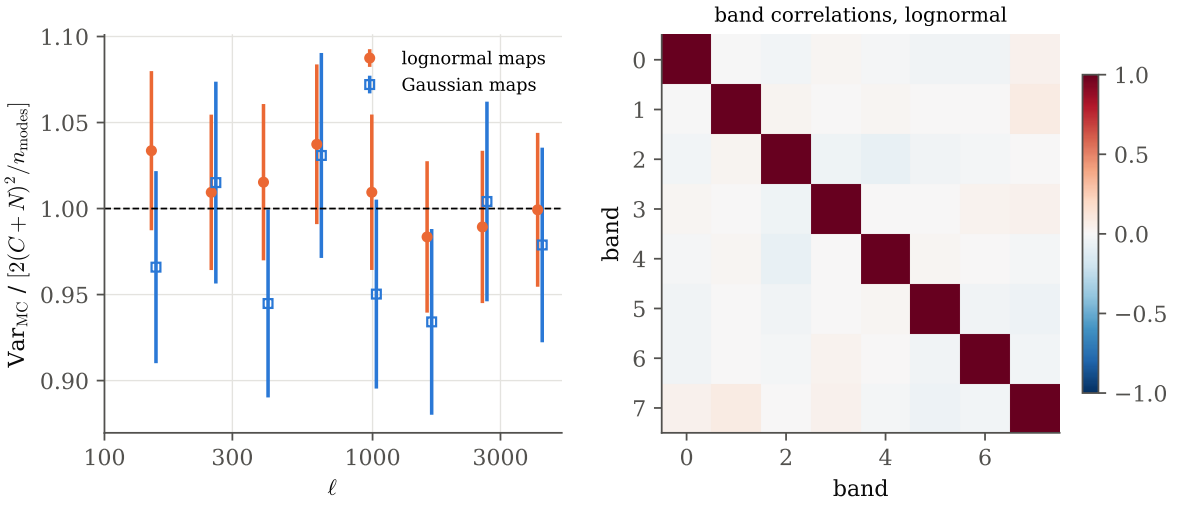

Figure 12.45: Left: the variance of each band power over the simulated maps divided by the Gaussian prediction (12.73), for lognormal and Gaussian maps with the same spectrum and the same shape noise. Right: the correlation matrix of the eight band powers of the lognormal maps. Both sets of maps agree with the formula within the Monte Carlo error, and the lognormal bands are no more correlated than noise allows: with this shape noise the non-Gaussian excess stays below what 1000 maps can detect.

trispectrum and a **super-sample** term, the response of all modes to density fluctuations larger than the survey, and check the sum against hundreds of simulations [45, 51]. Our forecast below uses the Gaussian formula, and Section 12.20 uses the simulated covariance throughout.

12.19.3 From band powers to (Ω_m, σ_8): the Fisher forecast

Recall the Gaussian Fisher matrix (10.20): for a data vector with mean $\boldsymbol{\mu}(\boldsymbol{\theta})$ and a covariance that does not depend on the parameters, $F_{ij} = \partial_i \boldsymbol{\mu}^{\mathsf{T}} \mathbf{C}^{-1} \partial_j \boldsymbol{\mu}$. With independent bands, $\mathbf{C}$ is diagonal with the variances (12.73), so

$$F_{ij} = \sum_b \frac{n_b}{2} \frac{\partial_i C_b \, \partial_j C_b}{(C_b + N)^2}, \qquad \boldsymbol{\theta} = (\Omega_m, \sigma_8), \tag{12.74}$$

the same expression as the signal-to-noise sum (T1.17) with the derivative of the amplitude replaced by the derivatives with respect to the parameters. The derivatives come from the Limber spectra at Ω_m and σ_8 moved by $\pm 5\%$, as central differences (Section 10.5), and the survey is $1000\,\mathrm{deg}^2$ with $n = 6.2\,\mathrm{arcmin}^{-2}$ and $\sigma_e = 0.27$ in one source bin.

Listing 12.15: The Gaussian band-power Fisher matrix (`code/ch12/w03_twopoint.py`)

```
def fisher(dC, C, N, edges, area_deg2):
    """Gaussian band-power Fisher matrix: F_ij = sum_b n_modes,b/2 dC_i dC_j / (C+N)^2,
    with n_modes,b = 2 pi l dl * A / (2 pi)^2 summed over the bin (mode counting on the
    sky)."""
    A = area_deg2 * (np.pi / 180) ** 2
    F = np.zeros((2, 2))
    for lo, hi, in zip(edges[:-1], edges[1:]):
        ell = np.arange(int(np.ceil(lo)), int(np.floor(hi)) + 1)
        nm = ell * A / (2 * np.pi)          # modes per unit l: 2 pi l A /(2 pi)^2, both
    halves
        w = nm / 2 / (C(ell) + N) ** 2
        d = [f(ell) for f in dC]
        for i in range(2):
```

```
            for j in range(2):
                F[i, j] += np.sum(w * d[i] * d[j])
    return F
```

Line 94 counts the modes per unit ℓ on the survey area, line 95 is the weight $n/2\,(C+N)^{-2}$, and the double loop adds the products of derivatives.

The answer. For $100 \le \ell \le 3000$ the marginal errors are $\sigma(\Omega_m) = 0.097$ and $\sigma(\sigma_8) = 0.145$, with a correlation coefficient $r = -0.999$ between them, and the error on S_8 is $\sigma(S_8) = 0.0218$, a precision of 2.6%. The individual errors are large and the combination is small: the ellipse is a long needle along the valley of Section T1.7 (Figure 12.46). Had Ω_m been known, σ_8 would be measured to 0.0069; freeing it inflates the error by the factor $1/\sqrt{1-r^2} = 21.2$ of (T1.19).

Example: why S_8 is not quite the needle. The long axis of the ellipse, in the logarithms of the two parameters, is the direction $\sigma_8\Omega_m^{\alpha} = \text{const}$ with $\alpha = 0.58$, the exponent found multipole by multipole in Section T1.7.5 (there 0.57 at $\ell = 500$). The survey convention fixes $\alpha = 0.5$. Write

$$\ln S_8 \overset{(1)}{=} \ln\sigma_8 + 0.5\ln\Omega_m + \text{const} \overset{(2)}{=} \ln\!\left(\sigma_8\Omega_m^{\alpha}\right) - (\alpha - 0.5)\ln\Omega_m + \text{const},$$
$$\sigma(\ln S_8) \overset{(3)}{\approx} |\alpha - 0.5|\;\sigma(\ln\Omega_m) \approx 0.08 \times \frac{0.097}{0.315} \approx 0.025. \tag{12.75}$$

(1) The definition $S_8 = \sigma_8(\Omega_m/0.3)^{0.5}$.
(2) Add and subtract $\alpha \ln\Omega_m$.
(3) The first term is the best-measured combination, nearly fixed; the second inherits the large error of Ω_m along the needle.

So $\sigma(S_8) \approx 0.025 \times 0.83 \approx 0.021$, which is most of the 0.0218: the error on S_8 is set less by the width of the needle than by the small tilt between the needle and the line of constant S_8. A survey that quotes $\sigma_8\Omega_m^{\alpha}$ with its own α, as HSC does with $\alpha = 0.45$ [49], quotes the narrowest number its data allow.

The banana. The Fisher ellipse is the quadratic approximation of the log-likelihood at the fiducial point (Section 10.1). Away from it the valley curves, because the constant-spectrum line is $\sigma_8 \propto \Omega_m^{-\alpha}$, a curve in the (Ω_m, σ_8) plane. `w03_twopoint.py` also evaluates the Gaussian likelihood of the band powers on a 300×300 grid, with a power-law emulator $C_b(\Omega_m,\sigma_8) = C_b^{\rm fid}(\sigma_8/\sigma_8^{\rm fid})^{a_b}(\Omega_m/\Omega_m^{\rm fid})^{b_b}$ built from the same logarithmic derivatives. Its contours (Figure 12.46) follow the ellipse near the centre and bend into the banana familiar from the published contours. From the grid, with a flat prior over the plotted box, $\sigma(S_8) = 0.0210$ and $\sigma(\Omega_m) = 0.099$, close to the Fisher values: along S_8 the likelihood is Gaussian, and the curvature only bends the long direction.

How the error depends on the scales used. With $\ell_{\max} = 1500$ instead of 3000 the forecast becomes $\sigma(S_8) = 0.0427$; with $\ell_{\max} = 5000$, 0.0170. The gain flattens because beyond the crossing multipole, where $C_\ell = N$ ($\ell \approx 286$ for our density, $\ell \approx 1064$ for a Stage-IV density of 30 arcmin^{-2}), each mode carries the factor $[C/(C+N)]^2$ of Section T1.8.4 and adds little.

12.19.4 Against the published surveys

Section T1.7.6 listed the published precisions: $\sigma(S_8) = 0.0225$ for KiDS-1000 (symmetrised), 0.024 for DES Year 3 and 0.0315 for HSC Year 1. Our 0.0218 for a KiDS-like survey is the same

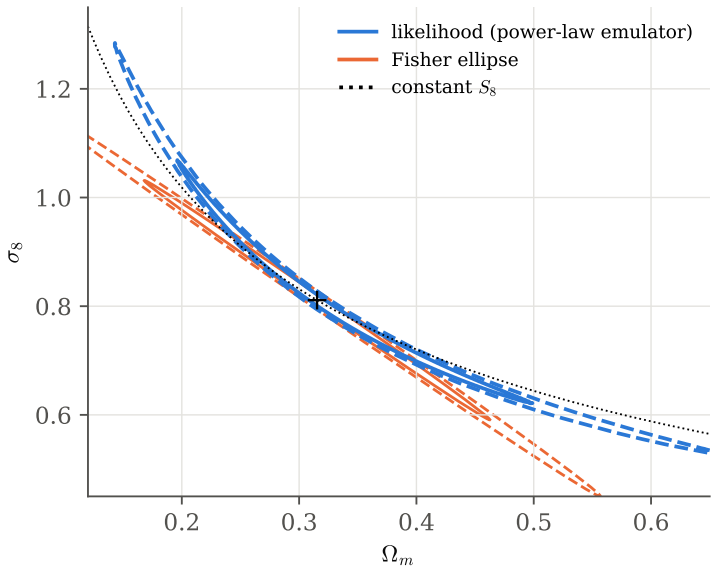

Figure 12.46: The 1σ and 2σ regions ($\Delta\chi^2 = 2.30, 6.18$) for (Ω_m, σ_8) from the convergence power spectrum of a KiDS-like 1000 deg^2 survey, $100 \le \ell \le 3000$, one source bin. The Fisher ellipse (orange) is the tangent approximation; the likelihood on a grid (blue) curves into a banana along the dotted line of constant S_8.

size. That agreement is a coincidence of errors that point in opposite directions, and it is worth taking apart, because each piece is a choice every analysis makes.

- *We use more scales.* KiDS-1000 uses band powers for $100 \le \ell \le 1500$ [45], HSC $300 \le \ell \le 1900$ [49]; small scales are cut because baryonic feedback and the non-linear model are uncertain there (Section T1.6). Cutting ours at 1500 doubles our error, to 0.0427.

- *We have no nuisance parameters.* Photometric-redshift shifts, the shear calibration m, intrinsic alignments and baryons are all marginalised in the real analyses. Each adds a direction in parameter space along which the spectrum can change, and (T1.19) says what that costs; Section 12.21 computes the cost of m.

- *We have no tomography.* KiDS-1000 splits its sources into five redshift bins. Each bin has its own exponent α (Figure T1.10), so the five needles are not parallel, and their intersection is much shorter than any one of them. This is what lets KiDS, with nuisances and a lower $\ell_{\max}$, reach 0.0225 while our single bin to $\ell = 1500$ reaches only 0.0427.

- *Our covariance is Gaussian.* The non-Gaussian variance, hidden by shape noise in Figure 12.45 but present in the signal, and the super-sample term both widen the real errors.

The lesson of the comparison: a forecast that matches a published error bar has not been validated by it; only a forecast that includes the same scales, nuisances and covariance terms can be compared number to number. What we can do honestly is compare summaries with each other under identical simplifications: whatever the nuisances do to the spectrum, they do to the peaks and the islands too.

12.20 Beyond two points: peaks, shapes and persistence of the mass map

The power spectrum of Section 12.19 pins down one combination of Ω_m and σ_8 and leaves the other almost free. Section 12.17.2 found a property of the map that responds to the two parameters differently: the lopsidedness of the convergence, whose reduced skewness is $3/\lambda$, set by the empty-beam shift and so by Ω_m alone. Two universes on the same S_8 line have the same spectrum, but the one with less matter, more clumped, has rarer and taller peaks and wider, shallower voids. The power spectrum cannot see this; it is blind to the phases of the Fourier modes, where that arrangement lives (Section 7.13). The peaks, islands and lakes of the map can.

The question. For the noisy signal-to-noise map of a KiDS-like survey, how well does each of four summaries (peak counts, Minkowski functionals, Betti curves, persistent Betti numbers) measure (Ω_m, σ_8), how much does each add to the power spectrum, and does the gain disappear, as it must, when the map is Gaussian?

12.20.1 Four summaries of one map

All four are computed from the same object: the κ_E map reconstructed from noisy shear (Section 12.18.1), smoothed with a Gaussian of $\theta_G = 3'$ and divided by the rms of the smoothed shape noise, $\sigma_{\rm noise} = 0.0102$ (12.65). This is the **signal-to-noise map** $\nu(\boldsymbol{\theta}) = \kappa_{E,s}(\boldsymbol{\theta})/\sigma_{\rm noise}$. The divisor is a fixed number, the same for every cosmology, so that a threshold $\nu = 2$ means the same convergence in every map, and the parameters can move the summaries. (Dividing each map by its own rms, as one does for a Gaussian field in Section 12.2, would remove the amplitude information we want to keep.) The thresholds are in the range $-1.5 \le \nu \le 3$, where the excursion sets are neither empty nor everything.

- *Peak counts.* A **peak** is a pixel higher than all eight of its neighbours. We histogram the heights ν of all peaks in eleven bins from -1 to 12. A peak is a local event; its count at height ν is the number of maxima of the field there, the quantity whose Gaussian average the Kac–Rice method of Section 12.5.2 gives.
- *Minkowski functionals.* At each of ten thresholds, the area fraction V_0, the boundary length per unit area V_1 and the Euler characteristic per unit area V_2 of the excursion set $\{\nu \ge \nu_t\}$ (Section 12.4.1): thirty numbers.
- *Betti curves.* At the same thresholds, the number of islands β_0 and of lakes β_1 of the excursion set (Section 12.9.3): twenty numbers. In the plane $V_2 \times \text{area} = \beta_0 - \beta_1$ at every threshold where the set does not wrap around the periodic patch.
- *Persistent Betti numbers.* From the persistence diagrams of the superlevel filtration (Section 12.9), for each pair of thresholds $\nu_{\rm lo} \le \nu_{\rm hi}$ from the grid $\{-1, 0, 1, 2, 3\}$, the number of islands, and separately of lakes, that exist at every level between them.

Working definition 12.6 (Persistent Betti number)

Lower a threshold ν through a map. Each island (or lake) of the excursion set $\{\nu(\boldsymbol{\theta}) \ge \nu\}$ is born at a level b and dies at a level $d < b$ (Section 12.9). The **persistent Betti number**

$$\beta_n(\nu_{\rm hi}, \nu_{\rm lo}) \equiv \#\big\{(b,d) \text{ in the diagram of dimension } n:\ b \ge \nu_{\rm hi} \text{ and } d < \nu_{\rm lo}\big\}, \qquad \nu_{\rm lo} \le \nu_{\rm hi},$$

counts the features alive over the whole range $[\nu_{\rm lo}, \nu_{\rm hi}]$ [born at or above the upper level,

not yet dead at the lower one]. For $\nu_{\text{lo}} = \nu_{\text{hi}} = \nu$ it is the ordinary Betti number $\beta_n(\nu)$ of (12.41).

This is eq. (10) of Heydenreich, Brück and Harnois-Déraps [56], translated. They lower nothing: they raise a threshold t through the signal-to-noise map and study the sets $\{\nu \le t\}$, the **sublevel** filtration, in which a minimum of the map starts a component and a maximum starts a hole. Our superlevel filtration of ν is their sublevel filtration of $-\nu$, so their interval $[t_i, t_j)$ is our pair $(b, d) = (-t_i, -t_j)$ and their condition $t_i \le t \le t' < t_j$ is ours with $\nu_{\text{hi}} = -t$, $\nu_{\text{lo}} = -t'$. In our convention the peaks of the map are islands, which matches the way we think of a mass map.

What persistence sees that counts do not: three small maps. Heydenreich and collaborators illustrate the difference with three tiny maps [56, Fig. 4], redrawn in Figure 12.47: a 7×10 grid of signal-to-noise values, zero except in a few pixels. Map 1 has four isolated spikes of heights 4, 3, 2 and 1. Map 2 has the same four peak heights, but the 4, the 3 and the 2 sit on one plateau of 1s and 2s, with only the 1 isolated. Map 3 has two separate hills, a 4 on a ring of 2s and a 3 on a ring of 1s. Pixels touch through edges and corners, as in Section 12.2.2.

	map 1	map 2	map 3
peak heights	4, 3, 2, 1	4, 3, 2, 1	4, 3
islands $\beta_0(\nu)$ at $\nu = 1, 2, 3, 4$	4, 3, 2, 1	2, 2, 2, 1	2, 2, 2, 1
island diagram (b, d)	$(4, \cdot), (3, 0), (2, 0), (1, 0)$	$(4, \cdot), (3, 2), (2, 1), (1, 0)$	$(4, \cdot), (3, 0)$
$\beta_0(\nu_{\text{hi}}{=}2, \nu_{\text{lo}}{=}1)$	3	1	2

Figure 12.47: Three signal-to-noise maps after [56, Fig. 4] (darker means higher). Peak counts cannot tell map 1 from map 2; Betti curves cannot tell map 2 from map 3; the persistence diagrams, and the persistent Betti number in the last row, differ for all three. The dot in $(4, \cdot)$ marks the island that never dies.

Work through them in the order of the question *what does each summary record? Peaks.* A pixel counts if it is higher than all eight neighbours. In map 2 the 3 (third row) has neighbours 2, 1, 1, 2, 1, 1, 1, 1, all lower, so it is a peak; so is the 2 in the fifth row, surrounded by 1s, and the lone 1, surrounded by 0s. Maps 1 and 2 both have peaks of heights 4, 3, 2, 1: identical peak counts. *Betti numbers.* Lower the threshold. In map 2 the set $\{\nu \ge 3\}$ is the 4 and the 3, two islands (the 2 between them is not yet dry); at $\nu = 2$ the 2s join the 4 and the 3 into one island while the lower 2 appears on its own, still two; at $\nu = 1$ the plateau is one island and the lone 1 another, still two; only the 4 is above 4. So $\beta_0 = 2, 2, 2, 1$ at $\nu = 1, 2, 3, 4$, the same as map 3, where the two hills stay apart at every level above zero. *Persistence.* The elder rule of Section 12.9 records when each island is absorbed. In map 2 the 3 is absorbed into the 4 at level 2, the pass between them, so its pair is $(3, 2)$; the 2 in the fifth row joins the plateau at level 1, $(2, 1)$; the lone 1 joins at 0, when the background goes dry, $(1, 0)$. In maps 1 and 3 every island survives until the background joins it at 0. The diagrams differ for all three maps. A single persistent Betti number already separates them: $\beta_0(2, 1)$ counts the islands born at or above 2 that are still separate at level 1, which is 3 in map 1 (the 4, 3 and 2), 1 in map 2 (only the 4; the 3 and the 2 merged before level 1) and 2 in map 3. Peaks record heights, Betti numbers record

how many pieces there are at each level, and persistence records how the pieces are connected across levels: whether a peak stands alone or sits on the shoulder of a bigger one.

`w04_beyond.py` repeats the three maps by machine, with the union–find code of Section 12.11.1 and with its periodic version used for the simulated maps; the diagrams of the two *agree* exactly.

The periodic version needs one more idea, for the lakes. On a patch that wraps around, there is no open sea to tell a lake from the rest of the water, so the trick of Section 12.11.1 (surround the map by sea) is not available. What is available is a duality between land and water. *When is a lake born?* At the level s where the land closes a ring around a body of water, which is the level where, seen from the water's side, two water bodies stop being connected: the pass between them. *When does it die?* At the level m where the last water inside the ring dries up, which is the water body's lowest point. So a lake of the land with pair $(b, d) = (s, m)$ is the same object as a water body that, as the level is *raised*, appears at its bottom m and merges with another body at the pass s. Raising the level through ν is lowering it through $-\nu$, so the water bodies are the islands of $-\nu$, and the lakes of the map come from the same union–find run on $-\nu$, with four neighbours instead of eight (two water pixels that touch only at a corner are separated by the land pixels that touch there). The two rings that wrap around the periodic patch never close up and have no pair; they are left out. The persistence diagrams of all 1600 fiducial maps were also computed separately, from the same seeds, with `gudhi`'s `PeriodicCubicalComplex` (`w04b_gudhi_check.py`); the Betti and persistent Betti numbers of the two codes differ by at most 0.

On a simulated 256×256 map, β_0 from the persistence diagram matches the component count of `lib_topo` at all ten thresholds (largest difference 0), and $\beta_0 - \beta_1$ matches the cubical Euler characteristic of Section 12.2.3 at every threshold $\nu \geq 1$, where nothing wraps around the patch (largest difference 0).

Redundancy between the summaries. The diagonal of the persistent Betti numbers repeats the Betti curves, and V_2 repeats $\beta_0 - \beta_1$. In a combined data vector such exact repetitions make the covariance matrix singular, and its inverse meaningless. When persistent Betti numbers are combined with Minkowski functionals we therefore keep only their off-diagonal entries, $\nu_{\rm lo} < \nu_{\rm hi}$, which hold the information the counts at single levels do not.

12.20.2 The machinery: simulated covariance, common random numbers, and a biased Fisher matrix

None of these summaries has a formula for its mean as a function of (Ω_m, σ_8) for a non-Gaussian map, nor for its covariance. Both come from simulations. The Fisher matrix of a data vector $\boldsymbol{s}$ with mean $\boldsymbol{\mu}(\boldsymbol{\theta})$ and covariance $\mathbf{C}$ is still $F_{ij} = \partial_i \boldsymbol{\mu}^{\mathsf{T}} \mathbf{C}^{-1} \partial_j \boldsymbol{\mu}$ (eq. 10.20, treating $\boldsymbol{s}$ as Gaussian, which a sum over many peaks or pixels nearly is), but now every ingredient is estimated, and each estimate has its own error.

The covariance. 1000 lognormal maps of the fiducial cosmology, each with independent shape noise, give the sample covariance $\hat{\mathbf{C}}$. Its inverse is biased high, and (8.78) gives the correction: multiply $\hat{\mathbf{C}}^{-1}$ by $(n - p - 2)/(n - 1)$, with n maps and p entries in the data vector [6]. For the largest data vector, $p = 65$, the factor is 0.93.

The derivatives. At each of 800 seeds we make four maps, with Ω_m and σ_8 in turn moved by $\pm 10\%$, and difference them: $\boldsymbol{D}_k = [\boldsymbol{s}(\theta_i + h_i) - \boldsymbol{s}(\theta_i - h_i)]/2h_i$ for seed k, and the derivative is the average over seeds. Why the same seed for all four? The scatter of a difference is

$$\operatorname{Var}\big[s(\theta + h) - s(\theta - h)\big] = \operatorname{Var} s(\theta + h) + \operatorname{Var} s(\theta - h) - 2 \operatorname{Cov}\big[s(\theta + h), s(\theta - h)\big], \quad (12.76)$$

and if the two maps share their white noise and their shape noise, they differ only through the small change of cosmology, the covariance is almost as large as the variances, and the difference is almost noise-free. These are **common random numbers**, the antithetic pairs of Section 6.15.1 used the other way round: there a negative covariance shrinks the variance of a sum, here a positive one shrinks the variance of a difference. For the power spectrum the cancellation is nearly perfect. For counts it is not: a 10% change of σ_8 lifts some peaks across a bin edge and joins some islands, and these whole-unit jumps differ from seed to seed. That is why the steps are ±10% here, twice those of the power spectrum, at the cost of four more CAMB runs (`w04a_spectra.py`): the jumps grow in proportion to the step, the difference divided by $2h$ shrinks, and the noise of the derivative falls.

The bias this noise causes. Write the estimated derivative as the true one plus an error, $\hat{\boldsymbol{d}}_i = \boldsymbol{d}_i + \boldsymbol{\epsilon}_i$, with $\langle\boldsymbol{\epsilon}_i\rangle = 0$ and, for $N_{\rm der}$ independent seeds, $\langle\boldsymbol{\epsilon}_i\boldsymbol{\epsilon}_j^{\mathsf{T}}\rangle = \boldsymbol{\Sigma}_{ij}/N_{\rm der}$, where $\boldsymbol{\Sigma}_{ij}$ is the covariance of the per-seed derivatives $\boldsymbol{D}_k$. The Fisher matrix is quadratic in the derivatives, and a quadratic form of a noisy vector is biased, exactly as the power of a noisy map is (8.19):

$$\begin{aligned}\left\langle \hat{\boldsymbol{d}}_i^{\mathsf{T}}\mathbf{C}^{-1}\hat{\boldsymbol{d}}_j\right\rangle &\overset{(1)}{=} \boldsymbol{d}_i^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}_j + \boldsymbol{d}_i^{\mathsf{T}}\mathbf{C}^{-1}\langle\boldsymbol{\epsilon}_j\rangle + \langle\boldsymbol{\epsilon}_i\rangle^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}_j + \left\langle\boldsymbol{\epsilon}_i^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\epsilon}_j\right\rangle \\ &\overset{(2)}{=} F_{ij} + \mathrm{Tr}\left[\mathbf{C}^{-1}\langle\boldsymbol{\epsilon}_j\boldsymbol{\epsilon}_i^{\mathsf{T}}\rangle\right] \overset{(3)}{=} F_{ij} + \frac{\mathrm{Tr}\left[\mathbf{C}^{-1}\boldsymbol{\Sigma}_{ji}\right]}{N_{\rm der}}.\end{aligned} \tag{12.77}$$

(1) Insert $\hat{\boldsymbol{d}} = \boldsymbol{d} + \boldsymbol{\epsilon}$ and multiply out.
(2) The cross terms vanish because $\langle\boldsymbol{\epsilon}\rangle = 0$; a number equals its own trace, and $\mathrm{Tr}(\boldsymbol{a}^{\mathsf{T}}\mathsf{M}\boldsymbol{b}) = \mathrm{Tr}(\mathsf{M}\boldsymbol{b}\boldsymbol{a}^{\mathsf{T}})$.
(3) The covariance of an average of $N_{\rm der}$ independent terms is that of one term divided by $N_{\rm der}$.

The bias is positive on the diagonal: noise in the derivatives looks like extra sensitivity. On its own it is small: for the largest data vector, 0.7% of the largest diagonal entry. But the quantity we care about is not on the diagonal. The ellipse is a needle because its two derivative vectors are nearly parallel. With correlation coefficient r between the two parameter errors, the smallest eigenvalue of $\mathbf{F}$, the one that measures the width across the needle, is a fraction of order $1 - r^2$ of the diagonal (for two equal diagonal entries a and off-diagonal ra the eigenvalues are $a(1 \pm r)$, and $1 - |r| \approx (1 - r^2)/2$). For the power spectrum $r = -0.998$, so $1 - r^2 \approx 0.4\%$ and the smallest eigenvalue is about 0.2% of the diagonal. A bias of 0.7% of the diagonal is then larger than the true width: noise in the derivatives turns two parallel vectors into two vectors at an angle, and an angle is exactly what breaks a degeneracy. The symptom is unmistakable in the Gaussian control of Section 12.20.3: without a correction, the Minkowski functionals of Gaussian maps give a smaller error on S_8 than the power spectrum (0.0139 against 0.0164), and adding them to the spectrum multiplies the figure of merit by 1.48. Both are impossible, since for a Gaussian field the spectrum holds all the information (Section 7.2).

Watch out: A Fisher matrix from simulated derivatives is optimistic

Estimated derivatives add the positive term (12.77) to the Fisher matrix, and its effect on the error along a degeneracy can be larger than the true information. Use common random numbers, steps large enough that counts change by many units, and many seeds; subtract the bias; and bracket the answer with an estimate that is biased the other way.

We report three estimates. The *plain* one, $\hat{\boldsymbol{d}}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\hat{\boldsymbol{d}}$ with the Hartlap factor, is biased high. The *corrected* one subtracts (12.77), with $\boldsymbol{\Sigma}_{ij}$ estimated from the scatter of the per-seed derivatives. The *compressed* one splits the seeds in two halves: the first half defines two combinations of the data vector, $t_i = \hat{\boldsymbol{d}}_i^{(1)\mathsf{T}}\hat{\mathbf{C}}^{-1}\boldsymbol{s}$, one per parameter (a linear compression in the spirit of the score of

Section 10.1.2), and the second half measures how t responds to the parameters; then the halves swap and the two results are averaged. Noisy compression vectors only lose information, and the second half's noise enters a two-entry vector instead of a p-entry one, so this estimate is biased low. The truth lies between the compressed and the plain values, and the corrected value is our best estimate.

12.20.3 What the simulations say

The signal-to-noise maps $\nu(\boldsymbol{\theta})$ of Section 12.20.1, the four summaries computed on them and the simulated Fisher machinery of Section 12.20.2 are all we need. `w04_beyond.py` makes 1000 fiducial lognormal maps for the covariance and 800 seeds of four shifted maps each for the derivatives; then the same again with Gaussian maps of the same spectrum (600 and 400), the control in which every gain over the power spectrum must vanish. That is 6400 maps of 256×256 pixels. Each patch is $6.4 \times 6.4\,\mathrm{deg}$; the Fisher matrices are multiplied by 24.4, the number of such patches in a $1000\,\mathrm{deg}^2$ survey, treating the patches as independent.

How the summaries respond. Figure 12.48 shows, for four of the summaries, how the mean of each entry moves when $\ln\sigma_8$ or $\ln\Omega_m$ changes, in units of the scatter of that entry on one patch. More clumping (larger σ_8) moves peaks from the middle heights to the top: fewer peaks at $\nu \approx 1$, more above $\nu \approx 3$. The Euler characteristic and the island count follow the same pattern, since at high thresholds islands are almost all there is, and the lakes respond where the excursion set is mostly land, below $\nu \approx 0$. The two curves in each panel have nearly the same shape, the Ω_m curve about half the σ_8 curve.

Example: reading the degeneracy off the responses. Suppose every entry μ_a of a summary had $\partial\mu_a/\partial\ln\Omega_m = \alpha\,\partial\mu_a/\partial\ln\sigma_8$ with one number α for all a. Move the parameters by $\delta\ln\sigma_8$ and $\delta\ln\Omega_m$:

$$\delta\mu_a \overset{(1)}{=} \frac{\partial\mu_a}{\partial\ln\sigma_8}\,\delta\ln\sigma_8 + \frac{\partial\mu_a}{\partial\ln\Omega_m}\,\delta\ln\Omega_m \overset{(2)}{=} \frac{\partial\mu_a}{\partial\ln\sigma_8}\left(\delta\ln\sigma_8 + \alpha\,\delta\ln\Omega_m\right) \overset{(3)}{=} \frac{\partial\mu_a}{\partial\ln\sigma_8}\,\delta\ln\left(\sigma_8\Omega_m^{\alpha}\right). \tag{12.78}$$

(1) First-order Taylor expansion of the mean in the two log-parameters.
(2) The assumed proportionality of the two responses.
(3) $\delta\ln\sigma_8 + \alpha\,\delta\ln\Omega_m = \delta\ln(\sigma_8\Omega_m^{\alpha})$.

Every entry would then move only through the single combination $\sigma_8\Omega_m^{\alpha}$; a change along the line $\sigma_8\Omega_m^{\alpha} = \text{const}$ would change nothing, and the Fisher matrix would have a zero eigenvalue. With the ratio of about one half read from Figure 12.48, the combination is close to $\sigma_8\Omega_m^{0.5} \propto S_8$: the peaks, islands and lakes of the map feel the same degeneracy as the power spectrum, for the same reason (the amplitude of the convergence is set mainly by S_8, Section T1.7). Whatever a summary measures beyond S_8 comes from the entries where the ratio differs from one half, which is why the derivative noise of (12.77), which also changes that ratio, is so dangerous.

The numbers. Table 12.1 lists, for each summary and for its combination with the power spectrum, the forecast error on S_8 and the figure of merit $1/\sqrt{\det\boldsymbol{\Sigma}}$ of Section 10.4.6, where $\boldsymbol{\Sigma} = \mathbf{F}^{-1}$ is the 2×2 covariance of (Ω_m, σ_8), divided by that of the power spectrum alone. All use the corrected estimate of Section 12.20.2; the plain estimate of the Gaussian control is shown too, to make the bias visible.

The control first. For Gaussian maps, adding any summary to the power spectrum must leave the figure of merit unchanged, because the spectrum holds all the information about a

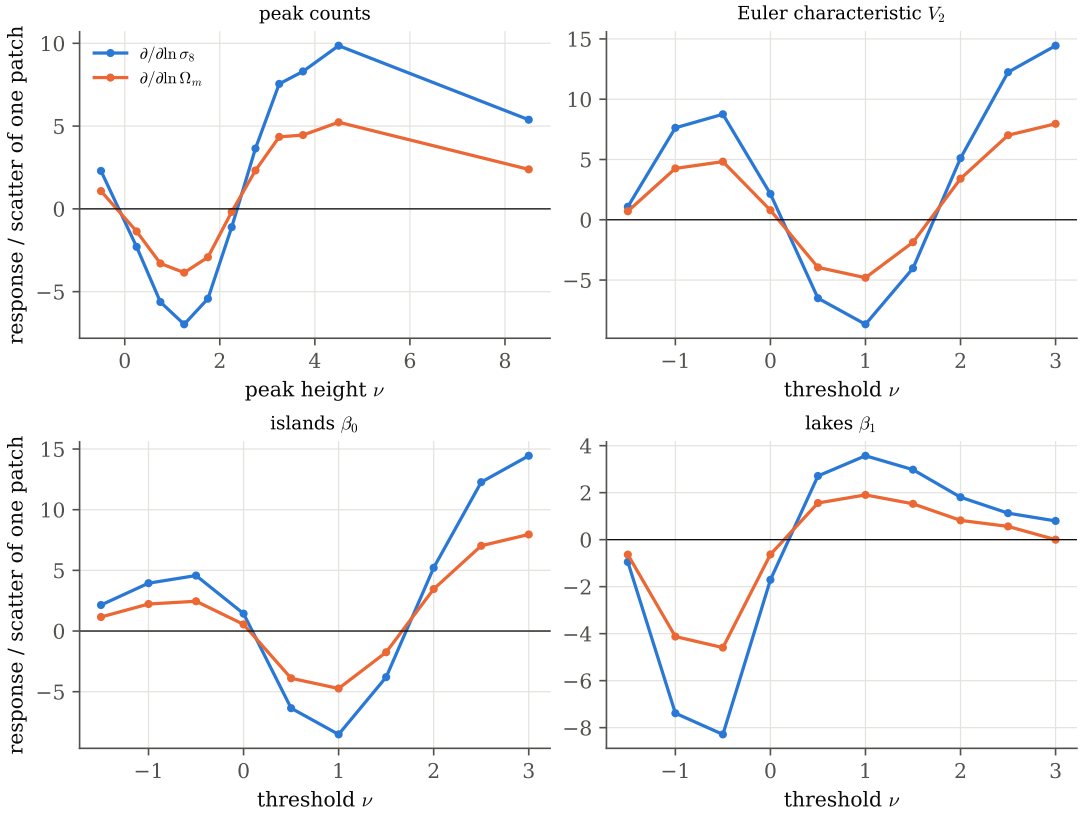

Figure 12.48: The response of four summaries of the signal-to-noise map to $\ln \sigma_8$ (blue) and $\ln \Omega_m$ (orange), each divided by the scatter of that entry on one 41 deg^2 patch. The orange curve is nearly the blue one halved: this is the S_8 degeneracy, entry by entry. The small departures from exact proportionality are what lets a summary measure the two parameters separately.

	lognormal maps		Gaussian maps (control)		
summary	$\sigma(S_8)$	FoM/FoM$_{C_\ell}$	$\sigma(S_8)$	FoM/FoM$_{C_\ell}$	plain estimate
C_ℓ (8 bands)	0.0164	1	0.0164	1	1
peaks (11)	0.0130	0.77	–	–	0.23
Minkowski (30)	0.0127	1.00	0.0365	0.32	0.97
Betti (20)	0.0184	0.50	0.0226	0.39	0.63
persistent Betti (26)	0.0173	0.49	0.0357	0.21	0.49
C_ℓ + peaks	0.0112	1.55	0.0163	1.00	1.08
C_ℓ + Minkowski	0.0111	1.59	0.0148	1.10	1.48
C_ℓ + Betti	0.0132	1.29	0.0148	1.11	1.31
C_ℓ + persistent Betti	0.0131	1.30	0.0147	1.11	1.30
all four	0.0109	1.63	0.0147	1.10	1.63

Table 12.1: Forecasts for (Ω_m, σ_8) from a KiDS-like 1000 deg^2 survey, one source bin, from each summary of the signal-to-noise map and from its combination with the power spectrum. The number of entries of each data vector (lognormal case) is in brackets; entries that never change are dropped. FoM is the figure of merit $1/\sqrt{\det \boldsymbol{\Sigma}}$; for the power spectrum it is 2321 (lognormal) and 2207 (Gaussian). The last column is the FoM ratio of the Gaussian control before the derivative-noise bias is subtracted. For Gaussian maps the corrected peak matrix is not positive: its measured width across the needle is pure noise.

Gaussian field. The corrected estimates give gains between 1.00 and 1.11, above one by up to about ten per cent: that excess is the residual error of our estimator, and any lognormal gain smaller than it means nothing. The plain estimates give gains up to 1.48, and would have announced a discovery. On their own, the counts of a Gaussian map are much weaker than its spectrum (FoM ratios between 0.21 and 0.39, and for the peaks so little that the corrected matrix is not even positive): they see the amplitude through the heights in units of a fixed $\sigma_{\rm noise}$, but they lose the scale information of eight separate bands.

Now the lognormal maps. Each summary alone is roughly as strong as the power spectrum: the Minkowski functionals match its figure of merit (1.00), and peaks fall a little short of it (0.77) but give a smaller error on S_8 (0.0130 against 0.0164, 20% less). The Betti curves and the persistent Betti numbers are weaker, about half the figure of merit of the spectrum. Combined with the spectrum, every summary helps by far more than the ten per cent the control allows: peaks multiply the figure of merit by 1.55, Minkowski functionals by 1.59, Betti and persistent Betti numbers by about 1.29, and all four together by 1.63, with $\sigma(S_8)$ down by 33%. Figure 12.49 shows why the combination does so much more than the parts. All the ellipses are needles along the same S_8 line; they differ slightly in angle, and two needles at a slight angle cross in a short segment.

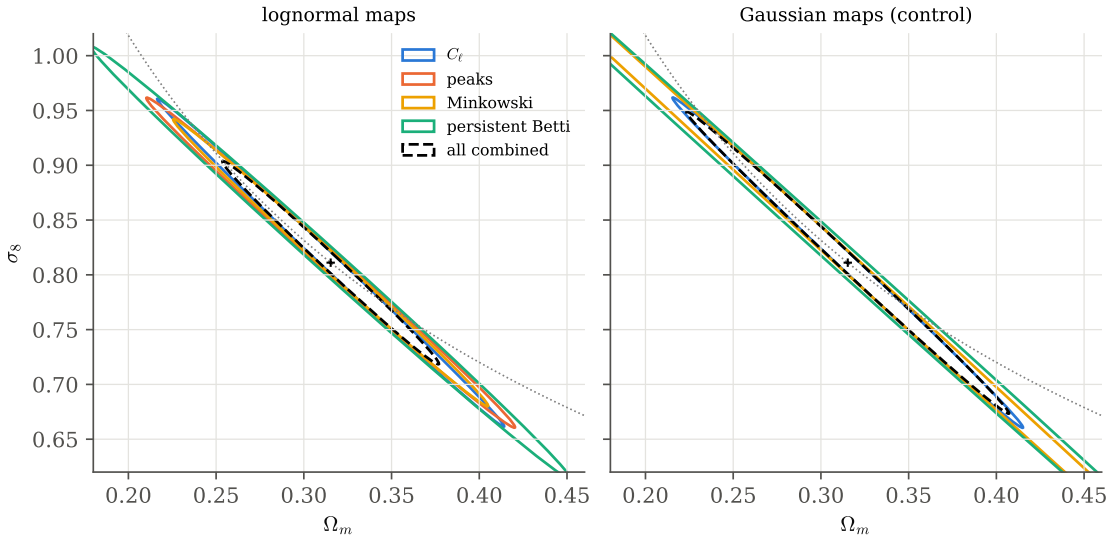

Figure 12.49: The 1σ Fisher ellipses ($\Delta\chi^2 = 2.30$) of (Ω_m, σ_8) for a $1000\,\mathrm{deg}^2$ survey, with the derivative-noise bias subtracted. Left: lognormal maps; the dashed ellipse, all four summaries together, is the shortest. Right: Gaussian maps of the same spectrum; the combination is hardly shorter than the power spectrum, as it must be. The dotted curve is the line of constant S_8. The Gaussian peak ellipse is missing because its corrected Fisher matrix is not positive.

Where the extra information comes from. Section 12.17.2 gave the answer before any simulation: the reduced skewness of a lognormal map is $3/\lambda$, and the empty-beam depth λ depends on Ω_m but not on σ_8. Two universes on the same S_8 line have the same spectrum but differently lopsided maps. Every one of our summaries sees the lopsidedness: the peak heights through the long upper tail, the Minkowski functionals and Betti numbers through the asymmetry between high and low thresholds. That is the lever on the valley, and the Gaussian control, which has no lopsidedness, has no lever.

Example: how much a covariance from simulations costs. The Hartlap factor $(n-p-2)/(n-1)$ of (8.78) rescales the inverse covariance. For all four summaries together, $p = 65$ entries from

$n = 1000$ maps:

$$\frac{n-p-2}{n-1} = \frac{1000-65-2}{999} \overset{(1)}{=} 0.934, \qquad \frac{\sigma_{\text{corrected}}}{\sigma_{\text{naive}}} \overset{(2)}{=} \left(\frac{n-p-2}{n-1}\right)^{-1/2} = 1.03.$$

(1) Arithmetic: 933/999.

(2) The Fisher matrix is proportional to $\hat{\mathbf{C}}^{-1}$, so it shrinks by the factor, and errors, which go as $\mathbf{F}^{-1/2}$, grow by its inverse square root.

A 3% correction. With the 126 simulations that Heydenreich and collaborators used for their covariance [56], the same data vector would have $(126-65-2)/125 = 0.47$: errors 46% larger, and the correction itself uncertain. That is why they kept their data vectors short and why they used the t-likelihood of Section 12.21 instead of the factor. Simulations for the covariance are the hidden price of every summary with many entries.

Example: what a figure-of-merit ratio means for the ellipse. For a 2×2 covariance $\mathbf{\Sigma}$ the ellipse $\Delta\chi^2 = q$ has area $\pi q \sqrt{\det \mathbf{\Sigma}}$ (Section 10.4.6), so the ratio of two figures of merit is the inverse ratio of the areas of their ellipses, at any confidence level. All four summaries together with the spectrum have 1.63 times the figure of merit of the spectrum alone, so their ellipse covers the fraction 1/1.63 of the area. Which dimension shrank? The area of a needle is its length times its width. The width, the error on the best-measured combination $\sigma_8\Omega_m^\alpha$, is set by the overall amplitude of the map, which the spectrum already measures well. The length is the error along the valley, which shows up as the error on Ω_m; it falls from 0.065 to 0.041. Almost all of the gain is a shorter needle. The error on S_8 falls by about the same fraction, from 0.0164 to 0.0109, because, as (12.75) showed, $\sigma(S_8)$ is mostly the small tilt between the needle and the line of constant S_8 times the needle's length.

Which peaks carry the information? Splitting the peak histogram into low ($\nu < 0.5$), medium ($0.5 \le \nu < 2.5$) and high ($\nu \ge 2.5$) peaks and computing the Fisher matrix of each part alone gives figures of merit 147, 545 and 872 (errors on S_8 of 0.060, 0.020 and 0.014). The low peaks, which in a noisy map are mostly noise bumps in underdense regions, carry little. The rest is shared between the medium and the high peaks; in units of the convergence the high group starts at $2.5\sigma_{\text{noise}} \approx 0.026$, well below the height of the peaks made by single massive clusters. The two papers that first asked the question looked at the same split, and their answer is compared with ours below.

Key idea

A summary beyond the power spectrum adds information only to the extent that the field is non-Gaussian. Measure the gain against a Gaussian control with the same spectrum, with the bias of simulated derivatives removed. For lognormal convergence maps of a KiDS-like survey every summary adds to the spectrum, all of them together multiplying the figure of merit by about 1.63; for Gaussian maps the gain is zero within the ten-per-cent error of the method.

12.20.4 Three published results, reproduced

Three papers asked, in turn, whether peaks are worth counting, whether they add to the two-point analysis, and whether persistence adds to the peaks. Each compared summaries by the area of a confidence region, so the one quantity to settle first is that area.

The yardstick. Dietrich and Hartlap define the figure of merit as one over the area of the 95% region in the (Ω_m, σ_8) plane [53]; Heydenreich and collaborators as one over the area of the 1σ region [56]; we use $1/\sqrt{\det \boldsymbol{\Sigma}}$. *How are they related?* For a Gaussian posterior the region is the ellipse $\Delta\chi^2 \le q$, of area $\pi q \sqrt{\det \boldsymbol{\Sigma}}$ (Section 10.4.6), and q is fixed by the probability it must hold. With two parameters $\Delta\chi^2$ follows the χ^2 distribution with two degrees of freedom, whose density is $\frac{1}{2}e^{-x/2}$ (Chapter 2), so

$$\mathrm{P}(\Delta\chi^2 > q) \overset{(1)}{=} \int_q^\infty \tfrac{1}{2}e^{-x/2}\,\mathrm{d}x \overset{(2)}{=} e^{-q/2},$$
$$q_{95\%} \overset{(3)}{=} -2\ln 0.05 = 5.99, \qquad q_{1\sigma} \overset{(4)}{=} -2\ln 0.317 = 2.30, \tag{12.79}$$

(1) The probability outside the ellipse is the tail of the χ^2_2 density.
(2) The antiderivative of $\frac{1}{2}e^{-x/2}$ is $-e^{-x/2}$.
(3) Set the tail to 5% and solve for q.
(4) "1σ" in two dimensions means the same 68.3% as in one, so the tail is 31.7%.

and the three figures of merit are $1/(\pi \times 5.99\sqrt{\det \boldsymbol{\Sigma}})$, $1/(\pi \times 2.30\sqrt{\det \boldsymbol{\Sigma}})$ and $1/\sqrt{\det \boldsymbol{\Sigma}}$. They differ by constant factors, so *the ratio* of the figures of merit of two summaries is the same in all three conventions, $\sqrt{\det \boldsymbol{\Sigma}_B / \det \boldsymbol{\Sigma}_A}$. That ratio is what we compare. The absolute values also depend on the survey area A: every Fisher matrix grows in proportion to A, so $\boldsymbol{\Sigma} \propto 1/A$, $\det \boldsymbol{\Sigma} \propto 1/A^2$, and the figure of merit grows in proportion to A.

Peaks, and what shape noise does to them

Their question. In 2009, cluster counts were a strong probe of dark energy, but finding clusters and weighing them brings selection effects. Kratochvil, Haiman and May asked whether one could skip the clusters and count the peaks of the lensing map itself, as a function of height, and still tell cosmological models apart [52].

Their setup. N-body simulations of three models with dark-energy equation of state $w = -0.8$, -1 and -1.2, with the same primordial amplitude, so that σ_8 differs (0.742, 0.798, 0.839). Convergence maps of 3×3 deg by ray tracing, for sources at $z_s = 2$; shape noise of 15 galaxies per arcmin^2 added pixel by pixel; Gaussian smoothing with $\theta_G = 1'$ in their convention (a standard deviation of $0.71'$, Section 12.18.2); a peak is a pixel higher than its eight neighbours, as for us; peaks histogrammed in bins of κ; covariance from 200 pseudo-independent maps.

Their key equation. How well can a histogram of peak counts $\boldsymbol{N}$ separate two models? They use $\chi^2 = \Delta\boldsymbol{N}^\mathsf{T}\mathbf{C}^{-1}\Delta\boldsymbol{N}$ with $\Delta\boldsymbol{N}$ the difference of the mean histograms [52, eq. 14]. For two nearby models, separated by $\Delta\boldsymbol{\theta}$, this is our Fisher matrix:

$$\Delta\boldsymbol{N}^\mathsf{T}\mathbf{C}^{-1}\Delta\boldsymbol{N} \overset{(1)}{=} \Big(\sum_i \frac{\partial \boldsymbol{N}}{\partial\theta_i}\Delta\theta_i\Big)^\mathsf{T}\mathbf{C}^{-1}\Big(\sum_j \frac{\partial \boldsymbol{N}}{\partial\theta_j}\Delta\theta_j\Big) \overset{(2)}{=} \sum_{ij}\Delta\theta_i\,F_{ij}\,\Delta\theta_j. \tag{12.80}$$

(1) First-order Taylor expansion of the mean histogram.
(2) Collect the terms; $F_{ij} = \partial_i \boldsymbol{N}^\mathsf{T}\mathbf{C}^{-1}\partial_j \boldsymbol{N}$ is (10.20).

So "which peaks distinguish the models best" is "which peaks contribute most to $\mathbf{F}$", the question of which peaks carry the information, asked at the end of Section 12.20.3. Their noise level is the $\sigma_{\text{noise}} = 0.0227$ worked out in the example of Section 12.18.2, from (12.65).

What they found, and what we compute. Shape noise raised the total number of peaks in a noise-free smoothed map from 1646 to 2432, by about 50%, and the peaks of medium height, $0 \lesssim \kappa \lesssim 0.06$, most of them not caused by any single cluster, carried most of the power to separate the models; the low peaks, $\kappa \lesssim 0$, carried little. `w04_beyond.py` counts the peaks of 50 lognormal maps with and without shape noise (Figure 12.50) and, from the full Fisher run, the information in low, medium and high peaks.

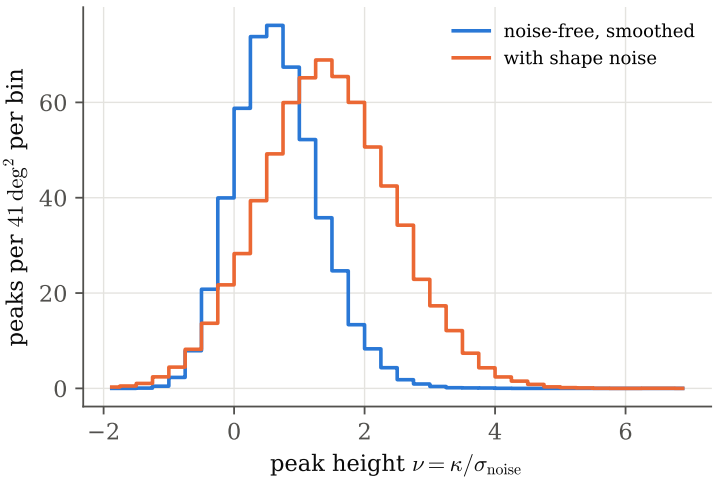

Figure 12.50: Mean histograms of peak heights on one 41 deg^2 lognormal patch, smoothed with $\theta_G = 3'$, without (blue) and with (orange) shape noise, heights in units of the smoothed noise rms. Noise adds peaks and pushes the existing ones up and down, so the histogram widens and shifts to larger ν.

Side by side.

	Kratochvil et al. (2010)	here
peaks per map, noise-free → noisy	1646 → 2432 (+48%)	490 → 685 (+40%)
smoothed noise rms $\sigma_{\rm noise}$	0.0227	0.0102
least informative peaks	low, $\kappa \lesssim 0$	low, $\nu < 0.5$ (FoM 147)
most informative peaks	medium, $0 \lesssim \kappa \lesssim 0.06$	$\nu \geq 0.5$ (FoM 545, 872)

Why they differ. The boost agrees in kind, +48% against +40%, and the difference of a few points is not something our single lognormal family can isolate: the smoothing is about four times wider in standard deviation than theirs, which changes the number of noise maxima per square degree (the Kac–Rice count of Section 12.5.2, a few θ_G^2 per maximum) and the share of the smoothed map that is noise, and the maps differ in the strength of their non-Gaussian peaks. Our split by height is in units of $\sigma_{\rm noise}$ rather than of κ; translated, our high bin starts at $\kappa \approx 0.026$, inside their medium range, and their result and ours agree that the information sits a few noise levels up, among peaks made by several structures along the line of sight, and not in the rare tall peaks of single clusters. Their maps are N-body maps of three dark-energy models, ours lognormal maps varied in (Ω_m, σ_8), so only these qualitative statements carry over.

The lesson. Shape noise does not just blur the peaks of the mass map, it makes new ones, and they sit on the signal; a peak count is only meaningful when the simulations it is compared with carry the same noise, processed the same way.

Peaks against, and with, cosmic shear

Their question. If most peaks are not clusters, are they just a noisy rewrite of the two-point function, or do they hold something else? Dietrich and Hartlap measured how well shear peaks constrain (Ω_m, σ_8) compared with cosmic shear, and how much the two do together [53].

Their setup. 158 N-body simulations spread over the (Ω_m, σ_8) plane and 35 more at the fiducial cosmology, ray-traced into 175 independent 6×6 deg fields; a CFHTLS-like survey of 180 deg^2 with 25 galaxies per arcmin^2 and total ellipticity dispersion $\sigma_\varepsilon = 0.38$ (that is 0.27 per component, the same as ours); peaks of the aperture-mass signal-to-noise map, a smoothed convergence map with a compensated filter; a Gaussian likelihood whose inverse covariance from the 175 fiducial fields carries the Hartlap factor [53, eq. 12], our (8.78).

Their key equation is the figure of merit, one over the area of the 95% region, which by (12.79) is $1/(\pi \times 5.99\sqrt{\det \boldsymbol{\Sigma}})$ for a Gaussian posterior. For a survey of 180 deg^2 instead of our 1000, our figures of merit are multiplied by 180/1000.

Side by side. Our power spectrum, peaks and their combination, in their convention and for their area:

	Dietrich & Hartlap (2010)		here	
	FoM	ratio to shear	FoM	ratio to C_ℓ
cosmic shear (C_ℓ here)	71	1	22	1
peaks	123	1.73	17	0.77
combined	173	2.44	34	1.55

The combined value is 1.41 times their peaks alone[1]; ours is 2.00 times our peaks alone.

Why they differ. *The absolute values*: their galaxy density is four times ours, so the noise power $\sigma_e^2/\bar{n}$ is four times smaller and more multipoles are signal-dominated (Section 12.19.3); their N-body maps carry the non-linear structure our lognormal maps lack; and their regions are the real, curved likelihood contours, cut by a flat prior, while ours are Fisher ellipses. *The ratios*: their peak statistic used almost exact source redshifts, while their cosmic shear used only two redshift bins, a mismatch they point out themselves; ours uses one source bin for both, and the peaks lose the scale-by-scale information of the spectrum. What survives is the shape of the result: peaks alone are comparable to the two-point analysis, and the combination beats both by a large factor, larger than either alone.

The lesson. Two summaries with the same degeneracy are not redundant: their needles differ by a small angle, and that angle, not the length of either needle, decides the gain of the combination.

Persistence against peaks

Their question. A peak count records the height of each maximum and nothing about its surroundings. Heydenreich, Brück and Harnois-Déraps asked whether the persistent Betti

[1] Their text says the combination has a figure of merit about 40% larger than cosmic shear alone; their Table 2 makes it 40% larger than the peaks alone and 2.4 times cosmic shear alone.

numbers of the signal-to-noise map, which also record how features are connected across levels (the three small maps of Figure 12.47), constrain cosmology better than peaks [56].

Their setup. Aperture-mass signal-to-noise maps of mock KiDS+VIKING-450 data (and, in a second test, of a 100 deg^2 Euclid-like survey with 30 galaxies per arcmin^2); their means emulated by a Gaussian process trained on the 26 cosmologies of the cosmo-SLICS; the covariance from 126 SLICS runs, with the t-likelihood of Sellentin and Heavens; four parameters (Ω_m, S_8, h, w_0) sampled by MCMC; persistent Betti numbers evaluated at the pairs of levels that best separate cosmologies, chosen on a dense grid.

Their key equation is the persistent Betti number of the working definition in Section 12.20.1, their eq. (10) translated into our superlevel convention, and the figure of merit, one over the area of the 1σ region, which by (12.79) has the same ratios as ours.

Side by side.

	Heydenreich et al. (2021)	here (lognormal)
FoM, persistent Betti / peaks	1.44 (KV450-like)	0.64
$\sigma(S_8)$, persistent Betti vs peaks	0.045 vs 0.048 (KV450) 0.027 vs 0.033 (Euclid)	0.0173 vs 0.0130
$\sigma(S_8)$, persistent Betti vs Betti	0.045 vs 0.048 (KV450)	0.0173 vs 0.0184

We do not reproduce their result. In our maps the persistent Betti numbers are no better than the Betti curves and weaker than the peaks.

Why they differ. The main reason can be derived. Our map before noise is $\kappa = \lambda[e^{G-s^2/2} - 1]$ (12.56), an increasing function of a Gaussian field G. For any level $k > -\lambda$,

$$\{\boldsymbol{\theta} :\ \kappa(\boldsymbol{\theta}) \geq k\} \overset{(1)}{=} \left\{\boldsymbol{\theta} :\ e^{G(\boldsymbol{\theta})-s^2/2} \geq 1 + \frac{k}{\lambda}\right\} \overset{(2)}{=} \left\{\boldsymbol{\theta} :\ G(\boldsymbol{\theta}) \geq \frac{s^2}{2} + \ln\!\left(1 + \frac{k}{\lambda}\right)\right\}. \tag{12.81}$$

(1) Divide by $\lambda > 0$ and add 1.
(2) The logarithm is increasing, so it keeps the inequality.

Every superlevel set of the lognormal map *is* a superlevel set of the Gaussian map, at a relabelled level. So every island and lake, every merger and the pass where it happens, is the Gaussian field's; only the heights at which they happen are moved. The persistence diagram of a noise-free lognormal map is the Gaussian diagram with its axes stretched, and the stretch depends on the cosmology only through λ and s, the one-point distribution that peak heights already see. Smoothing and noise, applied after the exponential, blur this exact correspondence, but they do not create the thing persistence was designed to see. Heydenreich and collaborators trace their gain to exactly that thing: whether peaks stand alone or sit together on a larger overdensity, the environment of haloes in filaments and superclusters [56, §4], which N-body maps have and lognormal maps do not. Their gain also grew with the galaxy density, as it should if it comes from resolving that structure. Smaller differences push the same way: their levels were chosen for their power to separate cosmologies, ours form a fixed grid of five, whose diagonal repeats the Betti curves; and their persistent Betti errors include the error of their emulator, without which their gain on S_8 in the KV450-like case rises from 5% to 8%.

The lesson. A gain from topology is a property of the maps, not of the method. Lognormal maps are a fair test of the machinery (the covariance, the derivatives, the Fisher bias) and an unfair test of persistence, because they contain no structure for persistence to find that the one-point distribution does not already give.

The three reproductions together.

result	theirs	ours	main reason for the difference
noise boost of peak counts	+48%	+40%	wider smoothing
FoM, peaks / two-point	1.73	0.77	their peaks had redshifts, their shear two bins
FoM, combined / two-point	2.44	1.55	as above; density, N-body
FoM, persistent Betti / peaks	1.44	0.64	lognormal maps have no environment

Each published gain beyond the power spectrum appears in our maps exactly as far as the maps contain the structure behind it: the skewness of a lognormal field, yes; the clustering of haloes, no.

12.21 How it is done in research, and what our simplifications cost

Every number computed so far came from a chain that a real survey also runs, link for link, but with each link simplified until it fits in a few minutes on a laptop. The chain of Figure T1.8 runs from the matter field to the summaries, with nuisances entering at every step. Figure 12.51 sets our version beside the research version. For each link the surveys do something heavier, we did something cheaper, and the difference has a price in the width of the error bars.

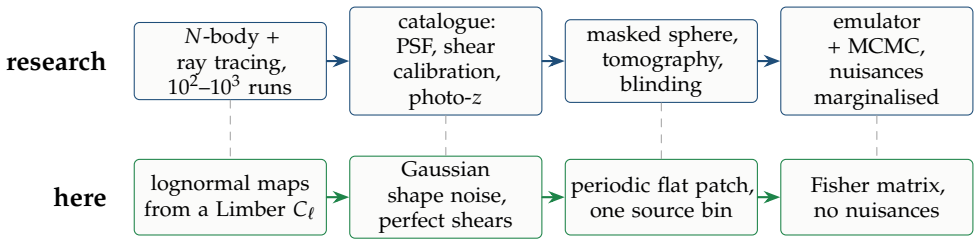

Figure 12.51: The four links of a weak-lensing analysis, as research does them (top) and as this part did them (bottom). Each dashed pair is one simplification; the text says what each costs.

The maps. The true sky is non-linear: haloes, filaments, voids, the lensing of lensing. Research analyses calibrate their summaries on ray-traced N-body simulations. Takahashi and collaborators produced 108 full-sky sets of convergence and shear maps for sources from $z = 0.05$ to 5.3, whose spectra match theory within 5% to $\ell = 3000$ [51]; the DES Y3 mass-map tests of Section 12.18.5 use one of them [54]. For summaries whose mean has no formula, a separate suite samples the parameters: Dietrich and Hartlap ran 158 cosmologies plus 35 fiducial runs, ray-traced into 175 independent fields [53]; Heydenreich and collaborators used the cosmo-SLICS, 26 cosmologies in a Latin hypercube, with a Gaussian-process emulator to interpolate between them, and 126 independent SLICS runs for the covariance [56]. Each run costs thousands of processor hours. We replaced all of this by shifted lognormal fields made from a Limber spectrum in milliseconds (Section 12.17.2). They have the right spectrum

and the right kind of one-point skewness, too little of it (the empty-beam shift is about 60% too deep, Section 12.17.3), and none of the structure of real haloes. The cost is in the size of the non-Gaussian gains: ours are a statement about lognormal maps, and the real gains are expected to be larger.

The catalogue. A survey measures shapes, not shears. The telescope's point-spread function smears every image and must be modelled star by star and removed; the remaining errors are calibrated on image simulations into a multiplicative bias m per redshift bin, $\varepsilon \to (1+m)\gamma$ (Section T1.6), whose prior is marginalised [45, 50]. The redshift distribution of each bin is estimated from photometry and calibrated against spectroscopic samples, and its uncertainty enters as shifts Δz_i or as many realisations of $n(z)$. Shape noise is measured, not assumed: HSC subtracts the noise power by rotating every galaxy's ellipticity by a random angle, which destroys the coherent shear and keeps the noise, and averaging many such rotations [49]; DES Y3 builds its mock noise the same way [54]. We assumed perfect shears, a known $n(z)$, and Gaussian noise of known amplitude. How much does the simplest of these nuisances cost? A multiplicative bias rescales the spectrum by $(1+m)^2$, which is degenerate with the amplitude. With a Gaussian prior of width 0.02 on m, added as a third parameter to the Fisher matrix of Section 12.19.3 (Section 10.4.4), `w05_costs.py` finds $\sigma(S_8) = 0.0245$ instead of 0.0218; cut at $\ell_{\max} = 1500$, 0.0438 instead of 0.0427 (Figure 12.52).

The sky. Real footprints are masked spheres with thousands of holes; analyses either model the mask in the estimator (pseudo-C_ℓ, Section 12.19.1) or apply it to every simulation, and topological summaries treat the masked pixels explicitly, for example with relative homology [56, §2.3.3]. The sources are split into four or five tomographic bins, which shortens the S_8 needle (Section 12.19.4), and the analysis is **blinded**: the catalogue is distributed with secret shifts (in HSC, offsets in m known only to a designated person [49]; KiDS and DES use several blinded catalogues [45, 50]) so that no one can tune the analysis towards an expected S_8 before every test has been passed. Our patch is a periodic flat square without holes for the higher-order summaries, and we did no blinding because there were no data to fool us. A DES-like survey, 4143 deg^2 at $n = 5.59$, $\ell \le 1500$, with the same m prior and one bin, would reach $\sigma(S_8) = 0.0243$ in our forecast.

The inference. Real analyses sample the posterior of cosmological and nuisance parameters together by MCMC (Chapter 9), with emulated or Boltzmann-code predictions, a covariance from simulations or an analytic model, and a likelihood that accounts for the noise of that covariance: Heydenreich and collaborators use the t-distribution of Sellentin and Heavens, $\ln \mathcal{L} = -\frac{N_s}{2} \ln[1 + \chi^2/(N_s - 1)]$ with $N_s = 126$ simulations [56, eq. 22], the exact version of the Hartlap correction. We computed Fisher matrices, which assume a Gaussian likelihood and are exact only for a linear model (Section 10.1); Figure 12.46 showed that for the power spectrum the curvature of the banana changes $\sigma(S_8)$ little. Our simulated Fisher matrices also carry the noise of their derivatives, which Section 12.20.2 measured and subtracted.

Where the full version would go. A Stage-IV survey, 15 000 deg^2 at 30 galaxies per square arcminute and $\ell \le 5000$, reaches $\sigma(S_8) = 0.0095$ in the same forecast, with the 2% prior on m; that number is set mostly by the prior, which is why Stage-IV shear calibration must be ten times better. For the higher-order summaries, the next step beyond our patch would be the same pipeline on HEALPix maps at $N_{\rm side} = 256$–512 cut from the Takahashi simulations, with the survey's mask and noise, a few hundred covariance maps and an emulator over a few dozen cosmologies; at the cost of each simulation run, that is a cluster project and not a laptop one.

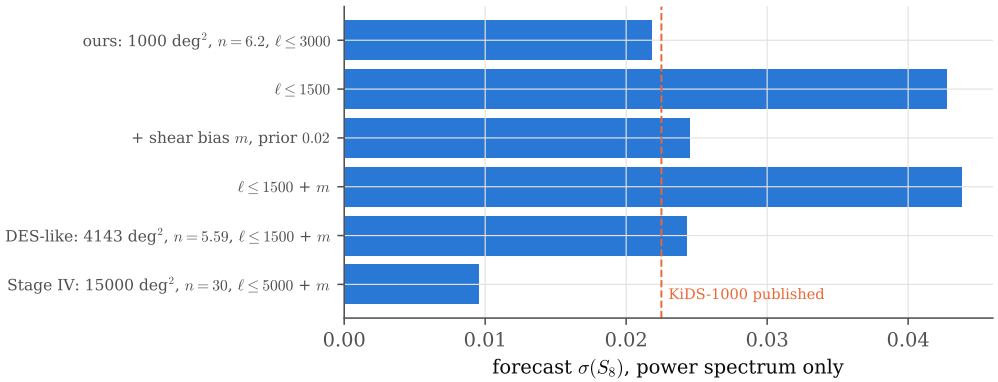

Figure 12.52: The forecast error on S_8 from the power spectrum alone, one source bin, Gaussian covariance, as the survey and the nuisances change. A multiplicative shear bias with a 2% prior, and a lower $\ell_{\max}$, each widen the error; a Stage-IV survey with 30 galaxies per arcmin^2 over 15 000 deg^2 narrows it, until the prior on m becomes the limit. The dashed line is the published KiDS-1000 precision, which uses five tomographic bins and marginalises many more nuisances.

How this is used in real research: The higher-order lensing analyses

Peak counts have been measured in KiDS, DES and HSC data, and persistent homology, Minkowski functionals and scattering transforms are being prepared for Stage-IV surveys, always with the same structure: summaries computed identically on data and on N-body mocks that include the mask, the noise and the photometric redshifts; a covariance from hundreds of independent mocks with the Hartlap or Sellentin–Heavens correction; an emulator of the mean over a few dozen cosmologies; and an MCMC over cosmology and nuisances. The summaries themselves are the cheap part, a second per map, as here; the simulations are the expensive part [44, 56].

Seen from the pipeline that runs through the whole book, from a physical model to a field, to a summary, to its sampling distribution and to the parameters, the weak-lensing analysis is the same chain at every scale: research spends its effort on the first link, realistic maps, and on the nuisances between the maps and the summaries, while the statistics of the last two links (covariance, Hartlap, Fisher, MCMC) is what we built here and does not change.

Recap

- A shifted lognormal map $\kappa = \lambda[e^{G-s^2/2} - 1]$ has the right spectrum and a floor at $-\lambda$, the empty beam; its reduced skewness is about $3/\lambda$, set by Ω_m and not by σ_8 (Section 12.17.2).
- Kaiser–Squires inversion is a rotation of each Fourier mode of the shear; it splits the map into κ_E and a κ_B that should vanish. Shape noise enters both with power $\sigma_e^2/\bar{n}$; smoothing with a Gaussian of width θ_G leaves $\sigma^2_{\text{noise}} = \sigma_e^2/(4\pi\theta_G^2\bar{n})$, and a mask leaks E into B (Section 12.18).
- The band powers of a 1000 deg^2 KiDS-like survey measure S_8 to 0.0164 in our lognormal forecast and leave Ω_m and σ_8 separately loose: a needle along $\sigma_8\Omega_m^\alpha = \text{const}$, which the real likelihood bends into a banana (Section 12.19).
- Summaries without a formula need simulated means and covariances: the Hartlap factor for the inverse covariance, common random numbers for the derivatives, and the subtraction of the derivative-noise bias (12.77), without which a Gaussian control shows gains that cannot exist (Section 12.20.2).

- On lognormal maps, peaks, Minkowski functionals, Betti curves and persistent Betti numbers each add to the power spectrum, all together multiplying the figure of merit by 1.63; on Gaussian maps they add nothing (Section 12.20.3). Published peak gains are reproduced in kind; the persistence gain over peaks is not, because a lognormal map has the topology of a Gaussian one, relabelled (12.81) (Section 12.20.4).
- Research replaces each simplification: ray-traced N-body maps, PSF and shear calibration, photometric redshifts, masks, tomography, blinding, emulators and MCMC over the nuisances (Section 12.21).

12.22 A topological summary is a random number

In Section 12.3.1 we took one Gaussian patch, coloured everything above a threshold, and counted: so many pieces, so many holes, an Euler characteristic of so much. Run the same script with a different seed and every one of those numbers changes. Nothing went wrong. A cosmological theory never predicts the map we observe; it predicts the statistics of maps like it, and the sky hands us one draw. The counts we take from that draw are therefore draws too. Counting pieces and holes did not take us out of probability. It gave us a new random variable, and everything the earlier chapters built for random variables applies to it.

Write the parameters of the physical model as θ (for the moment one number, the amount of non-Gaussianity), the random field the model produces as $\phi(\boldsymbol{x};\theta)$, and the summary we compute from it, a Betti curve, an Euler characteristic curve or a persistence diagram, as $S[\phi]$. Repeating the experiment, new field, same recipe, gives a distribution of values,

$$P(S \mid \theta), \tag{12.82}$$

the **sampling distribution** of the summary. It is the bridge between topology and inference. Once we have it, the ordinary questions return unchanged, and they can be said in words before any symbol:

1. What values does the summary take, and how often, if the model with parameter θ is true?
2. What is its average, how much does it scatter from map to map, and how does it co-vary with another summary computed from the same map?
3. If the field were Gaussian, would a value like the one we measured, or one even further from the Gaussian average, be something we would reasonably expect?
4. Which values of θ could have produced the value we measured, and how readily would each have produced it?

The first two are prediction, the last two inference (Chapter 5). Bayes' theorem connects them exactly as before, $P(\theta \mid S) \propto P(S \mid \theta)\, P(\theta)$. Topology does not compete with Bayesian inference; it supplies a representation of the data on which Bayesian inference can act. Two separate questions are in play, and it helps to keep them apart. *What should we measure*, because it has physical meaning or is robust to what we consider nuisance? That is what Sections 12.1 and 12.9 were about. *How does the uncertainty in what we measured become a statement about θ?* That is Monte Carlo, covariance, likelihood, Fisher matrix and Markov chain, the subject of Chapters 6, 9 and 10. In the pipeline of the book, physical model → field → choose what matters → summary → sampling distribution → physics, the previous parts built the first three arrows; here we walk the last two.

Working definition 12.7 (sampling distribution of a summary)

The **sampling distribution** $P(S \mid \theta)$ of a summary S [a number or a vector of numbers computed from one map, such as β_0 at thirteen thresholds] is the distribution of the values of S over independent realisations of the field [new random phases and amplitudes, same model, same θ], each passed through the same observation and the same computation. *Operational test:* simulate n fields at θ, compute S on each, histogram; the mean, covariance and quantiles of that sample estimate those of $P(S \mid \theta)$ with errors that fall as $1/\sqrt{n}$.

12.22.1 The smallest field: nine pixels

Before any map, take a field small enough that we can list every realisation. A 3×3 grid of pixels; each pixel is "hot" (above threshold) independently with probability p, and cold with probability $q = 1 - p$. This is the excursion set of a field whose pixels are uncorrelated, at the threshold that leaves a fraction p of them hot. The hot set is the union of the closed hot squares, so two hot pixels that touch only at a corner belong to the same piece, and a hole is a group of cold pixels, joined through shared sides, that cannot reach the outside of the grid (the dual conventions of Section 12.2.2).

The question. How many pieces β_0 and holes β_1 does the hot set have, and with what probabilities? What is the average Euler characteristic $\chi = \beta_0 - \beta_1$?

The average Euler characteristic, by hand. The pieces depend on how pixels connect, which makes β_0 awkward to average directly. The Euler characteristic has a second form that never mentions connections: $\chi = V - E + F$ (12.6), where F counts hot pixels, E counts unit edges that belong to at least one hot pixel, and V counts lattice points that belong to at least one hot pixel. Each of V, E, F is a sum of yes/no indicators, one per cell of the grid, and the average of a sum is the sum of the averages whether or not the terms are independent. So we only need, for each cell, the probability that at least one of the pixels touching it is hot.

The 3×3 grid has 16 lattice points and 24 unit edges, and they come in kinds according to how many pixels touch them (Figure 12.53). Of the 16 points, the 4 corners of the grid touch one pixel, the 8 other points on the boundary touch two, and the 4 interior points touch four. Of the 24 edges, the 12 on the boundary touch one pixel and the 12 interior ones touch two. A cell touched by m pixels is present unless all m are cold, which happens with probability q^m. Then

$$\begin{aligned}
\mathbb{E}[\chi] &\overset{(1)}{=} \mathbb{E}[V] - \mathbb{E}[E] + \mathbb{E}[F] \\
&\overset{(2)}{=} \left[4(1-q) + 8(1-q^2) + 4(1-q^4)\right] - \left[12(1-q) + 12(1-q^2)\right] + 9p \\
&\overset{(3)}{=} \left[4p + 12 - 8q^2 - 4q^4\right] - \left[12p + 12 - 12q^2\right] + 9p \\
&\overset{(4)}{=} p + 4q^2 - 4q^4.
\end{aligned} \tag{12.83}$$

(1) Linearity of the expectation applied to $\chi = V - E + F$.
(2) Each kind of cell contributes (number of such cells)$\times$ P(not all of its pixels are cold); a pixel is hot with probability p, so $\mathbb{E}[F] = 9p$.
(3) $1 - q = p$ turns $4(1-q)$ into $4p$ and $12(1-q)$ into $12p$; the other brackets expand as $8(1-q^2) = 8 - 8q^2$, $4(1-q^4) = 4 - 4q^4$ and $12(1-q^2) = 12 - 12q^2$.
(4) The constants cancel, $12 - 12 = 0$; the p terms give $4p - 12p + 9p = p$; the q^2 terms give $-8q^2 + 12q^2 = 4q^2$; and $-4q^4$ is left.

Two quick checks. At $p = 1$ (all hot) it gives 1: one square, no hole. At $p = 0$ it gives $4 - 4 = 0$: nothing there.

The average number of holes, by hand. A hole needs cold pixels that cannot reach the outside through shared sides. Every pixel except the centre lies on the boundary of the grid and so touches the outside; the only candidate hole is the centre pixel. The centre is enclosed when it is cold and its four side-neighbours are hot; those four touch each other at their corners, so they form one piece that rings the centre. The corner pixels do not matter: a cold corner shares no side with the centre. Hence

$$\mathbb{E}[\beta_1] = \mathrm{P}(\text{centre cold})\ \mathrm{P}(\text{four side-neighbours hot}) = q\,p^4,$$
$$\mathbb{E}[\beta_0] = \mathbb{E}[\chi] + \mathbb{E}[\beta_1] = p + 4q^2 - 4q^4 + p^4 q. \tag{12.84}$$

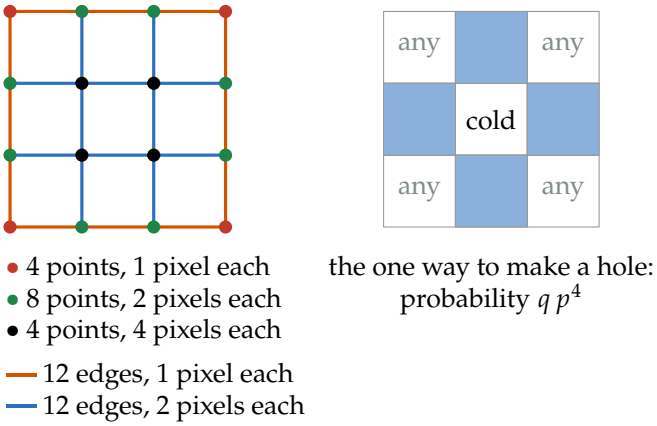

Figure 12.53: The bookkeeping behind (12.83) and (12.84). Left: the 16 lattice points and 24 edges of a 3×3 grid, sorted by how many pixels touch them; a cell is part of the hot set unless every pixel touching it is cold. Right: the centre is the only pixel that cannot reach the outside, so the only hole is a cold centre ringed by four hot side-neighbours; the corners can be anything.

Example: the numbers at $p = \frac{1}{2}$. With $q = \frac{1}{2}$, (12.83) gives $\mathbb{E}[\chi] = \frac{1}{2} + 4\cdot\frac{1}{4} - 4\cdot\frac{1}{16} = \frac{1}{2} + 1 - \frac{1}{4} = 1.25$, and (12.84) gives $\mathbb{E}[\beta_1] = \frac{1}{2}\cdot\frac{1}{16} = \frac{1}{32} = 0.03125$ and $\mathbb{E}[\beta_0] = 1.28125$. The enumeration below gives $\mathbb{E}[\chi] = 1.25000$, $\mathbb{E}[\beta_1] = 0.03125$ and $\mathbb{E}[\beta_0] = 1.28125$.

Example: when are holes most common? $\mathbb{E}[\beta_1] = p^4(1-p)$ is small at both ends: with few hot pixels there is no ring, with many there is no cold centre. Setting the derivative to zero,

$$\frac{\mathrm{d}}{\mathrm{d}p}\left[p^4(1-p)\right] \overset{(1)}{=} 4p^3 - 5p^4 \overset{(2)}{=} p^3(4-5p) = 0 \quad\Rightarrow\quad p = \tfrac{4}{5}, \qquad \mathbb{E}[\beta_1]_{\max} = \left(\tfrac{4}{5}\right)^4 \tfrac{1}{5} = 0.082.$$

(1) Product rule: $\frac{\mathrm{d}}{\mathrm{d}p}p^4 = 4p^3$ and $\frac{\mathrm{d}}{\mathrm{d}p}(p^4 \cdot p) = 5p^4$.

(2) Factor out p^3; the root $p = 0$ is the minimum.

The holes peak when four fifths of the pixels are hot, as in the large maps of Section 12.3, where holes dominate below the median threshold and pieces above it.

Example: why at most four pieces? Hot pixels that touch even at a corner are one piece, so separate pieces need cold pixels between them in every direction. The four corner pixels can be hot and separate if everything else is cold; a fifth hot pixel anywhere touches at least one of them or sits in the middle, which touches all four corners. So $\beta_0 \le 4$, and the enumeration confirms that the largest value is 4.

The whole distribution, and a Monte Carlo of it. The averages are not the whole story; we want $P(S \mid p)$ itself. With nine pixels there are $2^9 = 512$ configurations, and each has probability $p^k q^{9-k}$ if k of its pixels are hot. The script `code/ch12/c01_tiny.py` lists all of them, counts pieces and holes with the from-scratch routines of Section 12.2.2, adds up the probabilities, and checks every count against scikit-image:

Listing 12.16: All 512 configurations of a 3×3 grid, counted twice (`code/ch12/c01_tiny.py`)

```
configs = []
for bits in itertools.product([0, 1], repeat=9):
    m = np.array(bits, bool).reshape(3, 3)
    b0, b1 = betti_plane(m)
    chi = euler_cubical(m)
    assert chi == b0 - b1                                   # the Euler relation, checked
    512 times
    # scikit-image: 8-connected pieces, Euler number with 8-connectivity (connectivity=2)
    assert measure.label(m, connectivity=2).max() == b0
    assert measure.euler_number(np.pad(m, 1), connectivity=2) == chi
    configs.append((b0, b1, chi, m.sum()))
configs = np.array(configs)
w = p ** configs[:, 3] * q ** (9 - configs[:, 3])           # probability of each
    configuration
```

The loop builds each configuration as a 3×3 boolean array, counts it with `betti_plane` and `euler_cubical`, and asserts three things: the Euler relation $\chi = \beta_0 - \beta_1$, the number of pieces from scikit-image's `measure.label` with the 8-neighbour rule, and χ from its `measure.euler_number`. All 512×3 assertions pass. The last line stores, for each configuration, its counts and its number of hot pixels, from which its probability follows.

Then, as we would have to for a real map, the script forgets the enumeration and draws 10^5 random grids:

Listing 12.17: The same distribution by Monte Carlo (`code/ch12/c01_tiny.py`)

```
# ---- Monte Carlo: 100000 random grids
n = 100_000
grids = rng.random((n, 3, 3)) < p
mc = np.array([betti_plane(g) for g in grids])
mc_b0 = mc[:, 0].mean()
mc_b0_se = mc[:, 0].std() / np.sqrt(n)
mc_b1 = mc[:, 1].mean()
```

The Monte Carlo mean number of pieces is 1.2818 ± 0.0017 against the exact 1.28125, and the mean number of holes 0.0314 against 0.03125. Figure 12.54 shows the distribution of β_0 at $p = \frac{1}{2}$, exact and simulated side by side, and the three averages as functions of p.

What the nine pixels already show. Three things carry over to every real map. First, a count is a random variable with a shape: at $p = \frac{1}{2}$, $\mathrm{P}(\beta_0 = 2) = 0.1992$ and the standard deviations are $\sigma(\beta_0) = 0.544$ and $\sigma(\chi) = 0.586$, comparable to the means. Second, the counts of one map are correlated with each other: $\mathrm{Cov}(\beta_0, \beta_1) = -0.0088$, negative because a hole needs the four side-pixels to be hot, and four hot side-pixels make one piece out of what could have been several. A likelihood for a vector of counts therefore needs a covariance matrix, not a list of variances. Third, enumeration stops working almost at once: a 256×256 map has 2^{65536} binary configurations, and its pixels are correlated. What remains is the second route, simulation, whose error falls as $1/\sqrt{n}$ with the number of maps whatever the size of the map (Section 6.11.2). That route, followed all the way to a posterior, is what the local model of non-Gaussianity needs next.

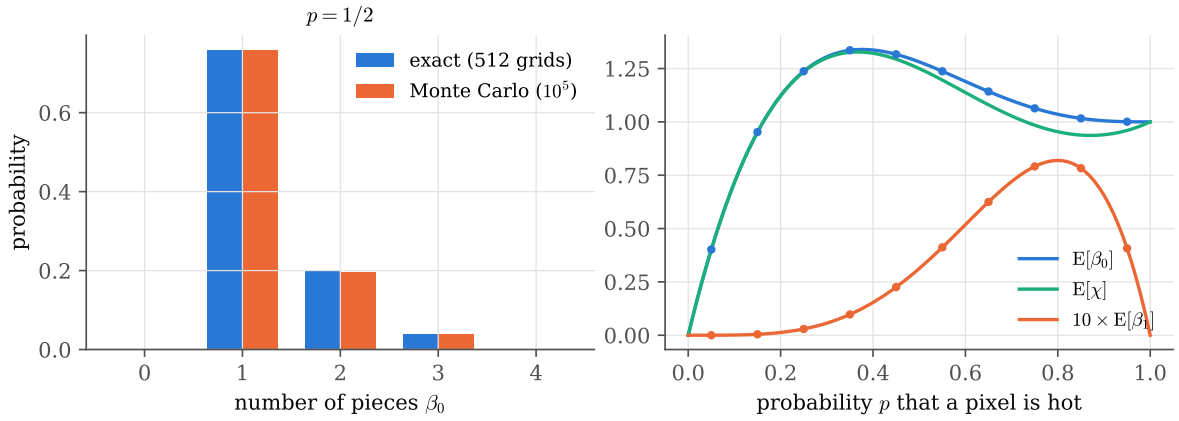

Figure 12.54: Left: the sampling distribution of the number of pieces on a 3×3 grid with $p = \frac{1}{2}$, from all 512 configurations (blue) and from 10^5 random grids (orange). One piece is by far the most common outcome; four, the largest possible, almost never happens. Right: the averages (12.83) and (12.84) (lines) against exact enumeration at ten values of p (dots); holes are multiplied by ten to be visible.

12.23 Two fields with one power spectrum

A Gaussian field is fixed completely by its power spectrum (Section 7.2). The moment a field is not Gaussian, the spectrum stops being the whole story, and in Section 7.7 we saw two maps with identical spectra that looked nothing alike. Primordial non-Gaussianity of the local type is the physical version of that situation: inflation with more than one field can add to the Gaussian potential a small piece of its own square ((T3.8); see the cosmology notes for the physics). The square adds a little power, but the dominant signature is in the shapes: high peaks become a little higher and more numerous than deep troughs, or the other way round. To study that signature cleanly we want a family of fields, labelled by the amount of non-Gaussianity, whose power spectrum is *exactly* the same for every member. Then whatever separates them cannot have come from the spectrum.

The question. Can we build two random fields with the same power spectrum, one Gaussian and one not; and if so, do the Euler characteristic and the Betti curves of Sections 12.2 and 12.9.3 tell them apart on average?

12.23.1 The model, and why its spectrum does not depend on ϵ

Start from a Gaussian field g on an $N \times N$ periodic grid ($N = 256$), with zero mean, unit variance per pixel and power spectrum $S_g(k) \propto k^{-2}$: equal power in every octave of wavenumber, the flat-sky version of a scale-invariant spectrum. Its correlation function $\xi(\boldsymbol{r}) = \langle g(\boldsymbol{x}) g(\boldsymbol{x}+\boldsymbol{r}) \rangle$ is the inverse Fourier transform of S_g, and $\xi(\boldsymbol{0}) = 1$. The non-Gaussian field adds a quadratic piece,

$$\phi = g + \epsilon\,(g^2 - 1), \tag{12.85}$$

which is the local model with $\epsilon = f_{\mathrm{NL}} \sigma_g$ in units where g has unit variance; subtracting $1 = \langle g^2 \rangle$ keeps the mean zero. How much power does the quadratic piece add? The power spectrum is the Fourier transform of the correlation function (Wiener–Khinchin, (7.12)), so we need the

correlation of ϕ at two points $\boldsymbol{x}$ and $\boldsymbol{y}$, with $g_x \equiv g(\boldsymbol{x})$ and $\xi \equiv \xi(\boldsymbol{x}-\boldsymbol{y})$:

$$\begin{aligned}\langle\phi_x\phi_y\rangle &\overset{(1)}{=} \langle g_x g_y\rangle + \epsilon\big[\langle g_x(g_y^2-1)\rangle + \langle (g_x^2-1)g_y\rangle\big] + \epsilon^2\langle (g_x^2-1)(g_y^2-1)\rangle \\ &\overset{(2)}{=} \xi + 0 + \epsilon^2\big[\langle g_x^2 g_y^2\rangle - \langle g_x^2\rangle - \langle g_y^2\rangle + 1\big] \\ &\overset{(3)}{=} \xi + \epsilon^2\big[(1\cdot 1 + 2\xi^2) - 1 - 1 + 1\big] \overset{(4)}{=} \xi + 2\epsilon^2\xi^2. \end{aligned} \tag{12.86}$$

(1) Multiply out $(g_x + \epsilon(g_x^2-1))(g_y + \epsilon(g_y^2-1))$.
(2) The middle terms are averages of an odd number of zero-mean Gaussian factors ($g_x g_y^2$ and g_x alone), which vanish by symmetry $g \to -g$.
(3) Wick's theorem (7.8) with the four factors g_x, g_x, g_y, g_y: the three pairings give $\langle g_x^2\rangle\langle g_y^2\rangle + 2\langle g_x g_y\rangle^2 = 1 + 2\xi^2$; and $\langle g^2\rangle = 1$.
(4) $1 + 2\xi^2 - 1 - 1 + 1 = 2\xi^2$.

Fourier transforming, the spectrum of ϕ is $S_\phi = S_g + \epsilon^2 S_2$, with S_2 the transform of $2\xi^2$: positive, of second order in ϵ, and with a shape of its own. We remove it with a fixed linear filter. Every Fourier mode of ϕ is multiplied by $R_\epsilon(k) = \sqrt{S_g(k)/S_\phi(k)}$, and then by a Gaussian smoothing $W(k) = e^{-k^2 s^2/2}$ of $s = 2$ pixels, which plays the role of a beam. A linear filter multiplies the power in each mode by its squared modulus (the convolution theorem, Section 7.6.1), so the observed map $u = W\,R_\epsilon\,\phi$ has the spectrum

$$S_u(k) = W^2(k)\,R_\epsilon^2(k)\,S_\phi(k) = W^2(k)\,S_g(k) \qquad \text{for every } \epsilon. \tag{12.87}$$

This is exact, because ϕ is a quadratic polynomial in g and (12.86) has no higher terms. The filter does one more thing we will need: it mixes neighbouring pixels, so u is *not* a pointwise function of a Gaussian map, and relabelling the thresholds (Section 12.3.2) will not undo ϵ completely.

Watch out: The same ensemble spectrum, not the same spectrum map by map

R_ϵ equalises the *average* power in each mode. Each individual map still has its own measured spectrum, scattered around the average by cosmic variance (Section 7.10.2), and the scatter itself depends weakly on ϵ through the four-point function. "The power spectrum cannot tell them apart" means: the estimated spectra of the two families have the same mean, so a likelihood built on the spectrum has no derivative with respect to ϵ.

Example: one map and its phase-randomised twin. A stronger version of the same statement holds for a single map. Take the Fourier transform of one $\epsilon = 0.2$ map, keep every modulus, and replace every phase by a random one (`randomise_phases` from Section 7.7). The two maps have the same $|\tilde{u}_k|$, and so the same periodogram, to machine precision: the largest relative difference of the moduli is 1.776×10^{-16}. Yet the skewness of the pixel values, $\langle u^3\rangle/\sigma^3$, is 0.936 for the original and 0.038 for the twin. Random phases make every pixel a sum of many independent contributions, which pushes it towards Gaussian (the central limit theorem, Chapter 2); the non-Gaussianity of the original lived entirely in how its phases were aligned. Figure 12.55 shows the two maps and the spectra.

The ensembles. The Monte Carlo behind every result below, `code/ch12/c02_mc_fnl.py`, draws three sets of 256×256 maps: 1000 maps at $\epsilon = 0$ (the *null* set, for means and covariances), 500 more at $\epsilon = 0$ (the *check* set, kept apart for calibrating tests), and 500 seeds at each of $\epsilon \in \{0, \pm 0.025, \pm 0.05, \pm 0.1\}$ (the *grid* set). In the grid set every value of ϵ of one seed is built from the *same* Gaussian field g, which will matter for derivatives (Section 12.26). For each

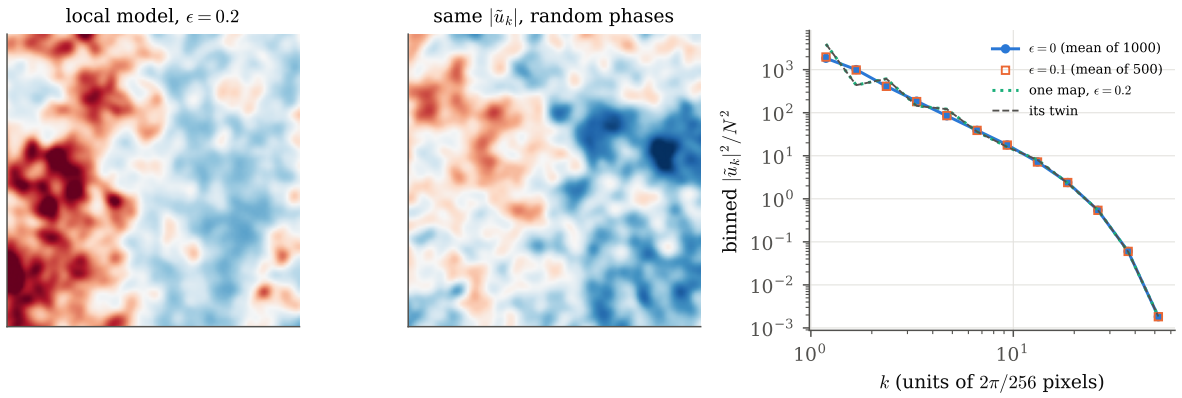

Figure 12.55: Left: a quarter of one map of the local model with $\epsilon = 0.2$ (red hot, blue cold), with sharp isolated hot spots and broad shallow cold regions. Middle: the same Fourier moduli with random phases; the hot and cold sides look alike. Right: binned spectra. The means over 1000 maps at $\epsilon = 0$ and 500 at $\epsilon = 0.1$ coincide, and the single map and its twin coincide exactly.

map it stores the binned periodogram, the skewness, the area fraction, χ, β_0 and β_1 at the thirteen thresholds $\nu = -3, -2.5, \ldots, 3$ (in units of the map's own standard deviation), the same three curves at area-fraction thresholds ν_A (12.10), and two-dimensional histograms of the persistence diagrams (Section 12.9) computed with gudhi, whose diagrams agree exactly with our union–find (Section 12.11.3). The ensemble spectra at $\epsilon = 0$ and $\epsilon = 0.1$ differ by at most 7.0% in any bin, against a Monte Carlo error of up to 3.2% on one mean. The difference of two independent means is noisier than either, and the worst of a dozen bins is expected near two standard errors: no sign of a difference.

12.23.2 What the topology sees

With the spectrum out of the way, the question is whether the average curves move. Because each grid seed has its own Gaussian g for all values of ϵ, the difference of a summary between $\epsilon = 0.05$ and $\epsilon = 0$ for the same seed contains almost no cosmic variance, and 500 seeds measure the mean shift precisely. Figure 12.56 shows the result for χ, β_0 and β_1.

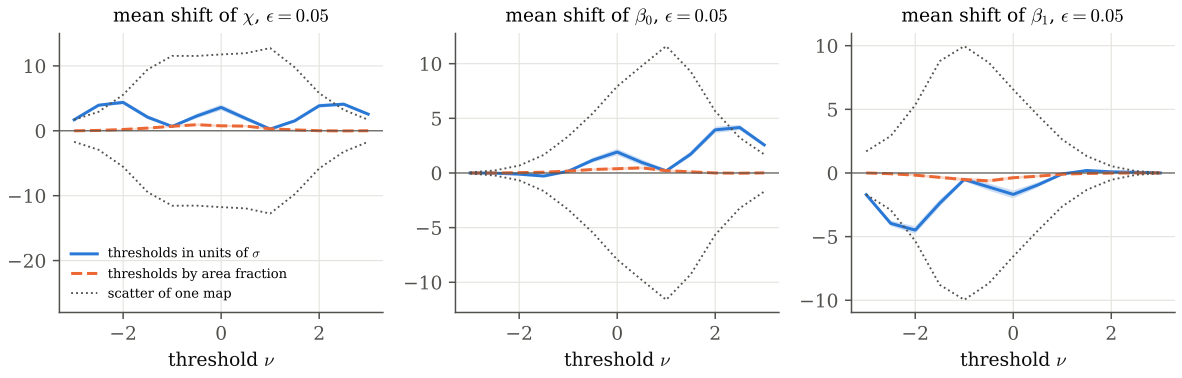

Figure 12.56: Average change of the Euler characteristic and the Betti curves when ϵ goes from 0 to 0.05, from 500 pairs of maps that share their Gaussian field (bands: ±2 standard errors). Solid: thresholds in units of the map's σ; dashed: thresholds by area fraction. Dotted: the scatter of a single map at $\epsilon = 0$. The extra hot peaks show up in β_0 at high thresholds, the shallower cold regions as fewer lakes in β_1 at low ones.

Three things are visible. The shift is real and has a shape: at $\nu = 1$ the mean Euler

characteristic moves by 0.27 ± 0.08 (out of an average of 56.5), at $\nu = -1$ by 0.67, and in the hot tail at $\nu = 3$ by 2.57. It is small compared with the scatter of one map at most thresholds (12.7 at $\nu = 1$), so no single threshold will detect $\epsilon = 0.05$; but in the tails, where both the counts and their scatter are small, the shift is a sizeable fraction of the scatter, and a vector of thresholds adds these pieces of evidence together, which is the job of the covariance matrix (Section 12.24). Finally, at area-fraction thresholds the shift almost disappears. Most of what ϵ does to the counts is to move pixel values up or down, which is a relabelling of the threshold; what survives at fixed area fraction is the part that comes from the smoothing mixing neighbours.

12.23.3 Checking the shift against Matsubara's formula

For a weakly non-Gaussian field the first correction to the Euler characteristic is known ((T3.10), from [108]). In two dimensions, per unit area and with thresholds in units of σ_0,

$$\mathbb{E}[\chi(\nu)] = \frac{\lambda}{(2\pi)^{3/2}}\, e^{-\nu^2/2}\Big\{H_1(\nu) + \Big[\frac{S^{(0)}}{6}H_4(\nu) + \frac{2S^{(1)}}{3}H_2(\nu) + \frac{S^{(2)}}{3}\Big]\sigma_0\Big\}, \tag{12.88}$$

where $\lambda = \sigma_1^2/(2\sigma_0^2)$ is the gradient variance per component in units of the field variance (Section 12.5), H_n are the Hermite polynomials ($H_1 = \nu$, $H_2 = \nu^2 - 1$, $H_4 = \nu^4 - 6\nu^2 + 3$), and $S^{(0)}\sigma_0, S^{(1)}\sigma_0, S^{(2)}\sigma_0$ are the three skewness parameters (T3.9): the averages of u^3, of $u^2\nabla^2 u$ and of $|\nabla u|^2\nabla^2 u$, suitably normalised. At $\epsilon = 0$ the bracket vanishes and we are back to (12.23).

The derivative with respect to ϵ. The three skewness parameters vanish at $\epsilon = 0$ and grow in proportion to ϵ; write their slopes as $S'_a \equiv \mathrm{d}(S^{(a)}\sigma_0)/\mathrm{d}\epsilon$. For a map of area A, differentiating (12.88) at $\epsilon = 0$ gives

$$\frac{\mathrm{d}\,\mathbb{E}[\chi(\nu)]}{\mathrm{d}\epsilon} = \frac{A\lambda}{(2\pi)^{3/2}}\, e^{-\nu^2/2}\Big[\frac{S'_0}{6}H_4(\nu) + \frac{2S'_1}{3}H_2(\nu) + \frac{S'_2}{3}\Big]. \tag{12.89}$$

For a pointwise distortion $u + \epsilon(u^2 - 1)$ all three slopes would be 6 (Section T3.2.2). The Monte Carlo script `c02_mc_fnl.py` measures the three parameters on every grid map, and a straight-line fit in ϵ gives $S'_0 = 4.29$, $S'_1 = 4.48$, $S'_2 = 5.19$: smaller than 6, because smoothing after squaring averages the square over neighbouring pixels, and unequal, because that averaging treats the field and its derivatives differently.

The same derivative at fixed area fraction. At area-fraction thresholds the term with $S^{(0)}$, the one-point skewness, should drop out. Why, and what replaces it? The area fraction above ν is, to first order ((T3.10), first line), $\Psi(\nu) + \varphi(\nu)\frac{S^{(0)}\sigma_0}{6}H_2(\nu)$, with Ψ the Gaussian tail probability (12.10) and $\varphi(\nu) = e^{-\nu^2/2}/\sqrt{2\pi}$ the Gaussian density. The threshold ν that encloses the area fraction $\Psi(\nu_A)$ therefore satisfies

$$\begin{aligned}\Psi(\nu_A) &\overset{(1)}{=} \Psi(\nu) + \varphi(\nu)\tfrac{S^{(0)}\sigma_0}{6}H_2(\nu) \overset{(2)}{=} \Psi(\nu_A) - \varphi(\nu_A)(\nu - \nu_A) + \varphi(\nu_A)\tfrac{S^{(0)}\sigma_0}{6}H_2(\nu_A)\\ &\Rightarrow \quad \nu = \nu_A + \tfrac{S^{(0)}\sigma_0}{6}H_2(\nu_A).\end{aligned} \tag{12.90}$$

(1) The definition of ν_A: the measured area fraction at ν equals $\Psi(\nu_A)$.
(2) Taylor-expand $\Psi(\nu)$ around ν_A with $\Psi' = -\varphi$; in the correction term, which is already first order, replacing ν by ν_A changes only second-order terms.

Now insert $\nu = \nu_A + \delta$ with $\delta = \frac{S^{(0)}\sigma_0}{6} H_2(\nu_A)$ into the Gaussian part of (12.88), $e^{-\nu^2/2} H_1(\nu)$, and keep first order:

$$e^{-\nu^2/2}\nu \overset{(1)}{=} e^{-\nu_A^2/2}\nu_A + \delta\,(1-\nu_A^2)\,e^{-\nu_A^2/2} \overset{(2)}{=} e^{-\nu_A^2/2}\Big[H_1 - \frac{S^{(0)}\sigma_0}{6} H_2^2\Big]$$
$$\overset{(3)}{=} e^{-\nu_A^2/2}\Big[H_1 - \frac{S^{(0)}\sigma_0}{6}\big(H_4 + 4H_2 + 2\big)\Big].$$

(1) $\frac{\mathrm{d}}{\mathrm{d}\nu}(\nu e^{-\nu^2/2}) = (1-\nu^2)e^{-\nu^2/2}$.
(2) $1 - \nu_A^2 = -H_2(\nu_A)$, and δ carries another H_2.
(3) $H_2^2 = (\nu^2-1)^2 = \nu^4 - 2\nu^2 + 1 = H_4 + 4H_2 + 2$, all at ν_A.

The H_4 terms cancel against the $S^{(0)}H_4/6$ of (12.88), and the remaining $S^{(0)}$ terms combine with the others:

$$\frac{\mathrm{d}\,\mathbb{E}[\chi(\nu_A)]}{\mathrm{d}\epsilon} = \frac{A\lambda}{(2\pi)^{3/2}}\, e^{-\nu_A^2/2}\Big[\frac{2(S_1' - S_0')}{3} H_2(\nu_A) + \frac{S_2' - S_0'}{3}\Big], \tag{12.91}$$

Matsubara's eq. (3.54) in the variable ν_A [108]. Only the differences between the slopes of the three parameters survive: for the one-point skewness they carry no new information. For a pointwise distortion they vanish; for our smoothed field they are $4.48 - 4.29$ and $5.19 - 4.29$, small but not zero.

The comparison. The formula is per unit area of a plane without edges, so the script `code/ch12/c03_same_spectrum.py` uses periodic maps (the counting of Section 12.2.3 with wrap-around) and 400 pairs at $\epsilon = \pm 0.05$ that share g, and measures $\lambda = 0.0204$ per pixel^2 (a correlation length $1/\sqrt{2\lambda} = 4.9$ pixels) on the maps themselves:

Listing 12.18: Matsubara's first-order prediction, at σ and at area-fraction thresholds (`code/ch12/c03_same_spectrum.py`)

```
sk = z["grid_sk"]                                   # (seed, eps, [S0, S1, S2, lambda])
epsv = np.array(eg)
slope = np.polyfit(epsv, sk[:, :, :3].mean(0), 1)[0]   # dS^(a) sigma0 / d eps for a = 0, 1, 2
lam = sk[:, i0, 3].mean()
nuf = np.linspace(-3.2, 3.2, 200)
H = {1: nuf, 2: nuf ** 2 - 1, 4: nuf ** 4 - 6 * nuf ** 2 + 3}
amp = N * N * lam / (2 * np.pi) ** 1.5 * np.exp(-nuf ** 2 / 2)
pred = amp * (slope[0] / 6 * H[4] + 2 * slope[1] / 3 * H[2] + slope[2] / 3)
predA = amp * (2 * (slope[1] - slope[0]) / 3 * H[2] + (slope[2] - slope[0]) / 3)
```

The first lines fit straight lines in ϵ to the skewness parameters measured on all grid maps (the slopes S_a') and take λ from the $\epsilon = 0$ maps; `amp` is $A\lambda e^{-\nu^2/2}/(2\pi)^{3/2}$ with $A = N^2$ pixels; `pred` and `predA` are (12.89) and (12.91). Figure 12.57 compares them with the Monte Carlo. At $\nu = -2.0$, where the predicted derivative is largest, the simulation gives 83 ± 3 and the formula 82. At area-fraction thresholds the derivative is at most 19 (formula: 16), about 0.19 of the σ-threshold amplitude.

The agreement says two things. The machinery is right: our counting, our maps and a perturbative formula derived by other means meet within the Monte Carlo errors, apart from the thresholds $\nu = \pm 1$ where both the Gaussian $\mathbb{E}\,\chi$ and its derivative change fastest across a pixel and the lattice effects of Section 12.2.2 are largest. And the physics is clear: most of the topological response to ϵ is a relabelling of the pixel values, and a smaller part, about a fifth here, is in how the values are arranged. Both are invisible to the power spectrum.

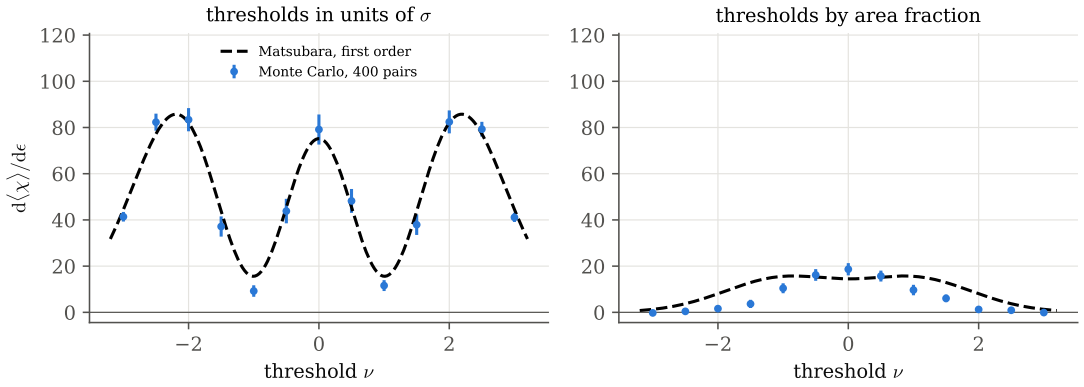

Figure 12.57: Derivative of the mean Euler characteristic of a periodic 256×256 map with respect to ϵ. Points: 400 pairs of maps at $\epsilon = \pm 0.05$ sharing their Gaussian field (± 2 standard errors). Dashed: Matsubara's first-order formula with the skewness parameters measured on the maps. Left, thresholds in units of σ: the H_4-dominated shape of a skewed histogram. Right, area-fraction thresholds: what is left is a small bump from the non-local smoothing.

Key idea: Same spectrum, different shapes

For the renormalised local model the power spectrum is the same for every ϵ (12.87), while the mean Euler characteristic and Betti curves move in proportion to ϵ, with the shape predicted by Matsubara's formula. Any statistical power to detect ϵ in this family comes from beyond the two-point function.

12.24 The sampling distribution by simulation

Simulated covariances are not new to us. In Sections 8.13 and 8.13.2 we estimated the covariance of masked CMB band powers from simulated skies and derived why its inverse must be multiplied by $(n - p - 2)/(n - 1)$; in Section 12.7.4 the same recipe gave the 36-number χ^2 of *Planck*'s Minkowski-functional test on Gaussian skies; and Section 12.20.2 used it for peak counts and Betti numbers of lensing maps. What is the same here is the recipe: simulate the null model many times, average, form the covariance, invert, correct. What is new is the use we make of it. In Section 8.13.2 the question was whether the *average* of the inverse is right. To test a hypothesis we need the whole *distribution* of the χ^2 of one map, including its tail, and our data vector is made of counts, some of them small integers, which are not Gaussian at all.

The question. If the field is Gaussian, what values does the χ^2 of one map's Betti curves take, when the mean and the covariance it is measured against were themselves estimated from a finite number of simulated maps?

12.24.1 The data vector and its covariance

For each map the data vector stacks the two Betti curves of Section 12.23.2 at the thirteen thresholds, $\boldsymbol{S} = (\beta_0(\nu_1), \ldots, \beta_0(\nu_{13}), \beta_1(\nu_1), \ldots, \beta_1(\nu_{13}))$. One entry, the number of lakes at $\nu = 3$, is zero in all but one of the simulated maps. An entry that never varied would carry no information and would make the covariance singular, so such entries are dropped; this one varies, if only just, and stays, leaving $p = 26$ numbers. From the $n = 1000$ null maps ($\epsilon = 0$) we

form the sample mean and the sample covariance,

$$\hat{\boldsymbol{\mu}} = \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{S}_i, \qquad \hat{\mathbf{C}} = \frac{1}{n-1}\sum_{i=1}^{n} (\boldsymbol{S}_i - \hat{\boldsymbol{\mu}})(\boldsymbol{S}_i - \hat{\boldsymbol{\mu}})^{\mathsf{T}}, \tag{12.92}$$

exactly as in Section 3.5.4. Figure 12.58 shows the mean curves with the scatter of one map, and the correlation matrix $\hat{C}_{ij}/\sqrt{\hat{C}_{ii}\hat{C}_{jj}}$.

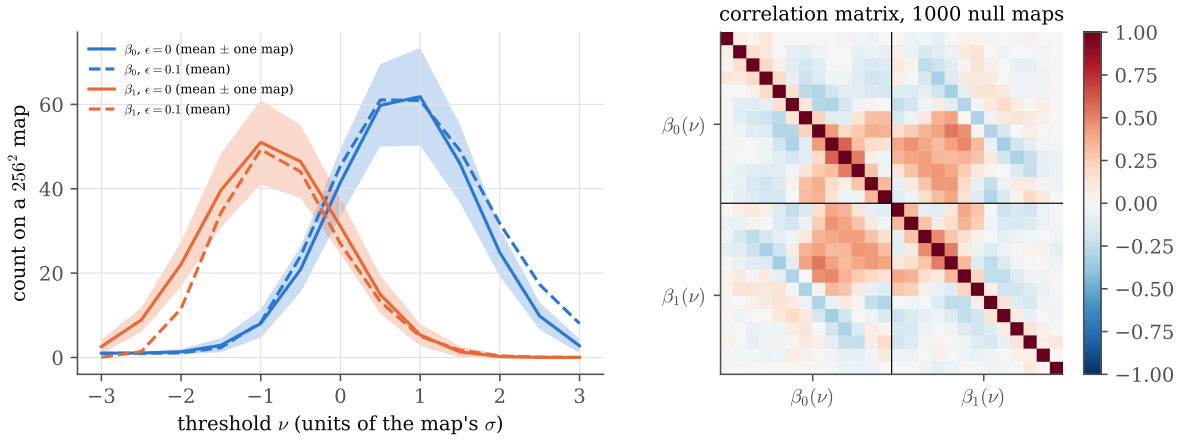

Figure 12.58: Left: mean Betti curves of 1000 Gaussian 256×256 maps (solid) with the $\pm 1\sigma$ scatter of one map (bands), and the mean at $\epsilon = 0.1$ (dashed). Pieces (β_0) dominate above the median, lakes (β_1) below. Right: the 26×26 correlation matrix of the counts. Neighbouring thresholds are positively correlated, and a broad positive block links the hot pieces above the median to the lakes below it.

Reading the correlation matrix. Two structures stand out. Neighbouring thresholds are correlated, for example 0.59 between $\beta_0(1)$ and $\beta_0(1.5)$, because they count largely the same islands: an island that is above 1.5 is also above 1. And there is a positive correlation of 0.40 between the hot pieces at $\nu = 1$ and the cold lakes at $\nu = -1$, which never share a pixel. Why should they rise and fall together? Because both are counts of features, and the number of features per unit area of a Gaussian field is set by one number, $\lambda = \sigma_1^2/2\sigma_0^2$ (Section 12.5). Thresholds are in units of each map's own standard deviation, and with equal power per octave a good part of that standard deviation comes from the few longest waves in the box, which differ from map to map. A map whose long waves happen to be weak has a smaller σ_0, the same small-scale roughness σ_1, a larger λ, and therefore more islands *and* more lakes at every threshold. Whatever the reason in a given case, the lesson of the nine pixels returns: the counts of one map are not independent, and a likelihood must use the full matrix.

How many simulations? Each entry of $\hat{\mathbf{C}}$ is an average over n maps, so its fractional error is about $\sqrt{2/n}$, 4.5% for $n = 1000$; and the inverse is biased high by $(n-1)/(n-p-2)$, a factor $1/0.973$ here ((8.78), [6]). Hobson et al. make the same point in the language of the inverse Wishart distribution: the covariance estimated from n_s simulations is usable only if n_s is well above twice the length of the data vector [HobsonBMC §3.4.3]. With $p = 26$ and $n = 1000$ we are far into the safe regime; with a 98-bin persistence histogram and 150 maps we will not be.

12.24.2 The χ^2 of a new map when the covariance is estimated

Take one more map, independent of the n simulations, and compute

$$\chi^2 = (S - \hat{\mu})^{\mathsf{T}}\, \hat{\mathbf{C}}^{-1}\, (S - \hat{\mu}). \tag{12.93}$$

If $\hat{\mu}$ and $\hat{\mathbf{C}}$ were the true μ and $\mathbf{C}$, and S were Gaussian, this would be a sum of p squared independent standard normal variables after whitening, a χ^2_p variable with mean p (Section 4.8.1). Both estimates add noise. How much?

Its average. Suppose S and the simulations are Gaussian with mean μ and covariance $\mathbf{C}$. Three facts are needed: S is independent of the simulations; for Gaussian samples $\hat{\mu}$ and $\hat{\mathbf{C}}$ are independent of each other (Section 8.13.2); and $\hat{\mu}$ has covariance $\mathbf{C}/n$. Then

$$\begin{aligned}\mathbb{E}[\chi^2] &\overset{(1)}{=} \mathbb{E}\Big[\mathrm{Tr}\big(\hat{\mathbf{C}}^{-1}(S-\hat{\mu})(S-\hat{\mu})^{\mathsf{T}}\big)\Big] \overset{(2)}{=} \mathrm{Tr}\Big(\mathbb{E}\big[\hat{\mathbf{C}}^{-1}\big]\ \mathbb{E}\big[(S-\hat{\mu})(S-\hat{\mu})^{\mathsf{T}}\big]\Big) \\ &\overset{(3)}{=} \mathrm{Tr}\Big(\frac{n-1}{n-p-2}\,\mathbf{C}^{-1}\,\Big(1+\frac{1}{n}\Big)\mathbf{C}\Big) \overset{(4)}{=} p\,\Big(1+\frac{1}{n}\Big)\frac{n-1}{n-p-2}.\end{aligned} \tag{12.94}$$

(1) A number is its own trace, and $\mathrm{Tr}(a^{\mathsf{T}}\mathsf{M}a) = \mathrm{Tr}(\mathsf{M}a\,a^{\mathsf{T}})$.
(2) $\hat{\mathbf{C}}$ is independent of both S and $\hat{\mu}$, so the average of the product is the product of the averages; the trace is linear.
(3) The Hartlap result (8.78); and $S - \hat{\mu}$ has mean zero and covariance $\mathbf{C} + \mathbf{C}/n$, because the two terms are independent and their covariances add.
(4) $\mathrm{Tr}(\mathbf{C}^{-1}\mathbf{C}) = \mathrm{Tr}\,\mathbb{1} = p$.

The factor $1 + 1/n$ comes from the noise in the mean, the factor $(n-1)/(n-p-2)$ from the noise in the covariance.

Its whole distribution. The same ingredients give the shape. Whiten the problem: in coordinates where $\mathbf{C} = \mathbb{1}$, the vector $w = (S - \hat{\mu})/\sqrt{1 + 1/n}$ is a standard normal vector, so $|w|^2 \sim \chi^2_p$. Now look at $\hat{\mathbf{C}}^{-1}$ along the direction of w. Section 8.13.2 showed, through the Schur complement (8.77), that the diagonal element of $(k\hat{\mathbf{C}})^{-1}$ along any fixed direction is one over a χ^2_{k-p+1} variable when $\mathbf{C} = \mathbb{1}$, with $k = n - 1$. In whitened coordinates the simulations look the same in every direction, and they are independent of w, so we may take the direction of w as the fixed one. Therefore

$$\chi^2 \overset{(1)}{=} \Big(1+\frac{1}{n}\Big)|w|^2\ \hat{e}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\hat{e} \overset{(2)}{=} \Big(1+\frac{1}{n}\Big)(n-1)\,\frac{\chi^2_p}{\chi^2_{n-p}} \overset{(3)}{=} \Big(1+\frac{1}{n}\Big)\frac{(n-1)\,p}{n-p}\,F_{p,\,n-p}, \tag{12.95}$$

(1) Write $S - \hat{\mu} = \sqrt{1 + 1/n}\,|w|\,\hat{e}$ with $\hat{e}$ the unit vector along w.
(2) $|w|^2 \sim \chi^2_p$; $\hat{\mathbf{C}} = A/(n-1)$ with A the scatter matrix of Section 8.13.2, and $\hat{e}^{\mathsf{T}}A^{-1}\hat{e} = 1/\chi^2_{n-p}$ (the degrees of freedom $k - (p-1) = n - p$), independent of the numerator.
(3) The ratio $(\chi^2_p/p)/(\chi^2_{n-p}/(n-p))$ of two independent χ^2 variables, each divided by its degrees of freedom, is Fisher's F distribution with $(p, n-p)$ degrees of freedom.

This is Hotelling's T^2 distribution, and its mean, $(n-p)/(n-p-2)$ for the F factor, reproduces (12.94). For $n \to \infty$ the denominator $\chi^2_{n-p}/(n-p)$ tends to one and χ^2_p returns.

Key idea: A χ^2 with a simulated covariance is wider than χ^2_p

If the mean and covariance of a Gaussian data vector of length p are estimated from n simulations, the χ^2 of a new independent vector is $(1+\frac{1}{n})\frac{(n-1)p}{n-p}F_{p,n-p}$, with mean $p(1+\frac{1}{n})\frac{n-1}{n-p-2}$. The Hartlap factor fixes the mean; it does not fix the width, which comes from the χ^2_{n-p} in the denominator.

How much wider? The spread of a χ^2_k variable relative to its mean is $\sqrt{2k}/k = \sqrt{2/k}$, so the logarithm of χ^2_k/k has a variance of about $2/k$ (the delta method: $\operatorname{Var}\ln X \approx \operatorname{Var} X/(\mathbb{E}\,X)^2$). The logarithm of the ratio in (12.95) is a difference of two independent such logarithms, so their variances add:

$$\operatorname{Var}\ln\chi^2 \approx \frac{2}{p}+\frac{2}{n-p} \qquad \text{instead of} \qquad \frac{2}{p}. \tag{12.96}$$

For the Betti vector, $p = 26$ and $n = 1000$, the second term is $2/974$, negligible next to $2/26$. For a persistence histogram with $p = 94$ bins and only $n = 150$ simulations it is $2/56 = 0.036$ against $2/94 = 0.021$: the χ^2 is spread $\sqrt{0.057/0.021} \approx 1.6$ times wider, in the logarithm, than the χ^2_p table assumes, and no constant factor can repair a wrong width.

The check. The script `code/ch12/c04_test.py` computes (12.93) for the 500 maps of the check set against the mean and covariance of the 1000 null maps:

Listing 12.19: Mean, Hartlap-corrected inverse covariance, and the χ^2 of new maps (`code/ch12/c04_test.py`)

```
def chi2(X, mu, Cinv):
    D = X - mu
    return np.einsum("...i,ij,...j->...", D, Cinv, D)

def fit(N, hartlap=True, rare=0.0):
    """Mean, inverse covariance (Hartlap-corrected) and kept columns of a null sample N (n, p);
    rare > 0 also drops bins in which fewer than that fraction of the maps differ from the median."""
    ok = (N.std(0) > 1e-9) & ((N != np.median(N, 0)).mean(0) >= rare)   # drop bins that (almost) never change
    N = N[:, ok]
    n, p = N.shape
    C = np.atleast_2d(np.cov(N.T))
    Ci = np.linalg.inv(C)
    if hartlap:
        Ci = Ci * (n - p - 2) / (n - 1)
    return N.mean(0), Ci, ok, n, p
```

`fit` drops the entries that never change (and, if asked through `rare`, those that almost never change; we use that in Section 12.25), estimates the mean and the covariance, inverts, and applies the Hartlap factor if asked; `chi2` evaluates the quadratic form for a whole stack of maps at once with `einsum`. For the Betti vector ($p = 26$, $n = 1000$) the average χ^2 of the independent maps is 30.4, against 26.7 from (12.94); a single map with a rare feature can move this average by a few units, as the next paragraph shows. For the persistence histograms ($p = 98$, $n = 1000$) it is 113.1 against 108.9. With only $n = 150$ maps for the covariance ($p = 94$) it is 273 against 261; the Hartlap factor would be 0.36, and the χ^2_p table, centred at 94, is not even in the right place. Figure 12.59 shows the three distributions.

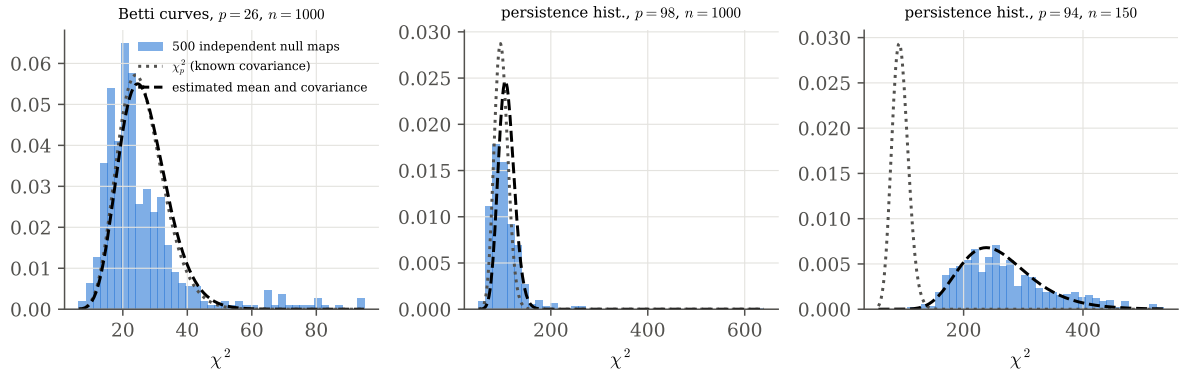

Figure 12.59: The χ^2 (12.93) of 500 Gaussian maps that were not used to estimate the mean and covariance (histograms). Dotted: χ^2_p, correct only if the covariance were known. Dashed: the Hotelling law (12.95). Left, Betti curves with 1000 simulations: the two curves nearly coincide. Middle, a 98-bin persistence histogram with 1000 simulations: shifted and widened. Right, the same with 150 simulations: the χ^2_p curve is far off, the Hotelling law still follows the histogram.

Where the Gaussian assumption fails. The derivation assumed Gaussian counts, and the bulk of the histograms agrees with it. The tail does not. Of the 500 Betti χ^2 values, 6.2% lie above the 99.9th percentile of χ^2_{26}, where 0.1% were expected, and the largest is 1099. That one map is not exotic. Its largest deviation is in $\beta_1(3)$, a count whose simulated mean is 0.00 with a scatter of only 0.03; the map had 1, a deviation of 32 standard deviations in one entry, and the square of that dominates the χ^2. Counts of rare features are small integers, closer to Poisson than to Gaussian, and a bin that is almost always the same number has a tiny variance that turns an ordinary jump of one into an enormous χ^2.

Watch out: Rare-feature bins

A bin that contains on average one or two features, or that almost never changes, makes the Gaussian χ^2 heavy-tailed and the covariance nearly singular. Either drop or merge such bins (Cole and Shiu discard bins whose fluctuations are not small compared with their mean [244]), or keep them and take the distribution of the statistic from simulations rather than from a table (Section 12.25.1).

12.25 Is this map Gaussian? A test with a simulated null

A colleague hands us one 256×256 map. Its power spectrum is exactly what a Gaussian field with spectrum $W^2 S_g$ would have, so the spectrum says nothing. Was it drawn from the Gaussian model, $\epsilon = 0$, or from one of its non-Gaussian twins of Section 12.23.1? The Gaussian model has a special status: it is the hypothesis whose sampling distribution we *know*, because we can simulate it as often as we like. That is what makes it the null hypothesis (Section 4.1.1): we do not try to prove the map is non-Gaussian; we ask whether "it is just a Gaussian map, and what we see happened by chance" is a reasonable account of it.

The question. If the map were Gaussian, would a χ^2 of its Betti curves as large as the one we measured, or larger, be something we would reasonably expect? And how often would the test catch a map that really has $\epsilon = 0.05$?

12.25.1 A p-value from simulations

Section 12.24.2 showed that the χ^2 of a Gaussian map is not distributed as χ^2_p, and that its tail is heavier still because counts are not Gaussian. Instead of a formula we use simulations a second time. The check set of Section 12.23.1, $N = 500$ Gaussian maps that played no part in estimating $\hat{\boldsymbol{\mu}}$ and $\hat{\mathbf{C}}$, gives N values $\chi^2_1, \dots, \chi^2_N$ of the statistic under the null hypothesis, computed exactly as for the observed map. With r the number of them at least as large as the observed χ^2_{obs}, define

$$p = \frac{1 + r}{1 + N}. \tag{12.97}$$

Why this is a valid p-value. If the null hypothesis is true, the observed map is just one more Gaussian map: its χ^2 and the N reference values are $N + 1$ independent draws from the same continuous distribution. Then no draw is special, and the observed one is equally likely to be the largest, the second largest, ..., the smallest. Write R for its rank counted from the top (the largest has $R = 1$); $R = 1 + r$. For any $k = 1, \dots, N + 1$,

$$\mathrm{P}\Big(p \le \frac{k}{N+1}\Big) \overset{(1)}{=} \mathrm{P}(1 + r \le k) \overset{(2)}{=} \mathrm{P}(R \le k) \overset{(3)}{=} \frac{k}{N+1}. \tag{12.98}$$

(1) Multiply both sides of $\frac{1+r}{N+1} \le \frac{k}{N+1}$ by $N + 1$.
(2) $1 + r$ is the rank from the top.
(3) Exchangeability: each of the $N + 1$ ranks has probability $1/(N + 1)$, and k of them are $\le k$.

So $\mathrm{P}(p \le \alpha) = \alpha$ whenever α is a multiple of $1/(N + 1)$, and $\mathrm{P}(p \le \alpha) \le \alpha$ otherwise: a p-value in the exact sense of (4.15), with no assumption about the shape of the distribution. The +1 in numerator and denominator is not a fudge: it counts the observed map among the draws, and it keeps p from ever being zero. The smallest attainable value is $1/(N + 1) = 1/500$ here, so with 500 reference maps no map can be called more extreme than about 1 in 500.

Working definition 12.8 (simulated p-value)

For a statistic T whose distribution under H_0 can be simulated, draw N independent realisations of H_0 through the same pipeline as the data, compute $T_1, \dots, T_N$, and report $p = (1 + \#\{T_i \ge T_{\text{obs}}\})/(1 + N)$ [the fraction of the $N + 1$ values, the observed one included, that are at least as extreme]. It is exact for any N. Its resolution is $1/(N + 1)$.

Why the reference maps must be new. It is tempting to reuse the 1000 null maps for the reference distribution. Their χ^2 values against their own mean and covariance are systematically too small:

$$\sum_{i=1}^{n} (\boldsymbol{s}_i - \hat{\boldsymbol{\mu}})^{\mathsf{T}} \hat{\mathbf{C}}^{-1} (\boldsymbol{s}_i - \hat{\boldsymbol{\mu}}) \overset{(1)}{=} \mathrm{Tr}\Big(\hat{\mathbf{C}}^{-1} \sum_{i=1}^{n} (\boldsymbol{s}_i - \hat{\boldsymbol{\mu}})(\boldsymbol{s}_i - \hat{\boldsymbol{\mu}})^{\mathsf{T}}\Big) \overset{(2)}{=} \mathrm{Tr}\big(\hat{\mathbf{C}}^{-1} (n-1) \hat{\mathbf{C}}\big) \overset{(3)}{=} (n-1)\, p,$$

(1) The trace trick of (12.94), and the trace is linear.
(2) The definition (12.92) of $\hat{\mathbf{C}}$.
(3) $\mathrm{Tr}\, \mathbb{1} = p$.

so their average is $p(n-1)/n$, exactly and for every set of simulations, while a new map has the larger average (12.94). The covariance was fitted to these very maps and "explains" them too well. A new map compared with the in-sample distribution looks too extreme, and the test raises false alarms. The check set exists to avoid this; with a single set of simulations one leaves each map out in turn, as the sphere analysis of Section 12.28 does.

12.25.2 Is the test honest?

Before using a test on data we run it on maps for which we know the answer. The 500 grid seeds at $\epsilon = 0$ are Gaussian maps independent of both the null and the check set. Their p-values should be uniform between 0 and 1 (Section 4.4.2).

First, a choice the pitfall of Section 12.24.2 asked for. A bin in which almost every map has the same count, such as the holes of the excursion set at $\nu = 3$ or its pieces at $\nu = -3$, has a tiny variance, and one map with a single rare feature there gets an enormous χ^2. Whether such a bin enters the vector at all then depends on whether one of the 1000 null maps happened to have the feature. For the tests we drop every bin in which fewer than 5% of the null maps differ from the median count. The Betti vector of the tests has $p = 22$ entries.

Now the check. 5.0% of the Gaussian maps get $p < 0.05$, where 5% were expected. How far off may that be? The guarantee (12.98) is for one map and a reference set drawn afresh. Our 500 maps all share the same 500 reference values, so the noise of that one set moves every p-value together. Two uncertainties add: the binomial one of 500 maps, $\sqrt{0.05 \times 0.95/500} \approx 1\%$, and the uncertainty of the 95th percentile of 500 reference values, about the same size. Together they give 1.4%, so 5.0% is 0.0 standard deviations from 5%. For the same reason a Kolmogorov–Smirnov test of the p-values against the uniform distribution would be wrong: it assumes independent draws. The honest question is whether the 500 values of χ^2 and the 500 reference values come from one distribution, and the two-sample Kolmogorov–Smirnov test (Section 4.8.4) answers it with $p = 0.11$.

Example: what goes wrong with a table. Repeat the test with the persistence histograms and only $n = 150$ simulations for the covariance, and compute the p-values of the same Gaussian maps in three ways. The χ^2_p table with the raw $\hat{\mathbf{C}}^{-1}$ rejects 100% of these Gaussian maps at the 5% level: the whole distribution sits far to the right of the table (Figure 12.59, right). Multiplying by the Hartlap factor puts the mean in the right place, and the false alarm rate drops to 20%, still about 4 times too many: the distribution is too wide (12.96), and maps pile up at both ends of the p-value histogram. The simulated p-value (12.97) gives 6%. The left panel of Figure 12.60 shows the three histograms. When the mean and covariance are estimated, the honest options are a likelihood that knows it (the t-distribution of Sellentin and Heavens, which integrates over the unknown true covariance [245]) or a reference distribution from independent simulations.

12.25.3 How often does it catch $\epsilon \neq 0$? Omnibus and aimed tests

A test that never raises false alarms is useless if it never raises true ones. The power of a test is the probability that it rejects H_0 when a specific alternative is true (Section 4.3). We measure it directly: compute the simulated p-value for 250 grid maps at each ϵ and count the fraction below 0.05.

The χ^2 test is an **omnibus** test: it asks whether the map is far from the Gaussian mean in *any* of the p directions of the data vector. Local non-Gaussianity moves the mean in one particular direction, the derivative $\boldsymbol{d} = \partial\boldsymbol{\mu}/\partial\epsilon$ that Figure 12.56 showed. A test aimed at that direction should do better.

The aimed test is the score. Model the summary as Gaussian with mean $\boldsymbol{\mu}(\epsilon)$ and a fixed covariance. The log-likelihood is $\ln \mathcal{L}(\epsilon) = -\frac{1}{2}(\boldsymbol{S} - \boldsymbol{\mu}(\epsilon))^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{S} - \boldsymbol{\mu}(\epsilon))$+const, and its slope at the null value $\epsilon = 0$, the score of Section 10.1.2, is

$$t \equiv \left.\frac{\partial \ln \mathcal{L}}{\partial \epsilon}\right|_{\epsilon=0} \overset{(1)}{=} -\tfrac{1}{2}\Big[-\boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{S} - \boldsymbol{\mu}_0) - (\boldsymbol{S} - \boldsymbol{\mu}_0)^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}\Big] \overset{(2)}{=} \boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{S} - \boldsymbol{\mu}_0). \tag{12.99}$$

(1) The product rule on the quadratic form; $\partial(\boldsymbol{S}-\boldsymbol{\mu})/\partial\epsilon = -\boldsymbol{d}$, with $\boldsymbol{\mu}_0 = \boldsymbol{\mu}(0)$.
(2) $\mathbf{C}^{-1}$ is symmetric, so the two terms are equal.

The score compresses the p numbers into one, weighting each by how strongly it responds to ϵ and how noisy it is. Under H_0 it has mean zero and variance $\boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}\mathbf{C}^{-1}\boldsymbol{d} = \boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d} \equiv F$, the Fisher information (10.20). At a small ϵ its mean is $\boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}(\epsilon\boldsymbol{d}) = \epsilon F$, so $t/\sqrt{F}$ is a unit normal shifted by $\epsilon\sqrt{F}$. By the Neyman–Pearson argument of Section 4.6, the one-sided test on t is the most powerful test of $\epsilon = 0$ against a small positive ϵ; since the sign of ϵ is not known in advance we use $|t|$. In practice $\boldsymbol{d}$ comes from the grid seeds 0–249 and the power is measured on seeds 250–499, so that the direction is not tuned to the maps it is tested on.

Example: how much the aim is worth. For the omnibus test write the whitened data as $\boldsymbol{x} = \boldsymbol{z} + \epsilon\mathbf{C}^{-1/2}\boldsymbol{d}$ with $\boldsymbol{z}$ a standard normal vector; then $\chi^2 = |\boldsymbol{x}|^2$ has mean $\mathbb{E}\,|\boldsymbol{z}|^2 + 2\epsilon\,\mathbb{E}[\boldsymbol{z}]^{\mathsf{T}}\mathbf{C}^{-1/2}\boldsymbol{d} + \epsilon^2\boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d} = p + \epsilon^2 F$. Its null scatter is $\sqrt{2p}$, so the shift has to compete with $\sqrt{2\cdot 22} \approx 7$ instead of 1. At the 5% level the score needs $\epsilon\sqrt{F} \approx 1.96$ for a 50% chance of detection (two-sided, the far tail neglected). The omnibus test needs its mean $22 + \epsilon^2 F$ to reach the 95th percentile of χ^2_{22}, 33.9, so $\epsilon^2 F \approx 11.9$ and $\epsilon\sqrt{F} \approx 3.5$: the omnibus test needs an ϵ about 1.8 times larger. With the Fisher error of the test's Betti vector, $F^{-1/2} = 0.0141$ (Section 12.26), the score's 50% point is $\epsilon \approx 0.028$ and the measured power at $\epsilon = 0.025$ is 54%; the omnibus test's estimated 50% point is $\epsilon \approx 0.049$, and the measured powers are 42% at 0.05 and 100% at 0.1. Each measured power comes from 250 maps, so it is uncertain by a few per cent, and all of them lean on the same reference set and the same covariance. The estimate ignores that the true null distribution is wider than χ^2_{22} (Section 12.24.2), which lowers the omnibus power.

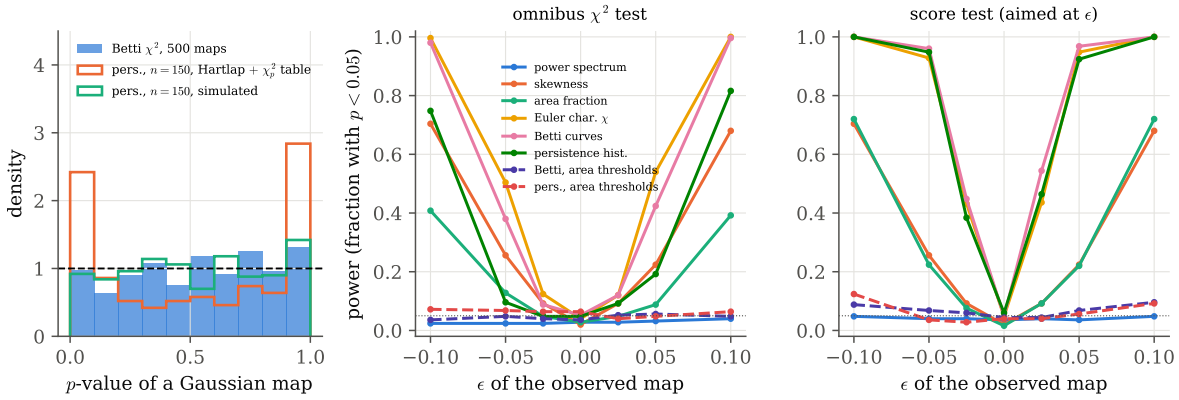

Figure 12.60: Left: p-values of Gaussian maps. Betti χ^2 with a simulated reference (filled): flat within its noise, which is larger than it looks because all 500 maps share one reference set. Persistence histogram with 150 simulations, Hartlap-corrected χ^2 referred to the χ^2_p table (orange): too many small *and* large values. The same with a simulated reference (green): flat. Middle and right: the fraction of maps rejected at $p < 0.05$ as a function of the true ϵ, for the omnibus χ^2 test and for the score test, for eight summaries. Dashed: summaries at area-fraction thresholds. The power spectrum stays at the 5% false-alarm level for every ϵ.

Which summary sees ϵ? Figure 12.60 answers it for eight summaries. The power spectrum never rises above the false-alarm rate (score test 5% and omnibus 4% at $\epsilon = 0.1$): by construction it cannot. The one-point summaries see ϵ, but weakly: at $\epsilon = 0.05$ the score test on the skewness rejects 22% of maps, on the area fractions 22%. The topological summaries are far stronger: Euler characteristic 95%, Betti curves 97%, persistence histograms 92%. At area-fraction thresholds the Betti curves drop to 7% at $\epsilon = 0.05$ and 10% at 0.1.

Why do counts beat the skewness? The last number says that most of what the Betti curves detect is the one-point effect, values pushed up or down. Why then do they detect it so much better than the skewness, which measures exactly that? Look at single entries. Per unit ϵ, measured in units of its own map-to-map scatter, the skewness responds by 27, the area fraction above $\nu = 2.5$ by 22, the number of pieces above 2.5 by 27 and the number of lakes below -2.5 by -26 (fewer lakes): all about the same size. The difference is in how much the entries repeat each other. The area fractions above 2.5 and above 3 have a correlation of 0.84 across maps, and the area fraction above 2.5 is correlated with the skewness at 0.79 and even with the area fraction below -2.5 at 0.41: they are moments of one histogram, pulled by the same extreme pixels and the same normalisation. The number of pieces above 2.5 and above 3 correlate at only 0.32, with the skewness at 0.36, and the hot pieces above 2.5 and the cold lakes below -2.5 at 0.09: separate peaks in separate places are nearly independent witnesses. The Betti vector collects many such witnesses, and the score test adds their evidence. The part of the signal that survives at fixed area fraction, the arrangement of values rather than the values themselves, is real (Section 12.23.3) but too weak for one map: even at $\epsilon = 0.1$ the score test on it rejects only 10% of the maps (Betti curves) and 9% (persistence histograms), against 5% for Gaussian maps.

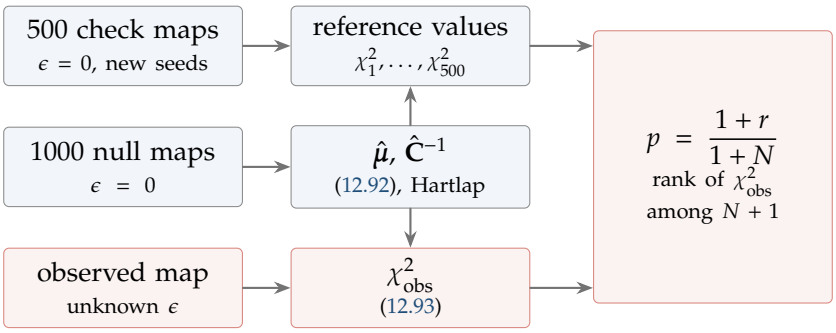

Figure 12.61: The test with a simulated null. One set of Gaussian maps (middle row) fixes the mean and the covariance, which every χ^2 uses; a second, independent set (top row) gives the distribution of the statistic under the null; the observed map (bottom row) goes through exactly the same steps, and its p-value is its rank among all of them. Every simulated quantity has its own map, so nothing is fitted to the maps it is judged by.

12.26 How well does one map measure ϵ? A Fisher forecast

A test answers yes or no. The next question is quantitative: if the map does have some ϵ, how precisely can one map measure it, and which summary measures it best? Before any data, the Fisher matrix answers this (Chapter 10). For a data vector that is Gaussian with mean $\boldsymbol{\mu}(\theta)$ and a covariance $\mathbf{C}$ that we hold fixed, the Fisher information is the mean part of (10.20), and with one parameter it is a single number:

$$F = \boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}, \qquad \boldsymbol{d} = \frac{\partial \boldsymbol{\mu}}{\partial \epsilon}, \qquad \sigma(\epsilon) \geq F^{-1/2}. \tag{12.100}$$

It is the same number that set the score test's variance in Section 12.25.3: the Fisher information is how much the mean moves, in units of the noise, per unit ϵ. Two features of our problem need comment. There is no formula for $\boldsymbol{d}$; it is estimated from simulations. And the full Gaussian Fisher matrix has a second term, $\frac{1}{2}\,\mathrm{Tr}[\mathbf{C}^{-1}\partial_\epsilon\mathbf{C}\,\mathbf{C}^{-1}\partial_\epsilon\mathbf{C}]$, from a covariance that changes with ϵ. Holding $\mathbf{C}$ at its $\epsilon = 0$ value, as almost every simulation-based analysis does, drops it; we return to what that costs in Section 12.27.3.

Derivatives from simulations, met before. In Section 12.20.2 we estimated derivatives of peak counts and Betti numbers of lensing maps with respect to Ω_m and σ_8 by central differences, with the same random numbers on both sides of each difference (*common random numbers*, (12.76)), and we found that the noise in estimated derivatives biases the Fisher matrix upwards by $\mathrm{Tr}[\mathbf{C}^{-1}\boldsymbol{\Sigma}_{\hat{d}}]/N_{\mathrm{der}}$ (12.77). There, with two nearly degenerate parameters, that bias was dangerous. Here there is one parameter and no degeneracy, and the same machinery is much better behaved, which is worth seeing in numbers.

The question. What is $F^{-1/2}$ for each summary, and can we trust the estimate: does it depend on the step, on the number of simulations, on whether the random numbers are shared?

12.26.1 The derivative, seed by seed

For each grid seed k we have maps at $\epsilon = \pm h$ made from the same Gaussian field g_k. The per-seed central difference and its average over N_{der} seeds are

$$\boldsymbol{D}_k = \frac{\boldsymbol{S}_k(+h) - \boldsymbol{S}_k(-h)}{2h}, \qquad \hat{\boldsymbol{d}} = \frac{1}{N_{\mathrm{der}}} \sum_{k=1}^{N_{\mathrm{der}}} \boldsymbol{D}_k. \tag{12.101}$$

Each $\boldsymbol{S}_k(\pm h)$ contains a large seed-specific part, the particular arrangement of peaks in g_k, and a small part that responds to ϵ. The difference removes the first and keeps the second (Figure 12.62).

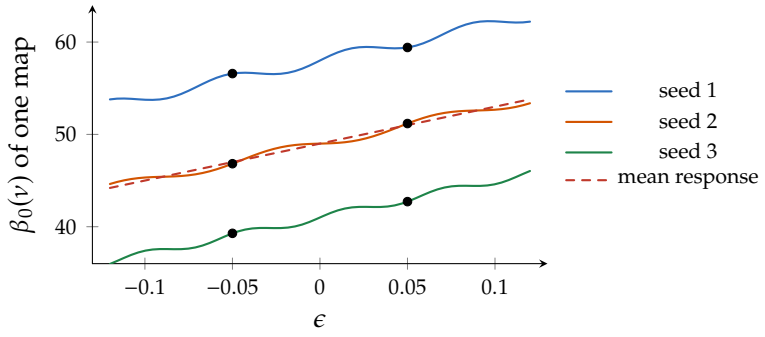

Figure 12.62: Why common random numbers work. Each seed (one Gaussian field g) gives a count that depends on ϵ; the three seeds differ by far more than ϵ moves them, but their slopes are nearly the same. A difference taken along one seed (the two dots on each curve, at $\epsilon = \pm h$) cancels the seed's offset and measures the slope; a difference between two seeds would measure mostly the offsets.

Example: how much the shared seed buys. For one entry, the number of pieces at $\nu = 1$, call σ^2 the variance of $S_k(\pm h)$ across seeds and ρ the correlation between $S_k(+h)$ and $S_k(-h)$ of the same seed. Then

$$\mathrm{Var}\big[S_k(+h) - S_k(-h)\big] \overset{(1)}{=} \mathrm{Var}\, S_k(+h) + \mathrm{Var}\, S_k(-h) - 2\,\mathrm{Cov}\big[S_k(+h), S_k(-h)\big] \overset{(2)}{=} 2\sigma^2(1-\rho), \tag{12.102}$$

(1) The variance of a difference (12.76).
(2) Equal variances on both sides and $\mathrm{Cov} = \rho\sigma^2$.

against $2\sigma^2$ for maps from different seeds. The measured correlation is $\rho = 0.983$, so the shared seed reduces the variance by $1/(1-\rho) \approx 61$; the script measures the ratio directly as 62. One pair with shared random numbers is worth about 61 pairs without.

12.26.2 Fisher errors for every summary

The script `code/ch12/c05_fisher_post.py` does this for each summary:

Listing 12.20: Fisher information with Monte Carlo derivatives, and its noise bias (`code/ch12/c05_fisher_post.py`)

```
def null_model(keys):
    N = vec("null_", keys)
    ok = N.std(0) > 1e-9
    N = N[:, ok]
    n, p = N.shape
    Ci = np.linalg.inv(np.atleast_2d(np.cov(N.T))) * (n - p - 2) / (n - 1)
    return N.mean(0), Ci, ok, n, p

def fisher(keys, step=0.05, seeds=slice(None), crn=True):
    """(F, noise bias of F, derivative, its standard error) for one summary."""
    mu, Ci, ok, n, p = null_model(keys)
    G = vec("grid_", keys)[seeds][..., ok]
    jp, jm = eg.index(step), eg.index(-step)
    if crn:
        D = (G[:, jp] - G[:, jm]) / (2 * step)            # same g on both sides
    else:
        h = len(G) // 2                                   # +step from one half, -step
    from the other
        D = (G[:h, jp] - G[h:2 * h, jm]) / (2 * step)
    d = D.mean(0)
    Sd = np.atleast_2d(np.cov(D.T)) / len(D)              # covariance of the averaged
    derivative
    F = d @ Ci @ d
    return F, np.trace(Ci @ Sd), d, np.sqrt(np.diag(Sd))
```

`null_model` gives the mean and the Hartlap-corrected inverse covariance from the 1000 null maps. `fisher` forms the per-seed differences (12.101), either along a seed (`crn=True`) or between different seeds, averages them, and returns $F = \hat{d}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\hat{d}$ together with the expected noise bias $\mathrm{Tr}[\hat{\mathbf{C}}^{-1}\boldsymbol{\Sigma}_d]/N_{\mathrm{der}}$, where `Sd` is the covariance of the per-seed derivatives divided by their number.

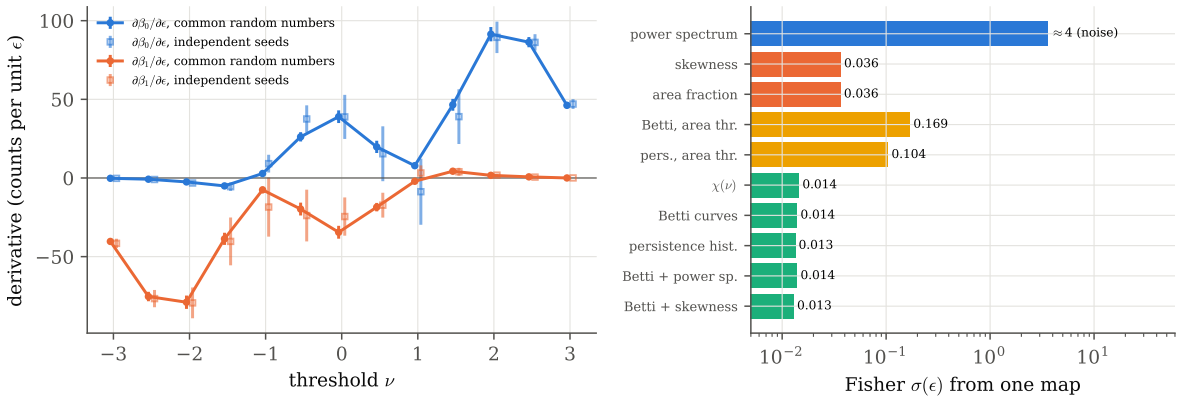

Figure 12.63: Left: the derivative of the Betti curves with respect to ϵ (± 2 standard errors), from 500 seeds with shared random numbers (filled) and from 250 pairs of different seeds (open): the same curve, with error bars several times smaller. The response is concentrated in the tails, more pieces above $\nu \approx 2$ and fewer lakes below $\nu \approx -2$. Right: the Fisher error $F^{-1/2}$ on ϵ from one 256×256 map. Blue: power spectrum (no information, the bar is pure derivative noise); orange: one-point summaries; yellow: topological summaries at area-fraction thresholds; green: topological summaries at σ-thresholds and combinations.

Figure 12.63 gives the results, with steps $h = 0.05$ and 500 seeds. The Euler characteristic

gives $\sigma(\epsilon) = 0.0145$, the Betti curves 0.0139, the persistence histograms 0.0133. The skewness gives 0.0365 and the area fractions 0.0364, nearly three times worse; at area-fraction thresholds the Betti curves give 0.169 and the persistence histograms 0.104. These are the same rankings the tests of Figure 12.60 showed, now as error bars. Adding the skewness to the Betti curves improves the error only to 0.0129: the Betti curves already contain most of what the histogram of values knows. Adding the power spectrum changes nothing (0.0139).

Example: a Fisher error made of noise. The power spectrum bar reads $\sigma(\epsilon) \approx 3.5$, as if one map could measure ϵ to within a few units. It cannot measure it at all: the true derivative is zero (12.87). What the bar shows is (12.77) with $\boldsymbol{d} = 0$: the estimated $\hat{\boldsymbol{d}}$ is pure noise, and $\hat{\boldsymbol{d}}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\hat{\boldsymbol{d}}$ is a positive number whose average is the noise term alone. The script's estimate of that term is 1.52 times the measured F; a measured information equal to (or, within its own noise, below) its expected noise bias is the signature of no information. For the topological summaries the same ratio is 0.1% (Betti curves), 0.3% (persistence histograms) and 3.7% (persistence at area-fraction thresholds, where the signal is weakest).

Example: why the noise bias is small here. Even without shared seeds the Betti Fisher error is 0.0138 and the bias below one per cent. Estimate it: without common random numbers, $\boldsymbol{D}_k$ has covariance about $2\mathbf{C}/(2h)^2 = 200\,\mathbf{C}$ for $h = 0.05$, so with $N_{\text{der}} = 250$ pairs

$$\frac{\mathrm{Tr}[\mathbf{C}^{-1}\boldsymbol{\Sigma}_d]}{N_{\text{der}}} \overset{(1)}{=} \frac{\mathrm{Tr}[\mathbf{C}^{-1}\,200\,\mathbf{C}]}{250} \overset{(2)}{=} \frac{200 \times 26}{250} \approx 21,$$

(1) The per-pair covariance $\boldsymbol{\Sigma}_d$: two independent maps, each with covariance $\mathbf{C}$, difference divided by $2h = 0.1$.
(2) $\mathrm{Tr}\,\mathbb{1} = p = 26$.

against $F = 1/0.0139^2 \approx 5182$: a 0.4% effect. The signal is strong, one parameter has no degeneracy to break, and noise in the derivative cannot fake a direction the data do not have. In Section 12.20.2 the true information across the degeneracy was a percent of the diagonal, and a bias of the same size changed the answer.

Checks on the derivative. Three changes should not move a trustworthy number, and they do not. The step: with $h = 0.025$, 0.05 and 0.1 the Betti error is 0.0138, 0.0139 and 0.0147; the largest step starts to feel the curvature of $\boldsymbol{\mu}(\epsilon)$ (a central difference has an error of order $h^2\mu'''$, Section 10.5). The number of seeds: with 25, 50, 100, 250 and 500 pairs it is 0.0135, 0.0135, 0.0139, 0.0140 and 0.0139. And shared versus independent seeds, 0.0139 against 0.0138.

Verification and research with the same machinery. Section 12.23.3 used simulations to *verify* a known result: Matsubara's perturbative formula for the mean Euler characteristic. The Fisher errors above are *research* numbers: no formula gives the covariance of Betti curves or the response of a persistence histogram, and the simulated derivatives and covariance are the only route. The same split appears in research. Cole and Shiu forecast f_{NL} from persistence diagrams of simulated CMB patches with exactly this construction, a simulated mean at a few values of f_{NL} and a covariance from 2000 Gaussian maps [244]; weak-lensing analyses forecast S_8 from peaks and persistent Betti numbers in the same way, with emulators of the mean in place of finite differences [56] (Section 12.20).

12.27 From one map to a posterior for ϵ

The Fisher error is a forecast: the width the posterior will have on average, if the likelihood is Gaussian and the mean is linear in the parameter. Now we take one map and compute the posterior itself. The reasoning is the one of parameter estimation in Chapter 5, applied to a new kind of data. The observed event is the Betti vector S_{obs} of one map. The candidate explanations are the values of ϵ. For each candidate the likelihood asks how readily a map with that ϵ would have produced these counts; Bayes' theorem combines the answers with a prior.

The question. For one map with $\epsilon_{\text{true}} = 0.05$: which values of ϵ could have produced its Betti curves, and how probable is each? And over many such maps, do the 68% intervals we report contain the truth 68% of the time?

12.27.1 The likelihood

We model the Betti vector as Gaussian, $S \sim \mathcal{N}(\mu(\epsilon), \mathbf{C})$. In the language of Section 3.8, for a given ϵ the model predicts the mean counts $\mu(\epsilon)$; the observed counts differ from it by a fluctuation $S_{\text{obs}} - \mu(\epsilon)$; and the likelihood is the probability density of exactly that fluctuation under the map-to-map scatter $\mathbf{C}$:

$$\ln \mathcal{L}(\epsilon) = -\frac{1}{2}\big(S_{\text{obs}} - \mu(\epsilon)\big)^{\mathsf{T}} \mathbf{C}^{-1} \big(S_{\text{obs}} - \mu(\epsilon)\big) + \text{const.} \tag{12.103}$$

A value of ϵ whose prediction requires an improbable fluctuation is disfavoured. Three ingredients have to be supplied, and each comes from simulations.

The mean. At the seven grid values of ϵ we average the Betti vectors of seeds 0–249. A straight line through them would miss the curvature that the step test of Section 12.26.2 hinted at, so each of the 26 components is fitted with a parabola in ϵ. The largest misfit of any component at any grid point is 0.03 of the scatter of one map: the parabola is as good as the simulations can tell.

The covariance. $\hat{\mathbf{C}}$ from the 1000 null maps, with the Hartlap factor, held fixed.

The prior. Uniform on $|\epsilon| < 0.15$, wide compared with the expected width and narrow enough that the parabola is never extrapolated.

Watch out: A Gaussian likelihood for counts is a model choice

(12.103) is not derived from the physics; it is an approximation to $P(S \mid \epsilon)$ that is good when every count is large and when $\mathbf{C}$ hardly changes with ϵ. Rare-feature bins violate the first (Section 12.24.2), and the coverage test below shows how the second fails. Replacing $\mathbf{C}$ by $\mathbf{C}(\epsilon)$ inside a Gaussian likelihood is not the cure: for non-Gaussian data it adds a spurious term to the information and can make the posterior narrower than the Cramér–Rao bound allows [246].

12.27.2 One map, three ways of computing its posterior

The held-out seeds 250–499 at $\epsilon = 0.05$ serve as mock data. For the picture we take the first of them whose posterior mean lies within one posterior standard deviation of the truth, a typical map, seed 250; the coverage test below uses all 250. With one parameter the posterior can be computed on a grid of 1201 values of ϵ, which gives the reference answer. The Metropolis sampler of Section 9.10 and the ensemble sampler emcee (Section 9.16.3) are then two independent checks:

Listing 12.21: The likelihood of the Betti vector, with a uniform prior (code/ch12/c05_fisher_post.py)

```
def mu_of(e):
    return coef[0] * e ** 2 + coef[1] * e + coef[2]

PRIOR = 0.15

def loglike(e, S):
    if abs(e) > PRIOR:
        return -np.inf
    r = S - mu_of(e)
    return -0.5 * r @ Ci @ r
```

`mu_of` evaluates the fitted parabolas, `loglike` returns (12.103) inside the prior and $-\infty$ outside, which the samplers read as "never accept". The chain makes 20000 steps with Gaussian proposals of width 1.5 times the grid posterior's standard deviation, somewhat narrower than the $2.38/\sqrt{D} = 2.38$ standard deviations that Section 9.11.1 found optimal for a Gaussian target; the price is a little efficiency, the chain accepting more proposals than it would at the optimal width.

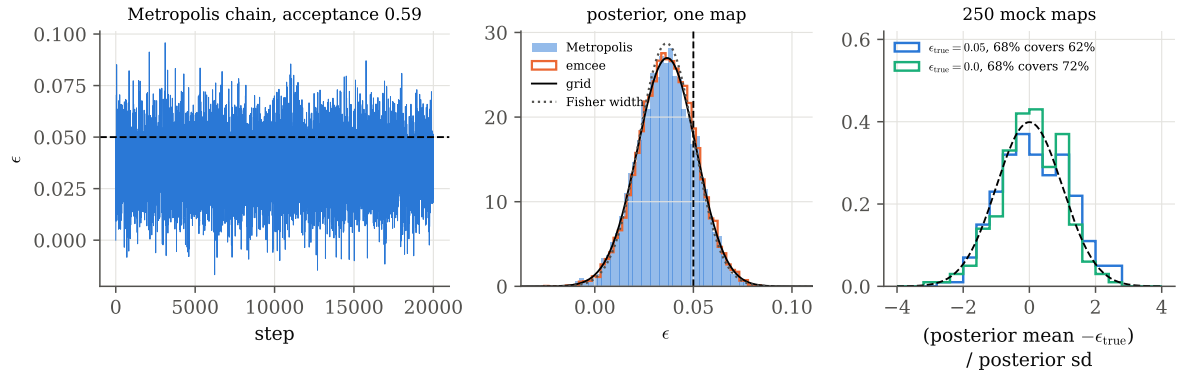

Figure 12.64: Left: the Metropolis chain for one map with $\epsilon_{\text{true}} = 0.05$ (dashed), well mixed from the first steps. Middle: its histogram, the emcee histogram, the posterior on a grid and a Gaussian of the Fisher width centred on the grid mean: four curves that lie on each other. Right: for 250 maps, the distance of the posterior mean from the truth in units of the posterior standard deviation, at $\epsilon_{\text{true}} = 0.05$ and 0; dashed: the unit normal these should follow if the intervals are honest.

The grid posterior has mean 0.0364 and standard deviation 0.0148; its central 68% interval is $[0.0216, 0.0509]$, which contains the true 0.05. The Metropolis chain gives 0.0361 ± 0.0147, with acceptance fraction 0.59 and integrated autocorrelation time 5.5 steps (Section 9.12.2), so its 19000 post-burn-in steps are worth about $19000/5.5 \approx 3400$ independent draws, enough for a standard deviation good to about one per cent. emcee gives 0.0368 ± 0.0144. The Fisher forecast was 0.0139. Four routes, one answer: for this problem the likelihood is nearly Gaussian in ϵ and the forecast is the posterior.

12.27.3 Do the intervals cover?

A 68% credible interval is a statement about one map. Whether intervals constructed this way contain the truth in 68% of repeated experiments is a separate, frequentist property, *coverage* (Section 4.12), and it can be tested only by repeating the experiment, which simulations let us do. For each of the 250 held-out maps at $\epsilon_{\text{true}} = 0.05$ we compute the grid posterior and check whether its central 68% interval contains 0.05; then the same at $\epsilon_{\text{true}} = 0$.

At $\epsilon_{\text{true}} = 0$ the intervals contain the truth in 72% of maps; at $\epsilon_{\text{true}} = 0.05$ only in 62%. With 250 maps the binomial uncertainty on such a fraction is $\sqrt{0.68 \times 0.32/250} = 3\%$. The right panel of Figure 12.64 shows the standardised errors (posterior mean $- \epsilon_{\text{true}}$)/posterior sd at $\epsilon_{\text{true}} = 0.05$: their standard deviation is 1.05 ± 0.05 instead of 1, and their mean 0.16 ± 0.07 instead of 0. With 250 maps these numbers are themselves noisy, so they hint at a problem rather than prove one. Is there a reason the posteriors should be too narrow at $\epsilon = 0.05$?

What could make them too narrow? Go through the ingredients one at a time. The prior is wide, so it cannot be it. The mean $\mu(\epsilon)$ was fitted at the very values of ϵ we test and fits to within 0.03 of one map's scatter, so it is not the mean. That leaves the covariance, which was measured at $\epsilon = 0$ and used at every ϵ. Is the scatter of the counts larger at $\epsilon = 0.05$? Project each map onto the direction that matters, the compressed statistic $t = \boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{S}$ of (12.99); its variance over the grid maps at $\epsilon = 0.05$ is 1.15 ± 0.09 times its variance at $\epsilon = 0$. Each seed gives both maps from the same Gaussian field, so much of the noise cancels in this ratio, but not all: it sits above one by somewhat less than two of its errors. That is a hint, not a proof, and it points the same way as the coverage. There is also a reason to expect it: a positive ϵ makes the high peaks higher and more numerous, and counts of rarer, more extreme features fluctuate more. If so, the likelihood underestimates the scatter by a factor $k = \sqrt{1.15} \approx 1.070$ in exactly the direction that determines ϵ.

Example: the coverage a wrong width produces. Suppose the estimate $\hat{\epsilon}$ scatters around the truth with standard deviation $k\sigma$ but we report $\hat{\epsilon} \pm \sigma$. The interval covers the truth when $|\hat{\epsilon} - \epsilon_{\text{true}}| < \sigma$:

$$\mathrm{P}\big(|\hat{\epsilon} - \epsilon_{\text{true}}| < \sigma\big) \overset{(1)}{=} \mathrm{P}\Big(|Z| < \frac{1}{k}\Big) \overset{(2)}{=} 2\Phi\Big(\frac{1}{k}\Big) - 1 \overset{(3)}{=} 2\Phi(0.934) - 1 \overset{(4)}{=} 0.650, \tag{12.104}$$

(1) Write $\hat{\epsilon} - \epsilon_{\text{true}} = k\sigma Z$ with Z a unit normal, and divide by $k\sigma$.
(2) Φ is the standard normal distribution function, and the normal is symmetric.
(3) $k = \sqrt{1.15} = 1.070$.
(4) $\Phi(0.934) = 0.825$ from a table.

A 7% error in the width turns a 68% interval into a 65% one. The simulations found $62 \pm 3\%$: consistent with this cause, though 250 maps cannot rule out others, such as the offset of the mean. At $\epsilon_{\text{true}} = 0$ the covariance is the right one, and the coverage, 72%, agrees with 68% within its uncertainty.

The remedy follows from the diagnosis. Measure the covariance near the answer rather than at an arbitrary fiducial point: after a first pass, simulate the null set again at the best-fit ϵ and repeat. Or drop the Gaussian form altogether and let simulations supply the likelihood, which is the subject of Section 12.29. What we should not do is skip the test: coverage is the only check that the error bars we publish mean what they say, and for a summary without a likelihood formula, simulations are the only way to run it.

12.28 The same experiment on the CMB sky

A temperature map is a function on the celestial sphere, $T : S^2 \to \mathbb{R}$, and we never see it directly. The telescope blurs it with its beam, the detectors add noise, and the Galaxy and bright sources force us to throw away part of the sky. In Chapter 8 each of these was an operation on the map whose effect on the power-spectrum estimator we measured by passing simulated skies through it: the beam and pixel window as a multiplicative transfer function, the noise as an

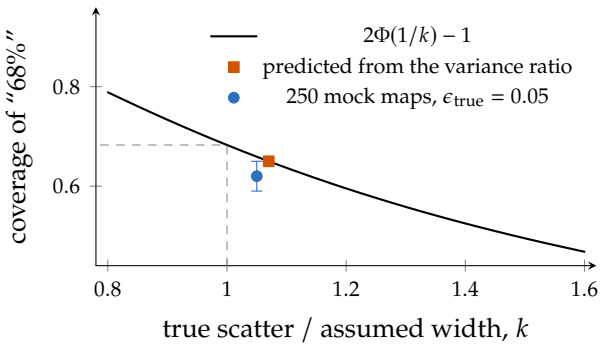

Figure 12.65: The coverage of a nominal 68% interval when the true scatter of the estimate is k times the width we report, (12.104). Honest intervals sit at $k = 1$ (dashed). The variance ratio measured for the compressed Betti statistic predicts the orange square; the blue point is the coverage actually found over 250 mock maps, placed at the measured spread of their standardised errors, with its binomial error bar.

additive bias, the mask as a coupling of multipoles. MASTER is built on that idea, effects of the observation "calibrated in Monte Carlo simulations of the modelled observation and analysis" [Hivon §1]. Topology has exactly the same problem. A mask cuts islands in two at its edge, noise creates tiny islands that the sky does not have, a beam merges islands the sky keeps apart. There is no formula for any of this on a masked, noisy sky, but there is the same remedy: treat each observational effect as an operator on the map, push Gaussian skies through it, and measure what it does to the summary.

The questions. What do the beam, the noise and the mask each do to the counts of hot and cold spots and to their persistence? And once all three are applied, can Gaussian simulations, passed through the same operators, tell a Gaussian sky from a slightly non-Gaussian one with the same power spectrum, as the *Planck* test does?

12.28.1 Counting on the HEALPix sphere

The skies are drawn from the fiducial *Planck* 2018 temperature spectrum (Chapter T1) at $N_{\text{side}} = 128$, with multipoles up to $\ell_{\max} = 383$ and pixels of 27′. The persistence of the hot spots is computed by the union–find algorithm of Section 12.11.1, with the grid neighbours replaced by the HEALPix neighbours that `healpy.get_all_neighbours` returns, eight per pixel (seven at a few special pixels):

Listing 12.22: Hot-spot persistence on the sphere by union–find (compiled with numba) (`code/ch12/c06_sphere.py`)

```
def h0_superlevel(u, nbr, active):
    """(birth, death) pairs of the islands of {u >= t} as t decreases (elder rule).

    nbr: (npix, k) neighbour table (-1 = none); active: pixels that are observed.
    Essential islands (one per observed region) get death = -inf.
    """
    n = u.size
    order = np.argsort(-u)
    parent = -np.ones(n, np.int64)
    birth = np.zeros(n)
    out_b = np.empty(n)
    out_d = np.empty(n)
    m = 0
    for p in order:
```

```
        if not active[p]:
            continue
        parent[p] = p
        birth[p] = u[p]
        for j in range(nbr.shape[1]):
            q = nbr[p, j]
            if q < 0 or parent[q] < 0:
                continue
            rp = _find(parent, p)
            rq = _find(parent, q)
            if rp == rq:
                continue
            if birth[rp] < birth[rq]:                    # the younger island dies
                young, old = rp, rq
            else:
                young, old = rq, rp
            if birth[young] > u[p]:                      # skip zero-persistence pairs
                out_b[m] = birth[young]
                out_d[m] = u[p]
                m += 1
            parent[young] = old
    for p in range(n):                                   # survivors: essential classes
        if active[p] and parent[p] == p:
            out_b[m] = birth[p]
            out_d[m] = -np.inf
            m += 1
    return out_b[:m], out_d[:m]
```

The pixels are visited from the hottest down (`order`). Each new pixel starts its own island, born at its own value. It is then joined to every already-active neighbour; when two different islands meet, the younger one, the one born at the lower value, dies at the current value and is recorded as a (birth, death) pair: the elder rule of Section 12.9. Pairs with zero persistence, a pixel merging at its own value, are skipped. Islands that never die get death $-\infty$. Masked pixels are never activated. The function is compiled with numba; drawing one full sky, observing it and computing both diagrams and both Betti curves takes 208 ms.

Hot spots and cold spots. Hot pixels touching at a corner belong to one island; cold pixels must share an edge, which on HEALPix means four of the eight neighbours (the diagonal directions SW, NW, NE, SE in healpy's ordering). This is the dual pair of Section 12.2.2. Cold spots are computed by the same function applied to $-T$ with the four edge-neighbours. The Betti curves are read off the diagrams: the number of islands of $\{T \geq \nu\}$ is the number of pairs alive at ν, born at or above ν and dying below it (12.41).

Example: the Euler characteristic from hot and cold spots. On the full sphere every lake of the hot set is a cold piece that does not reach "outside". On a sphere there is no outside, but there is one cold piece that plays its role. Precisely, Alexander duality on the sphere gives $\beta_1(\text{hot}) = \beta_0(\text{cold}) - 1$ when both sets are non-empty (see the topology notes). Then

$$\chi(\text{hot set}) \overset{(1)}{=} \beta_0(\text{hot}) - \beta_1(\text{hot}) \overset{(2)}{=} N_{\text{hot}} - (N_{\text{cold}} - 1) = N_{\text{hot}} - N_{\text{cold}} + 1, \tag{12.105}$$

(1) The Euler characteristic of a planar or spherical set is pieces minus holes (12.5).
(2) The duality, with N_{hot} and N_{cold} the numbers of hot and cold spots.

This is why *Planck* can compute its genus as a difference of hot-spot and cold-spot counts [109] (their eq. 15, Section T3.5.1); the +1 is the sphere's own contribution, the $2\Psi(\nu)$ term of (12.29) at low threshold.

Checks. On one noisy sky the Betti curves from the diagrams were compared with a direct count of connected components (scipy's sparse-graph labelling on the same neighbour lists, `lib_sphere.betti_sphere`) at all thirteen thresholds, for hot and cold spots: 0 disagreements in 26 comparisons. On a smaller sky ($N_{\rm side} = 32$) the hot-spot diagram was recomputed with gudhi, by inserting every pixel as a vertex and every neighbour pair as an edge into a `SimplexTree` with the lower-star filtration of $-T$: our code finds 198 finite pairs, gudhi 198, and the largest difference in any birth or death is $0.0e+00$.

12.28.2 Three operators, one at a time

The beam erases small structures. Figure 12.66, left, shows the mean numbers of hot and cold spots of 100 full skies for Gaussian beams of 40′, 80′ and 160′. The peak number of hot spots is 2556, 768 and 163. What should the ratios be? By the Gaussian kinematic formula, every count of features scales with $\lambda = \sigma_1^2/(2\sigma_0^2)$, the gradient variance per component in units of the field variance ((12.29)); on the sphere $\sigma_0^2 = \sum_\ell \frac{2\ell+1}{4\pi} C_\ell b_\ell^2$ and $\sigma_1^2 = \sum_\ell \frac{2\ell+1}{4\pi} \ell(\ell+1) C_\ell b_\ell^2$ ((T3.3), (T3.4)) with the beam b_ℓ. These give $\lambda = 6059$ and 307 per steradian at 40′ and 160′, a ratio of 19.8; the measured ratio of peak counts is 15.7. The same deficit shows in the Euler characteristic at $\nu = 1$, (12.105): 682 against the formula's 752 at 80′, and 2327 against 2932 at 40′. The cause is the pixel, not the formula: at 40′ the beam is only one and a half 27′ pixels wide, the smallest islands are not resolved, and the 8-neighbour rule merges what the continuous field keeps apart (Section 12.2.2). A beam is an operator that lowers λ, and with it every count, and the counting grid is part of the operator.

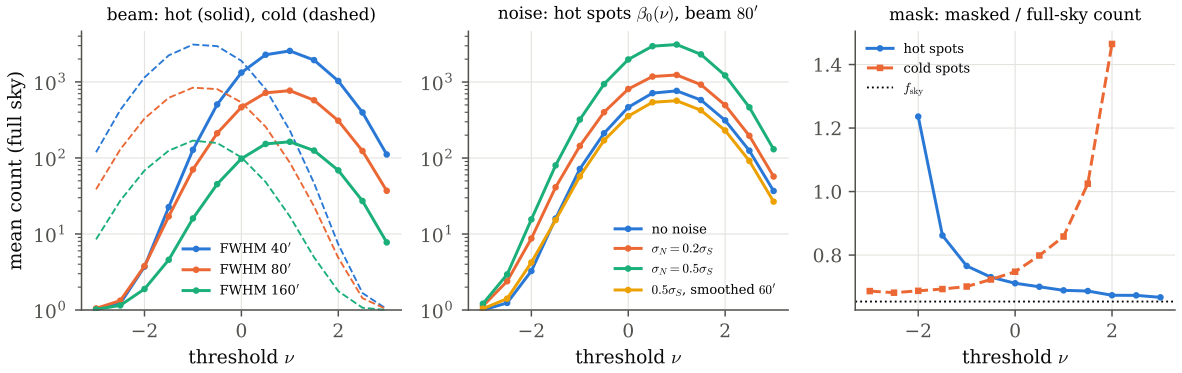

Figure 12.66: Three operators on the full-sky Betti curves, 100 skies each. Left: beams of 40′, 80′ and 160′; the counts of hot spots (solid) and cold spots (dashed) fall with the beam as λ does. Middle: white pixel noise of 0.2 and 0.5 times the signal rms on the 80′ map multiplies the hot spots; smoothing the noisy map by another 60′ removes them again. Right: the counts on a masked sky divided by the full-sky counts, against the observed sky fraction (dotted).

Noise creates short-lived features. White noise is added to every pixel of the 80′ map, with standard deviation $\sigma_N = 0.2$ and 0.5 times the rms σ_S of the beamed signal; the same skies and the same noise draws are used for every level, so differences between levels are not cosmic variance. Noise has power at every multipole up to the pixel scale, so it raises σ_1 far more than σ_0, and with it λ. The number of finite hot-spot pairs per sky goes from 3897 without noise to 8880 and 16143, and the hot spots above $\nu = 1$ from 765 to 3114 at $\sigma_N = 0.5\sigma_S$. Where do the new features sit in the diagram? Figure 12.67 shows it: along the diagonal. The stability theorem of Section 12.10 says that a perturbation of size η can only create pairs of persistence at most 2η, and a single pixel of noise moves the map only locally; the extra features are tiny bumps on the slopes of real hot spots, born and dead within a fraction of σ. The number of

pairs with persistence below 0.1σ triples, from 1119 to 2985 and 3004. Smoothing the noisy map by a further 60′ is a second operator that undoes most of the first: 3555 pairs, 1307 short ones and 568 hot spots above $\nu = 1$, now fewer than without noise because the total beam is wider.

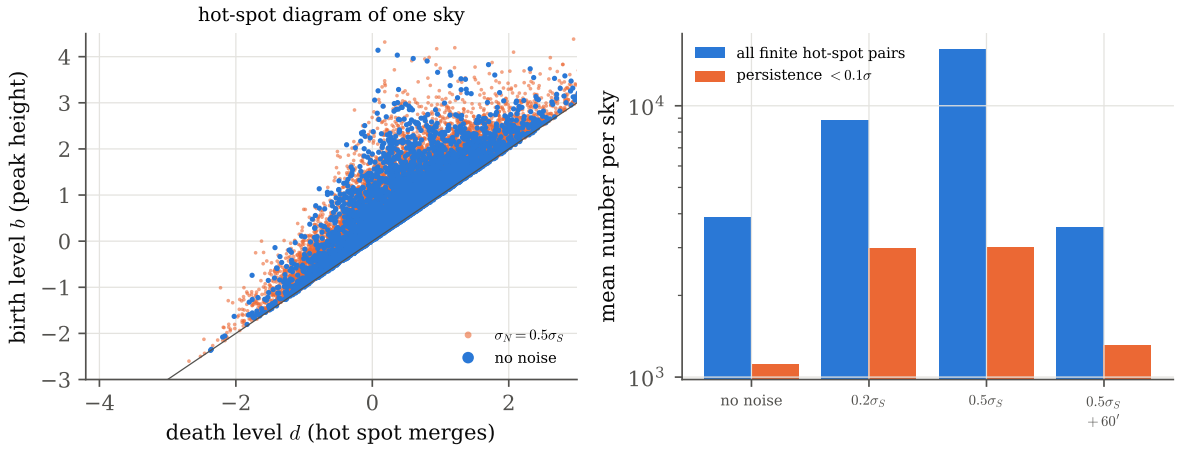

Figure 12.67: Left: the hot-spot persistence diagram of one sky with the 80′ beam, without noise (blue) and with white noise of $0.5\sigma_S$ (orange); every point is a hot spot born at height b that merges at level d. The noisy sky has about four times as many points, and the extra ones lie close to the diagonal (partly hidden under the blue points, which are drawn on top). Right: the mean number per sky of all finite pairs and of pairs with persistence below 0.1σ, for no noise, $0.2\sigma_S$, $0.5\sigma_S$, and $0.5\sigma_S$ smoothed by a further 60′.

The mask cuts and isolates. The mask removes the band $|b| < 20°$ around the Galactic equator and 100 discs of radius 1° at random positions, leaving $f_{\text{sky}} = 0.654$ of the sky. If the mask simply removed area, every count would fall to f_{sky} of its full-sky value. At $\nu = 1.5$ the hot spots fall to 0.687 of the full-sky count: slightly more than f_{sky}, because an island that crosses the edge of the mask is cut, and a cut island can fall apart into two. Where the excursion set is large, the effect is much bigger (Figure 12.66, right). At high thresholds the cold set is almost the whole sky, a single piece on the full sphere; on the masked sky the band alone splits it into a northern and a southern piece, and every source hole surrounded by hot pixels can isolate another. The ratio of cold counts climbs far above one. A mask has a topology of its own, two caps with a hundred holes, and it adds that topology to every large excursion set, the topological counterpart of the mode coupling of Section 8.10.

12.28.3 A *Planck*-style Gaussianity test on masked, noisy skies

Their question. *Planck* asked whether the shapes of the observed microwave sky are those of a Gaussian, isotropic field [109]. The test (Section T3.5.1) compares the Minkowski functionals of the data with 999 end-to-end simulations through a χ^2 and reports the fraction of simulations with a larger χ^2. On the real sky the answer was "yes, Gaussian", with probabilities between 24% and 99.8% for temperature (their Table 5). We reproduce the test, on simulations only (the real sky is analysed in Chapter 13), with Betti curves in place of the functionals, and with a non-Gaussian sky to see what a failure would look like.

Their equations, in ours. Their data vector is 36 numbers, three functionals at twelve thresholds; ours is $p = 26$ numbers, hot and cold counts at thirteen thresholds, after dropping entries that never vary. Their χ^2 (their eqs. 20–22) is (12.93) with mean and covariance from

simulations; their probability is the simulated p-value (12.97), whose validity we derived in (12.98). Their genus is (12.105) divided by the sky area. Nothing else is needed.

Our setup. The null model is a Gaussian sky with the 80′ beam, white noise of $0.2\sigma_S$ and the mask above: 1000 skies, of which 600 give the mean and the covariance (Hartlap factor 0.955) and 400 the reference distribution of χ^2. Calibration: we split the reference skies in two, use one half as the reference and test the other 200 Gaussian skies against it; 8.0% of them get $p < 0.05$, with an uncertainty of about 2.2%, and a two-sample Kolmogorov–Smirnov test of the two halves gives $p = 0.07$: with only 200 test skies, both are consistent with a calibrated test. (Ranking each reference sky among all the others would give 5% whatever the skies, since the ranks of a set among itself are just a reordering.) The alternative skies are made as in Section 12.23.1, now on the sphere: before the beam, the Gaussian sky s becomes $s + a(s^2 - \sigma^2)/\sigma$, and each multipole is rescaled by $R_\ell = \sqrt{C_\ell^s / C_\ell^\phi}$ so that the power spectrum is unchanged; R_ℓ is measured from the spectra of 100 skies with and without the quadratic term, built from the same Gaussian skies so that their ratio is nearly free of cosmic variance. For each of $a = 0.02$, 0.05 and 0.15, 100 skies go through the same beam, noise and mask. As a control, the same test is run with the pseudo-C_ℓ of the masked map in a dozen logarithmic bins (Section 8.9.3).

How large are these amplitudes? On large scales the temperature is $-\Phi/3$, and the local model gives $a = -3 f_{\rm NL} \sigma_t$ with $\sigma_t \approx 2 \times 10^{-5}$ (Section T3.2.3). Then $a = 0.02$ corresponds to $|f_{\rm NL}| \approx 0.02/(6 \times 10^{-5}) \approx 330$, some sixty times the *Planck* error (T3.15). Our skies are an exaggerated, pointwise version of the local model at $N_{\rm side} = 128$; they test the machinery, not the inflationary bound.

Side by side. Figure 12.68 is our version of the bracket plots: the counts of one sky, minus the simulation mean, in units of the simulation scatter. The Gaussian "data" sky stays inside the band at every threshold and has $p = 0.97$. The non-Gaussian sky with $a = 0.15$ leaves it in a characteristic pattern, too many hot spots at high thresholds and too few cold spots below -1, and its p is 0.002, the smallest value 400 reference skies allow (1/401).

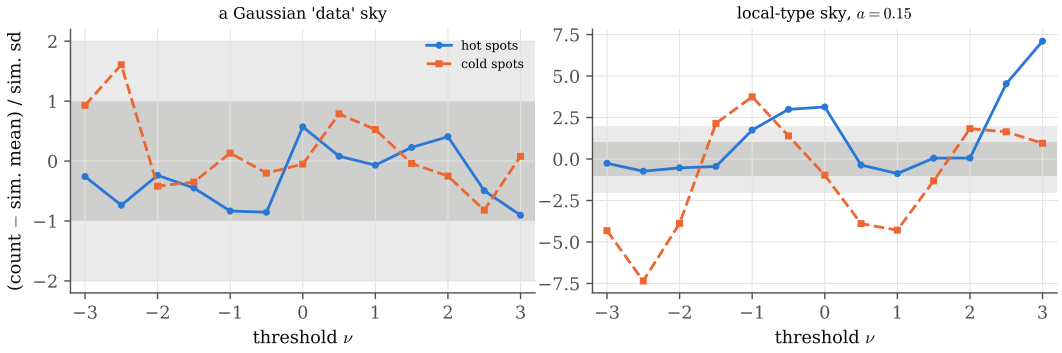

Figure 12.68: Hot-spot (solid) and cold-spot (dashed) counts of one masked, noisy, beamed sky, minus the mean of 600 Gaussian simulations processed identically, in units of their standard deviation; grey bands: ±1 and ±2. Left: a Gaussian sky, bracketed by the simulations as *Planck*'s sky was. Right: a local-type sky with $a = 0.15$ and the same power spectrum: many thresholds are several standard deviations out.

	Planck 2018 [109]	ours
summary	v_0, v_1, v_2 at 12 thresholds (36)	hot, cold counts at 13 thresholds (26)
simulations	999 FFP10, full pipeline	600 + 400 Gaussian, beam + white noise + mask
resolution	$N_{\rm side}$ 16 to 2048	$N_{\rm side}$ = 128, 80′
sky fraction	≈ 0.75	0.654
Gaussian sky, probability	24% to 99.8% (real T maps)	$p = 0.97$ (one Gaussian sky); $8.0 \pm 2.2\%$ below 0.05
non-Gaussian sky	not seen	$a = 0.02$: median $p = 0.22$, 14% detected
		$a = 0.05$: median $p = 0.007$, 98% detected
		$a = 0.15$: median $p = 0.002$, 100% detected
same, pseudo-C_ℓ	—	9%, 4%, 23% detected

Why they differ, and what the control shows. The numbers in the two columns answer different questions, and the differences have stated causes. *Planck*'s probabilities are for the real sky, so they say the sky is Gaussian; ours are for skies whose answer we know, so they say whether the test works: Gaussian skies are flagged at $8.0 \pm 2.2\%$, to be compared with the nominal 5%, and non-Gaussian ones are caught with a power that rises from 14% at $a = 0.02$ to 98% at $a = 0.05$. *Planck*'s simulations contain the real noise, its anisotropy across the sky, the component-separation residuals and lensing; ours contain white noise only, so our null distribution is narrower than theirs would be, and our power is an upper bound for a sky with real systematics. The pseudo-C_ℓ control behaves as designed: its median p stays near the middle (0.42, 0.46, 0.29) and its detection rate near the false-alarm rate, except at $a = 0.15$, where it rises to 23%. The spectra have the same mean, to within 2.5 standard errors of a 100-sky average in the worst bin; what differs is their scatter: the quadratic term adds a connected four-point function, which inflates the variance of each $\hat{C}_\ell$ (the pitfall of Section 12.23.1), and an omnibus χ^2 notices a larger scatter as well as a shifted mean.

Lesson. Rebuilding the test showed what its probabilities rest on: the null hypothesis enters only through simulations processed exactly like the data, so the mask, the beam and the noise need no formula, and the test is only as good as those simulations.

12.29 When there is no likelihood: inference from the simulator alone

Every inference so far went through a formula for $P(\boldsymbol{S} \mid \epsilon)$: Gaussian, with a mean and a covariance read off simulations. Section 12.27.3 showed what that formula costs: a covariance frozen at one value of ϵ made the intervals several per cent too narrow, and counts of rare features are not Gaussian anyway. Yet the simulator itself never assumed anything Gaussian about the counts. For any ϵ it produces maps, and the counts of those maps *are* draws from the true $P(\boldsymbol{S} \mid \epsilon)$. The likelihood is defined implicitly by the simulator, even if we cannot write it down. Can we get a posterior using only the ability to simulate?

The question. Without writing $P(\boldsymbol{S} \mid \epsilon)$, which values of ϵ could have produced the map we observed, and how probable is each, using nothing but the prior and the simulator?

12.29.1 Rejection ABC

The plainest answer is a direct imitation of Bayes' theorem by sampling, **approximate Bayesian computation** (ABC). Repeat many times: draw ϵ from the prior; simulate a map with that ϵ; compute its summary t; keep ϵ if t lands within a distance δ of the observed t_{obs}. The kept values are draws from the posterior. Why? A value ϵ is proposed with probability density $p(\epsilon)$ and, once proposed, kept with probability $\mathrm{P}(|t - t_{\text{obs}}| < \delta \mid \epsilon)$. So the density of kept values is

$$p_{\text{kept}}(\epsilon) \overset{(1)}{=} \frac{p(\epsilon)\,\mathrm{P}(|t - t_{\text{obs}}| < \delta \mid \epsilon)}{\int p(\epsilon')\,\mathrm{P}(|t - t_{\text{obs}}| < \delta \mid \epsilon')\,\mathrm{d}\epsilon'} \overset{(2)}{=} \frac{p(\epsilon)\int_{t_{\text{obs}}-\delta}^{t_{\text{obs}}+\delta} p(t \mid \epsilon)\,\mathrm{d}t}{\int p(\epsilon')\int_{t_{\text{obs}}-\delta}^{t_{\text{obs}}+\delta} p(t \mid \epsilon')\,\mathrm{d}t\,\mathrm{d}\epsilon'}$$
$$\overset{(3)}{\approx} \frac{p(\epsilon)\,2\delta\,p(t_{\text{obs}} \mid \epsilon)}{\int p(\epsilon')\,2\delta\,p(t_{\text{obs}} \mid \epsilon')\,\mathrm{d}\epsilon'} \overset{(4)}{=} p(\epsilon \mid t_{\text{obs}}). \tag{12.106}$$

(1) The probability of "proposed at ϵ and kept", normalised over everything kept (Bayes' theorem with the event "kept").
(2) The probability of landing in the window is the integral of the density of t over the window.
(3) For a small window the density is nearly constant across it: the integral is its width times the value at the centre.
(4) The 2δ cancels, and what remains is Bayes' theorem for the posterior given t_{obs}.

No likelihood was evaluated. The simulator decided, by producing or not producing a t close to t_{obs}, how readily each ϵ could have produced the observation; this is the likelihood of Chapter 5, estimated by counting. The approximation is the finite window: as $\delta \to 0$ the answer becomes exact, and the fraction of kept simulations goes to zero.

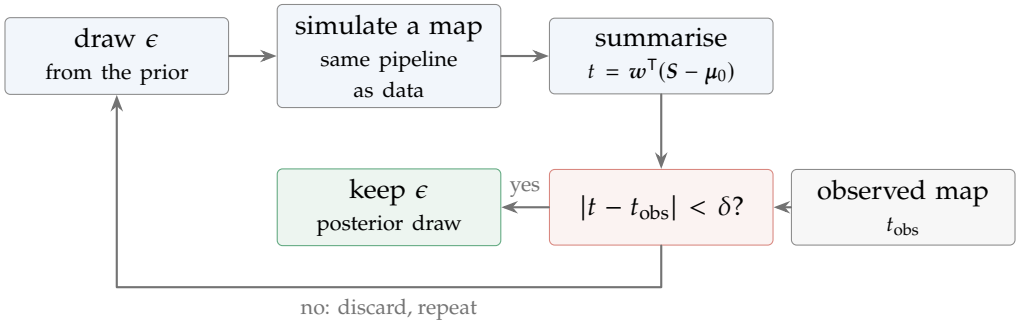

Figure 12.69: Rejection ABC. Parameters are drawn from the prior and pushed through the simulator; only those whose simulated summary lands close to the observed one survive. Surviving in proportion to how often each ϵ produces something like the data is exactly the likelihood weighting of Bayes' theorem.

12.29.2 Why compress first

The window in (12.106) is around one number. Why not around the whole 26-number Betti vector? Because in many dimensions "close" almost never happens. Measure the distance between a simulated vector and the observed one in units of the noise, $D^2 = (\boldsymbol{S} - \boldsymbol{S}_{\text{obs}})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{S} - \boldsymbol{S}_{\text{obs}})$. Even a simulation with exactly the right ϵ differs from the observation by two independent fluctuations, so its $\boldsymbol{S} - \boldsymbol{S}_{\text{obs}}$ has covariance $2\mathbf{C}$ and

$$\mathbb{E}[D^2] = \mathrm{Tr}\big(\mathbf{C}^{-1}\,2\mathbf{C}\big) = 2p = 52, \qquad D \approx 7, \tag{12.107}$$

while the effect of a wrong ϵ adds only $(\Delta\epsilon)^2 F$ to D^2. In 26 dimensions every simulation is far away, the right ϵ and the wrong one almost equally; keeping the nearest few per cent selects mostly on noise. This is the curse of dimensionality, and the cure is to compress the data to as few numbers as there are parameters while keeping the information.

The score as a compression. If the mean were linear, $\boldsymbol{\mu}(\epsilon) = \boldsymbol{\mu}_0 + \epsilon \boldsymbol{d}$, the Gaussian log-likelihood would be

$$\begin{aligned} \ln \mathcal{L}(\epsilon) &\overset{(1)}{=} -\tfrac{1}{2}(\boldsymbol{S} - \boldsymbol{\mu}_0 - \epsilon \boldsymbol{d})^{\mathsf{T}} \mathbf{C}^{-1} (\boldsymbol{S} - \boldsymbol{\mu}_0 - \epsilon \boldsymbol{d}) \\ &\overset{(2)}{=} -\tfrac{1}{2}(\boldsymbol{S} - \boldsymbol{\mu}_0)^{\mathsf{T}} \mathbf{C}^{-1} (\boldsymbol{S} - \boldsymbol{\mu}_0) + \epsilon\, \boldsymbol{d}^{\mathsf{T}} \mathbf{C}^{-1} (\boldsymbol{S} - \boldsymbol{\mu}_0) - \tfrac{1}{2}\epsilon^2 F, \end{aligned} \tag{12.108}$$

(1) (12.103) with the linear mean.
(2) Multiply out; the two cross terms are equal because $\mathbf{C}^{-1}$ is symmetric; $F = \boldsymbol{d}^{\mathsf{T}} \mathbf{C}^{-1} \boldsymbol{d}$.

The first term does not depend on ϵ and cancels in any posterior. The data enter the ϵ-dependence only through $\boldsymbol{d}^{\mathsf{T}} \mathbf{C}^{-1} (\boldsymbol{S} - \boldsymbol{\mu}_0)$, the score (12.99). Two maps with the same score have the same posterior: the score is a sufficient statistic for this model (Section 3.16.2), and dividing it by F turns it into an estimate of ϵ,

$$t = \frac{\boldsymbol{d}^{\mathsf{T}} \mathbf{C}^{-1} (\boldsymbol{S} - \boldsymbol{\mu}_0)}{\boldsymbol{d}^{\mathsf{T}} \mathbf{C}^{-1} \boldsymbol{d}}. \tag{12.109}$$

For a model that is only approximately linear and Gaussian, t is no longer exactly sufficient, but it keeps nearly all the Fisher information about ϵ near the fiducial point. This approximate score compression is how simulation-based analyses in cosmology reduce long data vectors to one number per parameter [247]. Note what the Gaussian model is used for here: only to choose the weights $\boldsymbol{w} = \mathbf{C}^{-1}\boldsymbol{d}/F$. If the weights are imperfect we lose some information, but the posterior is still correct for the t we use, because ABC takes the distribution of t from the simulator.

12.29.3 ABC on one map

The script `code/ch12/c07_abc.py` applies this to the same mock map as Section 12.27.2 (seed 250, $\epsilon_{\text{true}} = 0.05$). It draws 20000 new maps with ϵ uniform on $(-0.15, 0.15)$:

Listing 12.23: One ABC simulation: prior draw, map, summary (`code/ch12/c07_abc.py`)

```
def one(i):
    r = rng_for("ch12", "c07_abc", i)
    eps = r.uniform(-PRIOR, PRIOR)                    # 1. draw a parameter from the
    prior
    return eps, betti_vector(model.draw(eps, r))      # 2. simulate a map, 3. summarise
    it
```

and then keeps the 2% whose compressed summary is nearest to the observed one:

Listing 12.24: Compression weights, the observed summary, and rejection on t and on all 26 numbers (`code/ch12/c07_abc.py`)

```
    w = Ci @ d / F                                    # t = w . (S - mu0) estimates eps

    S_obs = np.concatenate([z["grid_b0"][MOCK, eg.index(TRUE)], z["grid_b1"][MOCK,
    eg.index(TRUE)]])[ok]
    t_obs = (S_obs - mu0) @ w

    eps, S = simulate()
```

```
    S = S[:, ok]
    t = (S - mu0) @ w
    nkeep = int(KEEP * len(eps))
    acc1 = np.argsort(np.abs(t - t_obs))[:nkeep]          # 4. keep the closest: compressed
    tol1 = np.abs(t - t_obs)[acc1].max()
    D = S - S_obs
    dist = np.sqrt(np.einsum("ij,jk,ik->i", D, Ci, D))
    acc2 = np.argsort(dist)[:nkeep]                       # 4'. keep the closest: all p
    numbers
    e1, e2 = eps[acc1], eps[acc2]
```

Line by line: the weights `w` are $\mathbf{C}^{-1}\boldsymbol{d}/F$ from the null maps and the derivative of Section 12.26.1; `t_obs` is the observed map's compressed summary, 0.0338; the 400 simulations with t nearest to it are kept, which sets the window at $\delta = 0.0028$; for comparison the 400 simulations nearest in the full 26-dimensional distance D are kept as well.

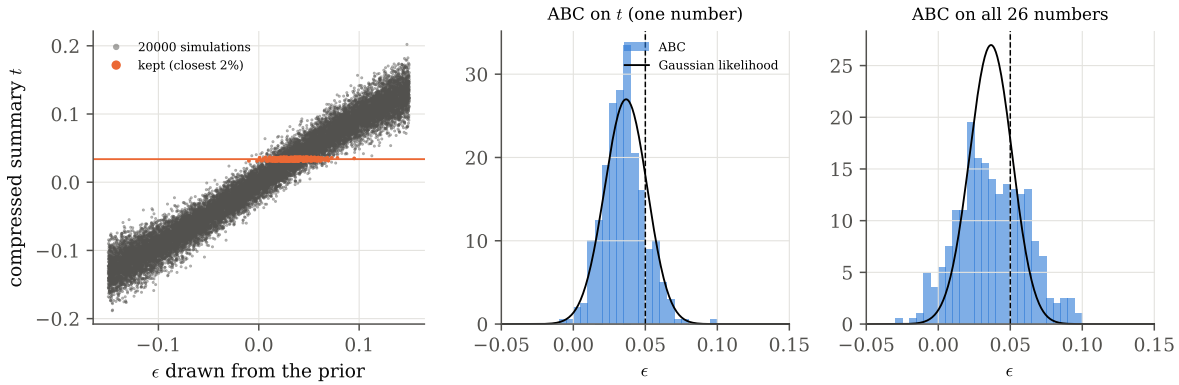

Figure 12.70: Left: the compressed summary t of 20000 maps against the ϵ they were made with. The band is the likelihood seen sideways: at each ϵ, the spread of t is its sampling distribution. The horizontal line is the observed t; the orange points, the simulations nearest to it, are the ABC posterior draws. Middle: their histogram against the Gaussian-likelihood posterior of Section 12.27.2. Right: the same with the window around all 26 numbers: much broader.

The result. ABC on t gives $\epsilon = 0.0351 \pm 0.0144$. ABC on all 26 numbers gives 0.0377 ± 0.0236, and its kept simulations are at distances up to $D = 4.9$, not far below the $D \approx 7$ that (12.107) predicts even for the right ϵ: the selection is mostly noise, as expected. The Gaussian likelihood gave 0.0364 ± 0.0148.

Is ABC more honest? On this one map ABC on t comes out a little narrower than the Gaussian likelihood (0.0144 against 0.0148). One map cannot settle the question. The width that 400 kept simulations give is itself uncertain by a few per cent, and the width of either posterior changes from map to map. But the ABC simulations do not depend on which map was observed, so the same 20000 of them serve all 250 mock maps of Section 12.27.3, at no extra cost. Over those maps the typical (median) ABC width is 0.0166, against 0.0140 for the Gaussian likelihood. The ABC interval contains the true ϵ in $65 \pm 3\%$ of the maps; the Gaussian interval does so in 62%, and both should do so in 68%.

Where does the extra width come from? The left panel of Figure 12.70 shows it. A straight-line fit of t against ϵ has slope 0.92 (an exactly linear model would give 1), and the points scatter around the line by 0.0163. The scatter grows with ϵ, from 0.0136 near $\epsilon = 0$ to 0.0143 near 0.05. A posterior from t alone is about as wide as the scatter divided by the slope, $0.0143/0.92 \approx 0.016$ near the truth. The window adds little: $\delta = 0.0028$ adds $\delta^2/3$ to

the variance, about one per cent. The Gaussian likelihood instead assumed the $\epsilon = 0$ scatter everywhere, which gives 0.0140. ABC uses the scatter the simulator really produces at each ϵ, so its intervals are wider and contain the truth about as often as they should. That is the width the coverage test asked for.

What it cost. ABC used 20000 simulations to give one posterior, against about 5000 for the Gaussian-likelihood analysis, which then serves any number of maps. Rejection wastes 98% of its simulations, and shrinking δ wastes more. Modern simulation-based inference keeps every simulation: it fits a flexible model of the density $p(t \mid \epsilon)$ or $p(\epsilon \mid t)$ (a neural density estimator) to the simulated pairs, and chooses where to simulate next by where the posterior is [247]. Akeret et al. built the same rejection-and-refinement loop for cosmological forward models [248]. The logic is (12.106) in every case: the simulator defines the likelihood, and the data are compared with it through a few well-chosen numbers.

Key idea: The simulator is the likelihood

If we can simulate the data for any parameter value, we never need to write $P(\boldsymbol{S} \mid \theta)$: keeping parameter draws whose simulations resemble the data samples the posterior (12.106). "Resemble" must be measured on a few informative numbers, such as the score-compressed summary (12.109), because in many dimensions nothing resembles anything.

12.30 Reproducing the literature: topology and $f_{\rm NL}$

Two papers made the claim tested above, that topological summaries see primordial non-Gaussianity that the power spectrum does not, and turned it into numbers. Cole and Shiu forecast $f_{\rm NL}$ from persistence diagrams of CMB maps [244]; Biagetti, Cole and Shiu detected it in the topology of simulated dark-matter haloes [111]. A third, Heydenreich and collaborators, did the same for cosmological parameters from weak-lensing mass maps [56], and was reproduced in Section 12.20. We redo the key result of each of the first two on our maps, with the machinery of the previous sections, and see what survives the change of setting.

12.30.1 Cole and Shiu (2018): are persistence diagrams worth more than Betti curves?

Their question. Betti curves count the features alive at each threshold; a persistence diagram also records which birth goes with which death. The diagram therefore contains the Betti curves ((12.41)) and possibly more. Is the extra information about local non-Gaussianity worth having? In 2017 nobody had tried persistence diagrams on the CMB.

Their setup. They used public simulations of CMB temperature with local non-Gaussianity: for each of 1000 realisations, a Gaussian set of $a_{\ell m}$ and a separate non-Gaussian part, combined as $a_{\ell m} = a^{\rm G}_{\ell m} + f_{\rm NL} a^{\rm NG}_{\ell m}$ so that any $f_{\rm NL}$ can be dialled in. From each sky they cut two square patches of 1024×1024 pixels around the poles, and computed the persistence diagrams of the sublevel filtration (lowering the threshold from the coldest pixel up) and the Betti curves. The diagrams were binned into two-dimensional histograms (birth $\times$ persistence), and the Betti curves divided by their maximum.

resolution	$N_{\text{side}} = 512$, $\ell_{\max} = 1024$, Gaussian smoothing $\theta_s = 90'$ (FWHM 212′)
maps	2000 patches of 1024^2 pixels per value of $f_{\text{NL}} \in \{0, 10, 25, 50, 100\}$
mean $\boldsymbol{\mu}(f_{\text{NL}})$	average of 800 patches at $f_{\text{NL}} = 0, 10, 50$
covariance	2000 patches at $f_{\text{NL}} = 0$, with the Hartlap factor
statistics	β_0, β_1, $\beta_0 + \beta_1$; histograms PD0, PD1, PD0+PD1

Their key equation. Their likelihood (their eq. 4.2) is our (12.103), $\ln \mathcal{L}(f_{\text{NL}}) = -\frac{1}{2}(\boldsymbol{d} - \boldsymbol{\mu}(f_{\text{NL}}))^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{d} - \boldsymbol{\mu}(f_{\text{NL}}))$, evaluated for "data" $\boldsymbol{d}$ equal to the simulated mean at $f_{\text{NL}} = 0$, and fitted with a Gaussian in f_{NL} whose width is the quoted error. With noise-free data at the fiducial point and a mean that is linear in the parameter, $\boldsymbol{\mu}(f) = \boldsymbol{\mu}_0 + f\boldsymbol{\mu}'$,

$$\ln \mathcal{L}(f) \overset{(1)}{=} -\tfrac{1}{2}(\boldsymbol{\mu}_0 - \boldsymbol{\mu}_0 - f\boldsymbol{\mu}')^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{\mu}_0 - \boldsymbol{\mu}_0 - f\boldsymbol{\mu}') \overset{(2)}{=} -\tfrac{1}{2}f^2\,\boldsymbol{\mu}'^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\mu}' \overset{(3)}{=} -\frac{f^2}{2\sigma^2}, \qquad \sigma = \left(\boldsymbol{\mu}'^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\mu}'\right)^{-1/2}, \tag{12.110}$$

(1) Insert $\boldsymbol{d} = \boldsymbol{\mu}_0$ and the linear mean.
(2) The constant vectors cancel; f comes out of both factors.
(3) A Gaussian in f centred on zero, with variance the inverse of the quadratic coefficient.

The fitted width is the Fisher error (12.100). Symbol map: their f_{NL} is our ϵ up to a constant factor (the variance of their potential against our unit-variance g), so absolute errors cannot be compared, but *ratios* of errors between statistics can. We compare every error with that of $\beta_0 + \beta_1$.

What we compute. `code/ch12/c08_repro.py` evaluates (12.100) for the same six statistics on our 256^2 maps, with derivatives from shared seeds at $\epsilon = \pm 0.05$ and the covariance from the 1000 null maps:

Listing 12.25: Fisher error for one statistic (optionally with each curve divided by its maximum) (`code/ch12/c08_repro.py`)

```
def vec(prefix, keys, norm=False):
    parts = []
    for k in keys:
        a = z[prefix + k].astype(float)
        if norm:                                          # divide each curve by its own maximum
            a = a / np.maximum(a.max(-1, keepdims=True), 1)
        parts.append(a)
    return np.concatenate(parts, axis=-1)

def sigma_fisher(keys, norm=False):
    N = vec("null_", keys, norm)
    ok = N.std(0) > 1e-9
    N = N[:, ok]
    n, p = N.shape
    Ci = np.linalg.inv(np.atleast_2d(np.cov(N.T))) * (n - p - 2) / (n - 1)
    G = vec("grid_", keys, norm)[..., ok]
    d = ((G[:, eg.index(0.05)] - G[:, eg.index(-0.05)]) / 0.1).mean(0)
    return 1 / np.sqrt(d @ Ci @ d)
```

It also repeats the Betti rows with every curve divided by its own maximum, as they did.

Side by side.

statistic	Cole & Shiu $\Delta f_{\rm NL}$	ratio	ours $\sigma(\epsilon)$	ratio
β_0	67.4	1.11	0.0245	1.76
β_1	66.1	1.09	0.0271	1.95
$\beta_0 + \beta_1$	60.6	1.00	0.0139	1.00
PD0	39.1	0.65	0.0229	1.65
PD1	37.4	0.62	0.0291	2.10
PD0+PD1	35.8	0.59	0.0133	0.96

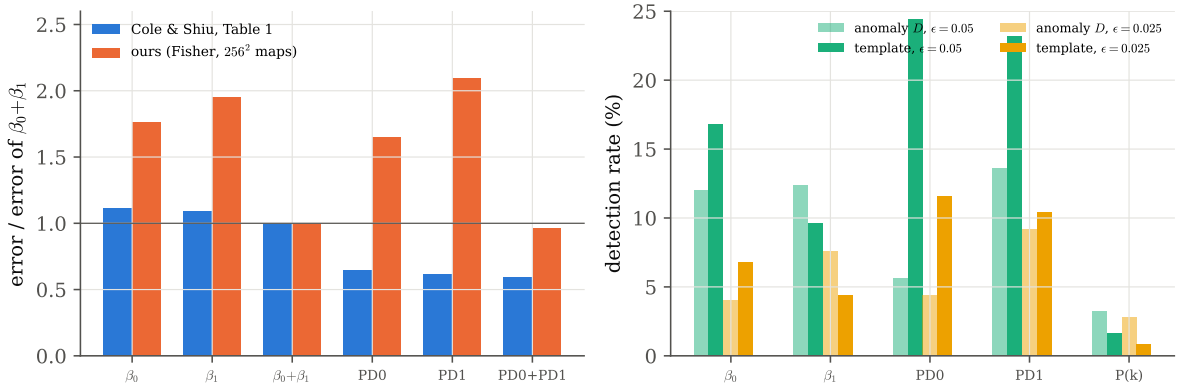

Figure 12.71: Left: errors on the non-Gaussianity amplitude relative to that of $\beta_0 + \beta_1$, from Cole and Shiu's Table 1 (blue) and from our Fisher matrices (orange). They find the diagrams 40% better than the curves; on our maps the two are equal, while each curve alone is about twice as bad as the pair. Right: detection rates of $\epsilon = 0.05$ and 0.025 with Biagetti et al.'s anomaly distance (pale) and template statistic (dark), for four topological summaries and the power spectrum.

Why they differ. Two results disagree. Their diagrams beat their Betti curves by a factor 0.59; ours tie. And their β_0 and β_1 each nearly match the pair, while ours are each about twice as bad. Go through the differences in setup one at a time.

The normalisation of the Betti curves. Dividing each curve by its maximum throws away its overall amplitude. On our maps it costs something: $\beta_0 + \beta_1$ normalised gives 0.0167 instead of 0.0139, so that the diagrams measured against normalised curves would come out at $0.0133/0.0167 \approx 0.80$ instead of 1. Part of their gap, not all of it.

Where the signal lives. In our model the quadratic term is applied to the field we observe, smoothed once; most of what ϵ does is move pixel values, a one-point effect (Section 12.23.2), and it shows up as more pieces in the hot tail and fewer lakes in the cold tail, two nearly independent witnesses (Section 12.25.3). Betti curves sampled out to $\pm 3\sigma$ capture that completely, and β_0 and β_1 see different tails, so each alone loses half. In their CMB maps the quadratic term acts on the primordial potential and passes through the acoustic transfer function, which mixes neighbouring points (Section T3.2.3); less of the signal is a simple shift of values, and more of it is in how features are arranged. If that is the reason, removing the one-point part from our maps should restore their result. It does: at area-fraction thresholds, where the one-point effect is gone by construction, our persistence histograms give $\sigma(\epsilon) = 0.104$ against 0.169 for the Betti curves, a ratio of $0.104/0.169 \approx 0.62$, against their 0.59. We cannot prove from their paper that this is the whole explanation, but it is the one we can test, and it passes.

Smaller differences. Their histograms are finer than our 10×5 bins; their patches have edges, which add pieces along the boundary (the reason they normalised); their maps hold far more correlation areas than our 256^2 pixels. None of these changes the ratios we compare by as much as the two effects above.

Lesson. "Persistence diagrams carry more information than Betti curves" is not a theorem; it depends on where in the field the signal lives. When the signal is a shift of values, a good Betti curve already has it; when it is in the arrangement, birth–death pairs add information, and on our maps they add it in the same proportion as on Cole and Shiu's.

12.30.2 Biagetti, Cole and Shiu (2021): detecting $f_{\rm NL}$ without a likelihood

Their question. Can the topology of the dark-matter halo distribution reveal a local $f_{\rm NL}$ as small as 10, through the structures it affects at scales of about $10\,h^{-1}$Mpc, where the usual signature in the halo power spectrum (a bias that grows on large scales) is negligible? And how can one attach a significance to such a detection without writing a likelihood for persistence summaries?

Their setup. N-body simulations with Gaussian initial conditions ("G85L") and with $f_{\rm NL} = 10$ ("NG10L"), in boxes whose five realisations add up to $40\,(h^{-1}\mathrm{Gpc})^3$, about a Euclid-like volume; persistence diagrams of the halo catalogues with a distance-to-measure filtration; summaries built from the diagrams (distributions of births B_p, deaths D_p, persistences, and Betti curves). Significance comes from splitting the realisations into a "survey" and a "fiducial" set in all possible ways: Gaussian against Gaussian splits give the null distribution, Gaussian against non-Gaussian splits give the detection rate. Two statistics are used.

Their equations, derived. The *anomaly* distance (their eq. 4.1) is

$$D_{\rm anomaly} = \Big[\frac{1}{N}\sum_{i=1}^{N}\frac{(d_i-\mu_i)^2}{\sigma_i^2}\Big]^{1/2}, \tag{12.111}$$

with μ_i, σ_i the mean and standard deviation of entry i under the null: the χ^2 of (12.93) with the covariance replaced by its diagonal, divided by N, square-rooted. It is an omnibus test, and it ignores correlations. A detection is a D above the 95th percentile of the Gaussian splits. The *template* (their eqs. 4.2–4.3) is the mean difference between a strongly non-Gaussian ($f_{\rm NL} = 250$) and a Gaussian simulation *with the same initial seed*, $\boldsymbol{T} = \overline{\boldsymbol{S}_{\rm NG} - \boldsymbol{S}_{\rm G}}$, and the statistic is the projection of the data on it, $D_{\rm template} = (\boldsymbol{S}-\boldsymbol{\mu})\cdot\boldsymbol{T}/\sigma_T$, with σ_T its standard deviation under the null; a detection is a value above the 97.5th percentile. What is the template, in our language? To first order the shared-seed difference is $\boldsymbol{T} \approx f_{\rm big}\,\boldsymbol{d}$, the derivative of Section 12.26.1 times the large amplitude, so

$$D_{\rm template} \overset{(1)}{=} \frac{f_{\rm big}\,\boldsymbol{d}^{\mathsf T}(\boldsymbol{S}-\boldsymbol{\mu})}{\sqrt{\mathrm{Var}[f_{\rm big}\,\boldsymbol{d}^{\mathsf T}(\boldsymbol{S}-\boldsymbol{\mu})]}} \overset{(2)}{=} \frac{\boldsymbol{d}^{\mathsf T}(\boldsymbol{S}-\boldsymbol{\mu})}{\sqrt{\boldsymbol{d}^{\mathsf T}\mathbf{C}\boldsymbol{d}}}, \tag{12.112}$$

(1) $\boldsymbol{T} \approx f_{\rm big}\boldsymbol{d}$, and σ_T is the null standard deviation of the projection.
(2) $f_{\rm big}$ cancels; the variance of $\boldsymbol{a}^{\mathsf T}\boldsymbol{x}$ is $\boldsymbol{a}^{\mathsf T}\mathbf{C}\boldsymbol{a}$.

This is the score (12.99) with $\mathbf{C}^{-1}$ replaced by the identity: it aims at the right direction but does not weight the entries by their noise. How much does that cost? For any weights $\boldsymbol{w}$, the statistic $\boldsymbol{w}^{\mathsf T}(\boldsymbol{S}-\boldsymbol{\mu})$ has, at a small ϵ, mean $\epsilon\,\boldsymbol{w}^{\mathsf T}\boldsymbol{d}$ and standard deviation $\sqrt{\boldsymbol{w}^{\mathsf T}\mathbf{C}\boldsymbol{w}}$. Write $\boldsymbol{a} = \mathbf{C}^{1/2}\boldsymbol{w}$ and $\boldsymbol{b} = \mathbf{C}^{-1/2}\boldsymbol{d}$; then

$$\frac{\boldsymbol{w}^{\mathsf T}\boldsymbol{d}}{\sqrt{\boldsymbol{w}^{\mathsf T}\mathbf{C}\boldsymbol{w}}} \overset{(1)}{=} \frac{\boldsymbol{a}^{\mathsf T}\boldsymbol{b}}{|\boldsymbol{a}|} \overset{(2)}{\le} |\boldsymbol{b}| \overset{(3)}{=} \sqrt{\boldsymbol{d}^{\mathsf T}\mathbf{C}^{-1}\boldsymbol{d}} = \sqrt{F}, \tag{12.113}$$

(1) $\boldsymbol{w}^{\mathsf T}\boldsymbol{d} = \boldsymbol{w}^{\mathsf T}\mathbf{C}^{1/2}\mathbf{C}^{-1/2}\boldsymbol{d} = \boldsymbol{a}^{\mathsf T}\boldsymbol{b}$ and $\boldsymbol{w}^{\mathsf T}\mathbf{C}\boldsymbol{w} = |\boldsymbol{a}|^2$.

(2) Cauchy–Schwarz, with equality when $\boldsymbol{a} \propto \boldsymbol{b}$, that is $\boldsymbol{w} \propto \mathbf{C}^{-1}\boldsymbol{d}$: the score.
(3) $|\boldsymbol{b}|^2 = \boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{d}$.

The score is the best linear statistic; the template reaches the bound only if $\boldsymbol{d}$ happens to be an eigenvector of $\mathbf{C}$. Figure 12.72 shows the geometry.

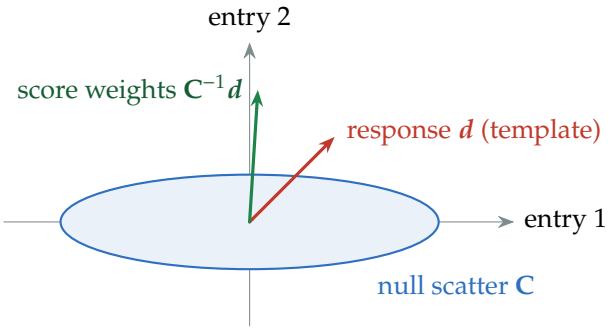

Figure 12.72: Why whitening matters. Two entries of a data vector, the first very noisy (long axis of the null ellipse) and the second quiet. A small ϵ moves the mean along $\boldsymbol{d}$ (red), equally in both. Projecting on $\boldsymbol{d}$ mixes in the large noise of entry 1; the score weights $\mathbf{C}^{-1}\boldsymbol{d}$ (green) lean on the quiet entry. For the ellipse drawn, with standard deviations 2 and 0.5, the signal-to-noise per unit ϵ is $2/\sqrt{4.25} = 0.97$ along $\boldsymbol{d}$ and $\sqrt{4.25} = 2.06$ along $\mathbf{C}^{-1}\boldsymbol{d}$.

What we compute. The same two statistics on our maps, in `c08_repro.py`: null mean and standard deviations from the 1000 null maps, the null distributions of D_{anomaly} and D_{template} from the 500 check maps, the template from the shared-seed differences between $\epsilon = 0.1$ and $\epsilon = 0$ for grid seeds 0–249 (twice the tested amplitude, where theirs was twenty-five times), and detection rates for seeds 250–499 at $\epsilon = 0.05$ and 0.025, for β_0, β_1, PD0, PD1 and the power spectrum.

Side by side. Biagetti et al. detect $f_{\mathrm{NL}} = 10$ in about 85% of survey volumes with the template on B_1 (births of loops) and 74% on D_1 (deaths of loops), at the 97.5% level, and several summaries reach detection rates above 60% with the anomaly distance at the 95% level; the halo power spectrum, on large scales, does about as well as the topology. On our maps, at $\epsilon = 0.05$:

	β_0	β_1	PD0	PD1	$P(k)$
anomaly D, 95% (%)	12	12	6	14	3
template, 97.5% (%)	17	10	24	23	2

and at $\epsilon = 0.025$ the template rates are 7, 4, 12, 10 and 1%.

Why they differ. Each rate comes from 250 maps, so a rate near 15% is uncertain by $\sqrt{0.15 \times 0.85/250} \approx 2$ percentage points, and both statistics are judged against the same 500 check maps. Within that precision the qualitative pattern is theirs: where the two statistics differ by several such errors, the template beats the anomaly distance, because it aims (Section 12.25.3); the anomaly distance, an unweighted omnibus statistic, is the weakest. The power spectrum is where our setting departs on purpose: our maps have the same spectrum by construction, so it detects nothing beyond the false-alarm rate, while in a halo catalogue local f_{NL} changes the large-scale bias and the spectrum does respond. The absolute rates differ because the experiments differ in size, one 256^2 map against $40\,(h^{-1}\mathrm{Gpc})^3$ of haloes. The rates are also low compared with what our data can do, and (12.113) says why: the template is unwhitened.

For β_0 alone the Fisher error is 0.0245, so the score at $\epsilon = 0.05$ is shifted by $0.05/0.0245 \approx 2.0$ standard deviations, and a one-sided test at 97.5% (threshold 1.96) would detect it about half the time; the template detects 17%. Our β_0 curve has entries with very different noise, large counts near the median and small, quiet counts in the tail where the signal is, exactly the situation of Figure 12.72.

Lesson. Their two statistics are the omnibus test and an unwhitened score. Reproducing them showed that the step from anomaly to template, aiming at the expected signal, is what raises the detection rate, and that the next step, weighting by the inverse covariance, is worth as much again whenever the entries of the summary are not equally noisy.

Heydenreich et al. (2021), recalled. The weak-lensing analogue was reproduced in Section 12.20: persistent Betti numbers of aperture-mass maps, with a simulated covariance and an emulated mean, constrain S_8 better than peak counts, by 44% in figure of merit in their KV450-like setup and 18% in error for a Euclid-like survey [56]. It is the same pipeline as for ϵ, with a cosmological parameter in place of ϵ and a non-Gaussian field produced by gravity rather than by inflation.

12.31 How it is done in research

Every step from the nine-pixel grid to the ABC posterior was a scaled-down version of an analysis that is run on real data. The steps are the same; the size of the maps, the realism of the simulations, the number of parameters and the care taken at each step are not. Figure 12.73 lays out the pipeline as a real analysis runs it, for a CMB Gaussianity test or an $f_{\rm NL}$ forecast from topology, and for its large-scale-structure and lensing relatives.

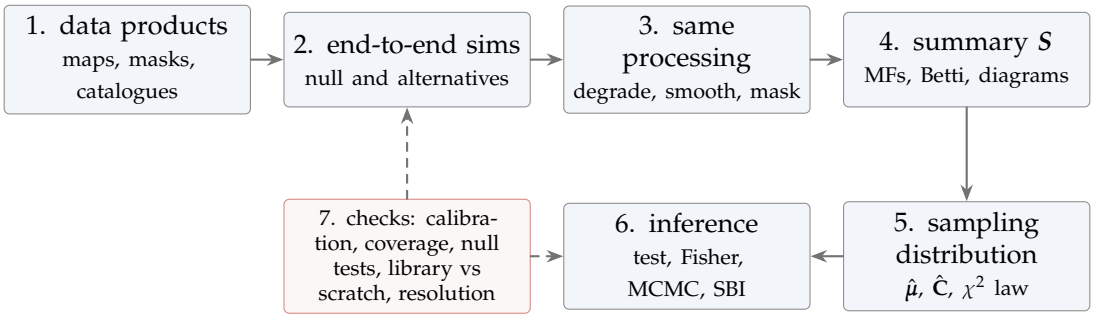

Figure 12.73: The pipeline of a simulation-based topological analysis. The data and every simulation pass through the same processing and the same summary; the simulations then supply the mean, the covariance and the distribution of the test statistic, and every inference is checked on simulations whose answer is known before it is applied to the sky.

1. Data products. For the CMB: the component-separated temperature and E-mode maps of *Planck* at $N_{\rm side} = 2048$, the common mask (about 75% of the sky kept) and the noise and beam models [109]. For large-scale structure: halo or galaxy catalogues, or N-body snapshots [111]; for lensing, shear catalogues and mass maps (Section 12.21). *Ours:* no data; flat 256^2 maps and full skies at $N_{\rm side} = 128$. *Cost:* everything here is a demonstration on simulations; the real sky is analysed in Chapter 13.

2. Simulations. *Planck* uses 999 FFP10 end-to-end simulations, which contain the lensed CMB, the instrument noise with its anisotropy and correlations, the scanning and the component-

separation pipeline [109]. Non-Gaussian alternatives are made by adding a separately computed non-Gaussian part to Gaussian $a_{\ell m}$, so that any $f_{\rm NL}$ can be dialled in, with the transfer functions of the full physics [244]. *Ours:* Gaussian fields with white noise; a quadratic term applied pointwise and then smoothed, renormalised to the same spectrum. *Cost:* our null distributions are narrower than real ones (no correlated noise, no foreground residuals), so our detection rates are upper bounds, and our non-Gaussian signal is mostly a shift of values, which favours Betti curves over persistence diagrams (Section 12.30.1).

3. Processing. The real maps are degraded to several resolutions, smoothed with a beam that grows with the pixel size, and masked, and every simulation is processed in exactly the same way; analyses at several resolutions or needlet scales probe several physical scales. *Ours:* one resolution and one beam per study. *Cost:* we test one scale at a time, and do not face the look-elsewhere effect that many resolutions and statistics create (Section 4.14).

4. Summaries. Area, boundary length and genus at a dozen thresholds for *Planck*; Betti curves and binned persistence diagrams for the topology papers, computed with gudhi, PHAT, ripser or dedicated cubical codes. *Ours:* our own union–find and cell counts, checked against gudhi and scikit-image (Sections 12.22.1 and 12.28.1). *Cost:* none in principle; the check against a library is the step a real analysis must also do once.

5. The sampling distribution. Mean and covariance from hundreds to thousands of simulations, the Hartlap factor or the Sellentin–Heavens t-likelihood for the noise in the covariance [6, 245], and the distribution of the test statistic from simulations rather than from tables. *Ours:* the same, with 1000 maps for the covariance and 500 for the reference distribution. *Cost:* with $p = 26$ and $n = 1000$ the noise in the covariance is small (Hartlap factor 0.973); with longer summaries, 98-bin persistence histograms, it is not, and Section 12.25.2 showed that the table then fails.

6. Inference. For a Gaussianity test, a χ^2 and a simulated probability. For $f_{\rm NL}$ itself, *Planck* uses the bispectrum, the optimal statistic for a known three-point shape, and keeps the Minkowski functionals as a model-independent check (Section T3.5.2). Forecasts from topology use Fisher matrices from simulated derivatives; parameter inference with several cosmological and nuisance parameters uses an emulator of $\boldsymbol{\mu}(\boldsymbol{\theta})$ over a few dozen simulated cosmologies and an MCMC [56], or simulation-based inference with neural density estimators [247]. *Ours:* one parameter, finite differences at seven values, a grid posterior checked by Metropolis and emcee, and rejection ABC. *Cost:* no degeneracies with other parameters (Section 12.20.2 showed how much they matter), and no nuisance parameters to marginalise.

7. Checks. The checks we ran are the ones a real analysis runs. *Calibration*: p-values of null simulations must be uniform (Section 12.25.2). *Coverage*: intervals must contain the truth at the stated rate over mock data sets (Section 12.27.3); ours did not at $\epsilon = 0.05$, and the diagnosis, a covariance fixed at the wrong parameter, is a real and common failure. *Null tests*: statistics that should see nothing must see nothing, as the power spectrum did here. *Implementation*: a from-scratch code against a library, and a convergence test in resolution and in the number of simulations.

How this is used in real research: how the tests are run on the real sky

Planck tested the Gaussianity and isotropy of the temperature and polarization maps with the three Minkowski functionals at resolutions from $N_{\rm side} = 16$ to 2048, using 999 simulations for the mean, the covariance and the distribution of χ^2; the temperature maps were consistent with Gaussian skies, with probabilities from 24% to 99.8%, and the bispectrum bounded the local $f_{\rm NL}$ to -0.9 ± 5.1 [107, 109] (Section T3.5). Persistent homology has entered the same pipelines as a summary: Betti curves and persistence diagrams for $f_{\rm NL}$ in CMB simulations [244] and in halo catalogues [111], and persistent Betti numbers of weak-lensing mass maps, which tightened S_8 beyond peak counts in survey-like analyses [56] (Section 12.20). In every case the topology is the cheap part, seconds per map; the simulations, processed exactly like the data, are the expensive part and the scientific core.

Each reduction, what the full analysis does instead, and what the reduction costs:

reduction	full research version	what the reduction costs
map size	full sky at $N_{\rm side} = 2048$; 1024^2-pixel patches	our 256^2 maps hold fewer correlation areas: errors on ϵ larger by roughly the square root of the area ratio
sphere resolution	$N_{\rm side} = 2048$, beams down to 5′	at $N_{\rm side} = 128$ the 40′ beam is barely resolved and counts fall short of the formula (Section 12.28.2)
non-Gaussian model	local $f_{\rm NL}$ through the radiation transfer functions	our signal is mostly one-point; amplitudes are ∼100 times the *Planck* bound
noise	anisotropic, correlated, with foreground residuals	white noise only; null scatter underestimated
simulations	999 end-to-end FFP10 skies; thousands of N-body volumes	1000 to 5000 Gaussian maps per study; p-values resolved to 1/501 or 1/401
covariance	t-likelihood or covariance at the best fit	fixed at $\epsilon = 0$; 68% intervals covered 62%
parameters	cosmology plus nuisances, emulated means	one parameter, finite differences

Recap

- A topological summary is a random variable with a sampling distribution $P(S \mid \theta)$ (12.82); on a 3×3 grid it can be enumerated ($\mathbb{E}\,\chi = p + 4q^2 - 4q^4$, $\mathbb{E}\,\beta_1 = p^4 q$), on a real map only simulated (Section 12.22).
- The local model $g + \epsilon(g^2 - 1)$, renormalised by $\sqrt{S_g/S_\phi}$ with $S_\phi = S_g + \epsilon^2\,\mathcal{F}[2\xi^2]$, has the same spectrum for every ϵ; its Euler characteristic moves as Matsubara's formula predicts, mostly through the one-point term, which area-fraction thresholds remove (Section 12.23).
- With $\hat{\boldsymbol{\mu}}$ and $\hat{\mathbf{C}}$ from n simulations, the χ^2 of a new map is $(1 + \frac{1}{n})\frac{(n-1)p}{n-p} F_{p,n-p}$: Hartlap fixes its mean, not its width; rare-feature bins give it a heavy tail (Section 12.24).
- The simulated p-value $(1 + r)/(1 + N)$ is exact by exchangeability; reference maps must be independent of those used for the covariance. Aimed (score) tests beat omnibus χ^2 tests by a factor ≈ 1.8 in detectable ϵ for $p = 22$ (Section 12.25).
- Fisher errors from shared-seed derivatives: Betti 0.0139, persistence 0.0133, skewness 0.0365, power spectrum none; a Fisher number equal to its own noise bias means no

information (Section 12.26).

- Grid, Metropolis and emcee posteriors agree with the Fisher width; 68% intervals covered 62 ± 3% at $\epsilon = 0.05$, consistent with a covariance that grows with ϵ by 1.15, which predicts $2\Phi(1/\sqrt{1.15}) - 1 \approx 0.650$ (Section 12.27).
- On the sphere: beams lower λ and every count; noise adds short-lived features on the diagonal; masks cut and isolate. A *Planck*-style test with these operators is calibrated and detects same-spectrum non-Gaussian skies that pseudo-C_ℓ misses (Section 12.28).
- ABC samples the posterior from the simulator alone (12.106); it needs compression to one number per parameter. Over 250 maps its intervals are wider than the Gaussian ones and contain the truth about as often as they should (Section 12.29).
- Reproduced: Cole and Shiu's diagram-to-curve ratio 0.59 appears on our maps once the one-point signal is removed (0.62); Biagetti et al.'s template statistic beats their anomaly distance, and whitening would add as much again (Section 12.30).

Reading the literature

- **Excursion sets and the geometry of random fields.** Rice on counting crossings and maxima [237]; Adler, and Adler and Taylor, for the Gaussian kinematic formula [238, 239]; Tomita on curvature invariants [240]; Hamilton, Gott and Weinberg on the genus of large-scale structure [110]; Schmalzing and Górski on Minkowski functionals on the sphere [105]; Matsubara on weakly non-Gaussian fields [108].

- **Persistent homology.** Edelsbrunner, Letscher and Zomorodian on persistence [241]; Cohen-Steiner, Edelsbrunner and Harer on stability [243]; Otter et al. for a roadmap of algorithms and software [242]; Pranav et al. and Wilding et al. on the topology of the cosmic web [4, 5].

- **Polarization singularities and lensing.** Vachaspati and Lue, and Huterer and Vachaspati, on the singularities of CMB polarization [1, 2]; Challinor and Chon, and Lewis and Challinor, on lensing of the CMB [3, 47].

- **The CMB tests.** *Planck* 2018 on isotropy and statistics, and on primordial non-Gaussianity [107, 109]; Cole and Shiu on persistence diagrams of CMB maps [244]; Biagetti, Cole and Shiu on persistent homology and $f_{\rm NL}$ in halo catalogues [111].

- **Weak lensing.** Bartelmann and Schneider, and Kilbinger, for reviews [43, 44]; Kaiser and Squires on mass reconstruction [46]; Xavier et al. on lognormal fields [55]; Jeffrey et al. on the DES mass maps [54]; Kratochvil et al. and Dietrich and Hartlap on peak counts [52, 53]; Heydenreich et al. on persistent Betti numbers [56]; the HSC, KiDS and DES cosmic-shear analyses [45, 49, 50].

- **Inference from simulations.** Hobson et al. on covariances from simulations [HobsonBMC §3.4.3]; Hivon et al. on Monte Carlo calibration of an estimator [Hivon §1]; Hartlap, Simon and Schneider, Taylor, Joachimi and Kitching, and Sellentin and Heavens on estimated covariances [6, 137, 245]; Carron on parameter-dependent covariances [246]; Akeret et al. on approximate Bayesian computation in cosmology [248]; Alsing et al. on density-estimation likelihood-free inference and score compression [247].

Chapter summary

What should we measure in a field when the power spectrum is not enough? The answer is the shape of its excursion sets. Above a threshold a field becomes a region; its pieces and holes are counted by Betti numbers, their difference is the Euler characteristic, and on pixels the counting needs dual neighbour rules and can be done by $V - E + F$. These counts survive smooth one-to-one remappings and monotone changes of the values, which is what makes them robust; for a Gaussian field their averages follow from counting critical points and depend on the spectrum only through λ. Sweeping the threshold turns the excursion sets into a filtration, and recording when each piece and hole is born and dies gives persistence diagrams, stable under small perturbations and computable by union–find. On weak-lensing mass maps the same ideas met a field made non-Gaussian by gravity: shear converted to convergence, noise and masks modelled, and peaks, Minkowski functionals and persistent Betti numbers compared with the two-point function. Finally the summaries became random observables: sampling distributions by simulation, covariances and their noise, tests with simulated null distributions, Fisher forecasts with simulated derivatives, posteriors, coverage, and inference from the simulator alone. In the pipeline of the book,

$$\text{physical model} \to \text{field or data} \to \text{what matters} \to \text{summary } S \to \boxed{P(S \mid \theta) \to \text{physics}},$$

topological summaries now have every arrow: a reason to choose them, a construction, and a sampling distribution that turns them into tests, forecasts and posteriors. Chapter 13 applies them to the real *Planck* sky, and Chapter 14 collects what the whole book's machinery assumes and where it breaks.

Excursion sets and Minkowski functionals (part 12a)

concept	operational meaning	used later in
nuisance and protection	operator $\phi \to \mathcal{N}[\phi]$; T protected if $T[\mathcal{N}\phi] = T[\phi]$	Chapters 13 and 14
excursion set, β_0, β_1, χ	pixels above ν; pieces, holes, $\chi = \beta_0 - \beta_1 = V - E + F$	Chapter 13
dual connectivity	8 neighbours for the set, 4 for its complement	Chapter 13
area-fraction threshold	$\Psi(\nu_A)$ = measured area; removes monotone (one-point) distortions	Chapter 13
Minkowski functionals	area, boundary length, χ; the additive shape measures	Chapter 13
Gaussian kinematic formula	$\mathbb{E}\,\chi/A = \lambda \nu e^{-\nu^2/2}/(2\pi)^{3/2}$, $\lambda = \sigma_1^2/2\sigma_0^2$; sphere adds $2\Psi(\nu)$	Chapters 13 and 14
Matsubara correction	first-order shift from $S^{(0)}$, $S^{(1)}$, $S^{(2)}$; only differences survive at fixed area	Chapter 13

Persistent homology (part 12b)

concept	operational meaning	used later in
filtration, birth, death	nested excursion sets as ν falls; elder rule pairs each death with the younger feature	Chapter 13
persistence diagram, barcode	the set of (b, d) pairs; Betti curve = pairs alive at ν	Chapter 13
stability	$d_B(\mathrm{Dgm} f, \mathrm{Dgm} g) \le \|f - g\|_\infty$; noise adds points near the diagonal	Chapters 13 and 14
union–find, duality	islands by merging; lakes as islands of $-\phi$ with a sea around the map	Chapter 13
Vietoris–Rips	complex of a point cloud; its H_0 is the minimum spanning tree	Chapter 11
cosmic web	clusters, tunnels and voids as H_0, H_1, H_2 of a density field; gravity moves the diagram away from the Gaussian one	Chapter 11
polarization singularities	zeros of $Q + iU$, index $\pm\frac{1}{2}$; kept by one-to-one remappings	Chapter 14

Weak-lensing maps (part 12w)

concept	operational meaning	used later in
lognormal convergence	shifted lognormal $e^Z - \lambda$ matching the mean, variance and skewness of κ	Chapter 14
Kaiser–Squires	$\tilde{\kappa} = \tilde{\gamma}\, e^{-2i\varphi_\ell}$ in Fourier space; E and B modes; mass-sheet constant	Chapter 14
mask on the mass map	leaks E into B in band powers; cuts and isolates features in counts	Chapter 14
shape noise	$\sigma_e^2/(n\, A_{\mathrm{pix}})$ per pixel; must be smoothed before counting	Chapter 14
band powers and S_8	pseudo-C_ℓ on a masked patch; Fisher banana in (Ω_m, σ_8)	Chapter 14
beyond two points	peaks, MFs, Betti and persistent Betti numbers with simulated covariance and derivatives	Chapter 14
Fisher noise bias	$\mathrm{Tr}[\mathbf{C}^{-1}\boldsymbol{\Sigma}_d]/N_{\mathrm{der}}$; dangerous along degeneracies	Chapter 14

Topological summaries as statistics (part 12c)

concept	operational meaning	used later in
sampling distribution	$P(S \mid \theta)$ from simulations through the data's pipeline	Chapters 13 and 14
same-spectrum twins	renormalised local model; only beyond-two-point statistics separate them	Chapter 13
χ^2 with simulated $\hat{\mathbf{C}}$	Hotelling law $(1 + \frac{1}{n})\frac{(n-1)p}{n-p} F_{p,n-p}$; Hartlap fixes the mean only	Chapters 13 and 14
simulated p-value	$(1 + r)/(1 + N)$ with independent reference simulations; exact	Chapter 13
score vs omnibus	$t = \boldsymbol{d}^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{S} - \boldsymbol{\mu}_0)$ aims; χ^2 spreads over p directions	Chapters 13 and 14
Fisher from simulations	shared-seed central differences; compare F with its noise bias	Chapter 14
coverage test	fraction of mock intervals containing the truth; $2\Phi(1/k) - 1$ for a width off by k	Chapter 14
operators on the sky	beam lowers λ, noise adds diagonal features, mask cuts and isolates	Chapter 13
ABC and compression	keep prior draws whose simulated t is near t_{obs}; compress to one number per parameter	Chapter 14

Chapter 13

Capstone: The Analysis on Real Data

Where this chapter is going

Every method in the book so far was tried on data whose truth we had chosen. The skies of Chapter 8 were drawn from a spectrum we fixed, the parameters of Section 9.22 were recovered from a mock spectrum generated with known values, and the galaxies of Chapter 11 were points we had scattered ourselves. That is how a method is tested: we know the answer, so we can see whether the method finds it. Real data take that luxury away. Nobody tells us the true spectrum of the sky, the true distance to a galaxy or whether a hot spot is primordial or a leftover of our own Galaxy. What replaces the known answer is a set of *checks*: things that must come out a certain way if our description of the data is right, and that we can test on the data themselves.

The chapter takes three public data sets through the pipeline the book has been building,

$$\text{physical model} \to \text{field} \to \text{what matters} \to \text{summary} \to \text{its sampling distribution} \to \text{inference},$$

and each time the same three ingredients do the work: a summary computed from the data, a sampling distribution for that summary obtained by simulating the observation, and a comparison between the two. The *Planck* temperature map comes first. Its summary is the angular power spectrum, its sampling distribution comes from Gaussian skies passed through the same mask, beam and noise, and the inference is a fit of two cosmological parameters and a set of consistency tests. The same map comes back in Section 13.9, where the summary is the shape of its hot and cold regions (Minkowski functionals, Betti numbers, persistence) and the inference is a test of whether the sky is Gaussian. The last data set is a catalogue of galaxies from the BOSS survey (Section 13.15). Its summary is the pair correlation function, its sampling distribution comes from the data themselves (the jackknife), and the inference is a distance to the galaxies, read off the acoustic peak (Figure 13.1).

13.1 One sky, and the questions we put to it

In Section 9.22 we fitted cosmological parameters to a spectrum that looked like *Planck*'s but was not. At every multipole we drew a number from the law that a masked sky's spectrum follows, a scaled χ^2 with $(2\ell+1)f_{\rm sky}$ degrees of freedom around the fiducial C_ℓ plus the noise of the 143 GHz channel, and then asked the sampler to find the parameters again. It did, and the widths of the posteriors came out close to the published ones. That exercise tested the likelihood and the sampler. It said nothing about the step before them: going from a map of the sky to a spectrum. Here we take that step on the real sky. The tools are those of Chapters 7 to 9, imported unchanged, and the input is a map that *Planck* measured.

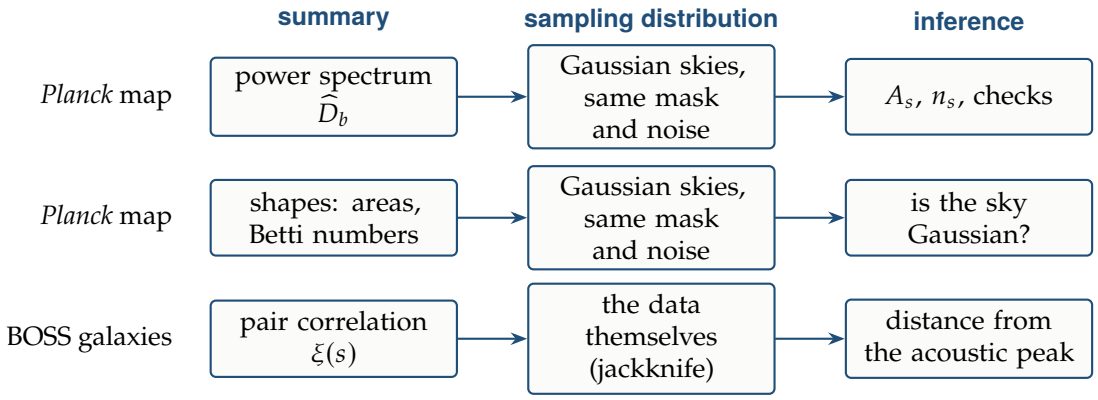

Figure 13.1: Three real data sets, one pipeline. Each row computes a summary from the data, finds how that summary would scatter if our description of the data were right, and draws a conclusion by comparing the two. The first row is the temperature power spectrum and two primordial parameters; the second row puts the same map's hot and cold regions to a Gaussianity test; the third measures a distance from the clustering of galaxies.

The event. The data are the **SMICA** temperature map of the 2018 *Planck* release [159]. It is a map of the CMB alone: the nine frequency maps of the satellite were combined, multipole by multipole, with weights chosen so that emission with the spectrum of the CMB passes and emission from our Galaxy and from other galaxies is suppressed. It comes at HEALPix resolution $N_{\rm side} = 2048$ [$12N_{\rm side}^2 \approx 5 \times 10^7$ pixels of 1.7′] (Section 7.11.2, [7]), smoothed by an effective beam that is a 5′ Gaussian. It also comes as two **half-mission maps**, made from the first and the second half of the observing time: the same sky, with independent noise. Our event is this map, and the summary we compute from it is its power spectrum, binned exactly as *Planck* bins its own.

What could have produced it? Before computing anything, we list the situations that could have made the map, one at a time, each with its reason.

1. *A Gaussian, statistically isotropic CMB with a spectrum $C_\ell(\boldsymbol{\theta})$, seen through the beam and the pixels, plus detector noise.* This is the standard model's prediction (Section 7.9). If it is the whole story, the spectrum carries all the information in the map, and the parameters $\boldsymbol{\theta}$ are what we want.
2. *Residual emission from our Galaxy or from other galaxies.* Component separation is not perfect. Dust and synchrotron residuals concentrate near the Galactic plane. Unresolved radio and infrared galaxies add power that grows with ℓ.
3. *Something the processing did.* The beam may not be exactly the one we assume, the noise of the two halves may be slightly correlated, and the filling of the masked regions may leak into the kept ones.

Only the first explanation comes with a sampling distribution we can produce: we can draw as many Gaussian skies as we like and observe each of them the way *Planck* observed the real one. For the second and third we cannot simulate the effect without saying how large it is, which we do not know. But we know where each would show up. Galactic residuals would make the spectrum depend on how much sky near the plane we keep. A mismatch between the two halves would show up in their difference. So the second and third candidates are tested by *checks*: quantities that the first candidate predicts and the other two would spoil.

The questions, in words.

(a) What is the temperature power spectrum of this map, in *Planck*'s bins, once everything the observation did to it (mask, beam, pixels, noise) has been undone on average?

(b) If the sky were a Gaussian realisation of the *Planck* best-fit spectrum, how much would those bandpowers scatter, and how would their errors be correlated?

(c) Is the best-fit spectrum a reasonable explanation of our bandpowers, and do they agree with the spectrum *Planck* published from the same sky?

(d) With the other four parameters held fixed, which amplitude A_s and tilt n_s of the primordial spectrum does the map prefer?

(e) Does anything in the map fail a test that a Gaussian CMB would pass?

The inputs, and what would break them. Every answer below rests on a short list of assumptions, and it helps to separate them. Two are *physical*. (i) Outside the mask, the map is a Gaussian isotropic CMB plus noise; residual foregrounds would break this, and the checks of Section 13.6 would see it as a spectrum that depends on where we look. (ii) The noise in the two half-mission maps is independent; correlated noise would bias the cross-spectrum upward at high ℓ, and the spectrum of the half-difference would disagree with its simulations. Two are *observational*: (iii) the beam is the one *Planck* supplies, and (iv) the mask removes every region we do not trust. A wrong beam would tilt the spectrum at high ℓ, which a fit would turn into a wrong n_s; a mask too small would let Galactic power in. One is *mathematical*: (v) the map is band-limited, with no power above $\ell = 3N_{\text{side}} - 1$, the highest multipole a HEALPix map of resolution N_{side} can represent (Section 7.11.2); we enforce this when we change resolution.

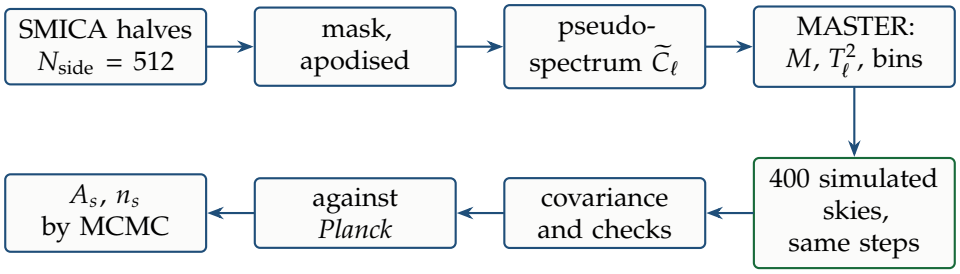

Figure 13.2: The pipeline on the real sky. The top row turns the map into bandpowers; it is the estimator of Section 8.11, applied once to the data. The simulated skies (green) go through exactly the same steps, and their scatter supplies the error bars, the checks and the likelihood used in the bottom row.

The top row of Figure 13.2 is one pass of the MASTER estimator of Section 8.11 over the data, and it yields a single set of bandpowers with no error bar. The error bar, the comparison, the checks and the fit all come from the bottom row: the same estimator applied to simulated skies gives the sampling distribution of the bandpowers, and that distribution is what lets us compare, check and fit.

13.1.1 The files, and a map small enough for a laptop

The *Planck* products are public. We downloaded them once with `curl` from the *Planck* archive at IRSA (Table 13.1). The SMICA maps sit under `all-sky-maps/maps/component-maps/cmb/` of the third release, one level deeper than the path often quoted. Each map file holds several fields: the temperature, the two polarisation components, an *inpainted* temperature map in which the masked regions are filled with a CMB-like constrained realisation, and two masks.

file	content	size
`COM_CMB_IQU-smica_2048_R3.00_full.fits`	SMICA map, full mission	2.0 GB
`COM_CMB_IQU-smica_2048_R3.00_hm1.fits`	first half-mission map	0.6 GB
`COM_CMB_IQU-smica_2048_R3.00_hm2.fits`	second half-mission map	0.6 GB
`COM_Mask_CMB-common-Mask-Int_2048_R3.00.fits`	common temperature mask	0.2 GB
`COM_PowerSpect_CMB-TT-binned_R3.01.txt`	TT bandpowers, $\Delta\ell = 30$	7 kB
`COM_PowerSpect_CMB-TT-full_R3.01.txt`	the same, unbinned	0.2 MB

Table 13.1: The public *Planck* 2018 products used for the power spectrum and, in Section 13.10, for the shapes of the sky.

Why we cannot use the map as it is. A map at $N_{\rm side} = 2048$ has

$$N_{\rm pix} = 12 \times 2048^2 = 50\,331\,648$$

pixels, 201 MB per map in single precision. Every simulated sky needs a few spherical-harmonic transforms of a map that size, and the cost of one transform grows as $N_{\rm pix}^{3/2}$ on the HEALPix grid (Figure 8.2). Four hundred simulations, each with a dozen transforms, at this resolution would take days. At $N_{\rm side} = 512$ the map has $12 \times 512^2 = 3\,145\,728$ pixels, sixteen times fewer, and each transform is $16^{3/2} = 64$ times cheaper. The price is the band limit: a map at $N_{\rm side} = 512$ holds multipoles only up to $3 \times 512 - 1 = 1535$, and we analyse only $\ell < 1020$, where the pixel window is still mild (below). *Planck*'s own temperature analysis runs to $\ell = 2508$ [70, Table 13]; the damping tail between 1000 and 2500 is lost to us, and with it most of the leverage on n_s that a long lever arm in ℓ provides (Section 13.7 measures how much).

How to change the resolution honestly. The question is: what map at $N_{\rm side} = 512$ would *Planck* have made of the same sky, with the same beam? Not the average of the 16 small pixels in each large one, although that is the first idea. Averaging inside a pixel is the pixel window (Section 8.2.1), so a pixel average applied to a map that already carries the $N_{\rm side} = 2048$ window would carry *both* windows, and the second one would only approximately be a pixel window of $N_{\rm side} = 512$. It is cleaner in harmonic space, where every effect of the instrument is a multiplication. Write the coefficients of the downloaded map, using the transfer function $T_\ell = B_\ell p_\ell$ of (8.12) with B_ℓ the beam and p_ℓ the pixel window, as

$$\begin{aligned} a_{\ell m}^{(2048)} &\overset{(1)}{=} B_\ell\, p_\ell^{(2048)}\, a_{\ell m}^{\rm sky} + n_{\ell m}^{(2048)}, \\ \frac{p_\ell^{(512)}}{p_\ell^{(2048)}}\, a_{\ell m}^{(2048)} &\overset{(2)}{=} B_\ell\, p_\ell^{(512)}\, a_{\ell m}^{\rm sky} + \frac{p_\ell^{(512)}}{p_\ell^{(2048)}}\, n_{\ell m}^{(2048)} \qquad (\ell \le 1535). \end{aligned} \tag{13.1}$$

(1) The observation model of Section 8.5: the sky's coefficients multiplied by the beam and the pixel window, plus noise.

(2) Multiply both sides by the ratio of the two pixel windows and keep only $\ell \le 3\times512-1$. The sky term now carries $B_\ell p_\ell^{(512)}$, exactly the transfer function of a map made at $N_{\rm side} = 512$ with the same beam.

Synthesising a map at $N_{\rm side} = 512$ from the right-hand side of (13.1) gives a map whose sky part is described by $T_\ell = B_\ell p_\ell^{(512)}$, the same form as every simulated map of Chapter 8. The noise term is changed by the same factor, which is why the noise of the degraded map is measured from the degraded maps themselves (Section 13.4.1).

Example: how large is the change? The pixel window of $N_{\rm side} = 2048$ is close to one over our range: $p_{1019}^{(2048)} = 0.9885$. The window of $N_{\rm side} = 512$ is not. Its small-ℓ form (8.11) with

$\Omega_{\rm pix} = 4\pi/3\,145\,728 = 3.995 \times 10^{-6}$ sr gives at $\ell = 1019$

$$p_{1019}^{(512)} \approx 1 - \frac{1019 \times 1020 \times 3.995 \times 10^{-6}}{24} = 1 - 0.173 = 0.827,$$

against the tabulated 0.829. The beam at the same multipole is $B_{1019} = 0.820$, so the power of the degraded map at our highest multipole is multiplied by $T_{1019}^2 = 0.462$ (Figure 13.3). Dividing it out is not a small correction, and neither is forgetting it.

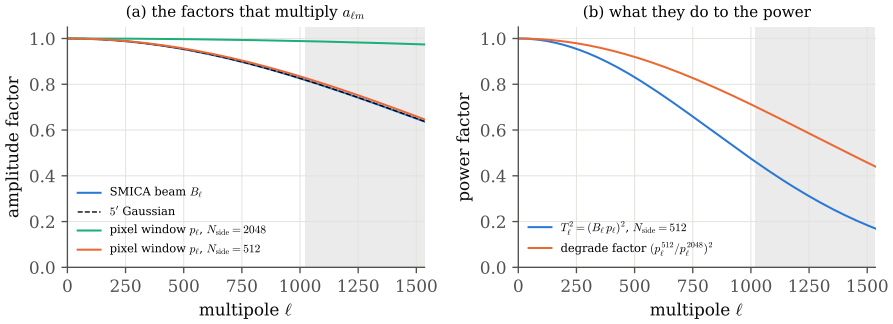

Figure 13.3: (a) The factors that multiply each $a_{\ell m}$ of the map: the SMICA effective beam (blue, on top of a 5′ Gaussian, dashed), and the pixel windows of the downloaded resolution (green) and of the working resolution (orange). (b) Their effect on the power: the squared transfer function of the degraded map (blue) and the squared ratio of pixel windows that the degrade applies (orange). Multipoles above $\ell = 1019$ (grey) are not analysed.

The holes have to be filled first. One more step is needed before the transform, and it is easy to miss. The SMICA map is not zero inside the mask; it contains the residual emission of the Galaxy and of bright sources, which the mask exists to hide. In the full-mission map the largest value inside the holes is 7899 μK, against 501 μK in the kept sky. Truncating a map at $\ell = 1535$ is a low-pass filter, and a low-pass filter applied to a sharp spike produces ripples around it (the Gibbs phenomenon of Fourier series): a hot point source of a few thousand μK would spread rings of tens of μK into the kept pixels around its hole. So before the transform we replace the pixels inside the mask by the inpainted CMB that *Planck* provides. Those pixels stay masked in everything that follows; the inpainting only guarantees that what is hidden in them is no brighter than the CMB, so that the band limit cannot carry it out of the holes.

Example: the mask at the lower resolution. The common mask is a 0/1 map at $N_{\rm side} = 2048$ that keeps a fraction 0.779 of the sky. Each pixel at $N_{\rm side} = 512$ contains $(2048/512)^2 = 16$ small pixels. We keep a large pixel only if all 16 are kept; a pixel that is partly in a hole is discarded, so a hole can only grow. The kept fraction drops to 0.775: the holes grow by at most one large pixel (6.9′) along their edges.

Listing 13.1: The harmonic degrade: fill the holes, transform, swap the pixel windows, synthesise (`code/ch13/01_planck_data.py`)

```
1
2  # ------------------------------------------------------------------ the maps
3  p2048 = np.asarray(hp.pixwin(2048, lmax=LMAX))
4  full_src = lp.raw_path("full")
5  mask2048 = hp.read_map(lp.raw_path("mask"), dtype=np.float64) < 0.5      # True in the holes
6  inpainted = hp.read_map(full_src, field=5, dtype=np.float64) * 1e6                    #
       I_STOKES_INP
7  for kind in ("full", "hm1", "hm2"):
8      if all(lp.degraded_path(kind, n).exists() for n in NSIDES):
```

```
        continue
    src = lp.raw_path(kind)
    m = hp.read_map(src, field=0, dtype=np.float64) * 1e6            # K_CMB -> muK, NESTED
    -> RING
    # the holes hold bright Galactic and source residuals; a sharp band limit would ring
    them out
    # over the kept sky, so fill the holes with Planck's inpainted CMB first (they stay
    masked)
    tag = {"full": "Full", "hm1": "HmOne", "hm2": "HmTwo"}[kind]
    nums[f"TwelveAHoleMax{tag}"] = f"{np.abs(m[mask2048]).max():.0f}"
    nums[f"TwelveAKeptMax{tag}"] = f"{np.abs(m[~mask2048]).max():.0f}"
    m[mask2048] = inpainted[mask2048]
    alm = hp.map2alm(m, lmax=LMAX, iter=1)
    del m
    for n in NSIDES:
        L = 3 * n - 1
        a = hp.resize_alm(alm, LMAX, LMAX, L, L)
        fl = np.asarray(hp.pixwin(n, lmax=L)) / p2048[: L + 1]          # swap the pixel
    windows
        hp.write_map(lp.degraded_path(kind, n), hp.alm2map(hp.almxfl(a, fl), n, lmax=L),
```

The loop reads each map (`full`, `hm1`, `hm2`) and converts it from K to μK. The two lines before the transform record the largest values inside and outside the holes and then overwrite the holes with the inpainted CMB. `hp.map2alm` computes the $a_{\ell m}$ up to $\ell = 3071$, `hp.resize_alm` keeps those up to $\ell = 1535$, `hp.almxfl` multiplies them by $p_\ell^{(512)}/p_\ell^{(2048)}$ as in (13.1), and `hp.alm2map` synthesises the new map. The whole preparation took 52 s; the 3.4 GB of downloads were then moved out of the working directory, and the degraded maps occupy 13 MB each.

The full analysis does none of this: *Planck* measures its spectrum at $N_{\rm side} = 2048$ from the frequency maps, not from SMICA, up to $\ell = 2508$. Our reduction to $N_{\rm side} = 512$ and $\ell < 1020$ costs the damping tail. The number of independent modes in a map grows as $\ell_{\rm max}^2$, so cutting at 1019 instead of 2508 keeps $(1019/2508)^2 \approx 17\%$ of them, and discards about four fifths of the modes *Planck* analyses (fewer in terms of information, since the noise and the foregrounds grow with ℓ).

13.2 The mask: which sky to trust, and how to let go of the rest

In Section 8.10.4 we met the trade that every mask forces on us. A mask with sharp edges keeps every observed pixel at full weight, but its window spectrum falls slowly, so the coupling matrix carries power from the acoustic peaks into multipoles far away; a field of small holes was the worst case, with a leakage nearly flat in ℓ. Tapering the edges, *apodisation*, cleans the kernel by orders of magnitude, and pays for it in modes: the effective sky fraction $f_{\rm sky} w_2^2/w_4$ drops (in the example of that section, from 802 modes to 600 in one bin). Those masks were caps and bands of our own design. The *Planck* common mask was designed by people who wanted to hide our Galaxy and every bright source in the sky, and its geometry is whatever the sky made it.

What the mask looks like. The common temperature mask at $N_{\rm side} = 512$ keeps a fraction 0.775 of the sky (Figure 13.5a). The masked region has two very different parts. A broad band along the Galactic plane, wider towards the Galactic centre, hides the dust, synchrotron and free-free emission of the Milky Way. Scattered over the rest of the sky are thousands of small holes, each hiding a radio or infrared source bright enough to be detected on its own.

The question. How should each kind of hole be tapered? A wide taper around the Galactic band costs little sky in proportion and cleans a long edge. A wide taper around each of thousands of small holes might cost a great deal. To taper them differently we first have to tell them apart.

13.2.1 Telling the holes apart

A **hole** is a connected set of masked pixels [masked pixels that can be joined by steps between neighbouring masked pixels, without crossing a kept one]. On the HEALPix grid every pixel has eight neighbours (four sharing an edge, four sharing a corner), which `hp.get_all_neighbours` lists. So the holes are the connected components of a graph whose nodes are the masked pixels and whose links join masked neighbours, the same idea as the clusters of Chapter 12. We find them with `scipy.sparse.csgraph.connected_components`, then measure each hole's area as its number of pixels times the pixel area. A hole larger than $20\,\mathrm{deg}^2$ is *Galactic*, the rest are *point-source holes*.

Example: what $20\,\mathrm{deg}^2$ means in pixels. The sky has $41\,253\,\mathrm{deg}^2$, so at $N_{\mathrm{side}} = 512$ one pixel covers $41\,253/3\,145\,728 = 0.0131\,\mathrm{deg}^2$, a square of 6.9′ on a side. A hole of $20\,\mathrm{deg}^2$ is about 1500 pixels, a disc of radius 2.5°. A point-source hole is a disc of a few tens of arcminutes, so tens of pixels: the two populations are separated by two orders of magnitude, and the threshold does not need to be chosen carefully.

The result: 3307 holes, of which 3 are larger than $20\,\mathrm{deg}^2$. The Galactic holes alone keep a fraction 0.796 of the sky; the point-source holes alone remove a fraction 0.021. Together they keep $0.775 = 0.796 - 0.021$, where the source holes that sit inside the Galactic band are not counted twice.

13.2.2 Two tapers

Planck apodises its Galactic masks with a Gaussian of 4.71° FWHM ($\sigma = 2°$) and its point-source masks with one of 30′ FWHM, and multiplies the two [70, §3.2.2]. The apodisation is computed from the distance of each pixel to the nearest mask border, which guarantees that the window is zero inside every hole. We follow the same logic with the cosine taper of Section 8.10.4: for a kept pixel at angular distance d from the nearest hole of a given kind,

$$W(d) = \begin{cases} \tfrac{1}{2}\bigl(1 - \cos(\pi d/\theta_{\mathrm{ap}})\bigr), & d < \theta_{\mathrm{ap}}, \\ 1, & d \geq \theta_{\mathrm{ap}}, \end{cases} \tag{13.2}$$

with $\theta_{\mathrm{ap}} = 2°$ for the Galactic holes and $\theta_{\mathrm{ap}} = 0.5°$ for the source holes, and the window of the analysis is the product of the two tapered masks (Figure 13.4). The window rises smoothly from 0 at the edge, through $\tfrac{1}{2}$ at $d = \theta_{\mathrm{ap}}/2$, to 1, with zero slope at both ends.

Why not one taper for all? Take the wider taper and put it around every source. The ring between the edge of a small hole and a distance of 2° has an area of nearly $\pi(2°)^2 = 12.6\,\mathrm{deg}^2$, and there are about 3300 such holes:

$$3300 \times 12.6\,\mathrm{deg}^2 \approx 41\,500\,\mathrm{deg}^2,$$

the whole sky. The rings overlap, so the real loss is smaller, but most of the sky would sit at reduced weight. With 0.5° the same count gives $3300 \times \pi \times 0.25\,\mathrm{deg}^2 \approx 2600\,\mathrm{deg}^2$, about 6% of the sky, and in fact less, because inside each ring the window is on average one half. The

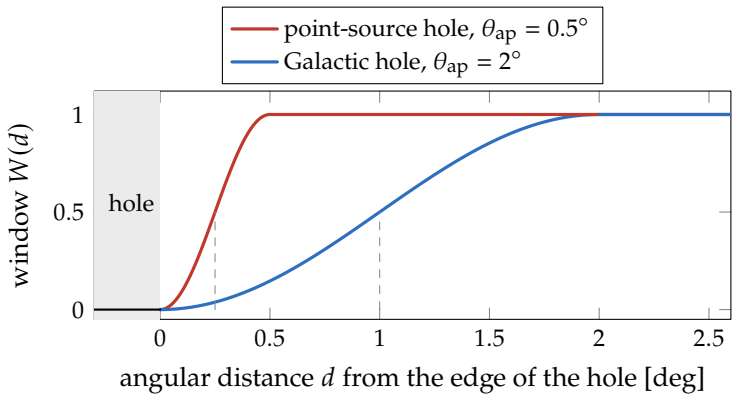

Figure 13.4: The two tapers of (13.2). Inside a hole (grey) the window is zero. Moving away from the edge it rises as half a cosine, reaching one half at half the taper width (dashed) and one at the full width: within 0.5° of a point source (red), within 2° of the Galactic band (blue).

Galactic band is one long edge, and a 2° taper along it costs a thin strip. So the widths are set by geometry: wide where there is a little edge, narrow where there is a lot of it. *Planck* reports the same rule of thumb: its large Galactic apodisation reduces the effective sky fraction by about 10% [70, §3.2.2].

Example: what the taper costs us. The moments of the window (Section 8.9: w_i is the average of W^i over the pixels where $W > 0$) are $f_{\rm sky} = 0.775$ and $w_2 = 0.894$, so the mean of W^2 over the whole sky is $f_{\rm sky} w_2 = 0.692$. The effective sky fraction that counts modes (8.81) is $f_{\rm sky} w_2^2 / w_4 = 0.708$, against 0.775 for the binary mask. Where the error is cosmic variance, it scales as one over the square root of the number of modes, so the taper makes the error bars larger by

$$\sqrt{0.775/0.708} \approx 1.05,$$

five per cent. What it buys is visible in Section 13.3: without it, the correction for mode coupling has to undo leakage of ten per cent and more.

13.2.3 Four more windows, for the checks

A real analysis does not trust a spectrum measured through one window. If the map outside the mask is a Gaussian isotropic CMB, the spectrum must not depend on which part of that sky we use, up to the scatter that using less sky brings. So we build four more windows, each designed to expose one of the explanations listed in Section 13.1 (Figure 13.5c,d).

- The *binary* common mask, with no taper ($f_{\rm sky} = 0.775$). Same sky, different weights: a difference tests the correction for mode coupling.
- The main window times a cut $|b| > 30°$, with a 2° cosine edge ($f_{\rm sky} = 0.488$). Galactic residuals would be stronger in the main window, which goes closer to the plane.
- The main window restricted to the northern or to the southern Galactic hemisphere ($f_{\rm sky} = 0.387$ and 0.387). A statistically isotropic sky gives the same spectrum in both, up to the scatter.

The coupling matrices. For each window we compute the spectrum $\mathcal{W}_\ell$ of the window with `hp.anafast` and the coupling matrix $M_{\ell\ell'}$ of (8.61) with the Wigner-3j code of Section 8.10.2, imported from `code/ch08/lib_masks.py`. We compute it up to $\ell = 1199$, not just to the last

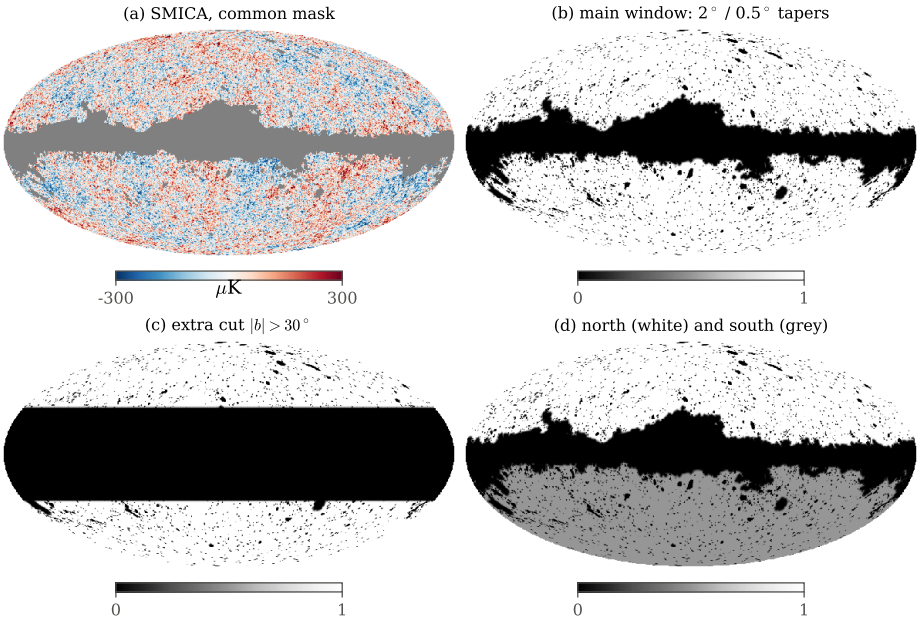

Figure 13.5: (a) The degraded SMICA map outside the common mask (grey), in Galactic coordinates. (b) The window of the analysis: the common mask with its Galactic holes tapered over 2° and its point-source holes over 0.5°. (c) The same window with everything at $|b| < 30°$ removed. (d) The northern (white) and southern (grey) Galactic hemispheres of the window. Panels (c) and (d) are used only by the checks.

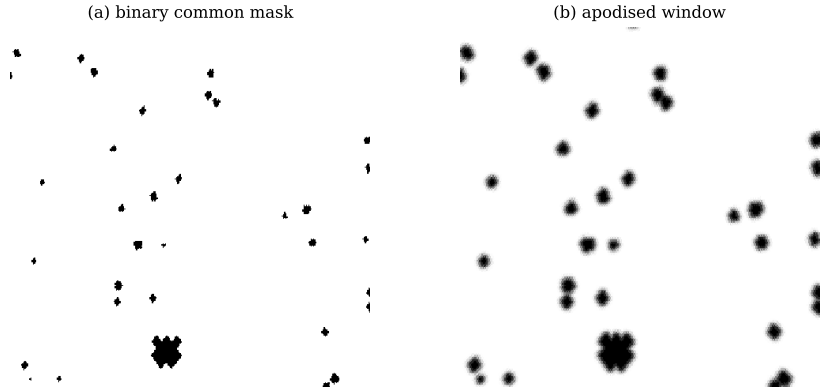

Figure 13.6: A 20° patch at high Galactic latitude, centred on $(l, b) = (-60°, 45°)$. (a) The binary common mask: a scatter of point-source holes. (b) The window: each hole is now surrounded by a grey ring where the weight rises from zero to one over 0.5°.

multipole we report, 1019: a true multipole slightly above 1019 leaks into our last bins, and the correction can remove that leakage only if the matrix knows about it. Each matrix is 1200×1200 and is cached in `data/ch13/`.

Listing 13.2: Splitting the holes, tapering each kind, and the four windows for the checks (`code/ch13/02_mask.py`)

```
binary = hp.read_map(lp.PLANCK / f"common_mask_n{NSIDE}.fits", dtype=np.float64)
gal, ps, ncomp, nbig = lp.mask_components(binary, NSIDE)
nums.update({"TwelveAHoles": ncomp, "TwelveAHolesBig": nbig,
             "TwelveAFskyGal": f"{gal.mean():.3f}", "TwelveAFskyPS": f"{1 -
    ps.mean():.3f}"})
print(f"{ncomp} holes, {nbig} extended; Galactic part removes {1 - gal.mean():.3f}, sources
    {1 - ps.mean():.3f}")
```

```

W_main = lp.apodise(gal, NSIDE, 2.0) * lp.apodise(ps, NSIDE, 0.5)
masks = {
    "binary": binary,
    "main": W_main,
    "cut30": W_main * lp.latitude_taper(NSIDE, "both", 30.0, 2.0),
    "north": W_main * lp.latitude_taper(NSIDE, "north", 0.0, 2.0),
    "south": W_main * lp.latitude_taper(NSIDE, "south", 0.0, 2.0),
}
```

`lp.mask_components` returns two 0/1 masks, one with only the Galactic holes and one with only the point-source holes. `lp.apodise` computes, for every kept pixel, the angle to the nearest masked pixel (a nearest-neighbour search on the unit vectors of the pixel centres, with `scipy.spatial.cKDTree`) and applies (13.2). The latitude cuts use the same cosine edge, as a function of Galactic latitude b instead of the distance to a hole.

Planck's own likelihood uses a different mask at each frequency (keeping 66%, 57% and 47% of the sky at 100, 143 and 217 GHz) with the point-source holes of each channel [70, §3.2.2, Fig. 29]; we use the single common mask of the SMICA map, which keeps more sky (0.775) because SMICA has already removed most of the Galactic emission. The cost of the substitution is that our spectrum is more exposed to any residual of SMICA's foreground cleaning near the plane, which is exactly what the $|b| > 30^\circ$ check is for.

13.3 From the map to bandpowers, one correction at a time

In Sections 8.11 and 8.11.1 three recipes for undoing a mask were tried on simulated skies. Dividing the pseudo-spectrum by the sky fraction was biased wherever the spectrum had structure, because the mask moves power between multipoles. Inverting the coupling matrix multipole by multipole was exact but noisy and, for a small patch, impossible. Inverting it between bins, the MASTER recipe, was unbiased for any spectrum that is flat inside each bin. On simulations we could see this because we knew the spectrum we had put in. On the real sky we do not, so we do the next best thing: apply the corrections one at a time and watch what each does to the numbers, with *Planck*'s published spectrum as a reference line (Figure 13.8). Before any of that, two small things must be removed from the map, and the spectrum must be computed in a way that has no noise bias.

13.3.1 The monopole and the dipole

The SMICA map has had the monopole of the CMB (its mean temperature) and the large dipole caused by our motion removed. What remains of $\ell = 0$ and $\ell = 1$ is an arbitrary offset and a residual of that subtraction, neither of which is part of the anisotropy we model. On the full sky they would sit in $\ell = 0, 1$ and never touch the multipoles we analyse. Behind a mask they do: Y_{00} and Y_{1m} are not orthogonal to the higher harmonics over the cut sky, so a pure dipole on the kept pixels has pseudo-coefficients at every ℓ (the leakage of Section 8.9.1). So we fit $c + \boldsymbol{d} \cdot \hat{\boldsymbol{n}}_p$ to the kept pixels by least squares, four numbers (c and the three components of $\boldsymbol{d}$), and subtract the fit from the whole map. The fit gives $c = 0.6\,\mu\mathrm{K}$ and $|\boldsymbol{d}| = 5.2\,\mu\mathrm{K}$, small next to the $100\,\mu\mathrm{K}$ fluctuations of the map. Because a mask breaks the orthogonality, this fit also absorbs the small part of the real CMB anisotropy that happens to look like a dipole on the kept sky; it is a few μK, and it affects mostly the buffer bin $2 \le \ell < 30$ that we do not report.

13.3.2 Two halves, one sky

The half-mission maps of Section 13.1 let us avoid the noise bias altogether. Recall (8.26): if the two maps have coefficients $d^{(i)}_{\ell m} = T_\ell a_{\ell m} + n^{(i)}_{\ell m}$ with independent noise, the cross-spectrum $\widehat{C}^{12}_\ell = \frac{1}{2\ell+1}\sum_m \mathrm{Re}\, d^{(1)}_{\ell m} d^{(2)*}_{\ell m}$ has mean $T^2_\ell C_\ell$: the noise of one half has nothing to multiply in the other, so it averages away instead of adding power. Behind a mask the same holds for the pseudo-spectra, since the mask multiplies both maps by the same W.

The two halves give a second map for free. Their half-difference (hm1 − hm2)/2 contains no sky, since the sky is the same in both, and its noise has the same level as the noise in their average (hm1 + hm2)/2. It is a **null map**: a map of what the noise looks like. The three spectra are tied by an identity. Write a and b for the masked coefficients of the two halves at some (ℓ, m):

$$\left|\frac{a+b}{2}\right|^2 - \left|\frac{a-b}{2}\right|^2 \overset{(1)}{=} \frac{|a|^2+|b|^2+2\mathrm{Re}\, ab^*}{4} - \frac{|a|^2+|b|^2-2\mathrm{Re}\, ab^*}{4} \overset{(2)}{=} \mathrm{Re}\, ab^*, \tag{13.3}$$

(1) $|a \pm b|^2 = (a \pm b)(a^* \pm b^*) = |a|^2 + |b|^2 \pm (ab^* + a^*b)$, and $ab^* + a^*b = 2\mathrm{Re}\, ab^*$.
(2) The squared moduli cancel.

Averaging over m: the spectrum of the average map minus the spectrum of the half-difference is exactly the cross-spectrum. The SMICA full-mission map is not exactly the average of the two halves (the halves are separated with their own weights), so on the data the identity holds only approximately, and how well it holds is one of the checks of Section 13.6.

13.3.3 *Planck*'s bins

To compare our spectrum with *Planck*'s we must bin exactly as *Planck* bins. The published binned spectrum uses bins of $\Delta\ell = 30$ starting at $\ell = 30$, and inside each bin it weights C_ℓ by $\ell(\ell+1)$ [70, (22)]:

$$C_b = \sum_{\ell \in b} w_{b\ell} C_\ell, \qquad w_{b\ell} = \frac{\ell(\ell+1)}{\sum_{\ell' \in b} \ell'(\ell'+1)}, \qquad \ell^{\mathrm{eff}}_b = \sum_{\ell \in b} w_{b\ell}\, \ell, \qquad D_b = \frac{\ell^{\mathrm{eff}}_b(\ell^{\mathrm{eff}}_b+1)}{2\pi} C_b. \tag{13.4}$$

The weight $\ell(\ell+1)$ is there because $D_\ell = \ell(\ell+1)C_\ell/2\pi$ varies slowly across a bin while C_ℓ falls steeply: weighting C_ℓ by $\ell(\ell+1)$ averages the slowly varying quantity. The file quotes D_b at the multipole ℓ^{eff}_b.

In the notation of the MASTER estimator (Section 8.11.3), binning is a matrix $P_{b\ell}$ that turns a spectrum into bandpowers, and $Q_{\ell b}$ is a matrix that spreads a bandpower back over the multipoles of its bin. Reading them off (13.4),

$$P_{b\ell} = \frac{\ell^{\mathrm{eff}}_b(\ell^{\mathrm{eff}}_b+1)}{2\pi} w_{b\ell}, \qquad Q_{\ell b} = \frac{2\pi}{\ell^{\mathrm{eff}}_b(\ell^{\mathrm{eff}}_b+1)} \quad (\ell \in b), \tag{13.5}$$

and both are zero for ℓ outside bin b. Q is the spectrum that the MASTER recipe assumes inside each bin: a C_ℓ that is constant across the bin, at the value whose D at ℓ^{eff}_b is the bandpower. Binning that spectrum must give the bandpower back:

$$\sum_\ell P_{b\ell} Q_{\ell b'} \overset{(1)}{=} \delta_{bb'} \sum_{\ell \in b} \frac{\ell^{\mathrm{eff}}_b(\ell^{\mathrm{eff}}_b+1)}{2\pi} w_{b\ell} \frac{2\pi}{\ell^{\mathrm{eff}}_b(\ell^{\mathrm{eff}}_b+1)} \overset{(2)}{=} \delta_{bb'} \sum_{\ell \in b} w_{b\ell} \overset{(3)}{=} \delta_{bb'}. \tag{13.6}$$

(1) $P_{b\ell}$ is zero unless $\ell \in b$ and $Q_{\ell b'}$ is zero unless $\ell \in b'$; bins do not overlap, so the product vanishes unless $b = b'$.

(2) The two prefactors cancel.
(3) The weights of a bin sum to one by construction.

So $PQ = \mathbb{1}$, the property the derivation of (8.67) needs.

Example: the first bin. For $30 \le \ell \le 59$, $\ell^{\rm eff} = \sum \ell^2(\ell+1)/\sum \ell(\ell+1) = 47.71$; the *Planck* file quotes 47.711, and our binning code reproduces every $\ell_b^{\rm eff}$ in the file to better than one part in 10^5 (the largest difference is 3.1e-06). Now take the fiducial spectrum and bin it. The plain average of D_ℓ over the bin is 1322 μK^2, and D_ℓ at $\ell = 48$ is 1384 μK^2, but (13.4) gives $D_b = 1463\,\mu\text{K}^2$. A bandpower is neither the spectrum at $\ell^{\rm eff}$ nor its average. To see why, take a $D_\ell = D$ that is flat across the bin, so that $C_\ell = 2\pi D/\ell(\ell+1)$:

$$D_b \overset{(1)}{=} \frac{\ell^{\rm eff}(\ell^{\rm eff}+1)}{2\pi} \sum_{\ell\in b} \frac{\ell(\ell+1)}{\sum_{\ell'\in b}\ell'(\ell'+1)} \frac{2\pi D}{\ell(\ell+1)} \overset{(2)}{=} \frac{\ell^{\rm eff}(\ell^{\rm eff}+1)\,\Delta\ell}{\sum_{\ell'\in b}\ell'(\ell'+1)} D \overset{(3)}{=} \frac{\ell^{\rm eff}(\ell^{\rm eff}+1)}{\overline{\ell(\ell+1)}} D. \tag{13.7}$$

(1) (13.4) with $C_\ell = 2\pi D/\ell(\ell+1)$.
(2) The factors $\ell(\ell+1)$ and 2π cancel, and the sum of 1 over the bin is its width $\Delta\ell$.
(3) $\overline{\ell(\ell+1)}$ is the plain average of $\ell(\ell+1)$ over the bin.

In the first bin the factor is 2324/2100 = 1.1069: the effective multipole is a weighted mean of ℓ, and squaring a mean is not the mean of the squares. In the last bin, $990 \le \ell \le 1019$, the same factor is 1.0002, because the bin is narrow compared with its ℓ. The lesson is a rule we will use repeatedly: a theory curve is compared with bandpowers only after it has been passed through *the same* binning (and, below, the same window).

We add a buffer bin $2 \le \ell < 30$ below the reported range and six bins $1020 \le \ell < 1200$ above it. They are solved for together with the reported bins, so that the power at those multipoles, which the mask spreads into our range, is accounted for, and then they are discarded. We report 33 bins, $30 \le \ell \le 1019$.

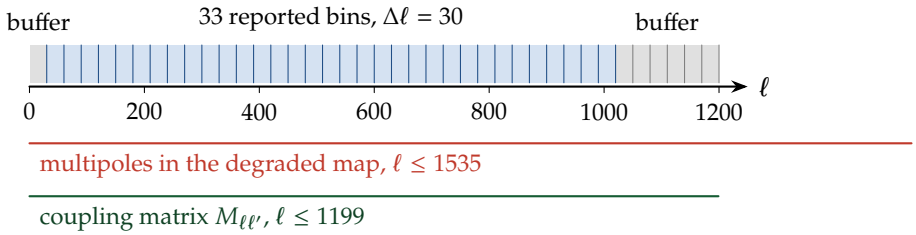

Figure 13.7: The bins. Thirty-three bins of thirty multipoles (blue) are reported, exactly *Planck*'s binning between $\ell = 30$ and 1019. Below and above them, buffer bins (grey) absorb the power that the mask moves into the reported range from outside it; they are solved for and discarded. The degraded map holds multipoles up to 1535; the coupling matrix is computed up to 1199.

13.3.4 MASTER with our own coupling matrix

With the coupling matrix M of the window (Section 13.2.3) and the squared transfer function $T_\ell^2 = (B_\ell p_\ell)^2$ of Section 13.1.1, the binned master equation (8.67) [Hivon (20)–(26)] reads, for the cross-spectrum (no noise term to subtract, and no time-domain filtering, $F_\ell = 1$),

$$\langle P\widetilde{C}^{12}\rangle = K\,D, \qquad K_{bb'} = \sum_{\ell\ell'} P_{b\ell} M_{\ell\ell'} T_{\ell'}^2 Q_{\ell' b'}, \qquad \widehat{D}_b = \sum_{b'} K^{-1}_{bb'} \sum_{\ell} P_{b'\ell}\widetilde{C}_\ell^{12}. \tag{13.8}$$

K is 40×40 (the 33 reported bins and the 7 buffer bins), and it is inverted once. As derived in (8.68), the mean of $\widehat{D}_b$ for the true spectrum is

$$\langle \widehat{D}_b \rangle = \sum_{\ell} \mathcal{F}_{b\ell} C_\ell, \qquad \mathcal{F}_{b\ell} = \sum_{b'} K^{-1}_{bb'} \sum_{\ell'} P_{b'\ell'} M_{\ell'\ell} T^2_\ell, \tag{13.9}$$

the **bandpower window functions**. They are the honest way to put a theory on the plot: a spectrum that is not flat inside each bin is turned into bandpowers by $\mathcal{F}$, not by P. NaMaster, the public code that implements MASTER for any mask, writes the same two equations, the binned coupling matrix and the filter that must be applied to any theory before it is compared with the data [142, (16)–(18)].

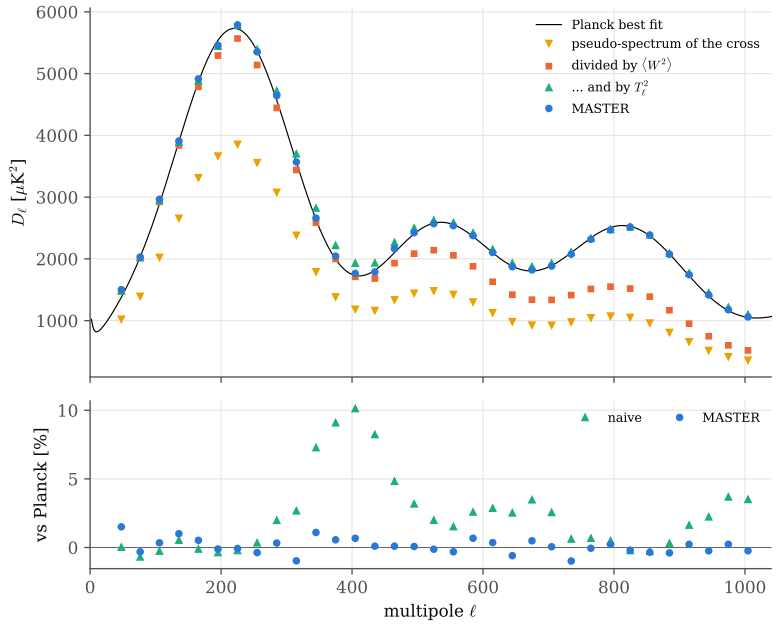

Figure 13.8: The SMICA half-mission cross-spectrum, binned in *Planck*'s bins, after each correction. Top: the binned pseudo-spectrum (yellow triangles); divided by the mean of W^2 (orange squares); then also by T^2_ℓ (green triangles, the naive estimator); and the MASTER bandpowers (blue). The black line is the *Planck* best fit. Bottom: the naive and the MASTER bandpowers relative to *Planck*'s published bandpowers.

What each step does, on the data. Figure 13.8 follows the cross-spectrum through the corrections.

1. *The pseudo-spectrum* is low everywhere. In the first bin it is 1023 μK^2, against 1479 in *Planck*'s spectrum.
2. *Dividing by the mean of* W^2 over the sky, $f_{\rm sky} w_2 = 0.692$, fixes the low multipoles ($1023/0.692 \approx 1478$), but the high ones stay low, and more so the higher ℓ.
3. *Dividing by* T^2_ℓ undoes the beam and the pixels; at $\ell = 1019$ that is a factor $1/0.462$. The result is the naive estimator (8.64), and it is off by up to 10%, with a characteristic pattern: too high in the troughs, especially the first one near $\ell = 400$, nearly right at the peaks.
4. *MASTER* removes the pattern. Its bandpowers differ from *Planck*'s by at most 1.5%, 0.5% in the root mean square.

Why the naive estimator fails in the troughs. Dividing by $f_{\rm sky} w_2$ assumes that the mask removes a fixed share of the power at each multipole and moves none of it: $M_{\ell\ell'} = f_{\rm sky} w_2 \, \delta_{\ell\ell'}$. The true coupling matrix has a narrow core around $\ell' = \ell$, set by the size of the large sky regions, and a broad low floor that comes from the thousands of small holes, whose window spectrum is nearly flat (Section 8.10.4). The floor moves a small fraction of every multipole's power to multipoles far away. At a peak the power that leaves and the power that arrives nearly balance. In the trough at $\ell \approx 400$, where $D_\ell \approx 1750\,\mu\mathrm{K}^2$, the arriving share of the first peak, where $D_\ell \approx 5800\,\mu\mathrm{K}^2$, is not balanced by the little that leaves, so the trough fills up by about a tenth. The 0.5° taper of the source holes weakens the floor but cannot remove it, because the holes themselves are small. MASTER does not need the floor to be small; it needs it to be known, and M knows it.

Example: the residual of MASTER, in perspective. The bottom panel of Figure 13.8 shows MASTER within 1.5% of *Planck*'s bandpowers. Is that agreement good, or suspiciously good? Neither question can be answered yet. Both bandpowers are measurements of nearly the same sky, so they share most of their cosmic variance, and their difference is much smaller than either one's error bar. How much smaller is a question about the joint sampling distribution of two estimators, and it needs simulated skies (Sections 13.4 and 13.5.4).

Listing 13.3: The spectra of every window: pseudo-spectra of the halves, their cross, their half-difference, and the MASTER correction (`code/ch13/03_bandpowers.py`)

```
# ------------------------------------------------------------- 1-4. spectra for every window
out = {"edges": EDGES, "rep": REP}
for name, W in masks.items():
    if name in ("gal", "ps"):
        continue
    W = W.astype(np.float64)
    M = lp.coupling(W, LC, name=name)
    mst = lp.Master(M, T2, EDGES)
    a1, a2, af = lp.pseudo_cl(W, [maps["hm1"], maps["hm2"], maps["full"]], LC)
    pcl = {"cross": hp.alm2cl(a1, a2), "null": hp.alm2cl(0.5 * (a1 - a2)), "auto": hp.alm2cl(af)}
    for k, c in pcl.items():
        out[f"{name}_{k}"] = mst(c)
        out[f"{name}_pcl_{k}"] = c
    out[f"{name}_F"] = mst.window()
    out[f"{name}_leff"] = mst.leff
    out[f"{name}_fw2"] = np.mean(W ** 2)
```

For each window the loop loads the cached coupling matrix and builds the MASTER operator (`lp.Master`: it forms K of (13.8) once and inverts it). `lp.pseudo_cl` multiplies each map by the window and transforms it. From the three sets of coefficients come the cross-spectrum of the halves, the spectrum of their half-difference and the auto-spectrum of the full map, each corrected by the same operator. `mst.window()` returns the bandpower windows $\mathcal{F}_{b\ell}$ of (13.9), which the comparison with theory uses.

13.4 How much would the bandpowers scatter? Simulated skies

We now have 33 numbers, one per bin, measured from one sky. Each of them is a draw from a sampling distribution that we cannot observe: the distribution of the bandpowers over all the skies the standard model could have produced, each seen through *Planck*'s beam, pixels, noise and our mask. In Chapter 8 that distribution was the research problem, and simulation was the answer: for a masked, noisy sky no formula gives the covariance of

MASTER bandpowers exactly, and the scatter of the estimator over many simulated skies is the measurement (Section 8.15). Here the same machine runs for real. Two things must be decided before it can: what noise the simulated maps carry, and how many of them we can afford.

13.4.1 A noise model built from the data

Planck simulates its noise end to end: the time-ordered data of every detector are simulated with the measured noise properties, made into maps by the same map-making code, and passed through the component separation, giving a few hundred noise realisations of each map (the FFP10 simulations). We have only the data. But the data contain a map of their own noise: the half-difference $d = (\mathrm{hm1} - \mathrm{hm2})/2$ of Section 13.3.2, in which the sky cancels.

The question. What random map, added to a simulated sky, would make a half-mission map whose noise looks like ours? Two features of d matter. Its *amplitude varies over the sky*, because *Planck*'s scanning covers some regions many more times than others and the component separation weights the frequencies differently in different places. And its *power varies with scale*, because SMICA's weights and the deconvolution of each channel's beam to the common 5′ make the noise anything but white. A model that captures both, and nothing more, is

$$n_{\mathrm{half}}(p) = \sqrt{2}\,\sqrt{v(p)}\;g(p), \tag{13.10}$$

where $v(p)$ is the local variance of d relative to its mean (the map d^2 smoothed with a 2° Gaussian and divided by its average over the kept sky), and g is a statistically isotropic Gaussian field whose spectrum N_ℓ^g is that of $d/\sqrt{v}$, measured through the window and divided by the mean of W^2 (Section 8.11.1), then averaged over 31 neighbouring multipoles to remove its own scatter.

Where the $\sqrt{2}$ comes from. Suppose the noise of each half has variance σ^2 in some pixel, and the two halves are independent. Then

$$\mathrm{Var}(d) \overset{(1)}{=} \mathrm{Var}\Big(\frac{n_1 - n_2}{2}\Big) \overset{(2)}{=} \frac{\mathrm{Var}\,n_1 + \mathrm{Var}\,n_2}{4} \overset{(3)}{=} \frac{\sigma^2}{2} \quad\Longrightarrow\quad \sigma^2 = 2\,\mathrm{Var}(d). \tag{13.11}$$

(1) The sky is identical in the two halves and cancels in d.
(2) The variance of a sum of independent variables is the sum of the variances, and a constant factor comes out squared: $(1/2)^2$, with $(-1)^2 = 1$ for the second term.
(3) Both halves have the same noise level.

So a half's noise has twice the variance of d, a factor $\sqrt{2}$ in amplitude. By the same steps, the average of the halves, $(n_1 + n_2)/2$, has variance $\sigma^2/2 = \mathrm{Var}(d)$: the noise of the full map has the spectrum of d itself, and the noise of one half has twice that spectrum.

Example: how much noise is there? Very little, at these multipoles. At $\ell = 1000$ the noise power of the full map is 2% of the beamed sky power $T_\ell^2 C_\ell$, and the noise of a single half stays below the beamed sky at every $\ell \le 1199$ (Figure 13.9a). In temperature, below $\ell \approx 1000$, *Planck* is limited by cosmic variance, not by its detectors, which is why the noise model can be approximate without changing the error bars much. Where the noise is, however, varies a lot: v reaches 11.8 times the mean in the worst regions (Figure 13.9b). Close to the mask edges v is artificially small, because the holes were filled with the same inpainted map in both halves, so $d = 0$ there and the smoothing pulls v down; a floor of 0.05 keeps $d/\sqrt{v}$ finite.

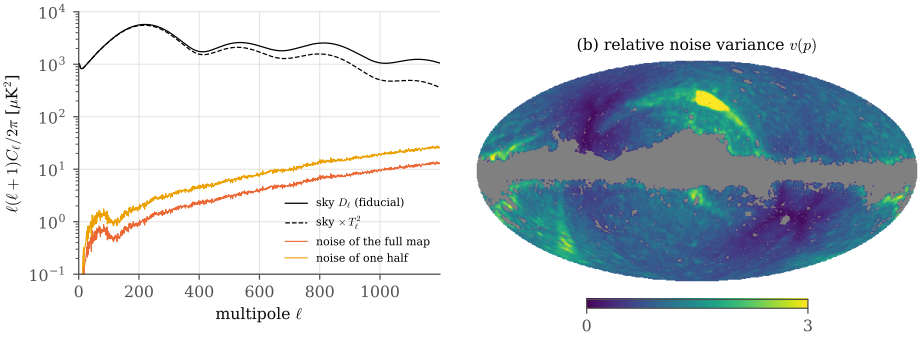

Figure 13.9: (a) The fiducial sky spectrum (solid black), the same after the beam and pixel window (dashed), and the noise spectra measured from the half-difference map: the noise of the full map (red) and of one half (orange). Below $\ell = 1200$ the sky dominates everywhere. (b) The relative noise variance $v(p)$ outside the mask: the noise level changes by more than a factor of ten over the sky.

What the model leaves out is equally important to state. The noise is drawn Gaussian, while residual glitches and foreground leftovers are not. Its correlations are those of a modulated isotropic field, while real scanning noise has stripes along the scan direction. The two halves are drawn independent, while *Planck* found small correlations between half-missions at high multipoles [70, §3.2.1]. And v and N_ℓ^g were estimated from the very map whose noise they describe, so the half-difference test of Section 13.6 is a consistency check of the model, not an independent test of it.

13.4.2 The simulated skies

The rule that makes simulations useful is simple and absolute: *whatever is done to the data is done to every simulation*. The same beam, the same pixel window, the same noise model, the same five windows, the same binning and the same MASTER operator.

Recipe for one simulated sky.

1. Draw $a_{\ell m}$ from the fiducial lensed spectrum C_ℓ (CAMB at the *Planck* 2018 best fit [8], Section 7.11.1), for $\ell \le 1535$.
2. Multiply by $T_\ell = B_\ell p_\ell^{(512)}$ and synthesise the sky map s at $N_{\rm side} = 512$.
3. Make two half-mission maps $s + n_1$ and $s + n_2$, with n_1, n_2 independent draws of (13.10).
4. For each of the five windows, compute the pseudo-coefficients of both halves, their cross-spectrum and the spectrum of their half-difference, and correct both with that window's MASTER operator (13.8).

The output is, for each sky and each window, 33 cross bandpowers and 33 null bandpowers.

One sky takes 1.7 s on four cores: three map syntheses and ten masked transforms at $N_{\rm side} = 512$. We ran 400 skies, in chunks of 50 cached in `data/ch13/` so that an interrupted run resumes where it stopped. The skies are Gaussian, while the real sky is slightly non-Gaussian through gravitational lensing; the lensed spectrum gets the mean right, and the extra covariance that lensing induces between multipoles is negligible at our error bars below $\ell \approx 1000$.

Listing 13.4: One simulated sky, observed and analysed like the real one (`code/ch13/04_sims.py`)

```
def one_sky(rng):
    a = cs.synalm(clf, LS, rng)                          # the sky
```

```
    s = hp.alm2map(hp.almxfl(a, T), NSIDE, lmax=LS)          # as seen through beam and
    pixels
    halves = []
    for _ in range(2):
        g = hp.alm2map(cs.synalm(ng, LS, rng), NSIDE, lmax=LS)
        halves.append(s + np.sqrt(2.0) * sqv * g)
    res = {}
    for k in WINDOWS:
        a1, a2 = lp.pseudo_cl(Ws[k], halves, LC)
        res[f"{k}_cross"] = msts[k](hp.alm2cl(a1, a2))
        res[f"{k}_null"] = msts[k](hp.alm2cl(0.5 * (a1 - a2)))
    return res
```

`cs.synalm` is the Gaussian $a_{\ell m}$ generator of Chapter 8 (`code/ch08/lib_cmbsim.py`). The sky map is made once and shared by the two halves; each half gets its own noise, a Gaussian field with spectrum N_ℓ^g multiplied pixel by pixel by $\sqrt{2v}$. The inner loop is Section 13.3.4 again, line for line.

13.4.3 What the simulations say

Is the estimator unbiased? If MASTER is unbiased, the average of the simulated bandpowers must equal the fiducial spectrum passed through the bandpower windows, $t_b = \sum_\ell \mathcal{F}_{b\ell} C_\ell$ (13.9). The question in words: if the theory were right, would an average of n simulated bandpower vectors as far from $\boldsymbol{t}$ as ours, or farther, be something we would reasonably expect? The average $\bar{\boldsymbol{x}}$ of n independent vectors with covariance $\mathbf{C}$ has covariance $\mathbf{C}/n$. For Gaussian vectors with mean $\boldsymbol{t}$,

$$\chi^2_{\text{bias}} = (\bar{\boldsymbol{x}} - \boldsymbol{t})^{\mathsf{T}} \left(\frac{\mathbf{C}}{n}\right)^{-1} (\bar{\boldsymbol{x}} - \boldsymbol{t}) = n\,(\bar{\boldsymbol{x}} - \boldsymbol{t})^{\mathsf{T}} \mathbf{C}^{-1} (\bar{\boldsymbol{x}} - \boldsymbol{t}) \tag{13.12}$$

is a χ^2 with $p = 33$ degrees of freedom: a quadratic form in a Gaussian vector, weighted by the inverse of its own covariance, is a sum of p squared independent unit Gaussians (Section 2.13.3). In practice $\mathbf{C}$ is itself estimated from the same simulations, and its inverse is multiplied by the Hartlap factor $(n - p - 2)/(n - 1) = 0.915$ derived in Section 8.13.2, which removes the bias of the inverse of a noisy matrix.

With the exact windows, $\chi^2_{\text{bias}} = 43.7$ for 33 degrees of freedom, a probability to exceed of 0.10: no sign of bias, at the precision of 400 simulations, which is $1/\sqrt{400}$ of an error bar. If instead the theory is binned with the plain operator P, as if it were flat inside each bin, $\chi^2_{\text{bias}} = 1099$ (Figure 13.10b). The difference between the two theory vectors is at most 1.2%, which is 0.46 of a single bandpower's error bar: small for one sky, but the average of 400 skies is twenty times more precise and sees it. The same is true of any analysis that averages many bandpowers into a few parameters, which is why the NaMaster authors insist on the exact windows [142, §2.1, Fig. 10].

How large are the error bars? The square roots of the diagonal of $\mathbf{C}$ are our error bars. Two estimates give them a size. The cosmic variance of a bin on the *full* sky, with no noise, is the variance of the average of $\Delta\ell$ independent $\widehat{D}_\ell$, each of variance $2D_\ell^2/(2\ell+1)$ (7.77). Our error bars are larger by a factor 1.47 in the first bin, 1.27 (median) over the first fifteen, and 1.30 in the last. The mode counting of (8.81) predicts $1/\sqrt{f_{\text{sky}} w_2^2/w_4} = 1.19$ where the noise is negligible, and more where it is not. The bins in the middle of the range, where the noise is still negligible, sit about 7% above that prediction, and the first bin sits $1.47/1.19 \approx 1.24$ times above it. Mode counting with one effective sky fraction describes the covariance of a masked spectrum only to leading order. What it leaves out (the coupling of neighbouring multipoles through the small

holes, and the amplification of fluctuations when MASTER inverts the coupling, which in the first bin is done together with the buffer bin below it) is exactly what the simulations contain.

Example: Knox's formula against the simulations. In the first bin, $\ell^{\mathrm{eff}} = 47.7$ and $\Delta\ell = 30$, Knox's formula with the effective sky fraction, $\sigma(D_b) \approx \sqrt{2/[(2\ell^{\mathrm{eff}}+1)\Delta\ell\, f_{\mathrm{sky}} w_2^2/w_4]}\; D_b$ (Section 8.4.2), gives 46.3 $\mu\mathrm{K}^2$; the simulations give 53.0 $\mu\mathrm{K}^2$. In the last bin the formula, which ignores the noise, gives 7.2 against 7.9. The formula is a good first guess, and the simulations are the answer.

Are neighbouring bins correlated? The mask couples multipoles, so the bandpowers of neighbouring bins share some of their fluctuations (Section 8.12.2). With bins of 30 multipoles, wide compared with the coupling kernel's core, the correlation is weak: on average -0.016 between neighbours, and at most -0.112 in magnitude in the other direction (Figure 13.10a). MASTER's deconvolution tends to make neighbours slightly *anti*-correlated: when it undoes the coupling, an upward fluctuation that the mask spread into the next bin is subtracted from it.

How good is the covariance itself? Every element of $\mathbf{C}$ is estimated from 400 draws. A diagonal element, a sample variance, has a relative error of $\sqrt{2/(n-1)}$ (Section 8.13.1); the error bar is its square root, so its relative error is half of that, $1/\sqrt{2(n-1)} = 3.5\%$. Our error bars are uncertain by about 3.5%, and the probabilities to exceed computed below are good to a few per cent of their value.

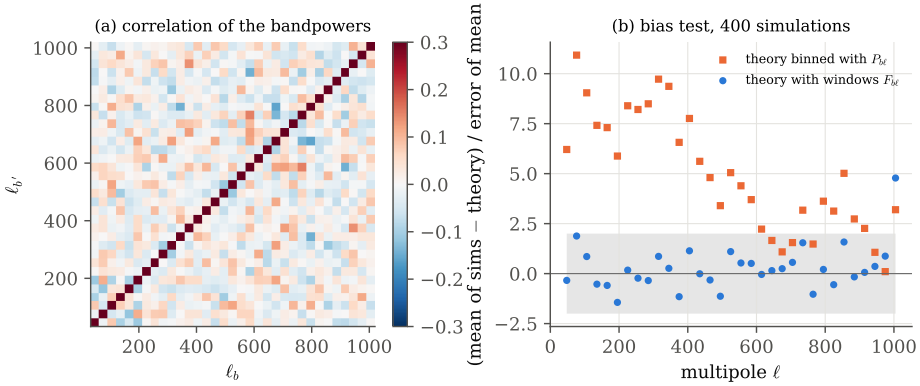

Figure 13.10: (a) The correlation matrix of the 33 bandpowers from the simulations: almost diagonal, with weak correlations between neighbours. (b) The bias test: the average of the simulated bandpowers minus the theory, in units of the error of the average. The theory passed through the exact bandpower windows (blue) is consistent with zero; the theory binned as if it were flat in each bin (orange) is not.

How research codes get the covariance. Here the simulations are the research instrument, not a check of a formula. *Planck*'s high-ℓ likelihood uses an analytic covariance instead, computed from the fiducial spectrum, the masks and a noise model, with corrections for the point-source holes and the anisotropic noise calibrated on simulations [70, §3.1]. Efstathiou showed why this is possible at high ℓ: for apodised masks the pseudo-C_ℓ covariance is close to an analytic expression, and the estimator is nearly as precise as the maximum-likelihood one [141]. The end-to-end FFP10 simulations then validate the analytic covariance rather than replace it. Both routes need the same thing we built: a model of the observation good enough that simulated and real skies are statistically indistinguishable.

13.5 Our spectrum against *Planck*'s

Their question. The *Planck* collaboration wanted the temperature power spectrum of the CMB over $30 \le \ell \le 2508$ with errors small enough that the six parameters of ΛCDM would be limited by the sky, not by the instrument, and a likelihood that turns that spectrum into parameters without bias [70, §1, §3]. The binned spectrum in the file we downloaded is one product of that work: the CMB spectrum after the foreground model has been subtracted and the frequency channels have been averaged.

Their setup, in plain terms. The high-ℓ likelihood code of the release is called Plik. It did not use a component-separated map. It measured cross-spectra between the half-mission maps of three frequency channels, 100, 143 and 217 GHz, each through its own mask (keeping 66%, 57% and 47% of the sky) with apodised Galactic and point-source holes, over a multipole range chosen per channel [70, §3.2.1–3.2.4, Table 13]. The residual emission of dust, of unresolved galaxies and of galaxy clusters was not masked away but *modelled*: each foreground has a spectrum with a few free amplitudes, fitted together with the cosmology. The covariance of the spectra is computed analytically from the fiducial model, the masks and a noise model. Our setup differs in almost every item (Table 13.2), and the point of the comparison is to see whether the two routes land on the same spectrum.

	Planck 2018 (Plik)	ours
maps	100, 143, 217 GHz half-missions	SMICA half-missions
resolution	$N_{\rm side} = 2048$	$N_{\rm side} = 512$
masks	one per frequency, 47–66% of the sky	common mask, 0.775 of the sky
foregrounds	modelled, amplitudes fitted	removed by SMICA, the rest masked
multipoles	$30 \le \ell \le 2508$	$30 \le \ell \le 1019$
covariance	analytic, validated on simulations	400 Gaussian simulations
binning (this file)	$\Delta\ell = 30$, weights $\ell(\ell+1)$	identical

Table 13.2: The two analyses compared. Only the binning is the same.

13.5.1 Their key equation: a Gaussian likelihood for bandpowers

Planck's high-ℓ likelihood is [70, (20)]

$$-\ln \mathcal{L}(\boldsymbol{\theta}) = \tfrac{1}{2}\big[\widehat{\boldsymbol{C}} - \boldsymbol{C}(\boldsymbol{\theta})\big]^{\mathsf{T}} \Sigma^{-1} \big[\widehat{\boldsymbol{C}} - \boldsymbol{C}(\boldsymbol{\theta})\big] + \text{const}, \tag{13.13}$$

with $\widehat{\boldsymbol{C}}$ the vector of measured bandpowers, $\boldsymbol{C}(\boldsymbol{\theta})$ the model passed through the same binning, and Σ their covariance. Where does it come from? Ask the likelihood's question (Section 3.8): for given parameters, how plausible is the fluctuation that turns the model prediction into the bandpowers we observed? Answering it needs the sampling distribution of the bandpowers. Each bandpower is an average over many modes, $(2\ell+1)\,\Delta\ell\, f_{\rm sky} w_2^2/w_4 \approx 2000$ already in our first bin, and an average of many independent pieces is close to Gaussian (the central limit theorem, Section 2.10). Hamimeche and Lewis checked how close: at high ℓ the Gaussian form, with a covariance computed at the fiducial model, gives the same parameters as the exact likelihood [16], while at $\ell \lesssim 30$, where the exact distribution is a skewed scaled χ^2, it does not (Section 9.19.4). That is why *Planck* splits its likelihood at $\ell = 30$, and why we start there. With

a Gaussian sampling distribution,

$$p\big(\widehat{\boldsymbol{D}} \mid \boldsymbol{\theta}\big) \overset{(1)}{=} \frac{1}{\sqrt{(2\pi)^p \det \mathbf{C}}} \exp\Big[-\tfrac{1}{2}\big(\widehat{\boldsymbol{D}} - \boldsymbol{t}(\boldsymbol{\theta})\big)^{\mathsf{T}} \mathbf{C}^{-1} \big(\widehat{\boldsymbol{D}} - \boldsymbol{t}(\boldsymbol{\theta})\big)\Big],$$

$$-2 \ln \mathcal{L}(\boldsymbol{\theta}) \overset{(2)}{=} \big(\widehat{\boldsymbol{D}} - \boldsymbol{t}(\boldsymbol{\theta})\big)^{\mathsf{T}} \mathbf{C}^{-1} \big(\widehat{\boldsymbol{D}} - \boldsymbol{t}(\boldsymbol{\theta})\big) + \text{const} \equiv \chi^2(\boldsymbol{\theta}) + \text{const}, \tag{13.14}$$

(1) The multivariate Gaussian density of p bandpowers with mean $\boldsymbol{t}(\boldsymbol{\theta})$, the model through the bandpower windows (13.9), and covariance $\mathbf{C}$ (Section 2.12).
(2) Read as a function of $\boldsymbol{\theta}$ with the data fixed; $\mathbf{C}$ is held at its fiducial value, so $\det \mathbf{C}$ is a constant and goes into it.

This is (13.13) in our symbols: $\widehat{C} \to \widehat{\boldsymbol{D}}$ (we work in D_b), $\boldsymbol{C}(\boldsymbol{\theta}) \to \boldsymbol{t}(\boldsymbol{\theta})$, $\Sigma \to \mathbf{C}$. In our analysis $\mathbf{C}$ is the simulated covariance of Section 13.4.3 and its inverse carries the Hartlap factor.

13.5.2 What we compute

Three things, all in `code/ch13/05_compare.py`. First, the value of χ^2 at the *Planck* best fit, $\boldsymbol{t} = \mathcal{F}\boldsymbol{C}^{\text{fid}}$: a goodness-of-fit test of the best-fit spectrum on our bandpowers. Second, the simplest possible fit, one overall amplitude. Third, the difference between our bandpowers and *Planck*'s, bin by bin.

Is the best fit a reasonable explanation? The null hypothesis is that our bandpowers are a draw from the Gaussian of (13.14) with $\boldsymbol{t}$ at the best fit: "the differences are chance", with chance fully specified. Under it the χ^2 is a sum of $p = 33$ squared unit Gaussians (Section 2.13.3), with mean 33 and standard deviation $\sqrt{66} \approx 8$. If the best fit were right, would a χ^2 as large as ours, or larger, be something we would reasonably expect? We find $\chi^2 = 33.5$. The χ^2_{33} tail above it is 0.44, and among the 400 simulations, whose χ^2 is computed in the same way, a fraction 0.30 has a larger one. (The two differ because each simulation is also one of the skies that estimated $\mathbf{C}$, which pulls its own χ^2 down a little; for the data, which are not in that set, the χ^2 tail is the better reference.) Either way the answer is yes: the best fit explains our spectrum as well as it explains a typical simulated sky.

Example: one amplitude. Let the model be $\boldsymbol{t} = A\,\boldsymbol{t}^{\text{fid}}$, the best-fit spectrum scaled by an unknown factor A. With Ψ the Hartlap-corrected inverse covariance, the χ^2 is a parabola in A,

$$\chi^2(A) \overset{(1)}{=} \big(\widehat{\boldsymbol{D}} - A\boldsymbol{t}^{\text{fid}}\big)^{\mathsf{T}} \Psi \big(\widehat{\boldsymbol{D}} - A\boldsymbol{t}^{\text{fid}}\big) \overset{(2)}{=} \widehat{\boldsymbol{D}}^{\mathsf{T}}\Psi\widehat{\boldsymbol{D}} - 2A\,\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\widehat{\boldsymbol{D}} + A^2\,\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\boldsymbol{t}^{\text{fid}},$$

$$\frac{\mathrm{d}\chi^2}{\mathrm{d}A} = 0 \overset{(3)}{=} \hat{A} = \frac{\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\widehat{\boldsymbol{D}}}{\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\boldsymbol{t}^{\text{fid}}}, \qquad \sigma_A \overset{(4)}{=} \big(\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\boldsymbol{t}^{\text{fid}}\big)^{-1/2}. \tag{13.15}$$

(1) (13.14) with $\boldsymbol{t} = A\boldsymbol{t}^{\text{fid}}$.
(2) Multiply out; Ψ is symmetric, so the two cross terms are equal.
(3) Set the derivative $-2\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\widehat{\boldsymbol{D}} + 2A\,\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\boldsymbol{t}^{\text{fid}}$ to zero.
(4) $\hat{A}$ is linear in the Gaussian data, so its variance is $\boldsymbol{a}^{\mathsf{T}}\mathbf{C}\boldsymbol{a}$ with $\boldsymbol{a} = \Psi\boldsymbol{t}^{\text{fid}}/(\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\boldsymbol{t}^{\text{fid}})$; with $\Psi\mathbf{C} \approx \mathbb{1}$ this is $1/\boldsymbol{t}^{\text{fid}\,\mathsf{T}}\Psi\boldsymbol{t}^{\text{fid}}$, the inverse of the curvature of $\chi^2/2$, as for every linear-Gaussian model (Eq. (8.80)).

On the SMICA bandpowers, $\hat{A} = 0.9992 \pm 0.0017$. The overall power of the CMB between $\ell = 30$ and 1019 agrees with the best fit to 0.1%, with an error of 0.2%. That size can be checked by counting. The number of independent modes behind the bandpowers is $f_{\text{sky}} w_2^2/w_4 \sum_{\ell=30}^{1019}(2\ell+1) = 0.708 \times (1020^2 - 30^2) \approx 7 \times 10^5$. Each mode is one squared Gaussian

number, whose relative scatter is $\sqrt{2}$ (Eq. (7.77)), so the average over N modes has relative error $\sqrt{2/N} = 0.17\%$, which is what we find. It is the same estimator that Section 8.13.4 used on simulated skies, now with one real sky.

13.5.3 Side by side

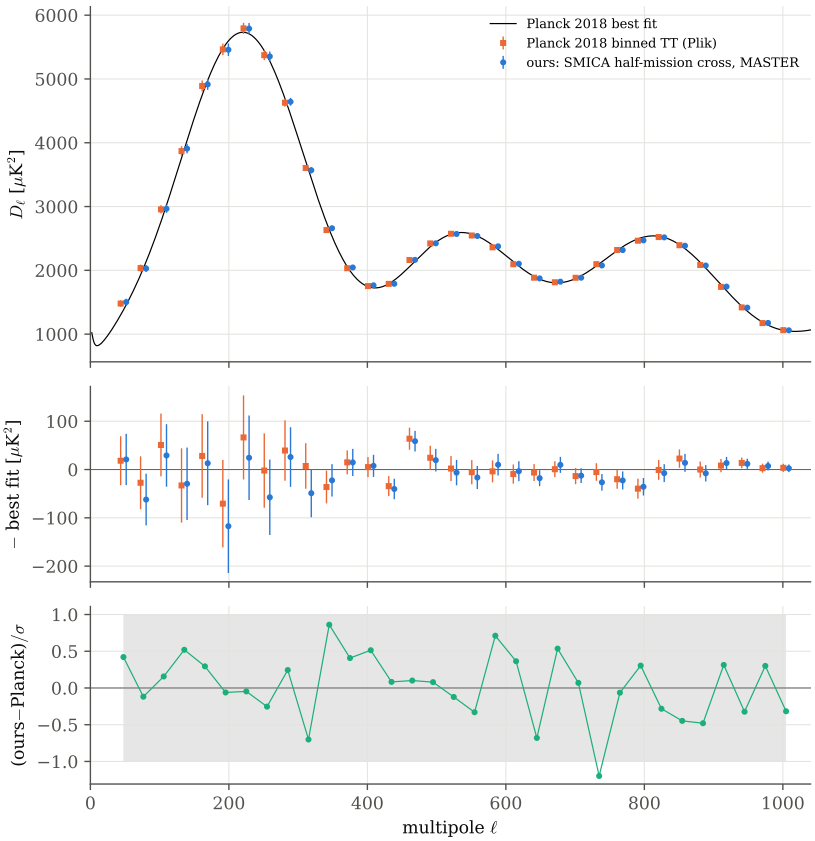

Figure 13.11: Top: our MASTER bandpowers of the SMICA half-mission cross-spectrum (blue) and *Planck*'s binned TT spectrum (orange), shifted by ±4 in ℓ to be seen side by side, with the best fit (black). Middle: both minus the best fit; each with its own error bars. Bottom: their difference in units of our error bar; the grey band is ±1.

Figure 13.11 puts the two spectra on one plot. Over the 33 bins they differ by 15 μK^2 in the root mean square, 0.43 of *Planck*'s error bar, and no bin differs by more than $|-1.2|$ of ours (at $\ell \approx 735$). The error bars themselves are almost equal: ours are 0.99 of *Planck*'s (median over the bins). An overall calibration difference would show up as a ratio different from one; the inverse-variance weighted mean of our bandpower divided by theirs is 0.9998.

13.5.4 Why they differ, and by how much they should

Two measurements of the *same* sky do not scatter around each other like two independent skies. Most of the error bar of each is cosmic variance, the luck of the particular sky, and the two share it. So the question "are 15 μK^2 differences reasonable?" needs the scatter of the *difference* of two estimators on one sky, and we can measure that with our simulations. Take the main window and the window with $|b| > 30°$, a part of the same sky, and compute both on each simulated sky. Their bandpowers are correlated with coefficient 0.81, and their difference scatters by 0.74 of the main error bar. The reason is a simple identity. Nested

regions share their sky, so write the smaller-sky estimate as the larger-sky estimate plus an extra piece, $A_{\text{small}} = A_{\text{large}} + E$, where E is what the less informative estimate adds, independent of A_{large} (the larger-sky estimate is the more precise one, and that is what makes the extra piece uncorrelated with it). The variance of a sum of independent pieces is the sum of the variances, $\sigma^2_{\text{small}} = \sigma^2_{\text{large}} + \text{Var}(E)$, and the difference $A_{\text{small}} - A_{\text{large}} = E$ has variance $\sigma^2_{\text{small}} - \sigma^2_{\text{large}}$. So it scatters by $\sqrt{(\sigma_{\text{small}}/\sigma_{\text{large}})^2 - 1} = \sqrt{1.26^2 - 1} \approx 0.77$ of the larger-sky error bar, close to the measured 0.74.

Planck's analysis uses a sky that overlaps ours far more than the $|b| > 30^\circ$ cut does (its masks keep 47–66% of the sky, almost all of it inside our 0.775), so the expected scatter of our difference is smaller than 0.74 of an error bar. We measure 0.43. The rest of the difference has identifiable causes, each small:

- *Different maps.* SMICA cleans foregrounds by weighting frequencies, Plik by modelling them. Where the foreground model and SMICA's weights disagree, the spectra differ; this is largest at high ℓ, where unresolved galaxies add power. Above $\ell = 700$ our bandpowers are on average $-3 \pm 4\,\mu\text{K}^2$ from *Planck*'s: no sign of excess point-source power in SMICA at these multipoles.
- *Different weights on the sky.* Different masks, and inside them different weights per frequency, sample the sky's fluctuations differently, which is the part estimated above.
- *Different best fits.* Our fiducial is the TT,TE,EE+lowE+lensing best fit, theirs in the file is their own; through our windows the two differ by up to 1.4%, which matters for the middle panel of Figure 13.11 but not for the difference of the two measurements.

What reproducing it taught us. A component-separated map, a common mask, our own coupling matrix and four hundred simulated skies at a sixteenth of the resolution give *Planck*'s temperature spectrum to a fraction of its error bar and its amplitude to 0.2%. What the comparison could not show by itself is how small the difference *should* be; for that we needed the joint scatter of two estimators on one sky, which only the simulations provide.

13.6 Is anything else in the map? The checks

The comparison with *Planck* told us that our spectrum agrees with theirs. It did not tell us that either spectrum is the spectrum of the CMB alone. Both could share a residual of the Galaxy, both are built from the same detectors, and a successful comparison between two analyses of one data set is weak evidence about what is in the data. Recall the three candidate explanations of the map listed in Section 13.1: a Gaussian isotropic CMB plus noise; residual foregrounds; something the processing did. The checks are how we put the second and third candidates on trial.

The idea of a null test. Choose a quantity that the first explanation predicts to be zero on average, and that the others would push away from zero. Spectra measured through two different windows are the standard example. If the map outside the mask is a statistically isotropic CMB, the spectrum through the northern half and the spectrum through the southern half have the same mean; their difference has mean zero. A residual of the Galaxy that is brighter in one hemisphere, or a stripe left by the scanning, would make it nonzero. The test then asks the question of every hypothesis test (Section 4.1.1): if the map were only CMB and noise, would a difference as large as the one we see, or larger, be something we would reasonably expect?

Why simulations, and not a formula. The answer needs the sampling distribution of the difference. The obvious guess, that the difference of two bandpowers has variance $\sigma_A^2 + \sigma_B^2$, is badly wrong whenever the two windows see the same sky. Take the binary common mask and the apodised window: almost the same pixels, slightly different weights. The simulations give a scatter of their difference of only 0.43 of a single bandpower's error, while $\sqrt{\sigma_A^2 + \sigma_B^2}$ would be about $\sqrt{2} = 1.4$ of it, three times too large, and a test built on it could never fail. The difference has the variance $\sigma_A^2 + \sigma_B^2 - 2\,\mathrm{Cov}(A, B)$, and the covariance of two estimators on one sky is exactly what our simulations contain, because each simulated sky is analysed through all five windows. So every test uses the same recipe:

1. the difference vector $\boldsymbol{\delta}$ of the data, over the 33 bins;
2. the same difference on each of the 400 simulated skies, giving its mean $\bar{\boldsymbol{\delta}}$ and covariance $\mathbf{C}_\delta$;
3. $\chi^2 = (\boldsymbol{\delta} - \bar{\boldsymbol{\delta}})^{\mathsf{T}} \Psi_\delta (\boldsymbol{\delta} - \bar{\boldsymbol{\delta}})$, with Ψ_δ the Hartlap-corrected inverse of $\mathbf{C}_\delta$;
4. the probability to exceed (PTE): the fraction of simulated skies whose χ^2, computed in the same way, is at least as large as the data's. For comparison, also the tail of χ^2_{33} above the data's value.

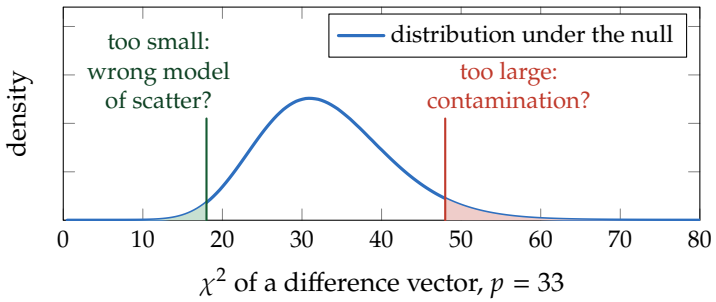

Figure 13.12: Reading a null test. Under the null hypothesis (CMB and our noise model, nothing else) the χ^2 of a difference vector of 33 bandpowers follows the blue curve, which the simulations sample. A value in the right tail (red) means the difference is larger than chance allows: something in the data is not in the model. A value in the left tail (green) means it is *smaller* than chance allows: the model of the scatter is wrong, because contamination can only add to a difference.

13.6.1 Four tests, and what each is for

difference	what would make it nonzero	χ^2 ($p = 33$)	PTE (sims)	PTE (χ^2_{33})
north − south	anisotropy, a one-sided residual	13.2	1.00	1.00
$\lvert b\rvert > 30°$ − main	Galactic residuals near the plane	27.5	0.59	0.74
binary − apodised	an error in the mode-coupling correction	14.7	1.00	1.00
half-mission null	a wrong noise model, sky in the difference	1312.3	0.00	0.00

Table 13.3: The checks. Each line is a difference that a Gaussian CMB plus our noise model predicts to vanish on average; the PTE is the fraction of simulated skies with a larger χ^2, and the tail probability of a χ^2 with 33 degrees of freedom.

The Galactic test passes. The window with $|b| > 30°$ removes everything within 30° of the plane, where dust and synchrotron residuals would be strongest. Its spectrum differs from the main one by $\chi^2 = 27.5$ for 33 bins, a PTE of 0.59 (Figure 13.13b). How small a residual

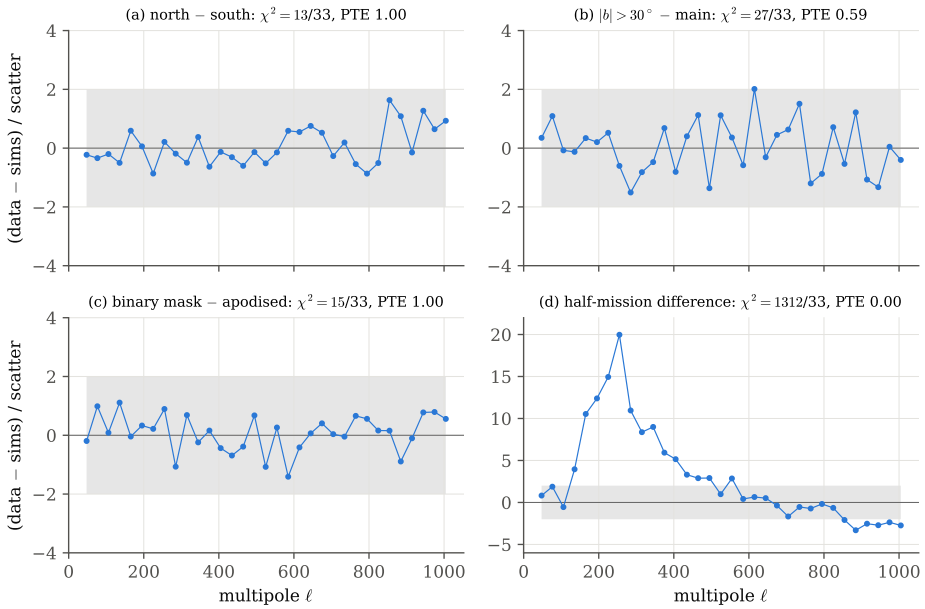

Figure 13.13: The four checks, bin by bin: the data's difference minus the average simulated difference, in units of the simulated scatter. The grey band is ±2. (a)–(c) compare spectra through different windows; (d) is the spectrum of the half-mission difference map against the simulated noise.

could it have seen? The scatter of this difference is 0.74 of a main error bar, so a residual that changed the main spectrum by a full error bar in several bins would have been detected; one much smaller than that could hide.

The half-mission null fails, and we can say why. Here the result is unambiguous: $\chi^2 = 1312.3$ for 33 bins, with single bins 20.0 standard deviations off (Figure 13.13d). The event: the spectrum of the half-difference map is up to 1.31 times the simulated one, at $\ell \approx 255$, and about 1% *below* it at high ℓ (on average 0.989 of it above $\ell = 600$). What could have produced it? We take the candidates one at a time.

1. *Our noise model has the wrong shape in ℓ.* It was built as a modulated isotropic field (13.10), with a spectrum averaged over 31 multipoles. If the real noise has a different spectrum in different parts of the sky, as SMICA's noise does, the product of one map v and one spectrum cannot reproduce it. This predicts a mismatch that varies slowly with ℓ, with either sign.
2. *Some sky survives in the difference.* If the two halves see the sky with slightly different gains, $1 + \epsilon/2$ and $1 - \epsilon/2$ (a calibration difference, or a slightly different effective beam), the difference map contains $\epsilon/2$ times the sky, and its spectrum contains $(\epsilon/2)^2$ times the sky's spectrum. This predicts an excess that follows the acoustic peaks, largest at the first one.
3. *The noise of the halves is correlated.* Correlated noise would *cancel* in the difference and lower its spectrum, not raise it. It cannot produce an excess.

How well does each explain the data? The excess peaks at $\ell \approx 255$, the first acoustic peak, which is what the second candidate predicts. Fitting the excess below $\ell = 600$ as $(\epsilon/2)^2$ times the fiducial bandpowers plus a constant gives $\epsilon = 1.2\%$, and explains 35% of the variance of the excess; the rest, and the deficit at high ℓ, is the first candidate. So both are at work: a percent-level difference between the halves' response to the sky, and a noise model whose shape is good to a few per cent at high ℓ and worse at low ℓ.

The test is this sensitive because the noise is measured with enormous precision: thousands of modes in each bin, and a simulated scatter of about 2% of the noise power. Does the failure matter for the cross-spectrum? Neither cause biases it. A gain difference changes the cross-spectrum by the factor $(1+\epsilon/2)(1-\epsilon/2) = 1-\epsilon^2/4$, a change of 0.0039%. A noise model wrong by 30% changes only the noise part of the error bars, and the noise is 0.15% of the signal at $\ell \approx 500$ and 1.9% at $\ell \approx 1000$. The failure is real, it is understood, and it is harmless for the questions we are asking; a likelihood that used the auto-spectra, where the noise must be subtracted, could not ignore it. (The identity (13.3) between the full-mission, the cross and the null spectra holds on the data to 11.41 $\mu\mathrm{K}^2$ at worst, not exactly, for the same reason: the SMICA full-mission map is not exactly the average of the two halves.)

Two tests are passed too well. The hemisphere test gives $\chi^2 = 13.2$ and the apodisation test $\chi^2 = 14.7$, for 33 bins each. Only 1 and 1 of the 400 simulated skies give smaller values (Table 13.3, where a PTE of 1.00 means "larger than in almost every simulation"). The data's differences are, bin by bin, 0.62 and 0.62 of the simulated scatter in the root mean square, against about one expected (and 0.89 for the Galactic test). What could produce two differences this small?

1. *Chance.* So few simulated skies fall this low that their count only bounds the chance: a χ^2 this low happens in at most about 0.01 of skies (95% upper limit). In the simulations the two tests are independent (the correlation of their χ^2 over the simulated skies is -0.05), so two of four tests this low has a probability below about 9×10^{-4}. Not plausible.
2. *A residual foreground.* No: contamination adds to a difference, it cannot remove one (Figure 13.12).
3. *The simulations overestimate the scatter of these differences.* The real map's spectra through different windows agree better than Gaussian skies passed through our model of the observation would. Our simulations lack two things the real map has been through: SMICA's component separation, and the inpainting that fills the holes (the band limit of the degrade spreads the filled values a few arcminutes into the kept pixels at the hole edges, exactly where the binary and apodised windows differ).

The third explanation is the likely one, and it limits what the simulations can certify: they describe the scatter of each window's spectrum well (the best-fit χ^2 of Section 13.5.2 is normal) but overestimate the scatter of the differences between windows. A low χ^2 cannot hide a contaminant, so the spectrum itself is not in question. What the full analysis would do is run the null tests on end-to-end simulations processed exactly as the data were, component separation and inpainting included, which our Gaussian skies are not.

Example: reading a PTE of 1.00 **correctly.** A PTE close to one is not "a perfect pass". The PTE is uniform between 0 and 1 when the null hypothesis and its simulated distribution are right (Section 4.4.2), so a value above 0.99 is as unusual as one below 0.01. A table of null tests whose PTEs cluster near one is a warning that the error model is too generous, just as a cluster near zero is a warning of contamination.

13.7 Two primordial numbers from the real sky

In Section 9.22 the Metropolis sampler of Chapter 9 was pointed at a mock *Planck*-like spectrum: $2 \le \ell \le 2500$, one 143 GHz-like channel, $f_{\mathrm{sky}} = 0.57$. With the amplitude and the tilt of the primordial spectrum free and everything else fixed, it returned errors of 0.0018 on $\ln(10^{10}A_s)$

and 0.0026 on n_s, with a correlation of -0.73; freeing the optical depth τ inflated the first error ninefold, to 0.0164, because the temperature spectrum above $\ell = 30$ measures only the combination $A_s e^{-2\tau}$ (9.132). Those were forecasts on a spectrum whose truth we chose. Now the same two parameters, the same emulator and the same sampler meet our bandpowers of the real sky.

The event, and the hypotheses. The observed event is our vector of 33 bandpowers $\widehat{\boldsymbol{D}}$. The hypotheses are the pairs $\boldsymbol{\theta} = (\ln 10^{10} A_s,\, n_s)$, with the baryon and dark-matter densities, the angular size of the sound horizon and τ held at the *Planck* best fit. For each pair the question is: had nature chosen these values, how plausible would the fluctuation be that turns the predicted bandpowers into the ones we measured? That is the likelihood of (13.14), and Bayes' theorem with a flat prior over $2.8 < \ln 10^{10} A_s < 3.3$, $0.85 < n_s < 1.10$ turns it into a posterior.

13.7.1 The model, the likelihood and the sampler

The model. The predicted bandpowers are $\boldsymbol{t}(\boldsymbol{\theta}) = \mathcal{F}\, \boldsymbol{C}(\boldsymbol{\theta})$: the theory spectrum passed through the bandpower windows (13.9). The spectrum $C_\ell(\boldsymbol{\theta})$ comes from the emulator of Section 9.20, a second-order Taylor expansion of $\ln C_\ell$ about the fiducial (9.123), which reproduces CAMB to far better than our error bars over this range (Section 9.20.3). A CAMB call takes seconds; the emulator takes microseconds, so a chain of tens of thousands of steps costs seconds.

The likelihood. Gaussian in the bandpowers, (13.14), with the simulated covariance and the Hartlap factor. The covariance is held fixed at the fiducial model, as *Planck* does; over the narrow range of parameters the data allow, the change of the covariance with the parameters is negligible [16].

The sampler. Random-walk Metropolis (Section 9.8), `code/ch09/lib_mcmc.py`, with a Gaussian proposal whose shape is the inverse Fisher matrix $\mathbf{F}^{-1}$ and whose scale is $2.38/\sqrt{d}$ for $d = 2$ parameters, the rule of Section 9.11. Four chains of 20 000 steps start from points scattered over three Fisher widths around the fiducial; the first 20% of each is discarded as burn-in (Section 9.12.1).

Example: the Fisher matrix as a first answer. For a model that is linear in the parameters near the peak, the posterior is Gaussian with covariance $\mathbf{F}^{-1}$, where $\mathbf{F} = J^{\mathsf{T}} \Psi J$ and $J_{bi} = \partial t_b / \partial \theta_i$ (Chapter 10). We compute J by central differences of the emulator. The Fisher errors are 0.0018 on $\ln 10^{10} A_s$ and 0.0039 on n_s. The chains give 0.0018 and 0.0039. Agreement to within a few per cent says the posterior is Gaussian to that precision: over a range of $\pm 3\sigma$ the bandpowers depend on the two parameters almost linearly.

Listing 13.5: The log-posterior: a flat prior and the Gaussian bandpower likelihood (`code/ch13/07_fit.py`)

```
def make_logpost(Fmat, data, prec):
    def logpost(th):
        if np.any(th < LO) or np.any(th > HI):
            return -np.inf
        r = data - Fmat @ emu.cl(th)[: Fmat.shape[1]]
        return -0.5 * r @ prec @ r
    return logpost
```

The function returned by `make_logpost` is all the sampler sees. Outside the prior box it returns $-\infty$, so every proposal there is rejected. Inside, it computes the residual between the bandpowers and the emulated theory through the windows, and returns $-\frac{1}{2}\chi^2$; the normalisation of the posterior never appears, because Metropolis only uses ratios (Section 9.8.1).

13.7.2 What the real sky says

The chains are healthy: acceptance 0.36, integrated autocorrelation time about 7 steps (Section 9.12.2), so the 64 000 kept samples are worth several thousand independent ones, and the split $\hat{R}$ of the four chains is 1.0009 (Section 9.13). The posterior means and standard deviations are

$$\ln(10^{10}A_s) = 3.0432 \pm 0.0018, \qquad n_s = 0.9686 \pm 0.0039, \qquad \rho = -0.28, \tag{13.16}$$

and at the maximum of the likelihood $\chi^2 = 32.4$ for $33 - 2 = 31$ degrees of freedom (a tail probability of 0.40): two parameters describe the 33 bandpowers as well as they should. With $\tau = 0.0544$ fixed, the quantity the temperature spectrum actually measures is $10^9 A_s e^{-2\tau} = 1.8811 \pm 0.0034$.

To separate what comes from *our* bandpowers from what comes from the multipole range, we run the same fit, same emulator, same sampler, on *Planck*'s published bandpowers, with their quoted errors as a diagonal covariance (the file gives no correlations): first over our range $30 \le \ell \le 1019$, then over $30 \le \ell \le 2489$, as far as our emulator goes.

data, multipoles, free parameters	$\ln(10^{10}A_s)$	n_s	ρ
ours (SMICA), 30–1019, 2 free	3.0432 ± 0.0018	0.9686 ± 0.0039	-0.28
Planck bandpowers, 30–1019, 2 free	3.0453 ± 0.0018	0.9661 ± 0.0040	-0.22
Planck bandpowers, 30–2489, 2 free	3.0451 ± 0.0017	0.9657 ± 0.0025	-0.73
mock spectrum of Section 9.22, 2–2500, 2 free	± 0.0018	± 0.0026	-0.73
Planck 2018 VI, TT+lowE, 6 free	3.040 ± 0.016	0.9626 ± 0.0057	

Table 13.4: The amplitude and tilt from our bandpowers, from *Planck*'s bandpowers through the same fit, from the forecast of Section 9.22, and as published with all six parameters free [25].

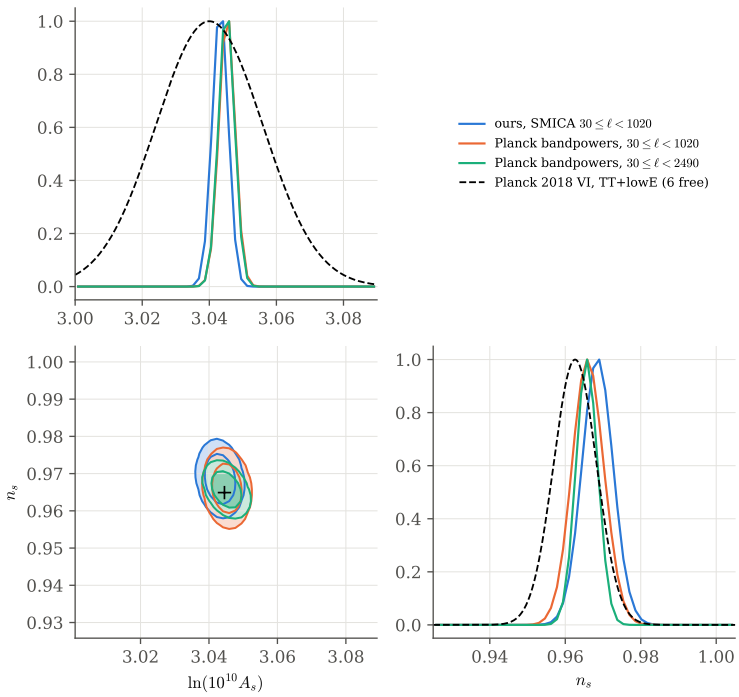

Figure 13.14: Posteriors of $\ln(10^{10}A_s)$ and n_s with the other four parameters fixed: from our SMICA bandpowers (blue), from *Planck*'s bandpowers over the same multipoles (orange) and over $30 \le \ell \le 2489$ (green). Contours enclose 68% and 95%. The black dashed curves are the published one-dimensional results with all six parameters free; the cross is the fiducial.

13.7.3 Reading the comparison with *Planck* 2018 VI

Their question and setup. *Planck* 2018 VI asked which ΛCDM parameters the CMB spectra prefer. Its "TT+lowE" result combines the high-ℓ temperature likelihood of (13.13), a low-ℓ temperature likelihood for $2 \le \ell < 30$, and the large-scale E-mode polarisation, which measures τ. All six parameters are free, together with nuisance parameters for the foregrounds and the calibration [25]. Its key equation is the same Gaussian likelihood we derived in Section 13.5.1, multiplied by the low-ℓ terms.

Side by side, and why the numbers differ. Figure 13.14 and Table 13.4 show three differences, each with a cause we can name.

1. *Our error on the amplitude is nine times smaller.* Above $\ell = 30$ the temperature spectrum depends on A_s and τ only through $A_s e^{-2\tau}$, so $\ln(10^{10}A_s) = \ln(10^{10}A_s e^{-2\tau}) + 2\tau$ and, the two terms being nearly independent, $\sigma^2(\ln 10^{10}A_s) \approx \sigma^2(\ln 10^{10}A_s e^{-2\tau}) + 4\sigma_\tau^2$ (9.132). We fixed τ, so the second term is zero and we quote the error of the first, 0.0018. *Planck* measures $\sigma_\tau = 0.008$ from polarisation, and $2 \times 0.008 = 0.016$ is its whole error on $\ln(10^{10}A_s)$. The well-measured combination agrees: $10^9 A_s e^{-2\tau} = 1.8811 \pm 0.0034$ for us, 1.884 ± 0.014 published.

2. *Our error on n_s is smaller than theirs although we use two fifths of the multipoles.* With six parameters free, a change of the tilt can be partly undone by a change of the baryon density, which also tilts the relative heights of the peaks; fixing the other parameters removes that escape route. Freeing them costs a factor of about two in Section 9.22 (0.0026 to 0.0053), the same factor that separates our full-range fit of *Planck*'s bandpowers (0.0025) from the published 0.0057.

3. *The multipole range matters for the tilt.* On *Planck*'s bandpowers, going from $\ell \le 1019$ to $\ell \le 2489$ shrinks the error on n_s from 0.0040 to 0.0025 and strengthens the anticorrelation with the amplitude from −0.22 to −0.73. A tilt is a lever, and the damping tail lengthens the arm; on a longer arm, raising the amplitude and lowering the tilt compensate each other over more of the range, hence the stronger correlation. The full-range numbers reproduce the forecast of Section 9.22 (0.0018, 0.0026, −0.73): that forecast described the real data correctly.

The central values agree within the errors. Our $n_s = 0.9686$ sits one standard deviation above the fiducial 0.9649, and 0.6σ above the fit to *Planck*'s bandpowers over the same range; the bin-by-bin differences of Section 13.5.3, a few tenths of an error bar each, are enough to move a two-parameter fit that much.

13.7.4 Do the low and the high multipoles agree?

A fit to a range of multipoles averages over it. If the low and the high multipoles wanted different parameters, the average would hide it, and *Planck* took this question seriously: in their temperature data some parameters differ by more than 2σ between $\ell < 800$ and $\ell > 800$, which they judge, after accounting for correlations, not to be especially unusual [25, p. 32]. We ask the same of our data, splitting at $\ell = 510$ so that both halves have similar constraining power.

The test statistic. Fit $(\ln 10^{10}A_s, n_s)$ separately to the bins below and above the split, and form the shift $\boldsymbol{\Delta} = \hat{\boldsymbol{\theta}}_{\text{low}} - \hat{\boldsymbol{\theta}}_{\text{high}}$. If both halves measure the same sky with the same model, $\boldsymbol{\Delta}$ has mean zero. Its covariance is not the sum of the two fits' covariances, since the two halves share

the mask and are weakly correlated, so we take it from the simulations: the same two fits on each simulated sky give 400 shifts and their covariance $\mathbf{C}_\Delta$. Then $\chi^2 = \boldsymbol{\Delta}^{\mathsf{T}}\mathbf{C}_\Delta^{-1}\boldsymbol{\Delta}$ has two degrees of freedom.

The result. The low multipoles prefer (3.051, 0.975) and the high ones (3.037, 0.986). The shift is $\Delta \ln 10^{10}A_s = +0.015 \pm 0.007$ and $\Delta n_s = -0.011 \pm 0.014$, and $\chi^2 = 4.49$. A fraction 0.11 of the simulated skies gives a larger one, the same as the χ^2_2 tail (0.11; Figure 13.15). The amplitude shift alone is a 2σ effect, but one of two correlated numbers at 2σ is what the two-dimensional test is for: it is a one-in-nine event, and the two halves agree.

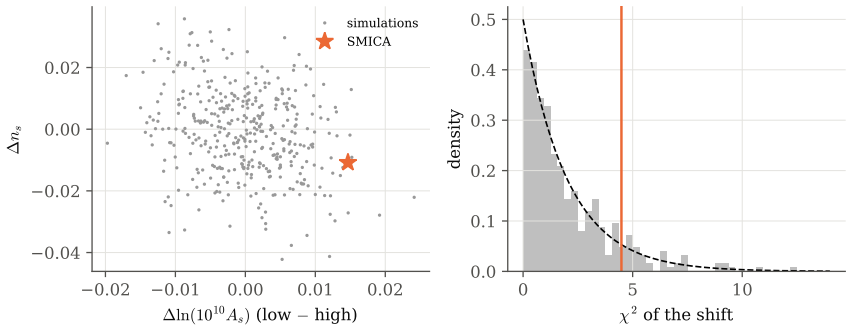

Figure 13.15: Low against high multipoles. Left: the shift between the parameters fitted to $\ell < 510$ and to $\ell > 510$ on each simulated sky (grey) and on the SMICA bandpowers (star). Right: the χ^2 of the shift over the simulations (histogram), the χ^2_2 density (dashed), and the data (vertical line).

Watch out: A fixed parameter is a prior of zero width

Holding four parameters at their best-fit values is the same as giving them delta-function priors. The errors in (13.16) are therefore *conditional* errors, smaller than the marginal ones of a six-parameter fit, and the central values inherit any error in the fixed values. Our ±0.0018 on $\ln(10^{10}A_s)$ is not a better measurement than *Planck*'s ±0.016; it is the answer to a narrower question.

13.8 The full analysis, and what the laptop version gives up

Everything above ran on four processor cores: the preparation of the maps in under a minute, each simulated sky in 1.7 s, the four hundred of them in about ten minutes, the fits in seconds. *Planck*'s analysis of the same sky used supercomputers for years. Each place where we took a shorter road costs something, and an honest result says what. Table 13.5 lists the reductions, and the paragraphs after it put a size on the ones that matter.

The multipole range. The largest single cost. Fitting *Planck*'s own bandpowers with our two-parameter model, the error on n_s is 0.0040 over our range and 0.0025 over theirs (Section 13.7.3): the damping tail is worth a factor 1.6 on the tilt. Going to $N_{\mathrm{side}} = 1024$, whose degraded maps already exist in `data/planck/`, would reach $\ell \approx 2000$ at eight times the cost per transform.

The simulations. *Planck*'s FFP10 simulations follow the photons through the instrument: time-ordered data of every detector, the map-maker, and the component separation. Ours start at the map and assume a Gaussian sky and a modulated Gaussian noise. For the error bars of the spectrum itself the difference is small, because below $\ell \approx 1000$ the error is cosmic variance,

step	full analysis (*Planck* 2018)	ours	what the reduction costs
maps	100, 143, 217 GHz half-missions, $N_{\rm side} = 2048$	SMICA half-missions degraded to $N_{\rm side} = 512$	multipoles above 1019; foreground uncertainty not propagated
multipoles	30–2508 (plus a separate 2–29 likelihood)	30–1019	error on n_s 0.0040 instead of 0.0025 on the same bandpowers
masks	per frequency, 47–66% of the sky	one common mask, 0.775	more exposure to residuals near the plane
foregrounds	modelled, amplitudes marginalised	cleaned by SMICA, then ignored	residuals at high ℓ unmodelled
beams	beam matrices per cross-spectrum, with leakage	one effective beam	a beam error would tilt n_s
covariance	analytic, validated on FFP10 end-to-end simulations	400 Gaussian skies, noise model from the data	errors uncertain by 3.5%; null and window-difference tests not validated
parameters	six, plus nuisance parameters, τ from polarisation	two, four fixed	conditional, not marginal, errors

Table 13.5: The full analysis and the laptop analysis, step by step.

which a Gaussian sky gets right; our errors agree with *Planck*'s to within a few per cent (0.99 of theirs, Section 13.5.3). For the checks it is not small: the half-mission null test fails because our noise model is too simple, and the window-difference tests come out too good, most likely because the real map has been through processing that our skies have not (Section 13.6).

The number of simulations. With $n = 400$ skies and $p = 33$ bins, the Hartlap factor is 0.915 and the error bars are known to 3.5%. Doubling n would reduce that to 2.5% at twice the cost; the gain matters for PTEs near the edges of the distribution, where $1/n$ sets the resolution, as in the two window-difference tests, which only 1 and 1 of the 400 simulated skies beat: too few to say how rare they are, only that they are rare.

How this is used in real research: Verification and research in one pipeline

Two different jobs were done by the same simulations. The bias test of Section 13.4.3 *verified* a known result: MASTER's mean is the theory through the bandpower windows, a statement derived in Section 8.11, and the simulations confirmed it to $1/\sqrt{400}$ of an error bar. Everything else was *research*: the covariance of masked, noisy, beamed bandpowers, the scatter of the difference between two windows on one sky, the distribution of a parameter shift between low and high multipoles. None of these has a formula we trust at the precision needed, and each was read off the simulations directly. Research codes package the same steps: NaMaster computes the coupling matrix, the binned inverse and the bandpower windows for spin-0 and spin-2 fields on any mask [142], and *Planck*'s likelihood code evaluates (13.13) with its analytic covariance. What no library supplies is the model of the observation, which here was ours to build and ours to test.

Every arrow of the pipeline, on real data. Each arrow of physical model → field → what matters → summary → its sampling distribution → inference was crossed on real data. The physical model was ΛCDM with two free numbers. The field was the SMICA map. What

mattered was the two-point statistics of a Gaussian field, so the summary was the binned power spectrum. Its sampling distribution came from four hundred skies observed like the real one. The inference was a posterior for A_s and n_s, and a set of tests that the data passed, failed, or passed suspiciously well. The same map returns in Section 13.9, where the summary changes from the spectrum to the shapes of the hot and cold regions, and with it the information it can see.

Recap

- A map is changed in resolution in harmonic space: multiply the $a_{\ell m}$ by the ratio of pixel windows and truncate at $3N_{\text{side}} - 1$, after filling the masked holes so that the band limit cannot spread their residuals.
- The common mask has a few large holes and thousands of small ones; they are tapered differently (0.5° and 2°) because a wide taper around thousands of holes would cost most of the sky.
- The cross-spectrum of the half-mission maps has no noise bias; their half-difference is a null map of the noise.
- *Planck*'s bins weight C_ℓ by $\ell(\ell+1)$ and quote D_b at ℓ^{eff}; a bandpower is not D_ℓ at ℓ^{eff}, and theory must go through the same binning and the bandpower windows.
- On the real sky the naive correction is off by 10% in the troughs; MASTER with our coupling matrix agrees with *Planck*'s bandpowers to 1.5% at worst.
- Four hundred Gaussian skies observed like the real one give the covariance, an unbiasedness test, and the scatter of every difference used by the checks.
- The best fit describes our bandpowers ($\chi^2 = 33.5$ for 33), the amplitude agrees to 0.2%, and our spectrum differs from *Planck*'s by 0.43 of an error bar.
- Null tests: the Galactic test passes; the half-mission null fails because of a percent-level gain difference between the halves and an approximate noise model, neither of which affects the cross-spectrum; two window-difference tests are passed too well, a sign that our simulations overestimate the scatter of differences.
- With four parameters fixed, $\ln(10^{10}A_s) = 3.0432 \pm 0.0018$ and $n_s = 0.9686 \pm 0.0039$; the comparison with *Planck*'s six-parameter result is explained by τ, by the fixed parameters and by the multipole range.

13.9 The shape of the one sky we have

Twice already we have watched the microwave sky's shapes being tested, and both times the sky itself stayed off stage. In Section T3.5.1 we read how the *Planck* collaboration measured the area, the boundary length and the Euler characteristic of the hot and cold regions of their maps at twelve thresholds, stacked the 36 numbers into one vector, and compared it through a χ^2 with 999 end-to-end simulations; every temperature map at every resolution came out unremarkable [109]. In Section 12.7.4 we rebuilt the Gaussian half of that test: 300 simulated Gaussian skies at $N_{\text{side}} = 256$ with a 40′ beam reproduced the curves of their Fig. 10, and the χ^2 of one Gaussian sky against the others came out at 1.01 per degree of freedom, as it should. What was missing both times is the step that makes it a measurement: putting the real map through the same code. The estimator, the thresholds and the normalisation stay exactly as they were. What changes is everything that comes with real data: the sky is cut by a mask with hundreds of holes, the map carries instrumental noise, the region behind the mask has been

filled in by the component-separation pipeline, and there is only one map.

The event. We point the pipeline at the *Planck* SMICA temperature map. At each of four resolutions it returns 36 numbers: the fraction of the observed sky above each of twelve thresholds, the length of the boundaries there, and the number of hot regions minus the number of holes in them. That vector is what happened. Call it $\boldsymbol{y}_{\rm obs}$.

What could have produced it? Before computing anything we list the situations that could have made the sky look the way it does, one at a time, each with its reason.

1. *A Gaussian, isotropic sky with the best-fit spectrum, seen through our instrument and our processing.* This is what the standard model predicts: inflation produces Gaussian initial fluctuations, linear physics up to recombination keeps them Gaussian, and the instrument adds a beam, pixels and noise.
2. *A primordial non-Gaussianity.* Many inflationary models give a small three-point function (Section T3.2); it would bend the curves asymmetrically, as Matsubara's expansion showed [108].
3. *Something left over from our Galaxy or from point sources.* Dust and synchrotron residuals, or unresolved radio galaxies, are not Gaussian and not isotropic; they would add hot spots at high thresholds and change the boundaries near the mask.
4. *A mismatch between the data and their model*: a wrong noise level, a beam slightly different from the one assumed, a spectrum different from the best fit, or the in-filled region leaking into the observed pixels. None of these is about the early universe, and all of them can move the numbers.

Only the first candidate comes with a sampling distribution we know how to produce. We can draw as many Gaussian skies as we like, pass each through the same beam, pixels, noise and mask, and measure them with the same code. For the others we would have to say *which* non-Gaussianity, *which* residual, how large. This is the defining property of a null hypothesis (Section 4.1.1): it is the explanation whose behaviour we can simulate, "it happened by chance" with chance fully specified. The test can tell us that the first candidate is a poor explanation of $\boldsymbol{y}_{\rm obs}$. It cannot, by itself, tell us which of the other three is right.

The question, in words. If the sky were a Gaussian, isotropic field with the best-fit spectrum, observed and processed exactly as the SMICA map was, would a vector of 36 numbers as far from the Gaussian average as ours, or even farther, be something we would reasonably expect?

13.9.1 What "Gaussian" contains

The null hypothesis sounds like one assumption. It is several, and it pays to separate them, because each can fail on its own and each failure would show up differently. Write the temperature fluctuation in direction $\hat{\boldsymbol{n}}$ as a sum of spherical harmonics, $T(\hat{\boldsymbol{n}}) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\hat{\boldsymbol{n}})$, as in Chapter 7. The inputs are these.

Physical inputs.

1. *Gaussianity*: the coefficients $a_{\ell m}$ are jointly Gaussian. Physically, the initial fluctuations were Gaussian and everything since was linear.

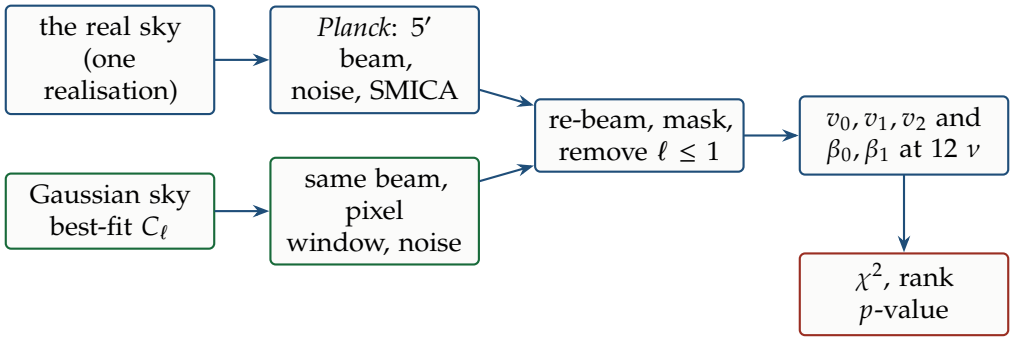

Figure 13.16: Two roads to the same statistics. The upper road is the data: one sky, observed once by *Planck* and cleaned by SMICA. The lower road (green) is the null hypothesis: Gaussian skies with the best-fit spectrum, given the same beam, pixels and noise. From the box "re-beam, mask" onwards the two roads run through identical code, so whatever that code does to the shapes, it does to both.

2. *Statistical isotropy*: the $a_{\ell m}$ are independent with variance C_ℓ that depends on ℓ only. Physically, no direction on the sky is special.
3. *The spectrum*: C_ℓ is the best-fit ΛCDM spectrum (Chapter T1).

Observational inputs (properties of the instrument and of the processing, not of the universe).

4. The map is the sky convolved with a Gaussian beam of 5′ FWHM and averaged over $N_{\rm side} = 2048$ pixels, plus noise.
5. The noise is Gaussian with a spectrum we can measure (Section 13.10.2).
6. Only the pixels outside the mask are used.

Nothing else is assumed. In particular, nobody assumes a formula for the distribution of the 36 numbers. Inputs 1–3 fix the distribution of the sky, inputs 4–6 fix what happens to it on the way to our code, and the distribution of the statistics follows by simulation, not by a derivation: the mask with its holes and the pixel counting (Section 12.2.2) make the exact distribution analytically out of reach, while simulating it is cheap.

Each input can break, and each break leaves a different fingerprint. A failure of input 1 bends the shapes of the curves at fixed spectrum, odd in ν for a skewed field. A failure of 2 makes one part of the sky differ from another; a whole-sky test like ours mixes the regions and is weak against it, which is why anisotropy is tested separately [109]. A failure of 3 changes σ_0 and σ_1, but the normalised functionals of Section 12.7.4 divide most of that out. Failures of 4–6 are the dangerous ones: they are mundane, they produce exactly the kinds of deviation a physical signal would, and they are the reason the simulations must copy the processing step by step.

13.9.2 From 36 numbers to one, and to a probability

Of the pipeline that runs through the book (a physical model, a field, a summary of it, the sampling distribution of that summary, and an inference), this part supplies the last two arrows for the real sky: the sampling distribution of the summaries comes from simulation, and the inference is the verdict on the Gaussian explanation. The test has three moving parts, each met earlier in the book. The statistics come from Chapter 12: for a threshold ν in units of the map's own standard deviation σ_0, the excursion set is the set of observed pixels with $u = (T - \bar{T})/\sigma_0 > \nu$, and we measure its area fraction v_0, its boundary length v_1 and its Euler

characteristic v_2, normalised as in (12.35), plus the two Betti numbers β_0 (pieces) and β_1 (holes) whose difference is the Euler characteristic. The comparison is the quadratic form

$$\chi^2(\boldsymbol{y}) = h\,(\boldsymbol{y}-\bar{\boldsymbol{y}})^{\mathsf{T}}\widehat{\mathbf{C}}^{-1}(\boldsymbol{y}-\bar{\boldsymbol{y}}), \tag{13.17}$$

where $\bar{\boldsymbol{y}}$ and $\widehat{\mathbf{C}}$ are the mean and the covariance of the statistics over n simulated skies and h is the Hartlap factor of (3.43); Section 13.12 derives why this is the right summary. And the probability is the rank of the data among the simulations,

$$\widehat{p} = \frac{\#\{\text{simulations } i:\ \chi^2(\boldsymbol{y}_i) \geq \chi^2(\boldsymbol{y}_{\text{obs}})\}}{n}, \tag{13.18}$$

the fraction of Gaussian skies that land at least as far from the Gaussian average as the real one, which is the p-value of Section 4.1.3 with the null distribution sampled instead of written down.

Example: how precisely n simulations measure a probability. Each simulation either lands beyond the data or does not, with probability p under the null hypothesis, independently of the others. So the count in (13.18) is binomial with n trials and success probability p, and

$$\operatorname{Var}\widehat{p} \overset{(1)}{=} \frac{1}{n^2}\operatorname{Var}\big(\#\{i:\chi_i^2 \geq \chi^2_{\text{obs}}\}\big) \overset{(2)}{=} \frac{1}{n^2}\,n\,p(1-p) = \frac{p(1-p)}{n}.$$

(1) $\widehat{p}$ is the count divided by the constant n, and a constant factor comes out of a variance squared.
(2) The variance of a binomial count is $np(1-p)$ (Chapter 2).

With $n = 1000$ simulations and $p = 0.9$ the Monte Carlo error is $\sqrt{0.09/1000} = 0.009$, so a quoted 90% means "between 89 and 91%". With $n = 400$ it is 0.015. And $1/n$ is the smallest probability that can be resolved at all: a sky beyond every one of 1000 simulations has $\widehat{p} = 0$, which means only "$p \lesssim 10^{-3}$". The precision is set by the number of simulations, not by the data; this is why *Planck* ran 999 (Figure 13.17).

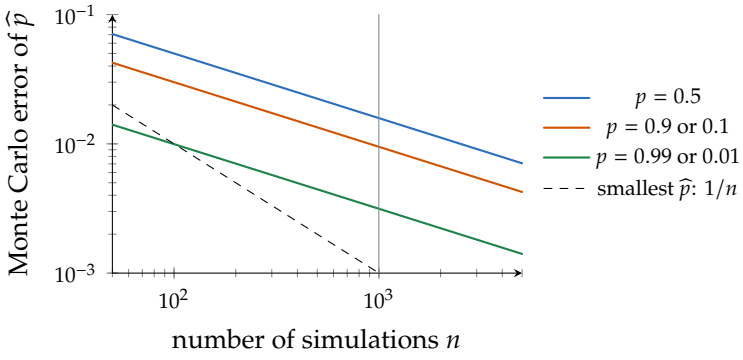

Figure 13.17: How well n simulated skies pin down a probability. The error $\sqrt{p(1-p)/n}$ falls as $1/\sqrt{n}$; the dashed line is the smallest nonzero probability that n simulations can express. The grey vertical line marks *Planck*'s 999 simulations.

Example: what a large p means. *Planck*'s Table 5 reports, for the SMICA temperature map at $N_{\text{side}} = 256$, a probability of 93.9% of a larger χ^2 [109]. Read with the question above: if the sky were Gaussian, 94 of every hundred Gaussian skies would land farther from the Gaussian average than the real one. Our sky is closer to the average than most. That is not evidence *for* Gaussianity in the sense of a probability that the null is true (Section 4.4.4); it says only

that these 36 numbers give no reason to doubt it. A probability close to 100% would itself be suspicious: a sky that matches the Gaussian average too well hints that the simulations are noisier than the data, for example a noise model that is too high. Both tails carry information, which is why *Planck* reports the fraction with a larger χ^2 and looks at both ends.

13.10 From the archive to a working map

The *Planck* Legacy Archive, mirrored at IRSA, holds the final (2018, "PR3") maps as HEALPix files at $N_{\rm side} = 2048$, about fifty million pixels of 1.7′ each. Three products are all a temperature-topology test needs, and the script `code/ch13/b01_prepare.py` turns them into maps we can measure. The SMICA CMB map (`COM_CMB_IQU-smica_2048_R3.00_full.fits`, 2.0 GB) is the sky after component separation: SMICA combines the nine frequency maps with weights, chosen multipole by multipole, that keep the black-body CMB and suppress everything with a different frequency dependence. It contains the temperature, the two Stokes polarization maps and, for each, an *inpainted* version in which the pixels inside the mask have been filled in by an inpainting algorithm with values that continue the CMB smoothly across the gap. The two half-mission maps (`..._hm1.fits` and `..._hm2.fits`, 0.6 GB each) are the same sky made from the first and the second half of the observing time; we use them only to measure the noise. The common temperature mask (`COM_Mask_CMB-common-Mask-Int_2048_R3.00.fits`, 0.2 GB) marks with zeros the Galactic plane and several hundred point sources where no component-separation method is trusted; it keeps 77.9% of the sky. All four files sit in `data/planck/` and are read with `healpy.read_map`, which also converts them from the "nested" pixel ordering of the archive to the "ring" ordering our code uses. The binned TT spectrum of the same release (`COM_PowerSpect_CMB-TT-binned_R3.01.txt`) is used only as a check.

Topology is not measured at $N_{\rm side} = 2048$. The pixel-counting estimators need a field that is smooth on the pixel scale (Section 12.2.2), and different smoothing scales look at different physics. We follow *Planck*'s Table 1 and work at four resolutions: $N_{\rm side} = 64, 128, 256, 512$ with Gaussian smoothing of FWHM 160′, 80′, 40′ and 20′, always about three pixels across [109]. At 160′ the map shows the large-angle sky, $\ell \lesssim 100$; at 20′ it reaches the third acoustic peak, $\ell \approx 800$ (Figure 13.18).

13.10.1 Changing the resolution of a map

The question. We hold a map that is the sky seen through a 5′ beam and stored in $N_{\rm side} = 2048$ pixels. We want the map that *would* have come out of an instrument with a 20′ beam and $N_{\rm side} = 512$ pixels. Can we get it without going back to the sky?

What the archive map is, in harmonic space. The beam and the pixel averaging are both (to a very good approximation) convolutions with a kernel that depends only on the angle, so each multiplies the harmonic coefficients of the sky by a number that depends only on ℓ: the beam transfer function b_ℓ of (8.10) and the pixel window p_ℓ of (8.11). Leaving out the noise for a moment, the coefficients of the archive map are $a^{\rm map}_{\ell m} = b^{5'}_\ell \, p^{2048}_\ell \, a^{\rm sky}_{\ell m}$, and the map we want has $a^{\rm new}_{\ell m} = b^{\rm new}_\ell \, p^{\rm new}_\ell \, a^{\rm sky}_{\ell m}$. Dividing one by the other removes the sky we do not know:

$$a^{\rm new}_{\ell m} \overset{(1)}{=} b^{\rm new}_\ell \, p^{\rm new}_\ell \, a^{\rm sky}_{\ell m} \overset{(2)}{=} b^{\rm new}_\ell \, p^{\rm new}_\ell \, \frac{a^{\rm map}_{\ell m}}{b^{5'}_\ell \, p^{2048}_\ell} = \frac{b^{\rm new}_\ell \, p^{\rm new}_\ell}{b^{5'}_\ell \, p^{2048}_\ell} \, a^{\rm map}_{\ell m}. \tag{13.19}$$

(1) The definition of the map we want: the sky through the new beam, averaged over the new pixels.

(2) Solve the archive relation for the sky, $a^{\rm sky}_{\ell m} = a^{\rm map}_{\ell m} / (b^{5'}_\ell \, p^{2048}_\ell)$, and substitute.

So we compute the $a_{\ell m}$ of the archive map once (up to $\ell = 1535$, the band limit $3N_{\rm side} - 1$ of the finest working map), multiply by the ratio of windows, and synthesise the new map directly at the new $N_{\rm side}$. This is the procedure of *Planck*'s Sect. 2 [109]. The step is safe because the new beam is much wider than the old one: the ratio in (13.19) is below one at every ℓ and falls steeply, so dividing by $b_\ell^{5'}$ never amplifies anything.

Example: the ratio at $\ell = 500$ for the 20′ map. With $\sigma_b = \mathrm{FWHM}/\sqrt{8\ln 2}$, the 20′ beam has $\sigma_b = 8.49' = 2.47 \times 10^{-3}$ rad and the 5′ beam $\sigma_b = 2.12' = 6.18 \times 10^{-4}$ rad. Then

$$\frac{b_{500}^{20'}}{b_{500}^{5'}} \overset{(1)}{=} \exp\Big[-\frac{500 \cdot 501}{2}\big(\sigma_{20'}^2 - \sigma_{5'}^2\big)\Big] \overset{(2)}{=} \exp\big[-125250 \times (6.10 - 0.38) \times 10^{-6}\big] = e^{-0.716} = 0.49.$$

(1) The ratio of two Gaussian beams (8.10) is a Gaussian beam whose σ_b^2 is the difference of the two: smoothing twice adds variances, and un-smoothing subtracts them.
(2) $\sigma_{20'}^2 = 6.10 \times 10^{-6}$ and $\sigma_{5'}^2 = 0.38 \times 10^{-6}$ in rad^2.

The pixel windows change this by a few per cent ($p_{500}^{512} = 0.956$, $p_{500}^{2048} = 0.997$). At $\ell = 500$ half of every coefficient survives; at $\ell = 1000$ the ratio is $e^{-2.9} = 0.06$, and the 20′ map holds almost nothing beyond.

Working definition 13.1 (changing the resolution of a sky map)

To bring a map with beam $b_\ell^{\rm old}$ and pixel window $p_\ell^{\rm old}$ to a new beam and pixelisation: compute its $a_{\ell m}$ [one harmonic transform at the old resolution, up to the new band limit $3N_{\rm side} - 1$], multiply by $b_\ell^{\rm new} p_\ell^{\rm new} / (b_\ell^{\rm old} p_\ell^{\rm old})$, and synthesise at the new $N_{\rm side}$. Valid when the new beam is wider than the old one, so that the ratio is below one at every ℓ.

The mask goes through the same procedure. The common mask is binary at $N_{\rm side} = 2048$. At $N_{\rm side} = 128$ with an 80′ beam, a working pixel near the Galactic plane is a weighted average of thousands of archive pixels, some trusted and some not. What is the right question to ask of it? Not "is the centre of this pixel inside the mask?", but "how much of the weight that went into this pixel came from trusted sky?" Smoothing the binary mask with the same beam answers exactly that: the smoothed mask at a working pixel is the beam-weighted fraction of trusted area around it. *Planck* keeps the pixels where this fraction is at least 0.9 [109], and so do we. The masks this produces keep 71.3%, 73.6%, 74.7% and 75.5% of the sky at the four resolutions, against 71.3, 73.6, 74.7 and 75.6% in their Table 1: the same masks, to within a tenth of a per cent of the sky. Wider beams lose more sky because more pixels near the edge collect weight from inside the mask.

Why the inpainted map, and what it does not give us. Smoothing mixes each pixel with its neighbours, so a pixel just outside the mask collects weight from pixels just inside it. With the raw map, an 80′ beam would drag the bright Galactic plane into every observed pixel near the edge of the mask. With the inpainted map it drags in the filled-in values instead, which continue the CMB smoothly and are tame. They are still not measurements. Statistics are computed only on the pixels the thresholded mask keeps; the in-filled values enter only through the smoothing near the edge, and the 0.9 threshold limits that to a tenth of the weight.

The monopole and the dipole. The map's average over the sky (its monopole) is set by an arbitrary zero level, and its dipole is dominated by our motion through the CMB rest frame; neither is part of the anisotropy we want to test. Both are removed by fitting $c_0 + \boldsymbol{c} \cdot \hat{\boldsymbol{n}}$ to

the observed pixels by least squares and subtracting the fit from the $\ell \le 1$ coefficients (the function `remove_monodipole` in `code/ch13/lib_skytopo.py`). Every simulated sky gets the same treatment, because a fit on a cut sky also removes a little of the $\ell \ge 2$ power that leaks into the fitted modes, and the simulations must lose the same little.

13.10.2 How much noise is in the map?

The simulations need a noise model, and the half-mission maps give it to us without any knowledge of the detectors. *The idea.* Both halves see the same sky, so the sky cancels in their difference and only the noise is left. Write the two half-mission maps as $h_1 = s + n_1$ and $h_2 = s + n_2$, with s the sky (after the same beam) and n_1, n_2 independent noise of equal variance σ_n^2 per pixel. The full-mission map averages the two halves. Its noise and the noise of the half-difference map are

$$\begin{aligned} \mathrm{Var}\Big(\frac{h_1+h_2}{2} - s\Big) &\overset{(1)}{=} \mathrm{Var}\Big(\frac{n_1+n_2}{2}\Big) \overset{(2)}{=} \frac{\sigma_n^2+\sigma_n^2}{4} = \frac{\sigma_n^2}{2}, \\ \mathrm{Var}\Big(\frac{h_1-h_2}{2}\Big) &\overset{(3)}{=} \mathrm{Var}\Big(\frac{n_1-n_2}{2}\Big) \overset{(4)}{=} \frac{\sigma_n^2+\sigma_n^2}{4} = \frac{\sigma_n^2}{2}. \end{aligned} \tag{13.20}$$

(1) The sky term cancels: $(s + n_1 + s + n_2)/2 - s = (n_1 + n_2)/2$.
(2) Independent terms add their variances, and a factor $\frac{1}{2}$ comes out squared.
(3) The sky cancels in the difference: $(s + n_1 - s - n_2)/2$.
(4) $\mathrm{Var}(-n_2) = \mathrm{Var}(n_2)$, so the minus sign changes nothing.

The half-difference map is therefore a noise map with exactly the statistics of the noise in the full map, and the same holds multipole by multipole. We measure its spectrum on the observed sky with the pseudo-C_ℓ of Section 8.9.3 divided by f_{sky} (good enough for a quantity that varies slowly with ℓ), and the simulations add Gaussian noise with that spectrum, re-beamed by (13.19) exactly as the data are. At multipoles 400–800 the noise corresponds to 32 μK arcmin, and after correcting for the 5′ beam it is 0.002, 0.019 and 0.144 of the CMB power at $\ell = 500$, 1000 and 1500 (Figure 13.18).

Example: does the noise matter for topology? The working beam has already removed the multipoles where the noise competes. The fraction of the working map's variance that is noise, $\sum(2\ell+1)N_\ell w_\ell^2$ over $\sum(2\ell+1)C_\ell w_\ell^2$ with w_ℓ the ratio of windows in (13.19), is 0.01%, 0.02%, 0.02% and 0.03% at 160′, 80′, 40′ and 20′. For the gradient variance σ_1^2, which weights each multipole by a further $\ell(\ell+1)$ and is the quantity the boundary length and the Euler characteristic depend on, it is at most 0.08%. So at these resolutions the temperature map is signal-dominated, and the noise model, crude as it is, cannot move the test. *Planck*'s noise simulations follow the scanning pattern, so the noise is deeper near the ecliptic poles than elsewhere; our noise is isotropic. That difference would matter at $N_{\mathrm{side}} = 1024$ and 2048, where the working beams reach $\ell \approx 2000$, and it does not matter here.

13.10.3 Does the map have the power of the simulations?

The simulations are drawn from the best-fit spectrum of Chapter T1. If the map's power differed from it substantially, the test would compare skies of different amplitude, and could fail for that reason alone. The check in Figure 13.18 is rough (the binary mask couples multipoles, Section 8.10, which the MASTER estimator of Section 8.11 would undo), but it is enough to see three things. Over $30 \le \ell < 800$, which carries almost all the variance of our working maps, the ratio of the map's power to the best fit is 1.005. Over $800 \le \ell < 1500$ it is 1.088, and 1.06 once

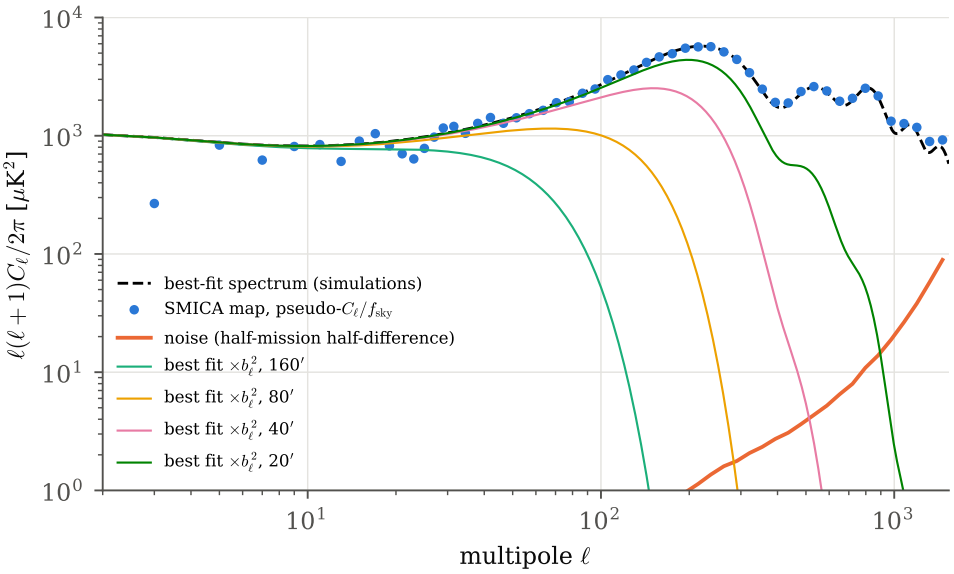

Figure 13.18: The power of the SMICA map against the spectrum used for the simulations. Blue points: the map's pseudo-spectrum on the observed sky divided by $f_{\rm sky}$, with the 5′ beam and the pixel window removed; dashed: the best-fit spectrum; orange: the noise from the half-difference map. The four thin curves are the best fit multiplied by the squared working beams: each working map sees only the multipoles under its curve, where the noise is far below the signal.

the noise power is subtracted; the remaining few per cent are the leakage of large-scale power through the edges of an unsoftened mask and the residual point sources that *Planck* also sees in the data and not in its simulations [109]. And over $2 \le \ell < 30$ the ratio is 0.71: the sky has less large-angle power than the best fit predicts. This is the well-known low-variance anomaly of the largest scales (Section T3.5.3), and it will show up again below as a smaller σ_0 of the real map at 160′.

Does a power mismatch spoil the test? Not much, by construction. The thresholds are in units of the map's *own* standard deviation, so a sky that is uniformly too faint or too bright gives the same excursion sets (Section 12.3.2); and the functionals are divided by the map's own $(\sigma_1/\sigma_0)^k$, which absorbs most of a change in the spectrum's shape (Section 12.7.4). What survives this normalisation is the shape of the curves, which is what Gaussianity predicts.

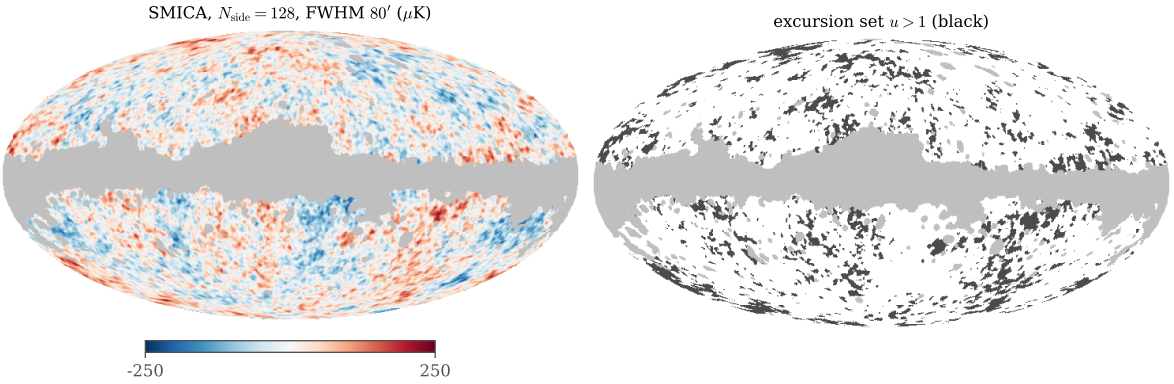

Figure 13.19: The working map at $N_{\rm side} = 128$ with an 80′ beam (left), outside the degraded common mask (grey), and its excursion set at one standard deviation (right): the observed pixels with $u = (T - \bar{T})/\sigma_0 > 1$. Every statistic below is a count or a measure of shapes like these, at twelve thresholds and four resolutions.

13.11 The area, boundary and Euler characteristic of the real sky

The working maps of Section 13.10 are ready: four resolutions, each with its mask of observed pixels. At each resolution we now ask the questions of Chapter 12 of the real sky. Standardise the map on its observed pixels, $u = (T - \bar{T})/\sigma_0$, with $\bar{T}$ and σ_0 the mean and the standard deviation over those pixels only. For a threshold ν, the excursion set X_ν is the set of observed pixels with $u > \nu$, the hot regions of Figure 13.19. How much of the observed sky does it cover? How long is its boundary? How many pieces does it have, minus how many holes? Each answer must come from code that a simulated sky passes through unchanged, and each needs one decision about pixels that the formulas of Section 12.5 never had to make.

13.11.1 Three estimators on a cut sphere

Area. The fraction of observed pixels with $u > \nu$. HEALPix pixels all have the same area, so counting them is measuring area, and $v_0(\nu)$ is this fraction.

Boundary length, without drawing a contour. Tracing the contours $u = \nu$ through a pixelised map and adding up their lengths is fiddly, especially where they run into the mask. There is a shortcut. *The question:* how is the length of a contour related to the area of a thin band around it? Take the band of points where u lies within $\Delta\nu/2$ of ν. Near a point of the contour, u changes fastest across the contour, at the rate $|\nabla u|$ per radian, so the band there is $\Delta\nu/|\nabla u|$ wide. A short piece of contour of length $\mathrm{d}s$ therefore carries a strip of band of area $\mathrm{d}A = \mathrm{d}s\,\Delta\nu/|\nabla u|$. Solving for $\mathrm{d}s$ and adding up the pieces,

$$L(\nu) \overset{(1)}{=} \int_{u=\nu} \mathrm{d}s \overset{(2)}{=} \lim_{\Delta\nu\to 0} \frac{1}{\Delta\nu} \int_{|u-\nu|<\Delta\nu/2} |\nabla u|\,\mathrm{d}A \overset{(3)}{=} \frac{A_{\mathrm{obs}}}{\Delta\nu} \left\langle |\nabla u|\, \mathbb{1}\big(|u-\nu| < \tfrac{\Delta\nu}{2}\big) \right\rangle_{\mathrm{obs}}. \tag{13.21}$$

(1) The length is the integral of the arc-length element along the contour.
(2) Each piece of contour, $\mathrm{d}s = |\nabla u|\,\mathrm{d}A/\Delta\nu$, comes with the piece of band beside it, so the integral over the contour becomes an integral over the band (this is the coarea formula, here in its simplest form).
(3) On equal-area pixels an integral over the observed sky is A_{obs} times the average over observed pixels; $\mathbb{1}(\cdot)$ is 1 inside the band and 0 outside.

The gradient comes exactly from the harmonic coefficients (`healpy.alm2map_der1` returns $\partial_\theta u$ and $\partial_\phi u/\sin\theta$), so no finite differences are needed; we use $\Delta\nu = 0.1$. *Planck*'s V_1 is a quarter of the length per unit area (their eq. 14), and we follow that convention: $v_1 = L/(4A_{\mathrm{obs}})$.

Example: the band estimator on a straight contour. Take $u = k\,x$ on a flat patch of side a, a field that rises steadily in one direction. The contour $u = \nu$ is the straight line $x = \nu/k$, of length a. The band $|u - \nu| < \Delta\nu/2$ is the strip $|x - \nu/k| < \Delta\nu/(2k)$, of area $a\,\Delta\nu/k$, and in it $|\nabla u| = k$. Then (13.21) gives $k \cdot a\,\Delta\nu/k/\Delta\nu = a$, the right answer for any slope: a steep field has a thin band but a large gradient, and the two compensate exactly.

The Euler characteristic, at every threshold at once. Section 12.2.3 computed χ of a union of closed pixels as $V - E + F$: vertices minus edges plus faces of the union. On the cut sphere we keep that rule and add one: an unobserved pixel never belongs to the set. *The question:* at which threshold does a given vertex, edge or face join the union? A face (a pixel) joins when ν drops below its value. An edge or a vertex belongs to the union as soon as *one* of the observed pixels

around it does, so it joins when ν drops below the largest observed value around it. Every element thus has an entry level, and

$$\chi(\nu) = \#\{\text{vertices entered above } \nu\} - \#\{\text{edges entered above } \nu\} + \#\{\text{faces entered above } \nu\}. \tag{13.22}$$

Sorting the three lists of entry levels once turns every $\chi(\nu)$ into three binary searches, which is how `entry_levels` and `chi_from_levels` in `code/ch13/lib_skytopo.py` work. On full-sky maps the result agrees exactly, threshold by threshold, with the pixel-by-pixel counter of Chapter 12.

Example: four pixels by hand. A 2×2 block of pixels has values 3 (top left), 1 (top right), 0 (bottom left) and 2 (bottom right): 9 vertices, 12 edges, 4 faces. Lower the threshold to $\nu = 1.5$. The faces above it are the top-left and bottom-right pixels, which touch only at the central vertex. Entry levels: the central vertex sees all four values, so it joins at $\max(3, 1, 0, 2) = 3$; every other corner of the top-left pixel has that pixel among its neighbours and joins at 3, every other corner of the bottom-right pixel joins at 2 or 3; an edge of either pixel joins at the larger of its two neighbouring values, at least 2; and every remaining vertex and edge touches only the pixels with values 1 and 0, so it joins below 1.5. Counting the elements that joined above 1.5: $V = 4 + 4 - 1 = 7$ (the central vertex is shared), $E = 4 + 4 = 8$, $F = 2$, so $\chi = 7 - 8 + 2 = 1$. The two diagonal pixels form one piece, because closed pixels that share a corner touch. This is the convention of Section 12.2.2 (hot pixels connect through corners, cold ones only through edges), and (13.22) implements it automatically.

Normalisation. As in Section 12.7.4, the functionals are divided by the power of σ_1/σ_0 that carries their dependence on the spectrum, with σ_1^2 the mean of $|\nabla T|^2$ over the observed pixels: v_1 by σ_1/σ_0, and the Euler characteristic per steradian of observed sky, $v_2 = \chi/A_{\text{obs}}$, by $(\sigma_1/\sigma_0)^2$. On the cut sky v_2 is not the Gaussian curve of (12.35) alone: the mask's own topology and its boundary add the terms $\mathcal{L}_0\Psi(\nu)$ and $\mathcal{L}_1\rho_1(\nu)$ of Section 12.8.1. The simulations are cut by the same mask and carry the same terms, so nothing has to be modelled.

13.11.2 What the real sky gives

Example: one threshold, read off the sky. At $N_{\text{side}} = 256$ and $\nu = 0.27$ (one of *Planck*'s twelve thresholds), the excursion set of the SMICA map has 1854 separate hot regions and 894 holes in them, so $\chi = 960$. The simulated skies, cut and processed identically, give $\chi = 830$ on average with a spread of 103.6 from sky to sky. The real sky lies $(960 - 830)/103.6 \approx 1.3$ standard deviations above the mean, a deviation that about one Gaussian sky in five exceeds in one direction or the other. A single number like this is easy to read, and also easy to over-read: there are 36 such numbers per resolution, and they are not independent.

Figure 13.20 shows the three normalised curves at $N_{\text{side}} = 256$ for the data and for the simulations; Figure 13.21 shows, at all four resolutions, each number's deviation from the simulated mean in units of the simulated standard deviation, $\Delta v/\sigma$. Three things stand out. First, the real sky's curves lie inside the band of Gaussian skies everywhere, at every resolution; the largest single deviation is 2.2, 1.8, 1.9 and 2.2 standard deviations at $N_{\text{side}} = 64$, 128, 256 and 512. Second, the deviations mostly change smoothly with ν: neighbouring thresholds tend to move together, because the excursion sets at ν and at $\nu + 0.55$ share most of their pixels. That smoothness is the correlation we will have to take into account. Third, no curve stays at zero: each wanders up and down by about one standard deviation, at every resolution. That is what a single realisation does. At $N_{\text{side}} = 64$ the observed sky holds only a few hundred

independent patches, so a slight surplus of hot area at some thresholds and a deficit at others is expected, not a sign of anything.

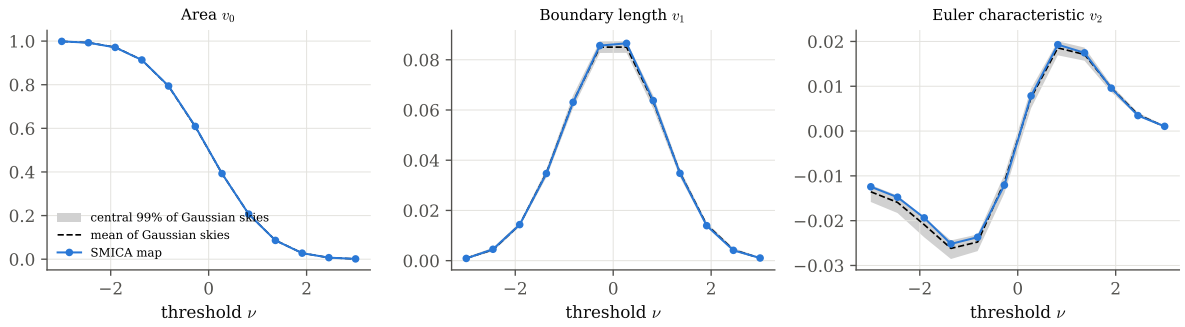

Figure 13.20: The three normalised Minkowski functionals of the SMICA map at $N_{\text{side}} = 256$ (40′), against 500 Gaussian skies with the best-fit spectrum, the same beam, pixels, noise and mask. Grey: the central 99% of the skies; dashed: their mean. The genus curve is asymmetric about zero because of the mask: its boundary and its holes add pieces to every excursion set.

The amplitude that was divided out. The normalisation removed σ_0 and σ_1/σ_0; it is worth looking at them directly, because they are where the spectrum lives. The real map's σ_0 is 46.7, 58.7, 75.6 and 90.9 μK at the four resolutions; the Gaussian skies give 52.7 ± 3.4, 63.4 ± 2.7, 79.5 ± 2.3 and 94.1 ± 1.9 μK. Only 1.6% of the skies have a σ_0 as small as the data at 160′: the deficit of large-angle power found in Section 13.10.3, now as a variance. The ratio σ_1/σ_0 is 114.1 per radian in the data at $N_{\text{side}} = 256$, against 108.7 ± 3 in the skies. Had we compared the unnormalised functionals, or set the thresholds in units of the simulations' average σ_0, the low variance would have shifted every curve and been mistaken for a change of shape. The normalisation keeps the two questions apart: "is the amplitude typical?" is a question about the power spectrum, and "is the shape Gaussian?" is the question asked here.

Watch out: looking for the largest deviation

With 36 numbers per resolution and four resolutions, the largest of 144 deviations of a Gaussian sky is typically well beyond two standard deviations, even though each single number exceeds two standard deviations only 5% of the time. A deviation found by scanning a figure must be judged against the largest deviation of the simulations scanned in the same way, not against the normal distribution: this is the look-elsewhere effect of Chapter 4. The χ^2 of Section 13.12 avoids the problem by fixing in advance one number per resolution.

13.12 Thirty-six numbers, one verdict

Figure 13.21 shows 36 deviations per resolution, all modest, all moving together with their neighbours. How surprised should we be by the whole pattern? Adding up the squared deviations would count the same fluctuation many times, once for every threshold it touches; picking the largest one invites the look-elsewhere trap. We need one number per resolution that measures how far the vector $\boldsymbol{y}_{\text{obs}}$ lies from the Gaussian average, counting each independent fluctuation once, and then the distribution of that number under the null hypothesis of Section 13.9.

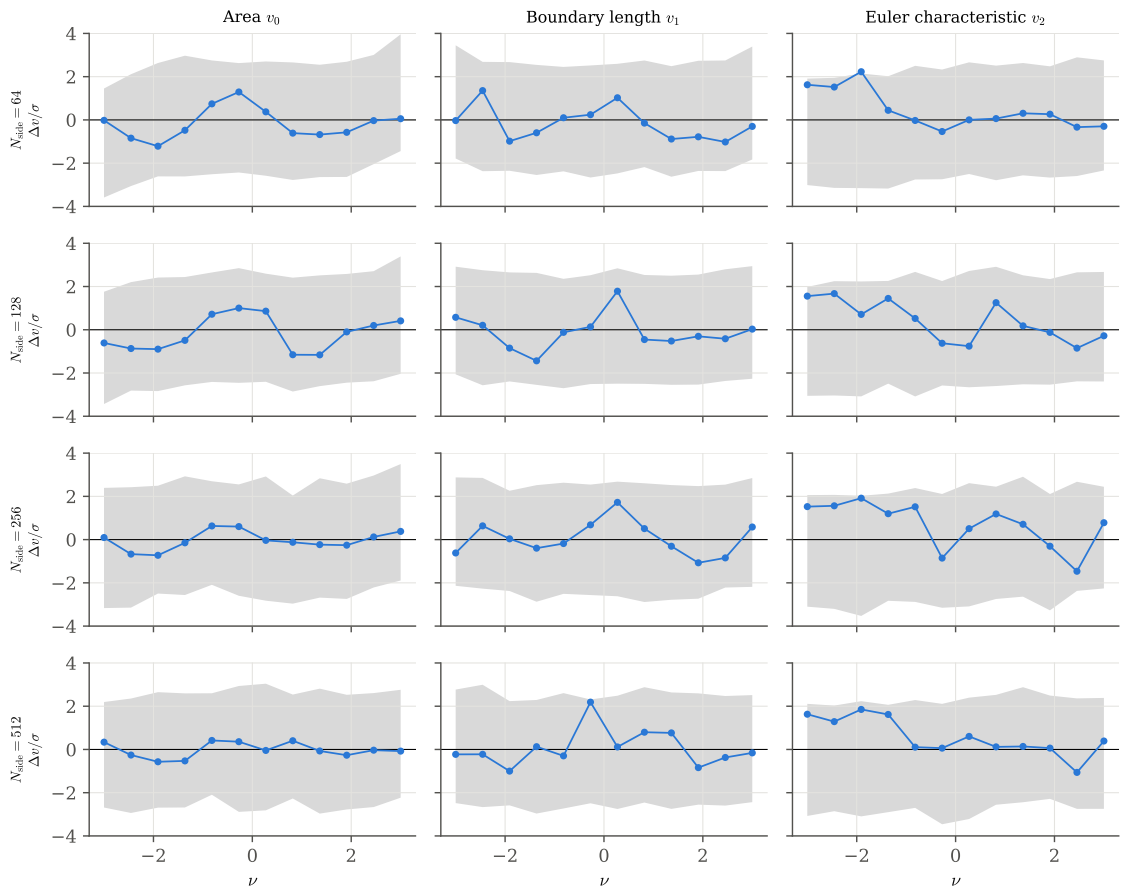

Figure 13.21: Deviation of each of the 36 numbers of the SMICA map from the mean of the Gaussian skies, in units of their standard deviation, at the four resolutions (rows). Grey: the central 99% of the skies, each measured the same way. Neighbouring thresholds move together, which is why the 36 deviations cannot be judged one at a time.

13.12.1 The distance that the null hypothesis itself defines

The question. Among all the vectors $\boldsymbol{y}$ that Gaussian skies can produce, which ones count as "farther from the average than ours"? The natural answer is: those that the null hypothesis makes *less probable* than ours. To use it we need the density of $\boldsymbol{y}$ under the null.

The density. Each component of $\boldsymbol{y}$ is an average over the observed sky: a fraction of pixels, a length per area, a count per area. The observed sky contains many patches a correlation length apart, and their contributions are nearly independent, so by the central limit theorem (Chapter 2) the vector is close to a multivariate Gaussian with some mean $\boldsymbol{\mu}$ and covariance $\mathbf{C}$:

$$p(\boldsymbol{y} \mid H_0) \approx \frac{1}{\sqrt{(2\pi)^p \det \mathbf{C}}} \exp\!\left[-\frac{1}{2}(\boldsymbol{y}-\boldsymbol{\mu})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{y}-\boldsymbol{\mu})\right], \tag{13.23}$$

with $p = 36$ components. The density depends on $\boldsymbol{y}$ only through the quadratic form in the exponent, and falls as it grows. So "less probable than ours" is the same as "a larger value of $Q(\boldsymbol{y}) = (\boldsymbol{y}-\boldsymbol{\mu})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{y}-\boldsymbol{\mu})$". The surfaces of constant Q are ellipsoids aligned with the correlations: a deviation along a direction in which the skies naturally fluctuate a lot costs little, a deviation in a direction they rarely take costs much. And if $\boldsymbol{\mu}$ and $\mathbf{C}$ were known exactly, Q would follow the χ^2 distribution with p degrees of freedom (Section 2.13.3): mean 36, standard deviation $\sqrt{72} \approx 8.5$, the scale of a χ^2 with 36 components that Section T3.5.1 already met.

Example: why correlated thresholds must not be added as if independent. Take two thresholds whose deviations, in units of their standard deviations, have correlation ρ, and suppose both came out at +1. With $\mathbf{C} = \left(\begin{smallmatrix} 1 & \rho \\ \rho & 1 \end{smallmatrix}\right)$,

$$Q \overset{(1)}{=} \frac{1}{1-\rho^2}\,(1,\ 1)\begin{pmatrix} 1 & -\rho \\ -\rho & 1 \end{pmatrix}\begin{pmatrix} 1 \\ 1 \end{pmatrix} \overset{(2)}{=} \frac{2-2\rho}{1-\rho^2} \overset{(3)}{=} \frac{2}{1+\rho}.$$

(1) The inverse of a 2×2 matrix: swap the diagonal, negate the off-diagonal, divide by the determinant $1 - \rho^2$.
(2) Multiply out: $1 - \rho - \rho + 1$.
(3) $1 - \rho^2 = (1 - \rho)(1 + \rho)$, and $1 - \rho$ cancels.

For independent thresholds ($\rho = 0$) the two deviations count twice, $Q = 2$. For $\rho = 0.9$, the strongest correlation between neighbouring area thresholds in Figure 13.22 (most neighbouring pairs lie between 0.5 and 0.9), $Q = 1.05$: two deviations that the skies almost always make together are worth hardly more than one. Had the second deviation come out at -1 instead, $Q = 2/(1 - \rho) = 20$: a pattern that cuts across the correlation is very improbable, even though each number on its own is ordinary. The quadratic form sees both effects.

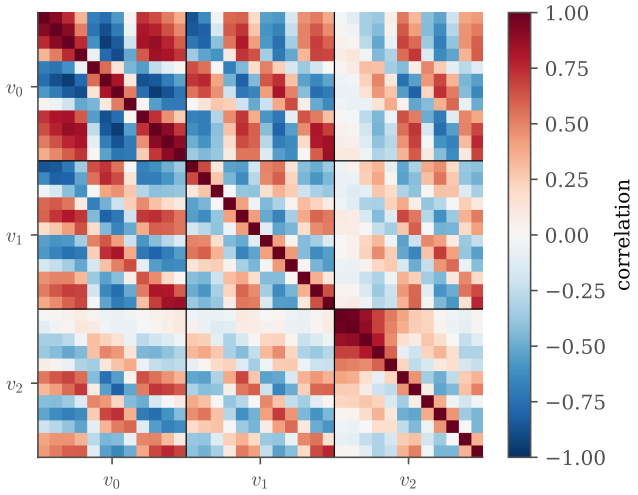

Figure 13.22: Correlation matrix of the 36 numbers at $N_{\text{side}} = 256$, estimated from the Gaussian skies. Blocks: area, length and Euler characteristic, each at twelve thresholds from -3 to 3. Each sky is measured in units of its own mean and rms, so its areas cannot all grow together: the area fractions at the tail thresholds ($|\nu| > 1$) move together, and against those in the core ($|\nu| < 1$). Neighbouring area thresholds on the same side of $|\nu| = 1$ are correlated at 0.5 to 0.9; the two pairs that straddle it hardly at all. Length and Euler characteristic are less tightly tied, but many entries far from the diagonal still reach ±0.5 or more.

13.12.2 When the mean and covariance come from simulations

We do not know $\boldsymbol{\mu}$ and $\mathbf{C}$; we estimate them from n simulated skies, $\bar{\boldsymbol{y}}$ and $\widehat{\mathbf{C}}$. Two corrections follow, both from Chapter 3.

The inverse of a noisy covariance is biased. $\widehat{\mathbf{C}}$ is unbiased, but its inverse is not: random errors make some directions look less variable than they are, and $\widehat{\mathbf{C}}^{-1}$ inflates them. For Gaussian vectors, $\mathbb{E}\,\widehat{\mathbf{C}}^{-1} = \frac{n-1}{n-p-2}\,\mathbf{C}^{-1}$ (3.43), so the unbiased estimate of the inverse is $h\,\widehat{\mathbf{C}}^{-1}$ with the Hartlap factor $h = (n - p - 2)/(n - 1)$ [6]. With 500 skies at $N_{\text{side}} = 256$ it is 0.926; with 300 skies at $N_{\text{side}} = 512$ it is 0.876. That is the factor h in (13.17).

A simulation must not judge itself. To get the null distribution of χ^2 we compute it for every simulated sky. If sky i were included in the mean and covariance it is compared with, it would pull both towards itself and look too typical. How much too typical? Sum the uncorrected quadratic forms of all n skies, with $\boldsymbol{d}_i = \boldsymbol{y}_i - \bar{\boldsymbol{y}}$ and $\widehat{\mathbf{C}} = \frac{1}{n-1}\sum_j \boldsymbol{d}_j \boldsymbol{d}_j^{\mathsf{T}}$:

$$\sum_{i=1}^{n} \boldsymbol{d}_i^{\mathsf{T}} \widehat{\mathbf{C}}^{-1} \boldsymbol{d}_i \overset{(1)}{=} \sum_{i=1}^{n} \operatorname{tr}\!\left(\widehat{\mathbf{C}}^{-1} \boldsymbol{d}_i \boldsymbol{d}_i^{\mathsf{T}}\right) \overset{(2)}{=} \operatorname{tr}\!\left(\widehat{\mathbf{C}}^{-1} \sum_{i=1}^{n} \boldsymbol{d}_i \boldsymbol{d}_i^{\mathsf{T}}\right) \overset{(3)}{=} \operatorname{tr}\!\left(\widehat{\mathbf{C}}^{-1} (n-1)\widehat{\mathbf{C}}\right) \overset{(4)}{=} (n-1)\,p. \tag{13.24}$$

(1) A number equals its own trace, and $\operatorname{tr}(\mathbf{AB}) = \operatorname{tr}(\mathbf{BA})$ moves $\boldsymbol{d}_i$ to the end.
(2) The trace is linear, so the sum goes inside.
(3) The definition of the sample covariance.
(4) $\operatorname{tr} \mathbb{1}_p = p$.

So the average in-sample value is $p(n-1)/n$, *exactly*, whatever the skies did: slightly below p, with no scatter in the average at all. A new, independent sky compared with the same $\bar{\boldsymbol{y}}$ and $\widehat{\mathbf{C}}$ has instead an average of about $p\,(n-1)/(n-p-2)$, above p. The data are a new sky in this sense, so each simulation is treated the same way: its χ^2 uses the mean and covariance of the *other* $n-1$ skies (with Hartlap factor $(n-p-3)/(n-2)$). This "leave-one-out" distribution is the null distribution the data are ranked in. Its mean, 1 per degree of freedom at $N_{\text{side}} = 256$, confirms that the corrections work.

The Gaussian approximation is not used for the probability. Equation (13.23) told us which statistic to use. It is not trusted for the tail: at $|\nu| = 3$ the counts are small and skewed, and $\bar{\boldsymbol{y}}$ and $\widehat{\mathbf{C}}$ carry their own noise. The probability is the rank (13.18) of the data's χ^2 among the simulations' χ^2, which needs no formula. The tail of the χ^2_{36} distribution is reported alongside, as a check on how far the approximation can be trusted.

Key idea: the simulation test of a sky map

Stack the statistics into a vector. Use simulations of the null hypothesis, processed exactly like the data, to estimate its mean and covariance; form the Hartlap-corrected χ^2 of the data and, leaving each one out in turn, of every simulation. The p-value is the fraction of simulations whose χ^2 is at least as large as the data's. The Gaussian density chooses the statistic; the simulations, not a formula, give its distribution.

13.12.3 The verdict at four resolutions

The simulated skies are made and measured once, by `code/ch13/b02_sims.py`, and cached. The test itself is a short function in `code/ch13/b03_mf_test.py`:

Listing 13.6: The χ^2 of the data and the leave-one-out χ^2 of every simulation (`code/ch13/b03_mf_test.py`)

```
    n, p = Y.shape
    C = np.cov(Y, rowvar=False)
    d = y - Y.mean(0)
    c_data = (n - p - 2) / (n - 1) * d @ np.linalg.solve(C, d)
    c_sims = np.zeros(n)
    for i in range(n):
        rest = np.delete(Y, i, axis=0)
        Ci = np.cov(rest, rowvar=False)
        di = Y[i] - rest.mean(0)
        c_sims[i] = (n - 1 - p - 2) / (n - 2) * di @ np.linalg.solve(Ci, di)
    return c_data, c_sims
```

The first four lines are (13.17) for the data, with the covariance of all n skies; the loop repeats it for each simulation against the other $n-1$. The rank (13.18) is then one line, `np.mean(c_sims >= c_data)`. Table 13.6 collects the results.

	$N_{\text{side}} = 64$ 160′	128 80′	256 40′	512 20′
simulated skies n	1000	1000	500	300
Hartlap factor h	0.963	0.963	0.926	0.876
χ^2/N_{dof} of the data	0.65	0.91	0.96	1.18
$\widehat{p}$ (rank among skies), %	91.7 ± 0.9	60.3 ± 1.5	50 ± 2.2	23 ± 2.4
tail of χ^2_{36}, %	94.9	63.1	53.5	21.5
area alone, %	92.7	33.6	32.4	58.7
length alone, %	64.2	79.8	59.4	6.3

Planck 2018, SMICA, %	90	85.4	93.9	80.7

Table 13.6: The Minkowski-functional test of the SMICA temperature map. $\widehat{p}$ is the fraction of Gaussian skies with a χ^2 at least as large as the data's, with its binomial Monte Carlo error; the three rows below use the twelve numbers of one functional at a time. The last row is the same probability from *Planck*'s Table 5 [109], with 999 end-to-end simulations.

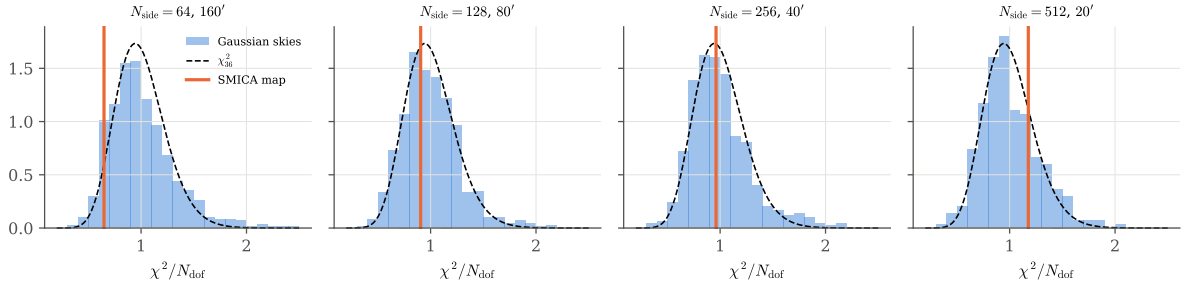

Figure 13.23: The χ^2 per degree of freedom of each Gaussian sky against the others (histogram), the χ^2_{36} density (dashed), and the SMICA map (vertical line), at the four resolutions. The data sit inside the bulk of the Gaussian skies at every resolution.

Reading the verdict. Go back to the four candidate explanations of Section 13.9. The data's χ^2 lands in the bulk of the null distribution at every resolution (Figure 13.23): between 23% and 91.7% of Gaussian skies are farther from the Gaussian average than the real one. So the first explanation, a Gaussian sky seen through our instrument, accounts for the shapes of the real sky without strain, and the other three are not needed to explain these 36 numbers. That is a statement about sensitivity as much as about the sky: a primordial non-Gaussianity, a foreground residual or a processing error smaller than the scatter of these statistics would pass unseen, and Section T3.5.2 shows how much tighter the bispectrum constrains the primordial kind.

One small number among twelve. The single-functional rows matter because a defect in one estimator (the boundary length near the mask, say) would show in one row and not in the others. Eleven of the twelve are unremarkable; the boundary length at $N_{\text{side}} = 512$ gives 6.3%. Is that a sign of something? Ask how often the smallest of twelve probabilities is that small when nothing is wrong. If the twelve were independent, each below 0.063 with probability 0.063, the chance that none of them is would be $(1 - 0.063)^{12} = 0.46$; in all the other perfectly Gaussian skies at least one row is this small. The rows are in fact correlated (the same sky

enters all of them), which lowers that chance somewhat but not to anything rare. This is the look-elsewhere effect again: the smallest probability was found by looking at twelve numbers, and it has to be judged as the smallest of twelve. The combined test, fixed in advance, is the one that carries the verdict.

13.13 Pieces, holes and their lifetimes on the real sky

The Euler characteristic of Section 13.11 is a difference, pieces minus holes, $\chi = \beta_0 - \beta_1$ (Section 12.2.1). A sky with ten more hot regions and ten more holes than a Gaussian one has the same χ. Could the real sky hide such a compensation? The Betti numbers separate the two counts, and the persistence diagram of Section 12.9 goes further: it follows each hot region from the threshold at which it appears to the threshold at which it merges with an older one. Both were developed for cosmic-web catalogues [5] and for primordial non-Gaussianity in galaxy surveys [111]; here they are applied to the real microwave sky, through the same simulation test.

The question. Does the real sky have, threshold by threshold, the number of separate hot regions and the number of holes in them that Gaussian skies have? And is the whole history of its hot regions, births and mergers, as close to that of a Gaussian sky as Gaussian skies are to one another?

13.13.1 Betti numbers on a cut sphere

Pieces. $\beta_0(\nu)$, the number of connected hot regions, is computed by the union–find algorithm of Section 12.11.1, run on the HEALPix neighbour graph: the observed pixels are added in order of decreasing u; each new pixel is joined to the observed neighbours already present (all neighbours, up to eight, that share an edge or a corner, the convention of Section 13.11.1); when it joins two regions, the younger dies (the elder rule). One pass gives the birth and death level of every hot region, and $\beta_0(\nu)$ is the number of regions born above ν and not yet merged at ν. In `code/ch13/lib_skytopo.py` the loop is compiled with `numba`, and it handles the 3 million pixels of an $N_{\rm side} = 512$ map in 1.01 s on one core of the cluster, most of it spent following the eight neighbours of each pixel.

Holes, from pieces and the Euler characteristic. Counting holes directly on a sphere with a mask is awkward: is a cold region that touches the mask a hole or not? There is no need to decide. For a surface, $\chi = \beta_0 - \beta_1 + \beta_2$, where β_2 counts closed two-dimensional shells. A subset of the sphere contains a closed shell only if it is the whole sphere, and with a mask our excursion sets never are, so $\beta_2 = 0$ and

$$\beta_1(\nu) = \beta_0(\nu) - \chi(\nu), \tag{13.25}$$

with χ from (13.22). A hole is then whatever χ says it is: a cold region enclosed by hot pixels, and also a hot region wrapped around one of the mask's holes. Both are features of the observed excursion set, and the simulations see the same mask. As a check of the code, on unmasked skies Alexander duality gives β_1 another way, as the number of cold regions (four-connected) minus one (Section 12.11.2, here on the sphere instead of the plane). The script `code/ch13/b05_checks.py` makes this comparison on 20 full-sky Gaussian maps at $N_{\rm side} = 64$ and 128, at 61 thresholds each: of the 1220 cases in which both the hot and the cold set are non-empty, 0 disagree.

Example: the split of χ at one threshold. At $N_{\rm side} = 256$ and $\nu = 0.27$ the real sky has $\beta_0 = 1854$ hot regions and $\beta_1 = 894$ holes, so that $\chi = 1854 - 894 = 960$ (Section 13.11.2). Near

$\nu = 0$ hot and cold areas are about equal and both counts are large; the Euler characteristic, their small difference, has a relative scatter much larger than either count. The Betti numbers are therefore not redundant with χ: they measure the two large numbers that χ subtracts.

The test. The statistics vector now holds β_0 and β_1 per steradian of observed sky at the twelve thresholds, 24 numbers per resolution. A threshold at which no simulated sky varied (if no sky ever had a hole in its hot set at $\nu = 3$, for example) would carry no information and would have to be dropped, since its row of the covariance would be zero; the script checks this, and at our four resolutions all 24 numbers vary. The test of Section 13.12 then runs unchanged. The SMICA map gives

	$N_{\text{side}} = 64$	128	256	512
numbers used	24	24	24	24
χ^2/N_{dof}	0.7	0.98	1.22	1.09
$\widehat{p}$, %	73.5 ± 1.4	38.9 ± 1.5	22 ± 1.9	33.3 ± 2.7

with the curves in Figure 13.24. As with the functionals, the real sky's pieces and holes are where Gaussian skies put them.

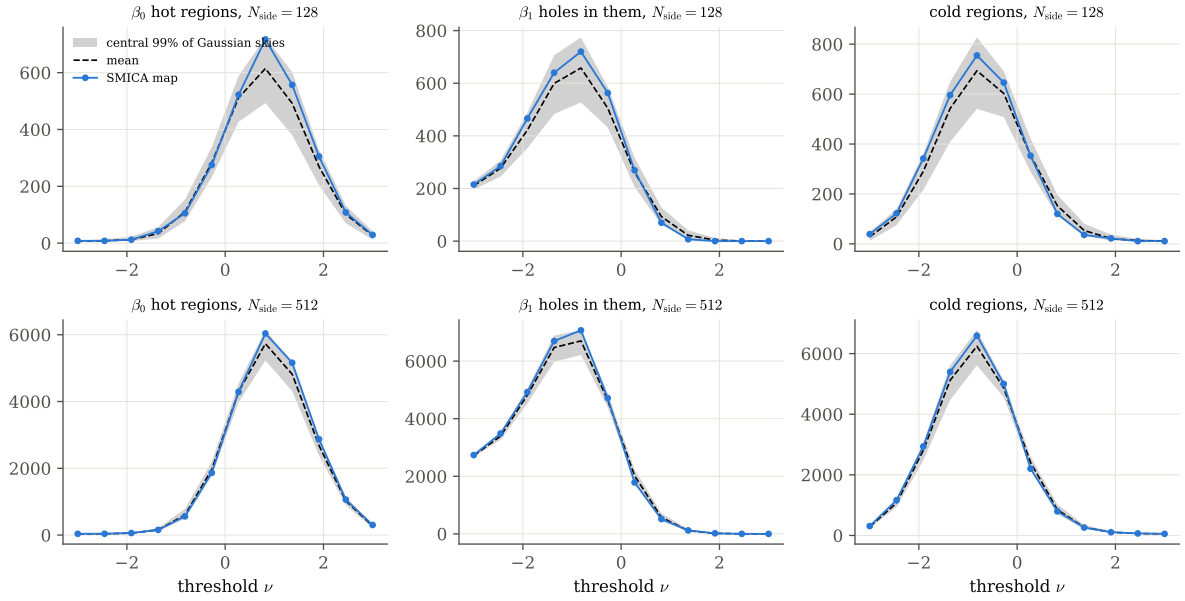

Figure 13.24: Betti curves of the SMICA map (blue) at $N_{\text{side}} = 128$ (80′, top) and 512 (20′, bottom): the number of hot regions β_0, the number of holes in them $\beta_1 = \beta_0 - \chi$, and the number of cold regions, against the central 99% (grey) and the mean (dashed) of the Gaussian skies. The counts are totals over the observed sky.

13.13.2 The whole history: persistence diagrams

The same union–find pass that counts β_0 records, for every hot region, a pair (birth level, death level). Plotted as points, these pairs form the H_0 persistence diagram of the map (Section 12.9): a point far from the diagonal is a hot spot that stood out over a wide range of thresholds, a point near the diagonal a blip. Two features of the cut sky are worth naming. A region cut off from the rest of the observed sky by the mask can never merge with it, so the diagram has one never-dying point for each separate island of observed sky; these carry information about

the mask, not the sky, and are left out. And the levels are in units of the map's own σ_0, so the diagram, like the curves, is insensitive to the overall amplitude.

Comparing a diagram with a population of diagrams. A diagram is a set of points, not a vector, so the χ^2 of Section 13.12 does not apply directly; nor is there a simple "mean diagram" of the Gaussian skies to compare with. What we do have is a distance. The 1-Wasserstein distance W_1 (Section 12.10.2) matches the points of two diagrams one to one, sending unmatched points to the diagonal, and adds up the costs of the best matching; each cost is the larger of the shifts in birth and in death, and the cost of a point sent to the diagonal is half its lifetime.

Example: W_1 by hand. Let $D = \{(2, 0.5)\}$ and $D' = \{(2.2, 0.4), (0.3, 0.2)\}$. Matching $(2, 0.5)$ with $(2.2, 0.4)$ and sending $(0.3, 0.2)$ to the diagonal costs

$$\max(|2 - 2.2|, |0.5 - 0.4|) + \frac{0.3 - 0.2}{2} = 0.2 + 0.05 = 0.25,$$

while sending everything to the diagonal costs $\frac{1.5}{2} + \frac{1.8}{2} + \frac{0.1}{2} = 1.7$, and matching $(2, 0.5)$ with $(0.3, 0.2)$ is worse still. So $W_1(D, D') = 0.25$: the long-lived spot moved by 0.2, and one short blip was created. Unlike the bottleneck distance, which keeps only the worst pair, W_1 adds up every change, so a sky with many slightly displaced spots is far from a Gaussian one even when no single spot moved much.

Computing the best matching. Finding the cheapest matching looks like a search over all pairings, but it is a standard problem in disguise. *The trick:* give every point a private copy of itself on the diagonal. If D has n points and D' has m, list as "rows" the n points of D followed by the m diagonal copies of the points of D', and as "columns" the m points of D' followed by the n diagonal copies of the points of D. A row–column pair is then one of four things: a point of D matched to a point of D' (cost: the larger shift), a point of D sent to its own diagonal copy (cost: half its lifetime), a point of D' sent to its diagonal copy (the same), or two diagonal copies paired with each other (cost 0, nothing happens). Every matching of the two diagrams is a one-to-one assignment of the $n + m$ rows to the $n + m$ columns, and the cheapest assignment of a square cost matrix is what `scipy.optimize.linear_sum_assignment` computes exactly (the Hungarian algorithm). The function `w1` in `code/ch13/b04_betti_persistence.py` builds this matrix in five lines, and on the example above it returns 0.25. Research code uses `gudhi`'s `hera.wasserstein_distance` (order 1, ground metric L^∞), which solves the same problem with a faster approximate auction algorithm.

The test statistic. For each map we compute its mean W_1 distance to a fixed set of reference skies (10 Gaussian skies at $N_{\text{side}} = 64$, 5 at 128). Before matching, points that live less than $0.1\,\sigma_0$ (at 64) or $0.5\,\sigma_0$ (at 128) are dropped. They are the many tiny wiggles of the field, each costing almost nothing, and they make the cost matrix large (the matching time grows as the cube of the number of points) without adding information about the long-lived spots. A Gaussian sky is at a typical distance from the references; a non-Gaussian one, whose spots are born and merge at the wrong levels, would be farther. The null distribution comes from 400 and 200 further Gaussian skies, not among the references, and the p-value is again the rank of the data. At $N_{\text{side}} = 128$ the SMICA diagram keeps 1016 points after the cut (a Gaussian sky about 956). Its mean distance to the references is 99.3, against 99.6 ± 11.9 for Gaussian skies, so 35.5% of Gaussian skies are farther; at $N_{\text{side}} = 64$ the numbers are 47.2 against 45.9 ± 4, and 26.2% (Figure 13.25).

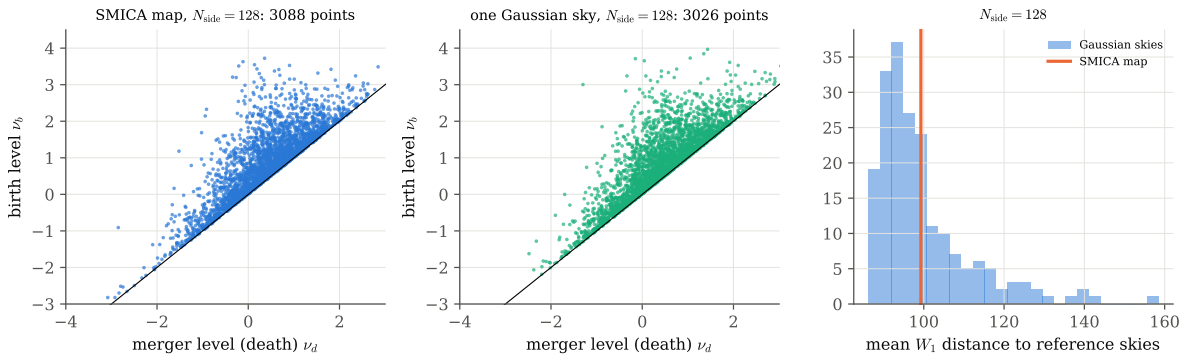

Figure 13.25: Left and middle: H_0 persistence diagrams of the hot regions of the SMICA map and of one Gaussian sky at $N_{\text{side}} = 128$, birth level against merger level in units of σ_0; points far above the diagonal are hot spots that stood out over a wide range of thresholds. All finite points are shown; the distances use only those living longer than $0.5\,\sigma_0$. Right: the mean W_1 distance of each Gaussian sky's diagram to the reference skies (histogram), and the same for the SMICA map (vertical line).

Why the noise does not matter here either. The stability theorem (Section 12.10.3) bounds the change of a diagram by the largest change of the field: adding noise of amplitude ϵ (in units of σ_0) moves every point by at most ϵ in the bottleneck distance. At these resolutions the noise is a few hundredths of a per cent of the variance (Section 13.10.2), an amplitude of order $10^{-2}\sigma_0$, so the noise moves the long-lived spots by far less than the sky-to-sky differences of Figure 13.25. Only the very short-lived blips near the diagonal are affected, and W_1 charges them only half their tiny lifetimes.

13.14 Side by side with *Planck* 2018

Their question. By 2018 the *Planck* temperature maps had reached the limit set by cosmic variance over most of the sky. The simplest models of inflation predict a Gaussian, statistically isotropic sky; non-Gaussianity of a few parts in 10^4 would point to more complicated physics in the early universe, and larger departures to foreground residuals or systematic errors in the maps. The collaboration therefore ran a battery of model-independent tests, one of which is the Minkowski-functional test we have just repeated on the same map [109]. The morphological approach on the sky goes back to the analysis of the four-year COBE maps by Schmalzing and Górski, who derived the estimators on the curved, pixelised and masked sphere [105] that Section 12.7.2 reproduced.

Their setup, in plain terms. Four temperature maps, one from each component-separation method; at each of eight resolutions ($N_{\text{side}} = 16$ to 2048), the map is degraded and smoothed as in (13.19), a common mask degraded and thresholded at 0.9 removes the Galaxy and the point sources, and the three normalised functionals are measured at twelve thresholds between $-3\sigma_0$ and $3\sigma_0$, with σ_0 the map's own standard deviation. The null hypothesis is represented by 999 FFP10 simulations: lensed Gaussian CMB skies from a fiducial ΛCDM spectrum (with $\tau = 0.060$, slightly above the final best fit), observed with the real beams, scanning and noise, and passed through each component-separation pipeline with the weights derived from the data.

	Planck 2018 VII	ours
maps	Commander, NILC, SEVEM, SMICA	SMICA
resolutions	$N_{\text{side}} = 16, \ldots, 2048$	$N_{\text{side}} = 64, 128, 256, 512$
simulations	999 FFP10, end to end	1000, 1000, 500, 300 Gaussian skies
noise	simulated time streams, map-making	isotropic, half-difference spectrum
statistics	v_0, v_1, v_2 (and needlet v_k)	v_0, v_1, v_2; β_0, β_1; H_0 diagrams
Euler characteristic	$(N_{\text{hot}} - N_{\text{cold}})/2\pi A$	$V - E + F$ per steradian

Their equation, and ours. Their eqs. (20)–(22) define $\chi^2 = \sum_{ij} [\mathsf{C}^{-1}]_{ij} (y_i - \bar{y}_i^{\text{sim}})(y_j - \bar{y}_j^{\text{sim}})$ with $\mathsf{C}_{ij} = \langle (y_i^{\text{sim}} - \bar{y}_i^{\text{sim}})(y_j^{\text{sim}} - \bar{y}_j^{\text{sim}}) \rangle$ over the simulations. Symbol map: their $\boldsymbol{y}$ is our $\boldsymbol{y}$ (the 36 normalised numbers), $\bar{\boldsymbol{y}}^{\text{sim}}$ is our $\bar{\boldsymbol{y}}$, their C our $\widehat{\mathbf{C}}$. This is (13.17) without the Hartlap factor, and it is the quadratic form that Section 13.12.1 derived from the Gaussian density of $\boldsymbol{y}$. Their normalised functionals, eqs. (16)–(19), are (12.35), derived in Section 12.7.4. Their probability, Table 5, is the fraction of simulations with a larger χ^2: our (13.18).

Why can they leave out the Hartlap factor, which Section 13.12.2 insisted on? Because of how the probability is computed. *The question:* does multiplying every χ^2 by the same positive number change the rank of the data among the simulations? It does not: if $\chi_i^2 \geq \chi_{\text{obs}}^2$, then $h\chi_i^2 \geq h\chi_{\text{obs}}^2$ for any $h > 0$, so the count in (13.18) is unchanged. The factor matters only when the χ^2 is compared with the χ_{36}^2 formula, as in the "tail of χ_{36}^2" row of Table 13.6. (In our leave-one-out version the simulations use $n - 1$ skies and the data n, so the two factors differ by one part in n; irrelevant here, but this is why we keep them.) What does matter, with either convention, is that the data and the simulations are compared with the same mean and covariance in the same way.

Their choice of σ_0. The thresholds could be set in units of the population standard deviation (the average over simulations) or of each map's own. *Planck* chose the map's own sample standard deviation, noting that it makes the test more sensitive (their Sect. 5.3 and footnote 9). Section 13.11.2 showed the reason on the real sky: at 160′ the data's σ_0 is below most of the simulations', and with population units that deficit of large-scale power would have shifted every curve and masqueraded as a change of shape.

13.14.1 What agrees, and what differs

N_{side} (FWHM)	64 (160′)	128 (80′)	256 (40′)	512 (20′)
f_{sky}, ours, %	71.3	73.6	74.7	75.5
f_{sky}, *Planck* Table 1, %	71.3	73.6	74.7	75.6
p, ours, %	91.7 ± 0.9	60.3 ± 1.5	50 ± 2.2	23 ± 2.4
p, *Planck*, SMICA, %	90.0	85.4	93.9	80.7
p, *Planck*, range over four methods, %	63.2–99.0	79.7–97.2	81.5–95.4	78.0–87.2

Table 13.7: The masks and the probabilities of a larger χ^2 for the Minkowski-functional test of the temperature map, from our pipeline and from *Planck* 2018 VII, Tables 1 and 5 [109].

What agrees. The masks agree with *Planck*'s: the sky fractions are identical at three resolutions and differ by a tenth of a per cent of the sky at the fourth (Table 13.7), so the degrading and thresholding of Section 13.10.1 is theirs. The conclusion agrees: at every resolution the real sky's χ^2 sits well inside the distribution of Gaussian skies (Figure 13.26), and no probability is

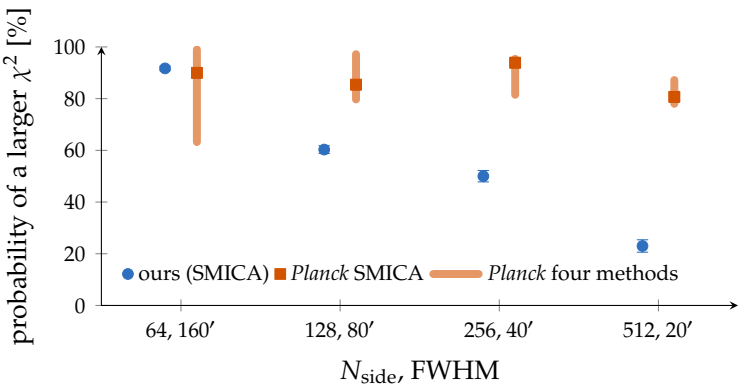

Figure 13.26: The probability of a larger χ^2 at four resolutions: our pipeline on the SMICA map (blue, with its Monte Carlo error), *Planck*'s SMICA result (orange square) and the spread of *Planck*'s four component-separation maps (orange bar). Every value lies in the bulk of the null distribution; no resolution is anomalous in either analysis.

small enough to suggest a departure from Gaussianity. The Betti curves and the persistence diagrams of Section 13.13, which *Planck* did not use, agree with the same conclusion.

What differs, and why. The individual probabilities are not the same numbers, and they should not be expected to be. Three causes, in decreasing order of size.

1. *A probability is a property of a statistic, not only of the sky.* If the null hypothesis is true, the p-value of a valid test is uniformly distributed between 0 and 1 over realisations (Section 4.4.2). Two different statistics computed on the same sky are two correlated draws of such a uniform number; unless the statistics are almost identical, their p-values can differ by tens of per cent. Our estimators measure the same three functionals in a different way (the Euler characteristic by $V - E + F$ instead of hot minus cold spots, the length by the band formula (13.21) instead of contour lengths), and those differences reweight the same fluctuations of the sky. *Planck*'s own Table 5 gives the size of this effect for a milder change: the same test on four cleanings of the same sky spans 81.5 to 95.4% at $N_{\mathrm{side}} = 256$ and 63.2 to 99.0% at 64.
2. *Different simulations.* FFP10 skies are lensed, carry the real noise pattern and go through component separation and inpainting; ours are Gaussian skies with the lensed spectrum and isotropic noise, not inpainted. Lensing makes the sky very slightly non-Gaussian, and the inpainting changes the pixels near the mask after smoothing; both shift the null distribution a little, and differently from the data.
3. *Monte Carlo error.* With 300 to 1000 skies our probabilities carry errors of one to two and a half per cent (Section 13.9.2); *Planck*'s, with 999, about one per cent. This is the smallest of the three.

None of these can turn an unremarkable sky into an anomalous one. A real non-Gaussian signal would push the probability towards zero in every version of the test at once; differences in the processing move it around within the bulk.

Lesson. Reproducing a published p-value means reproducing the published statistic and the published null distribution, not the published conclusion; with our own estimators and our own simulations we reproduce the masks to a tenth of a per cent and the conclusion fully, and the individual probabilities only within the spread that the choice of statistic itself creates. A

test of a single sky is a statement about one draw, and its p-value moves with every honest change of method: what is robust is whether it lands in the tail.

How this is used in real research: from a capstone test to a research result

Planck's analysis differs from ours in what it can rule out, not in its logic. Its simulations follow the data through the real instrument and the real component separation, so a non-Gaussianity created by the pipeline is in the null distribution and cannot be mistaken for the sky; ours would attribute such an effect to the sky. It tests four cleanings of the same data, whose agreement is a test of foreground residuals. It repeats the analysis on needlet maps, each restricted to a band of multipoles, which localises any deviation in scale: there the largest scales ($\ell \lesssim 32$) give probabilities of a few per cent (their Table 6), an echo of the large-angle anomalies (Section T3.5.3). It analyses E-mode polarization the same way. And when a specific non-Gaussian model is in mind, the functionals are fitted rather than only tested: the first-order expansion of [108] (Section T3.2.1) predicts their response to $f_{\rm NL}$, so the measured curves can be turned into an estimate of it; for a known three-point template the bispectrum, which weights every triangle of multipoles by the template, is far more sensitive (Section T3.5.2). Persistence-based statistics are being developed for the same purpose in galaxy surveys [111]. For polarization, the singularities of the Q, U field (Section 12.14) have predicted densities and correlations [1, 2] that Section 12.15.1 reproduced; applying them to *Planck*'s polarization needs the end-to-end noise simulations, because at the small scales where singularities are dense the polarization maps are noise-dominated.

Laptop scale, and what it costs. Each reduction, with what the full analysis does instead:

- *Resolutions. Planck* goes to $N_{\rm side} = 2048$ (5′); we stop at 512 (20′, $\ell \lesssim 800$). The cost: no test of the small scales where noise inhomogeneity and residual point sources would matter.
- *Simulations. Planck* uses 999 end-to-end FFP10 skies per method; we use 1000 to 300 Gaussian skies with isotropic noise from the half-difference spectrum. The cost: Monte Carlo errors of one to two and a half per cent on each probability, Hartlap factors down to 0.876, and a null distribution that does not contain lensing non-Gaussianity, the scanning pattern of the noise, component separation or inpainting.
- *One cleaning. Planck* tests four component-separation maps; we test SMICA only. The cost: no internal check on foreground residuals.
- *Persistence.* The W_1 test runs at $N_{\rm side} = 64$ and 128 against 10 and 5 reference skies; a research version would use all resolutions and a summary designed for sensitivity (persistence images or landscapes with a covariance). The cost: a coarse test whose power against specific non-Gaussian models has not been measured.

Recap

- The real-sky test asks: if the sky were a Gaussian, isotropic field with the best-fit spectrum, observed and processed like the SMICA map, would its topological statistics be as far from the Gaussian average as they are, or farther? The null hypothesis is the one explanation whose sampling distribution we can simulate.
- A map is moved to a working resolution by multiplying its $a_{\ell m}$ by $b_\ell^{\rm new} p_\ell^{\rm new} / (b_\ell^{\rm old} p_\ell^{\rm old})$; the mask by smoothing it with the same beam and keeping pixels with at least 90% trusted weight. The noise spectrum comes from the half-mission half-difference map, whose noise has exactly the full map's statistics.

- On a cut sphere the Euler characteristic is $V - E + F$ with entry levels, the boundary length a band integral of $|\nabla u|$, and $\beta_1 = \beta_0 - \chi$ because an excursion set of a masked sky has $\beta_2 = 0$.
- The χ^2 is the quadratic form of the (approximately Gaussian) statistics; with a simulated covariance it needs the Hartlap factor and leave-one-out simulations, and the probability is the rank of the data among the simulations, with Monte Carlo error $\sqrt{p(1-p)/n}$.
- The SMICA map is consistent with Gaussian skies at $N_{\rm side} = 64$–512 in its Minkowski functionals, its Betti curves and its H_0 persistence diagrams, as *Planck* 2018 found; the individual probabilities differ from *Planck*'s within the spread that different statistics and simulations produce.

13.15 A real galaxy catalogue: CMASS in the southern sky

Everything we know about measuring galaxy clustering we learned on catalogues we made ourselves. In Chapter 11 a lognormal field was sampled by a Poisson process, the points were counted in pairs, and the acoustic bump near 100 h^{-1}Mpc came out of mock surveys whose truth we had chosen. A real survey hands us a list of 208,426 galaxies, each with two angles on the sky and a redshift, and nothing else. Nobody tells us the true correlation function, the true distance to the galaxies, or how many of them the telescope missed. The machinery of Chapter 11 has to work on that list, and when it does, the bump tells us how far away the galaxies are.

Where we have met this measurement before. In Section 11.4.4 we rebuilt the first detection of the acoustic peak [42] on mock surveys: periodic boxes with the volume and galaxy density of the 2005 sample, a covariance matrix from more than a thousand of them, and a fit of the template of Eq. (11.30) with the dilation α. A survey of that size typically detected the peak at about 2σ, and the 2005 paper's 3.4σ sat in the upper tail. In Section 11.4.6 we compared the published DESI distances D_V/r_d with the Planck prediction. Here the estimator and the fit are the same, but three things change. The data are real, so the galaxies sit in a survey with an irregular edge, holes, and a density that falls with distance. There are no mocks, so the error bars must come from the data themselves. And we do not compare published numbers; we produce one, and then set it beside the numbers of the BOSS collaboration, which measured the same galaxies.

The question. Is the acoustic peak visible in the correlation function of real galaxies, how strongly, and what distance $D_V(z)/r_d$ does its position give? Answering it takes five steps: turn the catalogue into positions in space; correct the catalogue for the galaxies the survey could not observe properly; count pairs; estimate the uncertainty from the data alone; and fit the peak.

13.15.1 What the survey observed

The Baryon Oscillation Spectroscopic Survey (BOSS) used the 2.5-metre Sloan telescope in New Mexico between 2009 and 2014. Galaxies were first chosen from images, then a spectrograph measured a redshift for each through an optical fibre plugged into a metal plate at the galaxy's position, about a thousand fibres per plate [249]. The **CMASS** sample ("constant mass") was selected by cuts in colour and magnitude designed to pick galaxies of roughly the same stellar

mass at every distance, massive red galaxies at $0.43 < z < 0.7$. Massive galaxies are rare and bright, so they can be seen far away, and they live in dense regions, so they cluster strongly; both help to see a faint feature at a large scale.

The survey covered two regions of sky on either side of the Milky Way's disc, the northern and the southern Galactic caps. We use only the southern cap: its random catalogue is 1.2 GB, while the northern one is 3.2 GB, more than a laptop analysis should download. Table 13.8 sets our sample beside the full sample.

	CMASS North	CMASS South (ours)	CMASS total
galaxies used, $0.43 < z < 0.7$	568,776	208,426	777,202
effective area [deg^2]	6,851	2,525	9,376
close pairs without a fibre	34,151	11,163	45,314
redshift failures	10,188	5,157	15,345

Table 13.8: The DR12 CMASS sample [Reid2016 Table 2]. After the redshift cut our copy of the southern catalogue holds exactly the 208,426 galaxies of the middle column. The southern cap is 27% of the area.

13.15.2 Two files: the galaxies and the randoms

The public large-scale-structure catalogue for one sample and one cap is two files [249]. The *galaxy file* lists 230,831 objects with right ascension RA, declination Dec (the two angles on the sky), redshift z, four weights that we meet in Section 13.16, and the expected number density $\bar{n}(z)$ at each galaxy's redshift, in a column called `NZ`. Cutting to $0.43 < z < 0.7$ leaves 208,426 galaxies.

The *random file* lists 11,636,252 points, about fifty per galaxy, that mimic everything the survey did except clustering. It is the random catalogue of Section 11.2.1, built for a real survey, and its construction tells us exactly what "everything the survey did" means [Reid2016 §5.2].

- *The angles.* Points are thrown uniformly on the sphere and kept only inside the survey footprint, a union of polygons on the sky. In each small patch of sky (a "sector") a point is kept with a probability equal to the fraction of targets in that sector that received a good redshift, so a patch where the survey was 80% complete gets 80% of the randoms.
- *The holes.* Points are removed wherever galaxies could not have been seen: around bright stars, in fields with bad images, and at the centre of each plate, where the bolt that holds it leaves no room for a fibre.
- *The redshifts.* Each random point is given the redshift of a galaxy chosen at random from the galaxy file, with probability proportional to the galaxy's weight w_{tot}.

The last item needs a reason. The true redshift distribution of CMASS galaxies is not known from theory; it is whatever the colour cuts let through. So it is estimated from the galaxies themselves, and the randoms copy it. The price is that any real fluctuation in the number of galaxies with redshift, a large structure at one distance, is copied into the randoms too, and removed from the measured clustering along the line of sight. Ross et al. compared this "shuffled" choice with smooth fits to $\bar{n}(z)$ on mock catalogues: it gave the smallest systematic error of the methods they tried, and a negligible one for the spherically averaged correlation function that we measure [250]. We keep a random subsample of 10 randoms per galaxy, 2,084,260 points, chosen with `rng.choice`; a subsample of a uniform sample is still uniform.

13.15.3 From two angles and a redshift to a position

A galaxy's redshift is not a distance. To place it in space we need the distance–redshift relation, and that needs a cosmology. We take the comoving distance from the cosmology notes, for a flat universe:

$$D_C(z) = \int_0^z \frac{c\,\mathrm{d}z'}{H(z')} = \frac{c}{H_0}\int_0^z \frac{\mathrm{d}z'}{E(z')}, \qquad E(z) = \sqrt{\Omega_m(1+z)^3 + 1 - \Omega_m}, \tag{13.26}$$

with radiation neglected in E, which is accurate to better than 0.1% below $z = 1$ (Section T1.2 lists the full set of distances). The value of D_C we actually use comes from CAMB's background module, which keeps radiation and neutrinos; the formula is how to think about it.

Why surveys measure in h^{-1}Mpc. Write $H_0 = 100\,h\,\mathrm{km\,s^{-1}Mpc^{-1}}$, so $c/H_0 = 2997.9\,h^{-1}\mathrm{Mpc}$. The integral in (13.26) depends only on Ω_m. So in units of h^{-1}Mpc the distances of all galaxies depend on one parameter, Ω_m, and h never enters. A survey of redshifts cannot measure h by itself, because every distance in it scales with $1/h$ together; quoting lengths in h^{-1}Mpc removes that unknown common factor from every number. (It is the same invisible calibration that Section 11.20 met: an overall distance scale that the data cannot see.)

The position. A galaxy at angles $(\mathrm{RA}, \mathrm{Dec}) = (\phi, \delta)$ lies along the unit vector $\hat{\boldsymbol{n}}$, and its comoving position is

$$\boldsymbol{x} = D_C(z)\,\hat{\boldsymbol{n}}(\phi,\delta), \qquad \hat{\boldsymbol{n}} = (\cos\delta\cos\phi,\ \cos\delta\sin\phi,\ \sin\delta). \tag{13.27}$$

Because the observed redshift includes the galaxy's own motion along the line of sight, these are redshift-space positions (Section 11.5.1), and separations between them are written s rather than r. The cosmology we chose is the Planck 2018 model used throughout the book, with $\Omega_m = 0.315$. If it is wrong, every separation is stretched by a few per cent, in the way Section 11.4.1 worked out: the acoustic peak then appears at the wrong place, by the factor α that the fit will measure. A wrong fiducial cosmology is not an error in the analysis; it is what the analysis measures.

Example: the distance to $z = 0.565$ by hand. The weighted mean redshift of our galaxies turns out to be $z_{\mathrm{eff}} = 0.565$ (Section 13.16). Simpson's rule with four intervals of width $\Delta z = 0.14125$, with $\Omega_m = 0.3152$, needs $1/E$ at five points: 1, 0.93116, 0.86076, 0.79194, 0.72683. Then

$$D_C(0.565) \overset{(1)}{=} 2997.9\,h^{-1}\mathrm{Mpc} \times \frac{\Delta z}{3}\Big[1 + 4(0.93116) + 2(0.86076) + 4(0.79194) + 0.72683\Big]$$
$$\overset{(2)}{=} 2997.9 \times 0.04708 \times 10.3410\ h^{-1}\mathrm{Mpc} = 1459.6\,h^{-1}\mathrm{Mpc}.$$

(1) Simpson's rule, $\int_a^b f \approx \frac{\Delta z}{3}[f_0 + 4f_1 + 2f_2 + 4f_3 + f_4]$, applied to $1/E(z)$, times c/H_0.
(2) $\Delta z/3 = 0.047083$, and the bracket adds to 10.3410.

CAMB, with radiation and neutrinos, gives $1460\,h^{-1}$Mpc. The sample spans $D_C = 1153$ to $1742\,h^{-1}$Mpc, a shell $590\,h^{-1}$Mpc thick, about six acoustic scales.

Example: the separation of a pair. Two galaxies 3° apart on the sky, at $z = 0.55$ and $z = 0.56$, have $D_C = 1426.7$ and $1448.6\,h^{-1}$Mpc. Their separation follows from the law of cosines for the triangle formed with the observer,

$$s = \sqrt{D_1^2 + D_2^2 - 2D_1D_2\cos\theta} = 78.4\,h^{-1}\mathrm{Mpc}.$$

The transverse part is about $D\,\theta = 75\,h^{-1}$Mpc and the radial part $D_2 - D_1 = 22\,h^{-1}$Mpc. A change of 0.01 in redshift is a radial step of $22\,h^{-1}$Mpc, which is why redshift errors of $\sim 10^{-4}$ do not matter for the acoustic scale, while galaxy velocities of a few hundred km/s, $\Delta z \sim 10^{-3}$, do (Section 11.5).

Example: how dense is the sample? The effective area of $2525\,\mathrm{deg}^2$ is a solid angle $\Omega = 2525\,(\pi/180)^2 = 0.769$ sr. The comoving volume of the shell between D_1 and D_2 seen through that solid angle is $\Omega(D_2^3 - D_1^3)/3 = 0.96\,h^{-3}\mathrm{Gpc}^3$, and the mean density is $\bar{n} = 208{,}426/V = 2.17 \times 10^{-4}\,h^3\mathrm{Mpc}^{-3}$. The density peaks at 4.23×10^{-4} near $z = 0.5$. In the language of Section 11.3.2, with $P \approx 10^4\,h^{-3}\mathrm{Mpc}^3$ at the acoustic scale, $\bar{n}P$ is between 1 and 4: the sample is dense enough that sample variance, not shot noise, limits the measurement. The effective volume, $V_{\mathrm{eff}} = \int \mathrm{d}V\,[\bar{n}P_0/(1+\bar{n}P_0)]^2$ (Eq. (11.24)), is $0.40\,h^{-3}\mathrm{Gpc}^3$, against 0.13–0.55 for the 2005 sample of Section 11.4.4.

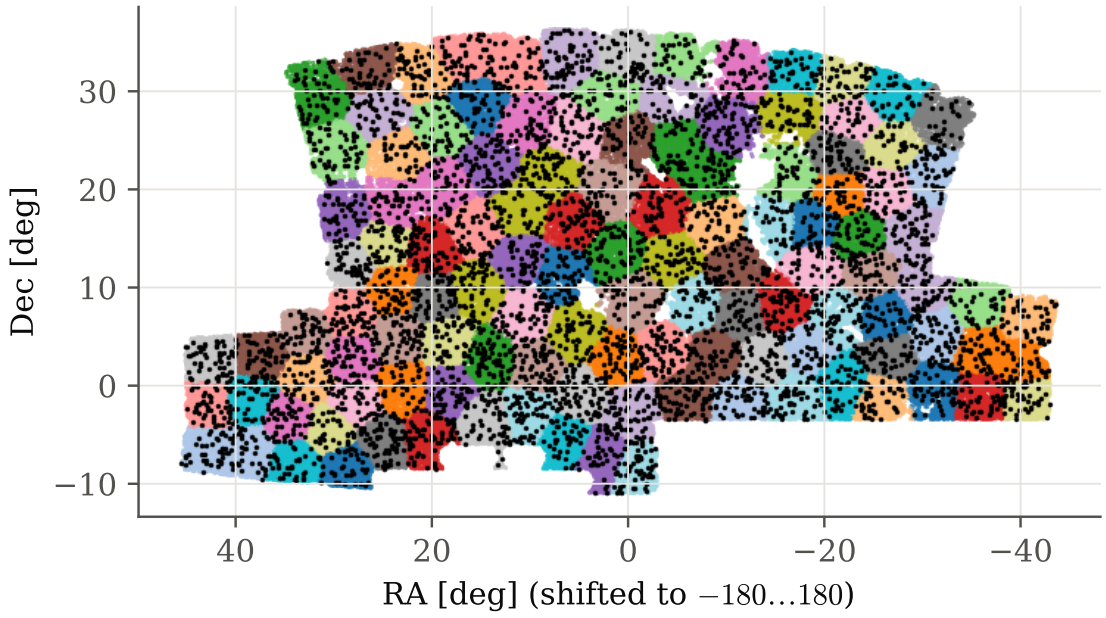

Figure 13.27: The southern CMASS footprint. Coloured dots: a subsample of the randoms, coloured by the jackknife region they belong to (Section 13.18); black dots: a subsample of the galaxies. The sky is seen from inside, so RA increases to the left. The ragged edge and the small holes are the mask the randoms copy.

The code. Figures 13.27 and 13.28 show the result of `code/ch13/21_cmass_catalogue.py`. The lines that matter are these.

Listing 13.7: From angles and redshift to a position (`code/ch13/21_cmass_catalogue.py`)

```
def comoving_distance_table():
    import camb
    p = camb.set_params(H0=FIDUCIAL["H0"], ombh2=FIDUCIAL["ombh2"], omch2=FIDUCIAL["omch2"],
                        mnu=FIDUCIAL["mnu"], ns=FIDUCIAL["ns"], As=FIDUCIAL["As"])
    bg = camb.get_background(p)
    zt = np.linspace(0.0, 1.0, 2001)
    h = FIDUCIAL["H0"] / 100
    dc = bg.comoving_radial_distance(zt) * h                  # Mpc -> Mpc/h
    hz = bg.hubble_parameter(zt)                              # km/s/Mpc
    rd = bg.get_derived_params()["rdrag"]                     # Mpc
    return zt, dc, hz, rd, h
```

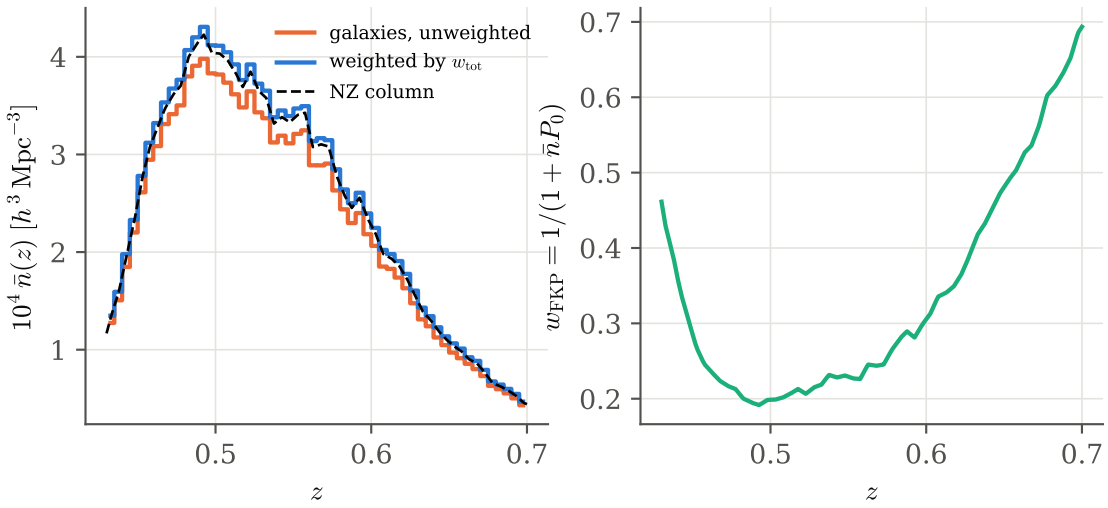

Figure 13.28: Left: the number density of CMASS South galaxies against redshift, counted in shells of the fiducial cosmology, without weights (orange) and with the weight $w_{\rm tot}$ of Section 13.16 (blue), and the catalogue's `NZ` column (dashed), which matches the weighted histogram. Right: the FKP weight each galaxy receives; it is lowest where the sample is densest.

```
67
68
69 zt, dct, hzt, RD_MPC, H = comoving_distance_table()
70 dc_of_z = lambda z: np.interp(z, zt, dct)
71
72
73 def to_xyz(ra, dec, z):
74     """Comoving Cartesian position: distance D_C(z) along the unit vector of (RA, Dec)."""
75     r = dc_of_z(z)
76     a, d = np.radians(ra), np.radians(dec)
77     return np.column_stack([r * np.cos(d) * np.cos(a), r * np.cos(d) * np.sin(a), r *
       np.sin(d)])
```

`comoving_distance_table` evaluates CAMB's $D_C(z)$ once on a fine grid and multiplies by h to work in h^{-1}Mpc; every galaxy's distance is then a linear interpolation in that table, and `to_xyz` is (13.27). The script also reads the weights (Section 13.16), keeps 10 randoms per galaxy, and assigns each object to one of 120 patches of sky for the jackknife (Section 13.18).

13.16 What the survey could not see: the weights

The random catalogue of Section 13.15.2 knows how complete the survey was in each patch of sky and how the density falls with redshift. It cannot know about losses that depend on the galaxies themselves or on what the sky looked like on the night the images were taken. A galaxy that sits right next to another one may not get a fibre; a faint galaxy may not give a usable spectrum; a patch of sky crowded with stars may yield fewer galaxy targets. None of these has anything to do with cosmology, and all of them imprint a pattern on the galaxy counts that would be read as clustering. The catalogue fixes them by attaching a **weight** to each galaxy: a number that says how many galaxies this one stands for.

The principle behind every weight. The model of Section 11.1 is that the galaxies are a Poisson sample of the density $\bar{n}(\boldsymbol{x})[1 + \delta_g(\boldsymbol{x})]$, where $\bar{n}(\boldsymbol{x})$ is the density the survey would

record if galaxies were not clustered. Suppose an effect that has nothing to do with cosmology multiplies the probability of recording a galaxy at $\boldsymbol{x}$ by a factor $f(\boldsymbol{x})$, so the recorded galaxies are a Poisson sample of $f\bar{n}(1+\delta_g)$. If each recorded galaxy is counted with weight $w = 1/f$, the expected weighted count in a small volume $\mathrm{d}V$ is

$$\mathbb{E}\Big[\sum_{i\in \mathrm{d}V} w_i\Big] \overset{(1)}{=} \frac{1}{f(\boldsymbol{x})}\,\mathbb{E}\big[N(\mathrm{d}V)\big] \overset{(2)}{=} \frac{1}{f(\boldsymbol{x})}\, f(\boldsymbol{x})\,\bar{n}(\boldsymbol{x})\big[1+\delta_g(\boldsymbol{x})\big]\mathrm{d}V = \bar{n}(\boldsymbol{x})\big[1+\delta_g(\boldsymbol{x})\big]\mathrm{d}V. \quad (13.28)$$

(1) All galaxies in the small volume share the same f, so the weight comes out of the sum, which is then the number $N(\mathrm{d}V)$ of recorded galaxies.
(2) The mean of a Poisson count is its intensity times the volume (Eq. (11.2)).

So the weighted galaxies are, on average, the galaxies a perfect survey would have recorded. The inputs are physical ones we should state: the loss factor f must not depend on the cosmological field δ_g itself, and it must be known, or measurable from something other than the galaxy clustering. Each weight below is a way of estimating $1/f$ for one kind of loss, and each one bends one of these inputs a little.

13.16.1 Close pairs: the galaxy that did not get a fibre

Two fibres cannot be plugged closer than 62″ on one plate [Reid2016 §6.1]. When two targets are closer than that and only one plate covers them, one of them gets no spectrum. At $z = 0.55$, 62″ is a transverse distance $D_C\theta = 1427 \times (62/206265) = 0.43\,h^{-1}$Mpc. The lost galaxy is, more often than not, a physical companion of the one that was observed: among close pairs where both members did get redshifts (because two plates overlapped), 52% belong to a component concentrated within about $5\,h^{-1}$Mpc of each other along the line of sight, and the rest are chance projections [Reid2016 §6.2, Fig. 10]. So the loss depends on the clustering itself, and the random catalogue, which knows nothing about clustering, cannot reproduce it.

The catalogue's fix is to give the lost galaxy's weight to its nearest neighbour with a good redshift: the column `WEIGHT_CP` is $w_{\mathrm{cp}} = 1$ plus the number of collided targets a galaxy stands for (Figure 13.29). This preserves the number of galaxies in every region much larger than $0.4\,h^{-1}$Mpc: one galaxy counted twice in place of two galaxies a few h^{-1}Mpc apart moves some pairs by a few h^{-1}Mpc, which hardly matters in bins $8\,h^{-1}$Mpc wide at the acoustic scale. Because the galaxy that got the fibre was chosen at random within the colliding group, it is statistically equivalent to the one that did not, and the correction is unbiased at transverse separations larger than the collision scale; below it, pairs are missing, which we do not fit [Reid2016 §6.2]. In our sample 4.3% of the galaxies carry $w_{\mathrm{cp}} > 1$, and they stand for 10164 collided targets in all.

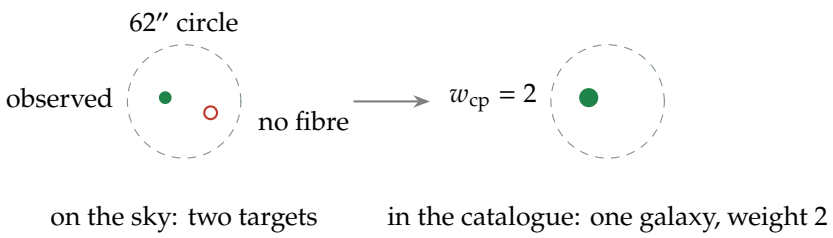

Figure 13.29: Nearest-neighbour upweighting. Left: two targets closer than 62″; only one received a fibre. Right: the observed galaxy carries the missing one's weight. Counts in any region much larger than the circle are unchanged on average.

13.16.2 Redshift failures, stars and seeing

Redshift failures. Some galaxies got a fibre but no reliable redshift, more often on fibres near the edge of a plate and for galaxies that look fainter through the fibre [249, 250]. Again the missing galaxy's weight goes to its nearest neighbour with a good redshift, in the column `WEIGHT_NOZ`; a small refinement in DR12 moves weight towards fainter neighbours, so the values are not exactly integers [Reid2016 §6.3]. In our sample 2.0% of galaxies carry $w_{\text{noz}} > 1$, standing for 4396 failures.

Stars, and the reasoning that finds them. *The event.* Ross et al. found that the number of CMASS targets per square degree falls in parts of the sky where many stars are seen [250]. *What could have produced it?* Two explanations are possible. Either the regions near the Galactic plane, where stars are many, happen to hold fewer galaxies, or stars interfere with finding galaxies. *How likely is the observation under each?* The galaxies are billions of light years away and the stars are in our own Galaxy. Under the first explanation the galaxy density would know nothing about the star density, and a steady trend with it across the whole survey would be a coincidence. Under the second the trend is expected: a star close to a galaxy on the sky hides it or spoils the measurement of its brightness and colours, on which the selection cuts act. The trend is also stronger for galaxies of lower surface brightness, the ones most easily spoiled, and only the second explanation predicts that [250]. So the density is modelled as the true density times $A + B\,n_s$, a linear function of the local star density n_s, with A and B fitted in bins of galaxy brightness [Reid2016 eq. (45)], and the weight is the inverse, $w_{\text{star}} = (A + Bn_s)^{-1}$: (13.28) with $f = A + Bn_s$. A second weight w_{see} does the same for the blurring of the images by the atmosphere, the seeing, and the catalogue stores their product, $w_{\text{systot}} = w_{\text{star}}\, w_{\text{see}}$ [Reid2016 eq. (49)]. In our sample 95% of the galaxies have $0.918 < w_{\text{systot}} < 1.263$, with mean 1.011. The correction is small per galaxy, but it varies smoothly over tens of degrees, and on large scales that is exactly the kind of pattern that masquerades as clustering: without it the stellar trend imprints an error larger than the statistical one at $s > 120\,h^{-1}$Mpc [250].

13.16.3 Putting the weights together

How many galaxies does one galaxy stand for? A galaxy with a good redshift stands for itself, plus the $w_{\text{cp}} - 1$ collided targets given to it, plus the $w_{\text{noz}} - 1$ failures given to it. All of these stand-ins are at the same place on the sky, so the same star and seeing correction applies to each. Therefore

$$w_{\text{tot}} \overset{(1)}{=} w_{\text{systot}} \left[1 + (w_{\text{cp}} - 1) + (w_{\text{noz}} - 1)\right] \overset{(2)}{=} w_{\text{systot}} \left(w_{\text{cp}} + w_{\text{noz}} - 1\right) \tag{13.29}$$

(1) The count of galaxies this one represents, each corrected by the angular factor $1/f = w_{\text{systot}}$ of (13.28).
(2) Collect the ones.

which is the total weight of the DR12 catalogues [Reid2016 eq. (50)], [Ross2012 eq. (25)]. Writing the sum minus one, rather than the product $w_{\text{cp}} w_{\text{noz}}$, says that a collided target and a failed redshift are two different missing galaxies, not one galaxy missing twice.

Example: the books balance. Summed over our 208,426 galaxies, $\sum(w_{\text{cp}} + w_{\text{noz}} - 1) = 222986$: the galaxies with redshifts plus the 10164 collided targets and the 4396 failures that they stand for. With the angular weights the total is $\sum w_{\text{tot}} = 225469$, about 1% more, the mean of w_{systot}. Figure 13.28 shows the redshift distribution before and after weighting; the weighted histogram is the one the randoms copy, and it matches the catalogue's `NZ` column.

The FKP weight is a choice, not a correction. The weights so far undo losses. The last one decides how much each part of the survey should count. In Section 11.3.2 we derived that the variance of the measured clustering at wavenumber k is smallest when each region is weighted by $w = 1/(1+\bar{n}P)$, where P is the power at that k (Eq. (11.23)). A sparse region is noisy, because its fluctuations are mostly shot noise, so it gets weight near 1; a dense region is limited by sample variance, so piling up more of its galaxies helps little, and each of them is down-weighted. The catalogue uses $P_0 = 10^4\,h^{-3}\mathrm{Mpc}^3$, the observed power near $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ [Reid2016 eq. (53)], so $w_{\mathrm{FKP}} = 1/(1+\bar{n}(z)\,10^4)$. Recomputing it from the `NZ` column reproduces the stored values to $6.5e-08$. Across our sample it runs from 0.19 at the density peak to 0.69 at the far edge (Figure 13.28, right).

Why the randoms carry the FKP weight but not w_{tot}. The randoms already follow $\bar{n}(\boldsymbol{x})$, the density of a complete survey: their angular density follows the completeness and their redshifts follow the weighted galaxies. The galaxies needed w_{tot} to be brought to that same density. The FKP weight is different: it multiplies the field we analyse, galaxies minus randoms (Eq. (11.17)), and both terms must be multiplied by the same function of position, or the weighted field would not average to zero where there is no clustering. So the final weights are [Reid2016 §6.7]

$$w_i^{\mathrm{gal}} = w_{\mathrm{tot},i}\,w_{\mathrm{FKP},i}, \qquad w_j^{\mathrm{ran}} = w_{\mathrm{FKP},j}. \tag{13.30}$$

Example: one galaxy's weight. A galaxy at $z = 0.50$, where $\bar{n} = 4.2\times10^{-4}\,h^3\mathrm{Mpc}^{-3}$, that received the weight of one collided neighbour ($w_{\mathrm{cp}} = 2$, $w_{\mathrm{noz}} = 1$) in a slightly star-crowded field ($w_{\mathrm{systot}} = 1.05$) has $w_{\mathrm{tot}} = 1.05\times(2+1-1) = 2.10$ and $w_{\mathrm{FKP}} = 1/(1+4.2) = 0.19$, so it enters the pair counts with weight 0.40. An isolated galaxy at $z = 0.68$, where $\bar{n} = 0.7\times10^{-4}$, has $w_{\mathrm{tot}} \approx 1$ and $w_{\mathrm{FKP}} = 0.59$: it counts for half again as much as the first, although the first stands for two galaxies.

13.16.4 Weighted pair counts, and why they still estimate ξ

With weights, the normalised counts of Eq. (11.11) become weighted sums, each divided by the total weight of all possible pairs of its kind:

$$DD(s) = \frac{\sum_{i\neq j} w_i w_j\,[s_{ij}\in\mathrm{bin}]}{\left(\sum_i w_i\right)^2 - \sum_i w_i^2}, \quad DR(s) = \frac{\sum_{i,j} w_i w'_j\,[s_{ij}\in\mathrm{bin}]}{\sum_i w_i \sum_j w'_j}, \tag{13.31}$$

and RR like DD with the random weights w'. Here $[\,\cdot\,]$ is 1 if the pair's separation falls in the bin and 0 otherwise, and the sums run over ordered pairs. The denominator of DD is $\sum_{i\neq j} w_i w_j$, the weight of all ordered pairs with $i \neq j$: the square of the sum contains every product $w_i w_j$ once for each order, including $i = j$, and subtracting $\sum w_i^2$ removes those.

Why the ratio still measures $1+\xi$. Take the galaxies as a Poisson sample of intensity $\lambda(\boldsymbol{x}) = f\bar{n}(1+\delta_g)$, each carrying the weight $w(\boldsymbol{x})$ of (13.30), so that $w\lambda = w_{\mathrm{FKP}}\bar{n}(1+\delta_g)$ on average by (13.28). Write $u(\boldsymbol{x}) \equiv w_{\mathrm{FKP}}(\boldsymbol{x})\bar{n}(\boldsymbol{x})$ for this weighted mean density. For distinct points of a Cox process the density of pairs at $\boldsymbol{x}_1, \boldsymbol{x}_2$ is $\bar{n}_1\bar{n}_2[1+\xi(s)]$ (Eq. (11.6)), so

$$\begin{aligned}\mathbb{E}\Big[\sum_{i\neq j} w_i w_j [s_{ij}\in\mathrm{bin}]\Big] &\overset{(1)}{=} \int\!\!\int u(\boldsymbol{x}_1)\,u(\boldsymbol{x}_2)\,\big[1+\xi(s_{12})\big][s_{12}\in\mathrm{bin}]\,\mathrm{d}V_1\mathrm{d}V_2 \\ &\overset{(2)}{=} \big[1+\bar{\xi}_{\mathrm{bin}}\big]\int\!\!\int u(\boldsymbol{x}_1)\,u(\boldsymbol{x}_2)\,[s_{12}\in\mathrm{bin}]\,\mathrm{d}V_1\mathrm{d}V_2.\end{aligned} \tag{13.32}$$

(1) The pair density times the two weights, integrated over all positions; the weight times the recorded density is u, by (13.28).
(2) In a bin narrow enough that ξ hardly changes across it, $1+\xi$ comes out as its value $1+\bar{\xi}_{\rm bin}$ in the bin.

The random catalogue has intensity proportional to $\bar{n}$ and weights $w_{\rm FKP}$, so its weighted pair count is the same integral without the factor $1+\bar{\xi}$, multiplied by a constant that the normalisations remove. The two survey integrals cancel in the ratio, and $DD/RR \to 1+\bar{\xi}_{\rm bin}$; the Landy–Szalay combination of Section 11.2.1 inherits the same property, with its reduced sensitivity to the edges. The derivation also shows what can go wrong: if the galaxies' weighted density $w\lambda$ and the randoms' weighted density differ in shape, through a systematic not captured by a weight, the cancellation fails and the difference is read as clustering.

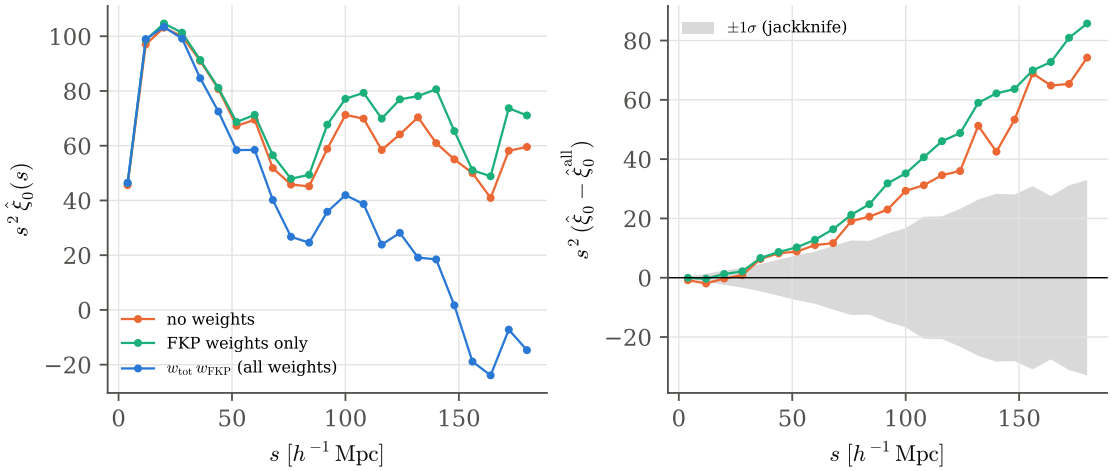

Figure 13.30: What the weights do to the measured monopole. Left: $s^2\hat{\xi}_0$ with no weights, with FKP weights only, and with all weights. Right: the difference from the fully weighted measurement, against the jackknife error band of Section 13.18. Without $w_{\rm tot}$ the clustering beyond 35 h^{-1}Mpc is too high, by more than one error bar over most of that range and by about two at the largest separations.

Figure 13.30 shows the measurement of Section 13.17 with three choices of weights. Below 30 h^{-1}Mpc the three agree to a few per cent. In the first bin, which holds ξ at 4 h^{-1}Mpc, the unweighted value is 1.8% lower, and with the small jackknife error there that is a 2σ difference; the FKP-only measurement reproduces the fully weighted value to a tenth of an error bar. So at small scales it is the redistribution of weight by the FKP factor, not the corrections for the lost galaxies, that matters, and the lost companions of Section 13.16.1, a few per cent of the galaxies, move ξ at 4 h^{-1}Mpc by much less than its error. The large scales are where the weights act. Without $w_{\rm tot}$ the monopole lies above the weighted one at every separation beyond 35 h^{-1}Mpc. The shift is nearly the same in ξ at all of these separations, about 0.003, which is 1–1.5 jackknife errors at 40–70 h^{-1}Mpc and about two errors at 150–180 h^{-1}Mpc, where the error bars are smaller (the right panel multiplies both by s^2). A nearly constant offset is not a feature at one scale but a change in the mean density that the pairs are measured against. That is the signature Ross et al. traced to the density of foreground stars [250]: where stars are dense, fewer galaxies are targeted, and since the stellar density varies smoothly over tens of degrees, the missing galaxies imprint a pattern on very large scales that pair counts read as extra clustering. The weight $w_{\rm star}$ removes the pattern, as (13.28) says it should. Beyond 35 h^{-1}Mpc the FKP weight alone moves the monopole by at most two-thirds of an error bar, since it only reweights galaxies by redshift. In all three versions the bump near 100 h^{-1}Mpc is present; what differs is the smooth shape it sits on, which the broad-band terms of the fit in

Section 13.19 are designed to absorb. Without the corrective weights the broad band would be wrong by more than the statistical error, and any analysis of the full shape of ξ, rather than only of the peak position, would be biased.

13.17 Counting pairs: the correlation function of CMASS South

We now have 208,426 weighted galaxies and, for the counts, 1,042,130 randoms (5 per galaxy) at known positions. The Landy–Szalay estimator of Section 11.2.1,

$$\hat{\xi}_0(s) = \frac{DD(s) - 2DR(s) + RR(s)}{RR(s)}, \tag{13.33}$$

with the weighted, normalised counts of (13.31), asks for three numbers in each separation bin. The subscript 0 says that pairs are counted in every direction, so the result is the angle average, the monopole, of the redshift-space correlation function. The difficulty is only the number of pairs: the randoms alone form 10^{12} ordered pairs, and a double loop that computes each distance would take days.

13.17.1 How a tree counts pairs without visiting them

A k-d tree sorts the points into nested boxes: the whole set is split in half along its longest side, each half again, and so on, until each box holds a few dozen points. For each box the tree stores its corners and the total weight of its points. To count the pairs between two boxes in our bins, `cKDTree.count_neighbors` looks first at the smallest and the largest distance that any point in one box can have from any point in the other, which follow from the corners alone.

- If both lie inside the same bin, every pair between the two boxes is in that bin, and the product of the two total weights is added at once.
- If both lie beyond the last bin edge, no pair counts, and the boxes are skipped.
- Otherwise the boxes are split and their children are compared.

Example. Two boxes of side 10 h^{-1}Mpc whose centres are 100 h^{-1}Mpc apart contain pairs from $100 - 17$ to $100 + 17$ h^{-1}Mpc (the diagonal of a cube of side 10 is 17), which spans five of our 8 h^{-1}Mpc bins; they must be opened. Two boxes of side 2 h^{-1}Mpc at the same distance span at most 3.5 h^{-1}Mpc, and most such pairs of boxes fall inside one bin. The work is therefore spent on box pairs that straddle a bin edge, a small fraction of all pairs, and the counts are exact. (The script of Section 11.2.4 used the same routine in two dimensions.) The cost still grows with the number of pairs inside the largest separation, which is why we stop at 184 h^{-1}Mpc and use 5 randoms per galaxy rather than the fifty of the BOSS analyses [251]. The random catalogue's own counting noise shrinks as the number of randoms grows; at five per galaxy it is a small addition to the counting noise of the galaxies, which is itself smaller than the sample variance at the acoustic scale for a sample with $\bar{n}P$ between 1 and 4 (Section 13.15.3).

13.17.2 Counts for the jackknife at no extra cost

Section 13.18 will need the correlation function recomputed 120 times, each time with one patch of sky left out. Recounting all pairs each time would multiply the cost by 120. It is not necessary, because a pair count is a sum over pairs, and a sum can be split by where the pairs live.

Divide the footprint into regions $k = 1, \dots, 120$ (the colours of Figure 13.27). For two sets of points A and B write $C(A, B)$ for the weighted count of ordered pairs with the first member in A and the second in B, in a given bin, and let D be all galaxies, D_k those in region k, and R, R_k the same for the randoms. Leaving region k out removes every pair with at least one member in D_k. Those are the pairs whose first member is in D_k, plus those whose second member is in D_k, minus the pairs counted twice, which have both members in D_k:

$$DD_{-k} \overset{(1)}{=} C(D,D) - \big[C(D_k,D) + C(D,D_k) - C(D_k,D_k)\big]$$
$$\overset{(2)}{=} C(D,D) - 2\,C(D_k,D) + C(D_k,D_k), \tag{13.34}$$
$$DR_{-k} \overset{(3)}{=} C(D,R) - C(D_k,R) - C(D,R_k) + C(D_k,R_k), \tag{13.35}$$

and RR_{-k} like DD_{-k} with R in place of D.

(1) The number of elements in a union of two sets is the sum of their numbers minus the number in their intersection (inclusion–exclusion).
(2) A distance does not care about the order of the pair, so $C(D, D_k) = C(D_k, D)$.
(3) For galaxy–random pairs the two members are of different kinds: remove pairs whose galaxy is in region k and pairs whose random is in region k, and add back the pairs where both are.

So for each region we compute five counts, $C(D_k, D)$, $C(D_k, D_k)$, $C(D_k, R)$, $C(D, R_k)$, $C(D_k, R_k)$, and two more for the randoms, $C(R_k, R)$ and $C(R_k, R_k)$. Summing $C(D_k, D)$ over k gives the full count $C(D, D)$, so the full measurement is a by-product, and the total work is about that of one full count. The normalisations of (13.31) are recomputed for each leave-one-out sample from the sums of the weights outside region k.

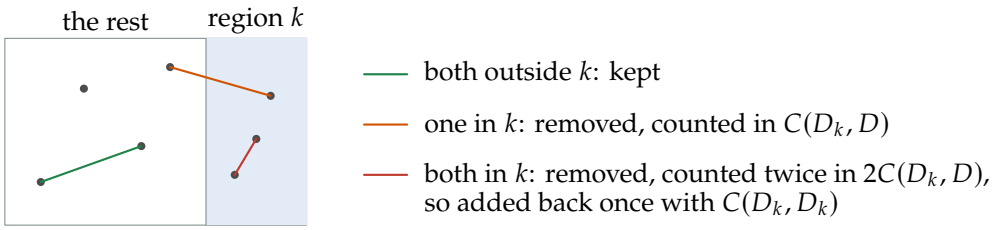

Figure 13.31: Leaving one region out of a pair count. A pair with one member in region k appears once, in $C(D_k, D)$ or in $C(D, D_k)$ according to its order. A pair with both members in k appears in both of those, so subtracting $2C(D_k, D)$ removes it twice, and $C(D_k, D_k)$ restores one copy.

13.17.3 The code, and what it measured

Listing 13.8: Region-by-region pair counts and the Landy–Szalay estimator (`code/ch13/22_cmass_xi.py`)

```
def region_counts(args):
    """Counts that involve region k: C(k, all) and C(k, k) for DD, DR (both ways) and RR."""
    k, wname = args
    wgal, wran = WEIGHTS[wname]
    ig, ir = np.flatnonzero(rg == k), np.flatnonzero(rr == k)
    tgk, trk = cKDTree(xg[ig]), cKDTree(xr[ir])
    out = {

    wgal[ig]),
        "dr_ka": pairs(tgk, TR, wgal[ig], wran), "dr_ak": pairs(TG, trk, wgal, wran[ir]),
        "dr_kk": pairs(tgk, trk, wgal[ig], wran[ir]),
```

```
    }
    if wname != "fkp":                          # "fkp" has the same random weights as "full"
        out["rr_ka"] = pairs(trk, TR, wran[ir], wran)
        out["rr_kk"] = pairs(trk, trk, wran[ir], wran[ir])
    out["wg"], out["wg2"] = wgal[ig].sum(), (wgal[ig] ** 2).sum()
    out["wr"], out["wr2"] = wran[ir].sum(), (wran[ir] ** 2).sum()
    return out

def landy_szalay(DD, DR, RR, Wg, Sg, Wr, Sr):
    """xi_LS = (DD - 2 DR + RR)/RR with each count divided by its total number of weighted
    pairs."""
    dd = DD / (Wg ** 2 - Sg)                    # ordered pairs i != j: (sum w)^2 - sum w^2
    dr = DR / (Wg * Wr)
    rr_ = RR / (Wr ** 2 - Sr)
    return (dd - 2 * dr + rr_) / rr_
```

`pairs` calls the tree with the bin edges $0, 8, \ldots, 184\,h^{-1}$Mpc and the weights of both sets, and drops the first entry, which holds the pairs at zero distance: a point paired with itself. `region_counts` builds small trees for the galaxies and randoms of one region and counts them against the full trees, the five plus two counts listed above. `landy_szalay` is (13.33) with the normalisations of (13.31). The regions are independent of each other, so the script farms them out to 8 processes; the fully weighted measurement took 338 s.

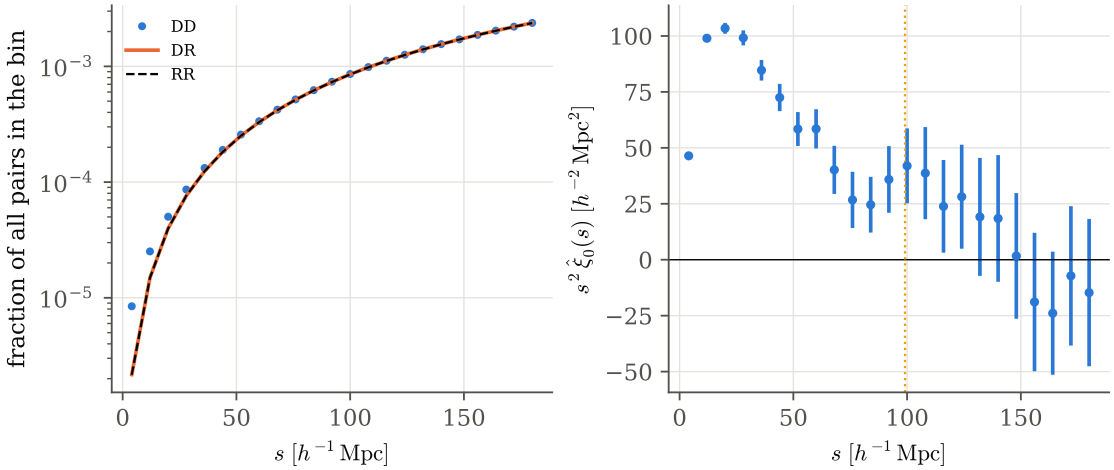

Figure 13.32: Left: the three weighted, normalised pair counts. Beyond $50\,h^{-1}$Mpc they differ by a few per cent at most, too little to see on a logarithmic axis; the correlation function lives in these small differences. Right: the Landy–Szalay monopole times s^2, with jackknife error bars (Section 13.18). The dotted line marks the fiducial sound horizon, $r_d h = 99.09\,h^{-1}$Mpc.

Figure 13.32 is the measurement. The three counts on the left follow the geometry of the survey: they rise as s^2, since a shell of radius s holds a volume growing as s^2, and grow more slowly once the shell starts to leave the survey. Only at small separations does DD visibly exceed RR; beyond $50\,h^{-1}$Mpc they agree to a few per cent, and the correlation function is that small excess. On the right, multiplying by s^2 makes the slow decay of ξ_0 visible on a linear axis, and a modest bump rises above the declining trend near $100\,h^{-1}$Mpc, close to the fiducial ruler $r_d h$. At $s = 100\,h^{-1}$Mpc we measure $\hat{\xi}_0 = (4.20 \pm 1.67) \times 10^{-3}$: a one-part-in-two-hundred excess of pairs, read off from 1.092×10^9 ordered galaxy pairs closer than $184\,h^{-1}$Mpc. Whether the bump is the acoustic peak or a fluctuation is a question for an error bar and a fit.

13.18 Error bars from the data alone: the jackknife

In the mock surveys of Section 11.4.4 the covariance of $\hat{\xi}$ came from fifteen hundred simulated boxes. The BOSS analyses did the same with about a thousand simulated copies of the real survey, each with its footprint, its density and its redshift distribution [197, 251]. Producing those copies is a research project in itself. We have one sky. The question an error bar answers is: if we could observe another patch of the Universe with the same shape and the same galaxies, how different would $\hat{\xi}_0$ be? We cannot observe another patch. But the survey is made of many smaller patches, and how much the answer moves when one of them is left out tells us how much it depends on which galaxies we happened to observe. That is the idea of the **jackknife**, a cousin of the bootstrap of Section 3.15 and of the leave-one-group-out error of Section 11.12.3.

13.18.1 The simplest case first: the mean of N numbers

Take N independent measurements $x_1, \dots, x_N$ with a common variance σ^2, and the estimate $\bar{x}$. Its variance is σ^2/N, estimated by s^2/N with $s^2 = \sum_k (x_k - \bar{x})^2/(N-1)$. The jackknife reaches the same number without knowing that the estimate is a mean. Leave out measurement k and recompute: $\bar{x}_{-k} = (N\bar{x} - x_k)/(N-1)$. The average of these N leave-one-out values is $\bar{x}$ itself, because each x_j is left out exactly once. How far does each leave-one-out value sit from it?

$$\bar{x}_{-k} - \bar{x} \overset{(1)}{=} \frac{N\bar{x} - x_k - (N-1)\bar{x}}{N-1} = \frac{\bar{x} - x_k}{N-1},$$

$$\frac{N-1}{N}\sum_{k=1}^{N}\big(\bar{x}_{-k} - \bar{x}\big)^2 \overset{(2)}{=} \frac{N-1}{N}\,\frac{1}{(N-1)^2}\sum_{k=1}^{N}(x_k - \bar{x})^2 \overset{(3)}{=} \frac{1}{N}\,\frac{\sum_k (x_k - \bar{x})^2}{N-1} = \frac{s^2}{N}. \tag{13.36}$$

(1) Put both terms over the common denominator $N-1$.
(2) Square the first line and sum over k.
(3) Cancel one factor of $N-1$.

So the jackknife variance, $\frac{N-1}{N}\sum_k (\bar{x}_{-k} - \bar{x})^2$, is exactly the usual estimate of the variance of a mean. The prefactor is the surprising part. For N independent repetitions we would divide by $N-1$; here we multiply by $N-1$. The leave-one-out values are far closer to each other than independent repetitions would be, because any two of them share $N-2$ of their $N-1$ measurements: each deviation is the deviation of one measurement shrunk by $1/(N-1)$, and the prefactor undoes that shrinkage.

Example: three numbers. For $x = (1, 2, 6)$, $\bar{x} = 3$ and $s^2 = (4 + 1 + 9)/2 = 7$, so $s^2/N = 2.33$. Leaving one out gives 4, 3.5, 1.5, which average to 3 with deviations 1, 0.5, −1.5; the jackknife gives $\frac{2}{3}(1 + 0.25 + 2.25) = 2.33$. The same number, from a recipe that only needed to recompute the estimate.

Working definition 13.2 (jackknife covariance)

Split the data into N subsets [here, 120 patches of sky of similar area]. Recompute the estimate with subset k removed, giving the vector $\hat{\xi}_{-k}$ [the binned correlation function without patch k], for each k, and let $\bar{\xi}$ be their average. Then

$$\hat{\mathbf{C}}_{\mathrm{JK}} = \frac{N-1}{N}\sum_{k=1}^{N}\big(\hat{\xi}_{-k} - \bar{\xi}\big)\big(\hat{\xi}_{-k} - \bar{\xi}\big)^{\mathsf{T}}. \tag{13.37}$$

Operationally: Section 13.17.2 gives every $\hat{\xi}_{-k}$ from region-by-region pair counts at the cost of one measurement.

The off-diagonal elements come for free: if leaving out a patch raises $\hat{\xi}$ in one bin, it usually raises it in the neighbouring bins too, because the same pairs and the same structures contribute to both, and (13.37) records that co-movement as a covariance.

13.18.2 What the jackknife gets wrong

For a mean, (13.36) is exact. For any other statistic of independent data, Efron and Stein proved that the jackknife variance is biased upward in expectation: on average it is too large, never too small [252]. The smallest example is the square of a mean, $\hat{\theta} = \bar{x}^2$, for N Gaussian measurements of mean μ and variance σ^2. Its true variance is that of the square of a Gaussian variable of mean μ and variance σ^2/N, namely $4\mu^2\sigma^2/N + 2\sigma^4/N^2$. With $d_k = \bar{x}_{-k} - \bar{x} = (\bar{x} - x_k)/(N-1)$ from (13.36),

$$\begin{aligned}
\hat{\theta}_{-k} - \hat{\theta} &\overset{(1)}{=} (\bar{x} + d_k)^2 - \bar{x}^2 = d_k\,(2\bar{x} + d_k), \\
\frac{N-1}{N}\sum_k \big(\hat{\theta}_{-k} - \hat{\theta}\big)^2 &\overset{(2)}{=} \frac{N-1}{N}\Big[4\bar{x}^2\sum_k d_k^2 + 4\bar{x}\sum_k d_k^3 + \sum_k d_k^4\Big] \overset{(3)}{=} \frac{4\bar{x}^2 s^2}{N} + O(N^{-3}), \\
\mathbb{E}\Big[\frac{4\bar{x}^2 s^2}{N}\Big] &\overset{(4)}{=} \frac{4}{N}\Big(\mu^2 + \frac{\sigma^2}{N}\Big)\sigma^2 = \frac{4\mu^2\sigma^2}{N} + \frac{4\sigma^4}{N^2}.
\end{aligned} \tag{13.38}$$

(1) Square out the bracket.
(2) Square the first line and sum. The sum is centred on $\hat{\theta}$ rather than on the average of the leave-one-out values, which differs from it by $O(N^{-2})$ and changes the result only at order N^{-3}.
(3) $\sum_k d_k^2 = s^2/(N-1)$ by (13.36). For a Gaussian sample $\bar{x}$ is independent of the deviations $x_k - \bar{x}$, so $\sum_k d_k^3$, odd in them, averages to zero, and $\sum_k d_k^4 \sim 3\sigma^4/N^3$.
(4) $\mathbb{E}[\bar{x}^2] = \mu^2 + \sigma^2/N$, because $\bar{x}$ has mean μ and variance σ^2/N, and $\mathbb{E}[s^2] = \sigma^2$.

The first term of the jackknife variance is the standard error-propagation result $(2\mu)^2\sigma^2/N$, and its next term, $4\sigma^4/N^2$, is twice the $2\sigma^4/N^2$ of the true variance. The jackknife is too large, here by a second-order amount that fades as N grows, in line with the theorem. A correlation function from patches of sky bends the inputs of that result in three ways.

- *The patches are not independent.* Neighbouring patches share large structures, and a fluctuation larger than a patch moves several of them together; the leave-one-out values then move together too, and that part of the variance is under-represented. Fluctuations on scales larger than the whole survey are invisible to any internal method.
- *Pairs straddle the boundaries.* Removing a patch removes the pairs between it and its neighbours as well. Our patches are about 21 deg^2, some 120 h^{-1}Mpc across on the sky at the sample's distance, so at the acoustic scale most of the pairs that a patch removes cross its boundary.
- *The patches are unequal.* Ours hold between 1018 and 2466 galaxies, while the derivation assumed exchangeable pieces.

Norberg et al. compared jackknife errors with the scatter of many simulated surveys [253]. The jackknife returned the right variance on large scales and too large a variance on small scales, and its errors were noisy enough that an interval quoted as 2σ from it could correspond to anything from 1σ to 3σ. We should therefore read our error bars as good to some tens of per cent, which is the price of not having mocks.

Inverting a noisy matrix. The fit of Section 13.19 needs $\hat{\mathbf{C}}^{-1}$, and the inverse of a noisy covariance estimate is biased high: noise makes some directions look better measured than

they are. For a covariance from N independent Gaussian samples and n_b bins, multiplying the inverse by $(N - n_b - 2)/(N - 1)$ removes the bias (Section 8.13.2). With $N = 120$ jackknife samples and the $n_b = 19$ bins of the fit this factor is 0.832. Jackknife samples are not independent draws, so the factor is only a guide; it is the reason for using many regions.

13.18.3 A check against the published mocks

There is one test we can make. Cuesta et al. published the CMASS monopole of the whole sample, north and south, with error bars from 956 simulated surveys [251]. How should our errors compare with theirs? The variance of a clustering measurement comes from the finite number of independent Fourier modes in the volume, and that number is proportional to the volume (the mode count of Section 11.4.5). At the same redshifts and density the error therefore scales as $V^{-1/2}$, so a sample with 3.71 times our area should have errors $\sqrt{9376/2525} = 1.93$ times smaller.

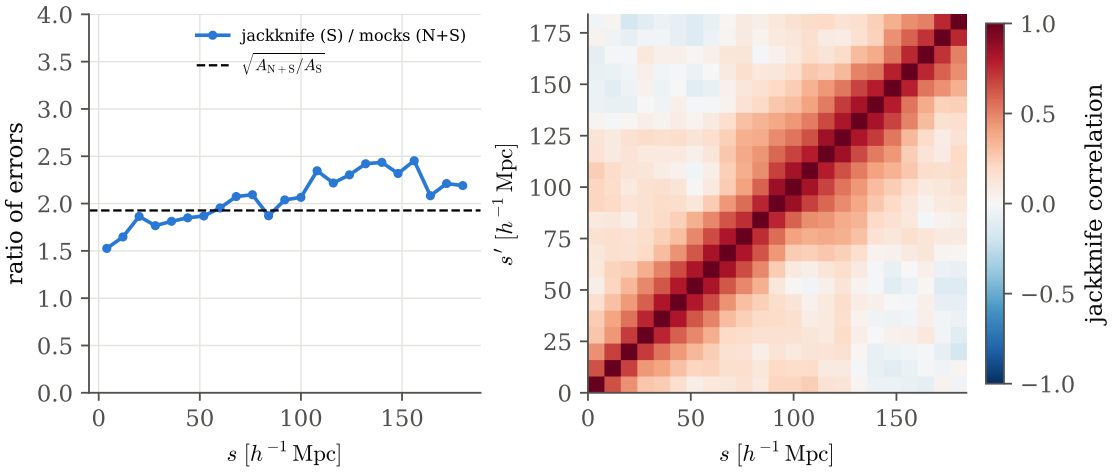

Figure 13.33: Left: our jackknife error on $\hat{\xi}_0$ (south only) divided by the mock error of the published north-plus-south measurement, bin by bin; the dashed line is the ratio $\sqrt{A_{N+S}/A_S}$ expected from the areas alone. Right: the correlation matrix of our jackknife covariance; neighbouring bins are strongly correlated, as they share pairs and structures.

Figure 13.33 shows the comparison. Over the fitted range $30 < s < 180\,h^{-1}$Mpc the median ratio is 2.09, against 1.93 expected from the areas: our jackknife errors are 1.09 times what scaling the mock errors would give. That is within the tens of per cent expected of a jackknife, and since the two error bars come from entirely different routes, one from the data alone and one from a thousand simulations, it is a real test of both. The right panel shows that neighbouring bins are strongly correlated. A fit that used only the diagonal errors would count the same information several times, which is why the fit uses the full matrix.

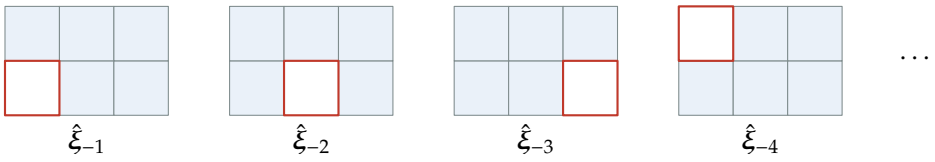

Figure 13.34: The jackknife in pictures: the footprint (six patches drawn here; 120 in the analysis) is measured again and again, each time with one patch removed (red). The spread of the leave-one-out results, multiplied by $(N - 1)/N$, is the covariance.

13.19 The acoustic peak of CMASS South, and the BOSS distance

The ratio $D_V(z)/r_d$ has appeared twice before. In Section 11.4.1 we saw why a galaxy survey measures it: the acoustic shell has a comoving radius r_d fixed in the early Universe, and the survey sees that shell at a size set by the distance to the galaxies, so only the ratio of the two is observed. In Section 11.4.6 we set the published DESI values of D_V/r_d beside the prediction of the Planck 2018 model and found them within one or two standard deviations of it, with errors of one to two per cent. Those were numbers someone else had measured. Now the same ratio comes out of our own pipeline, at the redshift $z_{\rm eff} = 0.565$ of the CMASS galaxies, from the correlation function $\hat{\xi}_0(s)$ of Section 13.17 and the jackknife covariance of Section 13.18. What is new is that nothing has been done for us: the coordinates, the weights, the pair counts and the error bars are all ours, and the comparison is with collaborations that measured the same galaxies.

13.19.1 Their question

When BOSS released its ninth data set in 2012, the acoustic peak had been seen in galaxy surveys for seven years, but never with enough galaxies to measure its position to better than a few per cent. Anderson et al. asked whether the first 264,283 CMASS galaxies could detect the peak beyond reasonable doubt and turn it into a distance at $z = 0.57$ precise to two per cent [235]. They found the peak at about 5σ and $D_V(0.57)/r_s = 13.67 \pm 0.22$, a 1.7% distance [Anderson2012 abstract, Table 2]. Four years later the survey was complete. Cuesta et al. repeated the measurement on all 777,202 CMASS galaxies of the final release [251], and Alam et al. combined it with the other BOSS analyses into the collaboration's final distances at three redshifts [197].

Our question is narrower. With 27% of the final sample (the southern cap, Table 13.8) and with error bars from the data alone, do we see the same peak, how strongly, and do we get a distance consistent with theirs?

13.19.2 Their setup, in plain terms

Every BAO analysis makes the same four choices, and the numbers in Table 13.9 are those choices for the three analyses we compare.

A fiducial cosmology. To turn $(\mathrm{RA}, \mathrm{Dec}, z)$ into positions one needs a distance–redshift relation (Section 13.15.3), so each analysis picks a cosmology and works in its coordinates. Anderson et al. used a model close to WMAP's ($\Omega_m = 0.274$, $h = 0.7$); Cuesta et al. used the cosmology of their simulated surveys ($\Omega_m = 0.29$, $h = 0.7$); we use the Planck 2018 model of Section 13.15.3. A wrong choice does not bias the answer; it only moves the peak, which is exactly what α measures.

A template. The model fitted to the data is (11.30): a damped acoustic template ξ_t, stretched by α, with an amplitude B^2 and three smooth terms $a_0 + a_1/s + a_2/s^2$ that absorb what is not modelled. The template is computed in some cosmology, and its bump sits at that cosmology's sound horizon, which we call the **template ruler** $r_d^{\rm tmpl}$.

A covariance. Anderson et al. and Cuesta et al. took it from 600 and 956 simulated copies of the survey; we take it from 120 jackknife regions.

A fit range and binning. All use the monopole in bins of $8\,h^{-1}$Mpc; Cuesta et al. and we fit $30 < s < 180\,h^{-1}$Mpc.

	Anderson et al. 2012	Cuesta et al. 2016	ours
sample	DR9 CMASS	DR12 CMASS, N+S	DR12 CMASS, S
galaxies	264,283	777,202	208,426
effective area [deg^2]	3,275	9,376	2,525
fiducial Ω_m, h	0.274, 0.70	0.29, 0.70	Planck 2018
template ruler [Mpc]	153.19 (fitting formula)	147.10	147.10
$D_V^{\rm fid}(z)$ [Mpc]	2026.49 at 0.57	2009.55 at 0.57	2048 at 0.565
covariance	600 mocks	956 mocks	120 jackknife regions
damping $\Sigma_{\rm nl}$ [h^{-1}Mpc]	8	from mocks	8

Table 13.9: The three analyses of the CMASS monopole before reconstruction [Anderson2012 §§3–5], [Cuesta2016 §§2–4, Tables 2, 5]. Our template ruler happens to agree with Cuesta et al.'s to the quoted digits, although the two cosmologies differ: theirs has a lower h and a higher $\Omega_m h^2$.

13.19.3 Their key equation: from a stretch to a distance

All three papers report D_V/r_d through one equation, $D_V/r_d = \alpha\, D_V^{\rm fid}/r_d^{\rm tmpl}$. Section 11.4.1 derived it in the special case where the coordinates and the template use the same cosmology. Comparing three analyses with three cosmologies, and refitting one paper's data with our template, needs the general case, with the coordinate cosmology ("fid") and the template cosmology ("tmpl") kept apart.

The event. The fit finds the template's bump best matched when it is stretched by α. *What does that say about the Universe?* Follow the true acoustic shell, of radius r_d, into the data, and the template's bump into the model, and ask where each one lands.

$$
\begin{aligned}
r_{\rm app} &\overset{(1)}{=} r_d\,\frac{D_V^{\rm fid}}{D_V}, \\
\xi_t(\alpha s)\ \text{peaks at}\ \alpha s = r_d^{\rm tmpl} &\overset{(2)}{=} \quad s = \frac{r_d^{\rm tmpl}}{\alpha}, \\
\frac{r_d^{\rm tmpl}}{\alpha} = r_d\,\frac{D_V^{\rm fid}}{D_V} &\overset{(3)}{=} \quad \frac{D_V}{r_d} = \alpha\,\frac{D_V^{\rm fid}}{r_d^{\rm tmpl}}.
\end{aligned}
\tag{13.39}
$$

(1) A true separation r is placed at $r\,D^{\rm fid}/D$ in the fiducial coordinates (Eq. (11.26)); for the angle-averaged monopole the relevant distance is the volume average D_V of (11.27). Here $r_{\rm app}$ is where the true shell appears in the data.

(2) The template $\xi_t(s)$ has its bump at $s = r_d^{\rm tmpl}$; the stretched model $\xi_t(\alpha s)$ has it where its argument equals $r_d^{\rm tmpl}$.

(3) The fit puts the model's bump where the data's bump is; solve for D_V/r_d.

In the special case of Section 11.4.1, $r_d^{\rm tmpl} = r_d^{\rm fid}$ and (13.39) is $D_V/r_d = \alpha\,(D_V/r_d)^{\rm fid}$, which is (11.27).

Where h goes. Positions are measured in h^{-1}Mpc. A distance in these units, $D^{\rm fid}[h^{-1}{\rm Mpc}] = (c/100\,{\rm km\,s^{-1}})\int_0^z {\rm d}z'/E(z')$, depends only on $\Omega_m^{\rm fid}$ and not on h; the template, computed from a power spectrum in $h\,{\rm Mpc}^{-1}$, has its bump at $r_d^{\rm tmpl}[{\rm Mpc}] \times h^{\rm tmpl}$. So (13.39) holds with both $D_V^{\rm fid}$ and $r_d^{\rm tmpl}$ in h^{-1}Mpc, each converted with its own cosmology's h, and the result is a pure number.

Example: our own conversion. In our Planck coordinates $D_V^{\rm fid}(0.565) = 1379.5\,h^{-1}$Mpc, and our template's ruler is $r_d^{\rm tmpl}h = 99.09\,h^{-1}$Mpc, so $D_V^{\rm fid}/r_d^{\rm tmpl} = 13.92$. This is the Planck prediction itself, because the fiducial model is the Planck model: a fit that returned $\alpha = 1$ would say that the galaxies are where Planck says they should be.

Example: Cuesta et al.'s number. Their fit gave $\alpha = 1.0153 \pm 0.0134$ before reconstruction [Cuesta2016 Table 10], in coordinates with $D_V^{\rm fid}(0.57) = 2009.55$ Mpc and with a template whose ruler is 147.10 Mpc; both use $h = 0.7$, which cancels. Then

$$\frac{D_V}{r_d} = 1.0153 \times \frac{2009.55}{147.10} = 1.0153 \times 13.661 = 13.87, \qquad \sigma = 0.0134 \times 13.661 = 0.18,$$

the value quoted in their §4.4 (where systematic errors raise the error to 0.19).

Example: a ruler with a different name. Anderson et al. quoted $D_V/r_s = 13.44 \pm 0.22$ from the correlation function [Anderson2012 Table 2], where r_s is the sound horizon from a fitting formula of Eisenstein and Hu [104], 153.19 Mpc in their fiducial model. CAMB's integral (11.25) for the same model gives $r_d = 149.28$ Mpc, the value BOSS adopted for that cosmology in later papers [Cuesta2016 §3]. Both are names for the same physical ruler; they differ because the formula is a fit to the integral, and their ratio is almost independent of cosmology near the fiducial model. By (13.39) the fitted α is the same whatever the ruler is called, so

$$\frac{D_V}{r_d} = \frac{D_V}{r_s} \times \frac{r_s^{\rm fid}}{r_d^{\rm fid}} = 13.44 \times \frac{153.19}{149.28} = 13.44 \times 1.0262 = 13.79,$$

with error 0.23. A 2.6% difference in convention is larger than the 1.6% error of the measurement itself, which is why a paper's ruler must be identified before its number is compared with anything.

13.19.4 What we compute

The script `code/ch13/23_cmass_bao.py` fits the model (11.30) to two data sets with the same function: our monopole with the jackknife covariance, and the published monopole of all CMASS galaxies with its mock covariance.

Listing 13.9: The fit: $\chi^2(\alpha)$ with the linear coefficients profiled out (`code/ch13/23_cmass_bao.py`)

```
def fitter(s, edges, d, C, nmock):
    """chi^2(alpha) for both templates with the linear coefficients profiled out (GLS)."""
    m = (s > SMIN) & (s < SMAX + 1)
    s_, d_, nb = s[m], d[m], int(m.sum())
    Cm = C[np.ix_(m, m)]
    hart = (nmock - nb - 2) / (nmock - 1)
    Ci = hart * np.linalg.inv(Cm)
    e = np.concatenate([edges[:-1][m], [edges[1:][m][-1]]])
    res = {}
    for name, xf in [("w", xi_w_fine), ("nw", xi_nw_fine)]:
        chi2, coefs = [], []
        for a in ALPHAS:
            X = np.column_stack([binned(xf, e, a), np.ones(nb), 1 / s_, 1 / s_ ** 2])
            b = np.linalg.solve(X.T @ Ci @ X, X.T @ Ci @ d_)
            r = d_ - X @ b
            chi2.append(r @ Ci @ r)
            coefs.append(b)
        chi2 = np.array(chi2)
```

```
        i = int(np.argmin(chi2))
        p = np.exp(-0.5 * (chi2 - chi2.min()))
        p /= p.sum()
        mean = np.sum(p * ALPHAS)
        sd = np.sqrt(np.sum(p * ALPHAS ** 2) - mean ** 2)
        res[name] = dict(chi2=chi2, i=i, alpha=ALPHAS[i], mean=mean, sd=sd, coef=coefs[i],
    chimin=chi2[i])
    res["dchi2"] = res["nw"]["chimin"] - res["w"]["chimin"]
    res["nb"], res["hart"], res["mask"], res["edges"] = nb, hart, m, e
    return res
```

The mask keeps the bins of the fit range. The inverse covariance is multiplied by the Hartlap factor of Section 13.18.2, here with the number of jackknife regions standing in for the number of simulations. For each α on a grid from 0.8 to 1.2, the design matrix holds the stretched template, bin-averaged by `binned` with weight s^2 because the number of pairs in a thin shell grows as s^2, and the three smooth terms; the next line is the generalised least-squares solution for (B^2, a_0, a_1, a_2) (Section 3.10.5). The resulting $\chi^2(\alpha)$ is turned into a posterior with a flat prior on the grid, $p(\alpha) \propto e^{-\chi^2(\alpha)/2}$ (Section 11.4.2), whose mean and standard deviation are reported. The same loop with the no-wiggle template gives the $\Delta\chi^2$ of (11.31). The template is the one of Section 11.4.2: the Planck linear spectrum from CAMB, its wiggles damped with $\Sigma_{\rm nl} = 8\,h^{-1}$Mpc as appropriate before reconstruction.

13.19.5 Side by side

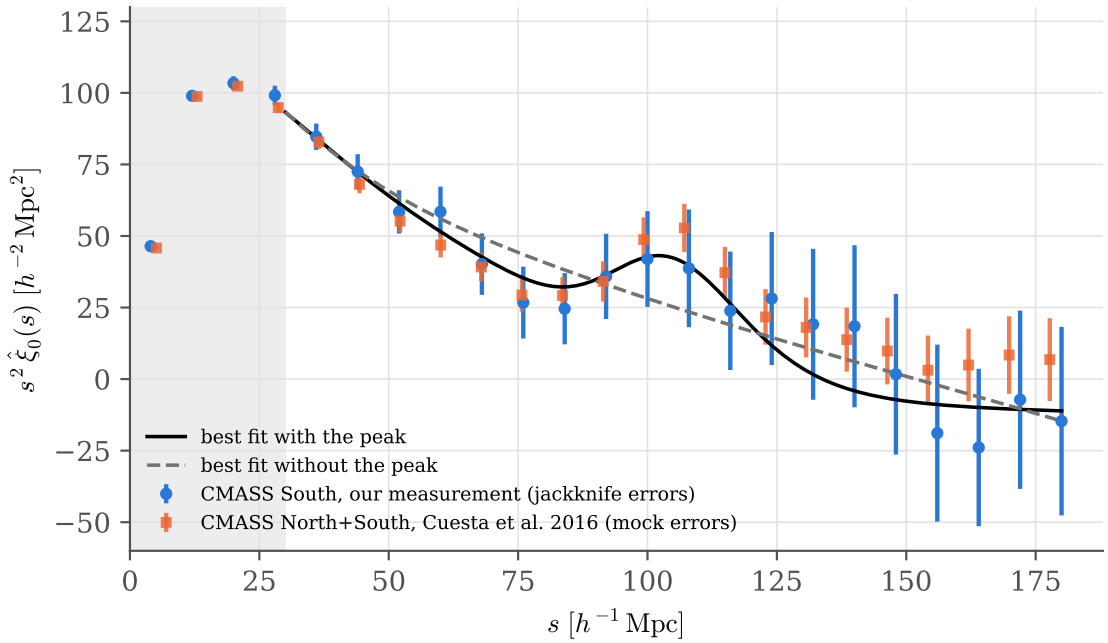

Figure 13.35: Our monopole of the southern cap (blue) and the published monopole of the whole CMASS sample (orange), both times s^2. The published separations are rescaled by 0.9807, the ratio of the two fiducial D_V, to put them in our coordinates. Lines: our best fits with and without the acoustic feature. The grey band is outside the fit range.

Figure 13.35 sets the two measurements on one axis. Below 90 h^{-1}Mpc they agree point by point within the error bars. Both show the bump. Ours is lower between 105 and 120 h^{-1}Mpc, and beyond 150 h^{-1}Mpc our points scatter by more than the published ones, as their error bars, about twice as large, say they should. The southern cap is part of the whole sample, so the

agreement at small separations is not a test of independent data; it is a test that our coordinates, weights and estimator reproduce theirs.

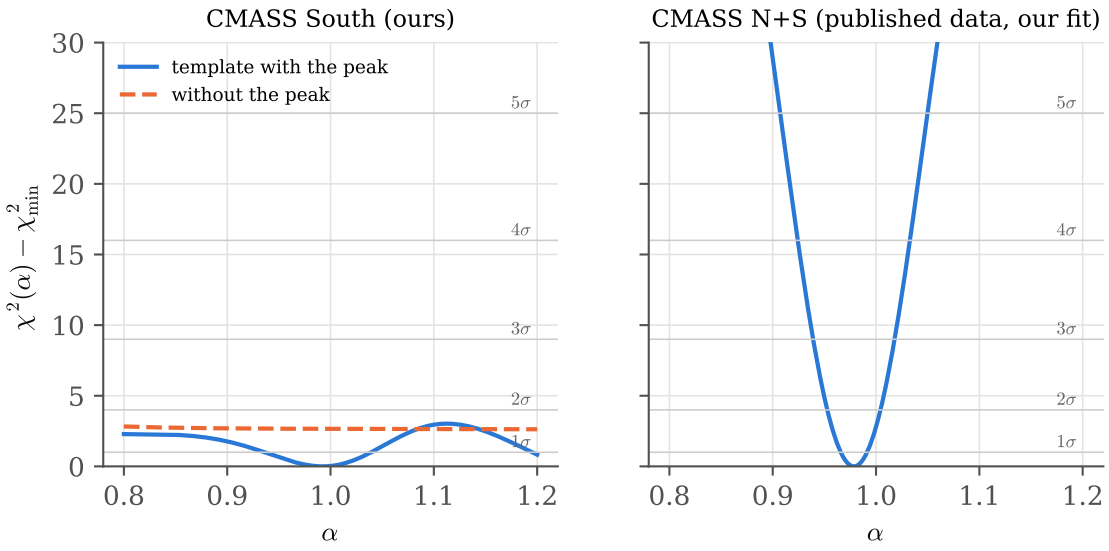

Figure 13.36: $\chi^2(\alpha) - \chi^2_{\rm min}$ for the template with the acoustic feature (solid) and without it (dashed), for our southern measurement (left) and for the published monopole of the whole sample refitted with our code (right). Grey lines: the $\Delta\chi^2 = n^2$ levels.

The published data, refitted. The right panel of Figure 13.36 is the textbook case. $\chi^2(\alpha)$ is a deep parabola with its minimum at $\alpha = 0.979 \pm 0.013$; the template without a peak is worse by $\Delta\chi^2 = 37.2$, a 6.1σ detection by the rule of (11.31). With (13.39), our template and their fiducial distance $D_V^{\rm fid} h = 1406.7\, h^{-1}$Mpc, this is $D_V/r_d = 13.89 \pm 0.18$, against their 13.87 ± 0.18. Our α differs from theirs by almost four per cent while the distances agree to a fraction of a per cent. Nothing went wrong: α is not a property of the Universe but of the pair (coordinates, template), and our template ruler in h^{-1}Mpc, 99.09 against $147.10 \times 0.7 = 102.97$, is shorter than theirs by the same fraction. Their result is reproduced by an independent code with an independent template.

Our southern measurement. The left panel is a different picture. The curve has a clear minimum at $\alpha = 0.992$, with $\chi^2_{\rm min} = 10.6$ for 14 degrees of freedom, a good fit. But it never rises far: within the grid it climbs at most 3.0 above its minimum, and the template without a peak is worse by only $\Delta\chi^2 = 2.6$. Anderson et al. separated two questions that a curve like this keeps apart [Anderson2012 §5].

- *Is there a peak?* The gap between the two curves at their minima. Ours is 2.6, so the acoustic feature is preferred at 1.6σ. As a test (Chapter 4), the null hypothesis is the smooth template, whose noise we know: if there were no acoustic feature, would a gain of 2.6 or more in χ^2 be something to expect? The tail of χ^2 with one degree of freedom beyond 2.6 is 0.11, one chance in nine, so yes, and the extra freedom of α only makes such gains more common. The same tail beyond the whole sample's 37.2 is 10^{-9}.
- *Where is it?* How far the solid curve rises away from its minimum. Near the minimum $\Delta\chi^2 < 1$ for $0.936 < \alpha < 1.038$, a local error of ± 0.051. Farther out the curve flattens into a plateau, because a template stretched far from the data's bump puts its own bump where there is none, and the smooth terms then fit almost as well as without a bump.

The plateau decides the posterior's width. At $\alpha = 0.8$ the curve is only 2.3 above its minimum, so $p(\alpha)$ there is still 0.32 of its peak value, and the standard deviation over the grid, $\sigma_\alpha = 0.101$, is set as much by the edges of the flat prior as by the data. A wider prior would give a wider error. This is what a weak detection looks like, and the right summary of our measurement is two numbers: $\alpha = 0.997 \pm 0.101$ over the prior $0.8 < \alpha < 1.2$, or ± 0.051 if one accepts that the minimum at 0.992 is the acoustic peak. Through (13.39),

$$\frac{D_V(0.565)}{r_d} = 13.88 \pm 1.41 \quad \text{(local: } \pm 0.71\text{)}, \qquad \text{Planck: } 13.92. \tag{13.40}$$

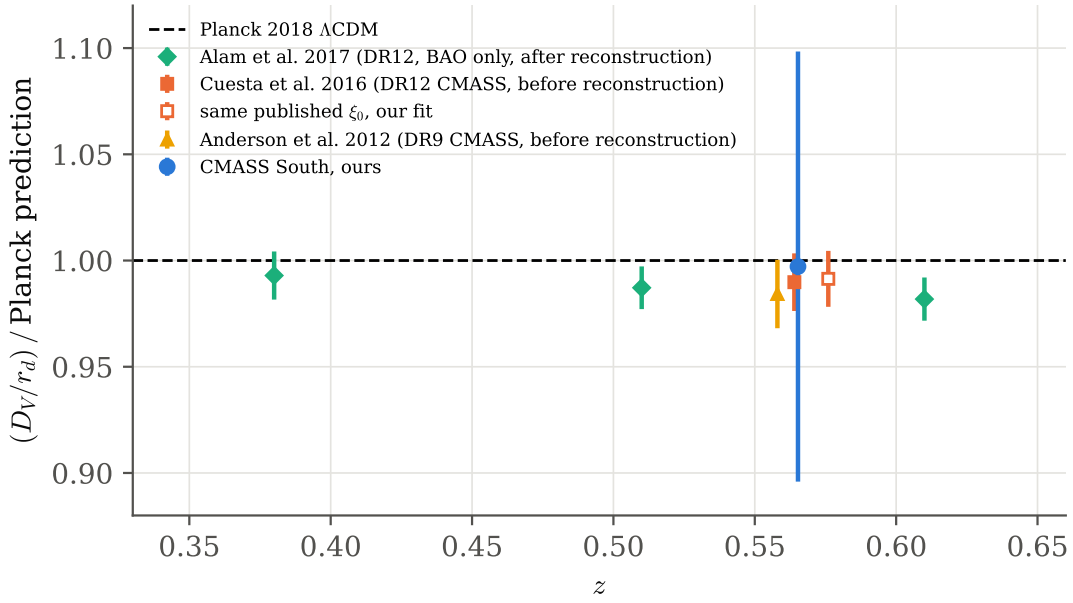

Figure 13.37: D_V/r_d divided by the Planck 2018 prediction at each redshift. BOSS results (Anderson et al. converted to CAMB's r_d; Alam et al.'s D_M and H combined into D_V), our refit of the published monopole (open square), and our southern measurement (blue, with the posterior error over $0.8 < \alpha < 1.2$). Points at $z \approx 0.57$ are spread slightly in z to be visible.

Figure 13.37 and Table 13.10 collect the numbers. For Alam et al.'s final distances we form D_V/r_d from their $D_M\, r_d^{\text{fid}}/r_d$ and $H\, r_d/r_d^{\text{fid}}$ with (11.27) and the delta-method error (11.34), using their covariance between the two; they include reconstruction and both directions, so their errors are smaller, and their bins at $z = 0.51$ and 0.61 bracket ours.

analysis	sample	z	D_V/r_d	Planck
Anderson et al. 2012	DR9 CMASS	0.57	13.79 ± 0.23	14.01
Cuesta et al. 2016	DR12 CMASS, N+S	0.57	13.87 ± 0.19	14.01
their $\hat{\xi}_0$, our fit	DR12 CMASS, N+S	0.57	13.89 ± 0.18	14.01
ours	DR12 CMASS, S	0.565	13.88 ± 1.41	13.92
Alam et al. 2017	DR12, all	0.51	12.67 ± 0.13	12.83
Alam et al. 2017	DR12, all	0.61	14.50 ± 0.15	14.76

Table 13.10: Paper against ours. All values use CAMB's r_d (Anderson et al.'s 13.44 ± 0.22 converted as in Section 13.19.3); the first four are before reconstruction and from the monopole, Alam et al.'s after reconstruction and from both directions. The last column is the Planck 2018 prediction at that z.

13.19.6 Why they differ

Three numbers need explaining: why our error is so much larger than the published one, why our detection is weaker than expected, and whether our α agrees with theirs. The distances themselves need little explaining: they agree with each other and with the Planck prediction to within two standard deviations, the BOSS values sitting one to two per cent below the prediction.

The area, and the jackknife. The southern cap is 27% of the area, so by the mode counting of Section 13.18.3 its errors on $\hat{\xi}_0$ should be 1.93 times the published ones; with the jackknife's slight excess they are 2.09 times. The significance $\sqrt{\Delta\chi^2}$ is the bump's amplitude divided by its standard error (Eq. (11.31)), so for a southern cap with an average bump it would be $6.1/2.09 = 2.9\sigma$. We found 1.6σ.

A weaker bump than average. Is 1.6 against an expected 2.9 a surprise? The estimated amplitude $\hat{A}$ of the bump scatters from survey to survey with standard deviation σ_A, so $\sqrt{\Delta\chi^2} \approx \hat{A}/\sigma_A$ scatters by about one unit. Our cap is 1.3 units below the expectation; a Gaussian falls that low or lower in about 10% of cases. The mock surveys of Section 11.4.4 showed the same spread from the other side, where the 2005 detection sat in the upper tail. Figure 13.35 shows where the deficit is: our points between 105 and 120 h^{-1}Mpc fall below the published ones, so the south's bump is narrower and lower than the whole sample's.

Why a weak bump is also badly located. The width of the χ^2 minimum is tied to the strength of the detection. Near the best fit, write the model as the smooth part plus the bump, $B^2\xi_t = B^2(\xi_{\rm nw} + \Delta)$, where $\Delta(s)$ is the acoustic feature, and suppose the smooth terms absorb the change of $\xi_{\rm nw}$ with α, so that only the bump's motion is informative. Then the two curvatures of χ^2 are

$$\begin{aligned}
\frac{1}{\sigma_\alpha^2} &\overset{(1)}{=} \Big(B^2\,\partial_\alpha\Delta\Big)^{\mathsf T}\mathbf{C}^{-1}\Big(B^2\,\partial_\alpha\Delta\Big) \overset{(2)}{=} B^4\,\big(s\Delta'\big)^{\mathsf T}\mathbf{C}^{-1}\big(s\Delta'\big),\\
\Delta\chi^2 &\overset{(3)}{=} \frac{1}{\sigma_A^2} \overset{(4)}{=} B^4\,\Delta^{\mathsf T}\mathbf{C}^{-1}\Delta,\\
\sigma_\alpha\sqrt{\Delta\chi^2} &\overset{(5)}{=} \left[\frac{\Delta^{\mathsf T}\mathbf{C}^{-1}\Delta}{(s\Delta')^{\mathsf T}\mathbf{C}^{-1}(s\Delta')}\right]^{1/2}.
\end{aligned} \tag{13.41}$$

(1) For a model linear in a parameter near its best fit, $1/\sigma^2$ is the derivative vector of the model sandwiched by $\mathbf{C}^{-1}$ (the Fisher matrix of a Gaussian mean, Section 10.3).
(2) $\partial_\alpha\Delta(\alpha s) = s\,\Delta'(\alpha s)$, evaluated at $\alpha = 1$.
(3) (11.31) with the data preferring the full amplitude.
(4) The bump's amplitude A multiplies $B^2\Delta$, so its Fisher information is that vector sandwiched by $\mathbf{C}^{-1}$.
(5) Divide the second line by the first, so that B^4 cancels, and take the square root.

The right-hand side depends only on the shape of the bump and of the covariance, not on how strong the signal is. A bump detected half as strongly is located half as precisely. The check: $\sigma_\alpha\sqrt{\Delta\chi^2}$ is 0.083 for our cap (local width) and 0.073 for the whole sample, equal within the roughness of the approximation although the covariances come from different methods. So the large error on our α is not a separate failure; it is the weak detection seen again. Had our bump been average, the local error would have been about 0.025.

Our α against theirs. Are 0.992 (ours, south) and 0.978 (the whole sample, same template) consistent? The two are not independent, since the south is inside the whole sample, so the usual rule of adding variances does not apply. Treat the whole-sample estimate as the inverse-variance average of a southern estimate α_S and a northern one α_N, independent, with variances σ_S^2 and σ_N^2, and ask for the variance of the difference $\alpha_S - \alpha_{NS}$.

$$\begin{aligned}
\alpha_{NS} &= \sigma_{NS}^2\Big(\frac{\alpha_S}{\sigma_S^2} + \frac{\alpha_N}{\sigma_N^2}\Big), \qquad \frac{1}{\sigma_{NS}^2} = \frac{1}{\sigma_S^2} + \frac{1}{\sigma_N^2}, \\
\alpha_S - \alpha_{NS} &\overset{(1)}{=} \sigma_{NS}^2\Big(\frac{1}{\sigma_S^2} + \frac{1}{\sigma_N^2}\Big)\alpha_S - \sigma_{NS}^2\Big(\frac{\alpha_S}{\sigma_S^2} + \frac{\alpha_N}{\sigma_N^2}\Big) = \frac{\sigma_{NS}^2}{\sigma_N^2}\,(\alpha_S - \alpha_N), \\
\mathrm{Var}(\alpha_S - \alpha_{NS}) &\overset{(2)}{=} \frac{\sigma_{NS}^4}{\sigma_N^4}\big(\sigma_S^2 + \sigma_N^2\big) \overset{(3)}{=} \frac{\sigma_S^4}{\sigma_S^2 + \sigma_N^2} \overset{(4)}{=} \sigma_S^2 - \sigma_{NS}^2.
\end{aligned} \tag{13.42}$$

(1) Multiply α_S by $1 = \sigma_{NS}^2(1/\sigma_S^2 + 1/\sigma_N^2)$ and subtract; the α_S/σ_S^2 terms cancel.
(2) α_S and α_N are independent, so their variances add.
(3) $\sigma_{NS}^2 = \sigma_S^2\sigma_N^2/(\sigma_S^2 + \sigma_N^2)$, so $\sigma_{NS}^4/\sigma_N^4 = \sigma_S^4/(\sigma_S^2 + \sigma_N^2)^2$.
(4) $\sigma_S^2 - \sigma_{NS}^2 = \sigma_S^2\big[1 - \sigma_N^2/(\sigma_S^2 + \sigma_N^2)\big] = \sigma_S^4/(\sigma_S^2 + \sigma_N^2)$.

A subset's estimate differs from the whole sample's by noise of variance $\sigma_S^2 - \sigma_{NS}^2$, smaller than either naive sum. With the local widths, $\sqrt{0.051^2 - 0.012^2} = 0.050$, and the difference 0.014 is a 0.3σ deviation. The north and south caps really were analysed separately by BOSS and agreed within 2σ in DR9 [250].

Smaller differences. Our randoms are 5 times the galaxies, not 50 (Section 13.17.3); the shot noise of RR and DR then adds a few per cent to the variance at the acoustic scale. All analyses in Table 13.10 except Alam et al.'s are before reconstruction; reconstruction sharpens the bump and shrinks the error by about a quarter (from 0.19 to 0.14 for the whole sample, [Cuesta2016 §4.4]). The DR9 sample of Anderson et al. is a third of DR12 and partly the same galaxies, so its agreement with DR12 is again a subset comparison.

Lesson. Reproducing a BAO distance taught two things that reading the papers did not. A fitted α is meaningless without its coordinates and its template, and two analyses that disagree by four per cent in α can agree to a fraction of a per cent in D_V/r_d; equation (13.39) is what makes them comparable. And the error on a peak's position does not follow the area alone. It scales with the inverse of the detection significance, and that scatters by about one unit from sky to sky. The southern cap has 27% of the area, which makes the errors on ξ about 1.93 times larger, yet its local error on α is 0.051 against 0.012 for the whole sample, and its posterior over the prior range is wider still. A weak detection is also a poor location.

13.20 The survey window, and what the full analysis adds

The galaxy catalogue and the Planck map share one difficulty. Neither covers the whole sky evenly: the CMB is hidden behind the Galaxy and point sources, and the galaxies were observed only inside the BOSS footprint, with a density that falls with distance. For the CMB that difficulty took a whole machinery, the mode-coupling matrix of Section 8.10 and its inversion in MASTER (Section 8.11, [140]). For the galaxies we never built a coupling matrix, and yet Figure 13.35 agrees with the published measurement. Where did the window go?

13.20.1 The random catalogue is the mask

The question. A survey multiplies the true galaxy density by a window $W(\boldsymbol{x})$, the expected number of weighted galaxies per unit volume at $\boldsymbol{x}$ when there is no clustering. In our analysis $W = \bar{n}\, w_{\rm FKP}$: zero outside the footprint and the redshift slice, and shaped inside by $\bar{n}(z)$ and the FKP weight of (13.30). What does W do to the expected pair counts?

Count pairs whose separation falls in a thin shell of radius s and width δs. Write $\Theta_s(\boldsymbol{r})$ for the indicator of that shell, 1 if $s < |\boldsymbol{r}| < s + \delta s$ and 0 otherwise. The weighted galaxy density has mean $W(\boldsymbol{x})$ and pair correlation ξ (Section 11.1.2), and the randoms sample W with no correlation.

$$\begin{aligned}
\langle DD(s)\rangle &\overset{(1)}{=} \int\!\!\int W(\boldsymbol{x})\, W(\boldsymbol{y}) \left[1 + \xi(|\boldsymbol{x}-\boldsymbol{y}|)\right] \Theta_s(\boldsymbol{x}-\boldsymbol{y})\, \mathrm{d}\boldsymbol{x}\, \mathrm{d}\boldsymbol{y} \\
&\overset{(2)}{=} \left[1 + \xi(s)\right] \int\!\!\int W(\boldsymbol{x})\, W(\boldsymbol{y})\, \Theta_s(\boldsymbol{x}-\boldsymbol{y})\, \mathrm{d}\boldsymbol{x}\, \mathrm{d}\boldsymbol{y}, \\
\langle RR(s)\rangle &\overset{(3)}{=} \int\!\!\int W(\boldsymbol{x})\, W(\boldsymbol{y})\, \Theta_s(\boldsymbol{x}-\boldsymbol{y})\, \mathrm{d}\boldsymbol{x}\, \mathrm{d}\boldsymbol{y}, \qquad \text{so} \qquad \frac{\langle DD(s)\rangle}{\langle RR(s)\rangle} \overset{(4)}{=} 1 + \xi(s).
\end{aligned} \tag{13.43}$$

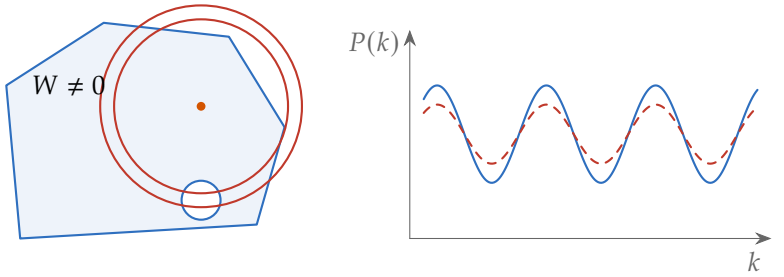
(1) The expected number of pairs in two small volumes is the product of the mean densities times $1 + \xi$ (Eq. (11.5)), summed over all pairs of volumes whose separation is in the shell.
(2) Inside a thin shell $|\boldsymbol{x} - \boldsymbol{y}| \approx s$, so ξ is the same for every pair and comes out of the integral.
(3) The randoms have the same mean density shape W and no clustering.
(4) The double integral is the same in both; it cancels. (The normalisations of (13.31) make the total pair numbers agree.)

The double integral is the window's own pair count: how many pairs at separation s the footprint can hold at all. It is the configuration-space twin of the mask's power spectrum $\mathcal{W}_\ell$ that builds the coupling matrix in [Hivon (14), (A31)]. Because the correlation function depends only on the separation, and a thin shell fixes the separation, the window multiplies each bin by its own number and mixes nothing: dividing by RR undoes it bin by bin. The randoms are the mask, and RR is its coupling "matrix", which here is diagonal. The Landy–Szalay combination (13.33) keeps this property and also cancels the leading edge terms in the variance (Section 11.2.2).

Why the power spectrum is different. The FKP estimator of Section 11.3 Fourier transforms the weighted density on a grid. Multiplication by W in configuration space is a convolution in Fourier space, so the measured power at $\boldsymbol{k}$ is the true power averaged over neighbouring wavevectors with weight $|\tilde{W}(\boldsymbol{k} - \boldsymbol{k}')|^2$. Every k-bin mixes with its neighbours, exactly as the mask mixes multipoles on the sphere, and a sharp feature such as the acoustic wiggles is smoothed (Figure 13.38). A $P(k)$ analysis must therefore convolve the model with the window, the analogue of the forward-modelling route of MASTER, before comparing it with data.

Example: how much a window smooths a wiggle. Take a wiggle $1 + A\sin(kr_d)$ and a window whose $|\tilde{W}|^2$, normalised to unit integral, is a Gaussian of width σ_k in k. The convolved wiggle is the average of $\sin\big((k-q)r_d\big)$ over $q \sim \mathcal{N}(0, \sigma_k^2)$. Write the sine as the imaginary part of $e^{i(k-q)r_d}$; the average of e^{-iqr_d} over a Gaussian is $e^{-\sigma_k^2 r_d^2/2}$ (complete the square in the exponent), a real number, so the average is $\sin(kr_d)\, e^{-\sigma_k^2 r_d^2/2}$ and the wiggle survives with amplitude $A\, e^{-\sigma_k^2 r_d^2/2}$. A survey $L \approx 1\, h^{-1}$Gpc deep has $\sigma_k \sim 1/L$, and with $r_d \approx 100\, h^{-1}$Mpc the factor is $e^{-0.005}$: a large survey barely blurs the BAO. A thin slice $100\, h^{-1}$Mpc deep in one direction has $\sigma_k r_d \sim 1$ along it and keeps only $e^{-1/2} \approx 60\%$ of the wiggle in that direction. Pair counts would see the same peak at full height.

Where the cancellation fails. Equation (13.43) assumed that the randoms trace the true window. They do not if the mean density is itself estimated from the same galaxies: the randoms' redshifts are drawn from the galaxies (Section 13.15.2), and the total number is normalised to the observed number. Both remove the large-scale fluctuations that the survey's own volume contains, the integral constraint of Section 11.2.3, which pulls $\hat{\xi}$ down by a nearly constant amount; the term a_0 in the fit (11.30) absorbs it. Ross et al. compared ways of giving the randoms their redshifts on mock catalogues and found that drawing them from the galaxies ("shuffling") biased the clustering least [Ross2012 §6.1].



shell of radius s in the footprint true (blue), window-convolved (red)

Figure 13.38: The window in two spaces. Left: in configuration space, pairs at one separation are counted in a shell; the footprint (blue, with a masked hole) cuts the shell, but it cuts the galaxy pairs and the random pairs alike, so their ratio is untouched. Right: in Fourier space the window convolves the spectrum; for a Gaussian window of width σ_k a wiggle of period $2\pi/r_d$ keeps the fraction $e^{-\sigma_k^2 r_d^2/2}$ of its amplitude (drawn for $\sigma_k r_d = 1$).

13.20.2 The full analysis, and what our shortcuts cost

Each step of our pipeline has a research-grade version. Table 13.11 lists them with the price of the shortcut; the largest prices are the area, which costs a factor of about two in every error, and the absence of mocks, which makes the error bars themselves uncertain by some tens of per cent.

step	ours	BOSS DR12, and the cost of our choice
sky	southern cap, 27% of the area	both caps [251]; errors 1.93 times larger, detection 1.6σ instead of 6.1σ
randoms	5 per galaxy in the counts	50 per galaxy [249]; a few per cent more variance
covariance	120 jackknife regions	about a thousand quick-particle-mesh (QPM) mocks (956 for CMASS) and a second set as a check; our errors uncertain by tens of per cent, Hartlap factor only a guide
statistic	monopole only	monopole and quadrupole; we measure D_V only, not D_M and H separately
reconstruction	none	displacements estimated from the density field and undone; our errors about 25% larger
template	fixed $\Sigma_{\rm nl} = 8\,h^{-1}$Mpc	damping calibrated on mocks, systematic error budget for template and fiducial cosmology
blinding	none	catalogue-level blinding, now standard [DESI2024VI §2.3.1]

Table 13.11: Our analysis of CMASS South against the published BOSS analysis.

All of it ran at laptop scale: the fully weighted pair counts took 338 s on 8 cores, and the fits

a few seconds. The full DR12 random catalogues of both caps, at 50 times the galaxies, would need more than 4 GB of downloads and several hundred times our pair-counting time, because the number of random pairs within 184 h^{-1}Mpc grows as the number of randoms times their density.

Two further summaries of the same catalogue follow from earlier chapters, and our analysis did not compute them. The power-spectrum monopole with FKP weights (Section 11.3) measures the same wiggles in Fourier space, and Section 13.20.1 says what it needs: the model convolved with the window of our footprint. The Betti curves of the smoothed galaxy density (Section 12.13.2) would test the morphology of the cosmic web, but their null distribution, like that of the CMB sky in Section 13.9, must come from mocks that pass through the same window: a mask changes the topology of every excursion set it cuts.

How this is used in real research: verification and research in a BAO analysis

Two of our checks were verifications: refitting the published monopole (Section 13.19.5) tested our fitting code against a known answer, and comparing jackknife errors with mock errors (Section 13.18.3) tested an error method against a better one. In the research analysis the same Monte Carlo machinery is the instrument. Thousands of mock surveys, each with the real footprint, density and fibre collisions, give the covariance; the same mocks measure whether reconstruction or the template shifts α, which sets the systematic error; and the fitted α of each mock gives the sampling distribution of $\hat{\alpha}$, against which non-Gaussian error behaviour like that of our Figure 13.36 is calibrated [197, 251]. DESI adds blinding: the catalogue is shifted in a hidden way until the analysis choices are frozen, so that agreement with a favoured model cannot steer them [DESI2024VI §2.3.1].

Recap

- A galaxy catalogue becomes a set of positions through a fiducial distance–redshift relation; the error made by choosing the wrong one is exactly what the dilation α measures.
- Weights restore the galaxies the survey could not observe properly (close pairs, redshift failures, stars and seeing) and the FKP weight balances signal and shot noise; the randoms carry only the FKP weight because they already trace the survey's completeness.
- The Landy–Szalay estimator with weighted counts divides out the survey window bin by bin, because in a thin shell the correlation function is constant; in Fourier space the same window convolves the spectrum and must be modelled.
- Counting pairs region by region gives every leave-one-region-out count by inclusion–exclusion, and with them the jackknife covariance $\frac{N-1}{N}\sum_k(\hat{\boldsymbol{\xi}}_{-k}-\bar{\boldsymbol{\xi}})(\hat{\boldsymbol{\xi}}_{-k}-\bar{\boldsymbol{\xi}})^{\mathsf{T}}$, exact for a mean and biased upward otherwise; on CMASS South it agrees with scaled mock errors to 1.09.
- A fitted α becomes a distance through $D_V/r_d = \alpha\, D_V^{\mathrm{fid}}/r_d^{\mathrm{tmpl}}$; the ruler's name and the coordinates must be identified before numbers are compared.
- CMASS South shows the acoustic peak at 1.6σ and gives $D_V/r_d = 13.88 \pm 1.41$, consistent with BOSS and Planck; the whole sample, refitted with our code, gives 13.89 ± 0.18 at 6.1σ, as published.
- A weak detection is also a poor location, $\sigma_\alpha\sqrt{\Delta\chi^2}$ being fixed by the shape of the bump; and a subset differs from its parent sample by noise of variance $\sigma_S^2 - \sigma_{NS}^2$.

13.21 A Higgs search on collider open data

On the fourth of July 2012 two collaborations at CERN showed, one after the other, a histogram of the invariant mass of photon pairs. Each had a smooth background falling from left to right and, near 125 GeV, a small excess that a smooth curve could not explain. Together with the four-lepton channel, those excesses were the discovery of the Higgs boson [113, 119]. In 2020 the ATLAS collaboration released part of its 2016 data at a collision energy of 13 TeV to the public, with the simulated Higgs-boson events that go with it [116, 118]. So the same search can be done from the recorded collisions to the final significance, with every step under our control. The physics of what is recorded, the photons and their momenta, the cross section and the luminosity, is set out in Chapter T4; what follows is the statistics.

What we have already seen, and what is new. The search is not new to us. In Section 4.14.3 we hunted for a bump in a simulated diphoton-like spectrum of 3000 background events with a known background shape and a Gaussian peak of width 1.5 GeV. The largest excess sat at 142.50 GeV with a local significance of 3.28σ; background-only toys turned that into a global 2.15σ, a trials factor of about 31.3, and the Gross–Vitells formula of Section 4.14.4 reproduced it from the upcrossings of a hundred toys. In Sections 4.15 and 4.16 the same kind of pseudo-spectrum, now generated with a signal, became a likelihood with nuisance parameters: q_0 for discovery, $\tilde{q}_\mu$ and CL_s for exclusion, the Asimov data set for the expected results and the Brazil band for the expected limit. The statistics is the same now. Four things are different, and each one is a real-data problem that the pseudo-experiments allowed us to ignore.

1. *Nobody knows the background shape.* In Section 4.14.3 it was the exponential we had used to generate the data. Here it is whatever the mixture of photon pairs, photon–jet and jet–jet events produces after our selection, and it must be described by a smooth function chosen from the data. A wrong choice can manufacture a bump or hide one.

2. *The signal shape comes from simulation,* and it is not a Gaussian: some photons lose energy before reaching the calorimeter, which leaves a tail on the low side of the peak.

3. *The expected signal is uncertain,* through quantities measured elsewhere (efficiencies, luminosity, the energy scale and resolution of the photons). They enter as nuisance parameters with constraint terms, as in Section 4.15.2.

4. *The sample is big.* About 76394 events lie in the window instead of 3000, so the background is measured very precisely and small imperfections of the background function matter as much as the statistical fluctuations.

The questions in words.

1. Which recorded collisions contain two well-measured photons, and what does the spectrum of their invariant mass look like?

2. How large and how wide a peak would a Standard Model Higgs boson make in that spectrum, and which smooth function can describe everything else without inventing or hiding a peak?

3. If the background alone were present, would an excess like the one in the data, or an even larger one, be something we would reasonably expect, at one mass and anywhere in the range searched?

4. How strong is the signal compared with the Standard Model prediction, and where is it?

5. At which masses can a Standard Model Higgs boson be excluded, and how does the whole result compare with what ATLAS reported in 2012?

13.21.1 From collisions to a list of masses

The files. The release contains, for the diphoton search, four files of recorded collisions (the 2016 data-taking periods A to D, together $10.06\,\text{fb}^{-1}$) and four files of simulated Higgs bosons with $m_H = 125\,\text{GeV}$ decaying to two photons, one for each way of producing it: gluon fusion (ggH), vector-boson fusion (VBF) and production together with a W or Z boson (WH, ZH). Together they are 1.9 GB. They were already reduced by ATLAS to events in which the diphoton trigger fired and two photon candidates were found [116]. Each file is a ROOT tree with one entry per collision; the script `code/ch13/31_hyy_select.py` reads the columns it needs with `uproot`. For every photon candidate the tree stores its transverse momentum p_T [the momentum component perpendicular to the beams], its pseudorapidity η [a measure of the polar angle, $\eta = -\ln\tan(\theta/2)$, zero at right angles to the beams], its azimuth ϕ around the beams, and flags describing how cleanly it was measured (Chapter T4).

Why the invariant mass. *The question:* if two photons come from the decay of one particle of mass M, what combination of their measured momenta tells us M? Energy and momentum are conserved in the decay, so the four-momentum of the parent is the sum of the two photon four-momenta, $P = p_1 + p_2$. The square of a four-momentum is the same in every frame, and in the rest frame of the parent it is M^2 (with $c = 1$). So $M^2 = (p_1 + p_2)^2$ whatever the motion of the parent. A photon is massless, so its four-momentum is fixed by (p_T, η, ϕ):

$$p = (E,\ p_T\cos\phi,\ p_T\sin\phi,\ p_T\sinh\eta), \qquad E = p_T\cosh\eta,$$

because $p_z = p_T\sinh\eta$ follows from the definition of η, and then

$$E = \sqrt{p_T^2 + p_z^2} = p_T\sqrt{1+\sinh^2\eta} = p_T\cosh\eta.$$

With the metric $p\cdot q = E_pE_q - \vec{p}\cdot\vec{q}$,

$$\begin{aligned} m_{\gamma\gamma}^2 &\overset{(1)}{=} p_1^2 + p_2^2 + 2\,p_1\cdot p_2 \overset{(2)}{=} 2\big(E_1E_2 - \vec{p}_1\cdot\vec{p}_2\big) \\ &\overset{(3)}{=} 2p_{T1}p_{T2}\big[\cosh\eta_1\cosh\eta_2 - \sinh\eta_1\sinh\eta_2 - \cos\phi_1\cos\phi_2 - \sin\phi_1\sin\phi_2\big] \\ &\overset{(4)}{=} 2p_{T1}p_{T2}\big[\cosh(\eta_1-\eta_2) - \cos(\phi_1-\phi_2)\big]. \end{aligned} \tag{13.44}$$

(1) Expand the square of the sum.
(2) A massless particle has $p^2 = E^2 - |\vec{p}|^2 = 0$.
(3) Insert the components above.
(4) The addition formulas $\cosh(a-b) = \cosh a\cosh b - \sinh a\sinh b$ and $\cos(a-b) = \cos a\cos b + \sin a\sin b$.

Only differences of η and ϕ appear: the mass does not care how fast the pair moves along the beams or which way it points around them. That is why the invariant mass, and not the energy of either photon, is where a resonance shows up as a peak; the same argument, for any pair of particles, is Section T4.3.1.

Example: one photon pair. Take a pair with $p_{T1} = 60\,\text{GeV}$, $p_{T2} = 52\,\text{GeV}$, $\Delta\eta = 1.0$ and $\Delta\phi = 2.9\,\text{rad}$. Then $\cosh 1.0 = 1.543$ and $\cos 2.9 = -0.971$, so

$$m_{\gamma\gamma}^2 = 2 \times 60 \times 52 \times (1.543 + 0.971) = 6240 \times 2.514 = 15\,688\,\text{GeV}^2, \qquad m_{\gamma\gamma} = 125.3\,\text{GeV}.$$

The photons are nearly back to back in azimuth ($\Delta\phi$ close to π), as the two decay products of a slowly moving particle must be. Nothing in this pair says whether it came from a Higgs boson: a pair of photons from ordinary quark–antiquark annihilation can have exactly these momenta. Single events are never signal or background; only the distribution of many events can be.

The selection. Most recorded events with two photon candidates contain no real photon pair at all: a jet of hadrons can contain a neutral pion whose two photons merge into one deposit. Each cut below removes a specific kind of fake or badly measured event, and each is copied from the `HyyAnalysis` example of the release.

- *Trigger*: the diphoton trigger fired.
- *Exactly two good photons*: each passes the tight identification [the shape of its shower in the calorimeter looks like one photon, not several], has $p_T > 25\,\text{GeV}$ and $|\eta| < 2.37$, outside $1.37 < |\eta| < 1.52$ where the barrel and end-cap calorimeters meet and the energy is poorly measured.
- *Isolation*: the momentum of tracks within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.3$ and the calorimeter energy within $\Delta R < 0.2$ around each photon are both below 6.5% of its p_T. A photon from a Higgs decay is alone; a fake photon inside a jet is surrounded by hadrons.
- *Relative momenta*: $p_{T1}/m_{\gamma\gamma} > 0.35$ and $p_{T2}/m_{\gamma\gamma} > 0.25$ for the leading and subleading photon.
- *Mass window*: $105 < m_{\gamma\gamma} < 160\,\text{GeV}$.

Why relative cuts on p_T? An absolute cut, say $p_T > 40\,\text{GeV}$ on both photons, removes almost every pair below $m_{\gamma\gamma} \approx 80\,\text{GeV}$ and fewer and fewer pairs above it, so it bends the background spectrum near the window. A cut on $p_T/m_{\gamma\gamma}$ is a cut on the decay angle, the same at every mass, so it changes the background's size but not its smoothness. A smooth background is what the fit of Section 13.22 assumes.

What survives. Of 7798424 triggered events, 979404 have exactly two good photons, 362972 of these are isolated, 322243 pass the relative momentum cuts and 76394 fall in the mass window (Figure 13.39). The four periods contribute 4227, 14804, 21876 and 35487 events, in proportion to their luminosity.

How many Higgs bosons should be among them? *The question:* the simulation produced about a million ggH events, far more than the data contain; how does one turn a selected simulated event into a number of expected real events? If a process has cross section σ [the effective area of the collision for that process, here including the probability that the Higgs boson decays to two photons] and the data correspond to an integrated luminosity L [the number of collisions per unit area that were recorded], the expected number of such events produced is $L\sigma$ (Chapter T4). The expected number selected is that times the probability ε of passing the selection, which the simulation estimates. The simulation's events carry generator weights w_j (some generators produce weighted, even negatively weighted, events), and a selected event also carries scale factors SF_j that correct the simulated efficiencies of the trigger,

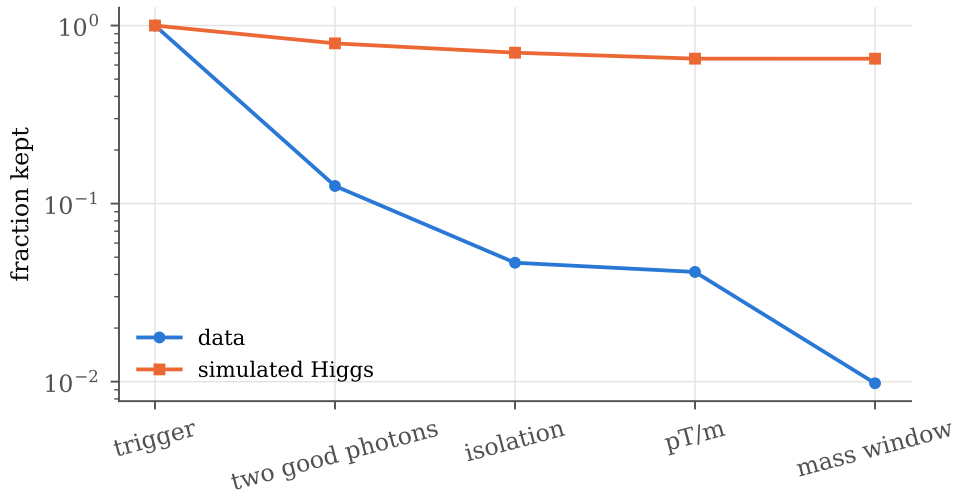


Figure 13.39: The fraction of events kept after each step of the selection, for the recorded data (blue) and for the simulated Higgs bosons (orange), both relative to the events that passed the trigger. The photon identification and the isolation remove most of the data and little of the signal: that is the purpose of each cut. The mass window removes most of the remaining data, whose spectrum extends far beyond 160 GeV.

the photon identification and the pile-up to those measured in data. As in Section T4.4.2,

$$S \overset{(1)}{=} L\,\sigma\,\varepsilon \overset{(2)}{=} L\,\sigma\,\frac{\sum_{j\in\text{selected}} w_j\,\mathrm{SF}_j}{\sum_{\text{all } j} w_j} \overset{(3)}{=} \sum_{j\in\text{selected}} \underbrace{\frac{L\,\sigma}{\sum_{\text{all } k} w_k}\,w_j\,\mathrm{SF}_j}_{\text{weight of event } j}\,. \tag{13.45}$$

(1) Expected selected events: produced events times the selection probability.
(2) The weighted fraction of simulated events that pass; with all weights one it is the plain fraction $N_{\text{sel}}/N_{\text{gen}}$. The sum in the denominator runs over all generated events, before any selection, and is stored in the files.
(3) Bring the constant inside the sum: every selected event contributes its own weight.

With $L = 10.06\,\text{fb}^{-1}$ the expected Higgs signal after all cuts is $S = 397.9$ events: 357.2 from gluon fusion, 29.9 from vector-boson fusion, 5.6 and 5.3 from production with a W or Z. A fraction 0.651 of the signal events in the files survives the selection (Figure 13.39), against 76394/7798424 of the data.

The spectrum. Figure 13.40 shows the 76394 masses in 1 GeV bins and, below them, the 397.9 expected Higgs events on their own. The data fall smoothly from about 3000 to about 600 events per GeV. The Higgs peak is 60 to 70 events per GeV high at its top, a few per cent of the background there, and no bump is visible by eye: the error bar of a single bin, $\sqrt{1600} = 40$ events, is not much smaller than the whole peak. Whether the peak is there has to be decided by the likelihood, using all the bins at once.

The full analysis, and ours. ATLAS in 2012 split its events into ten categories of different mass resolution and signal-to-background ratio, fitted each with its own background function, chosen with large simulated background samples, and combined two collision energies [113]; the later analyses of the same detector use many times more data and more categories. We keep the published selection and one inclusive spectrum, read 1.9 GB of files once, and use two

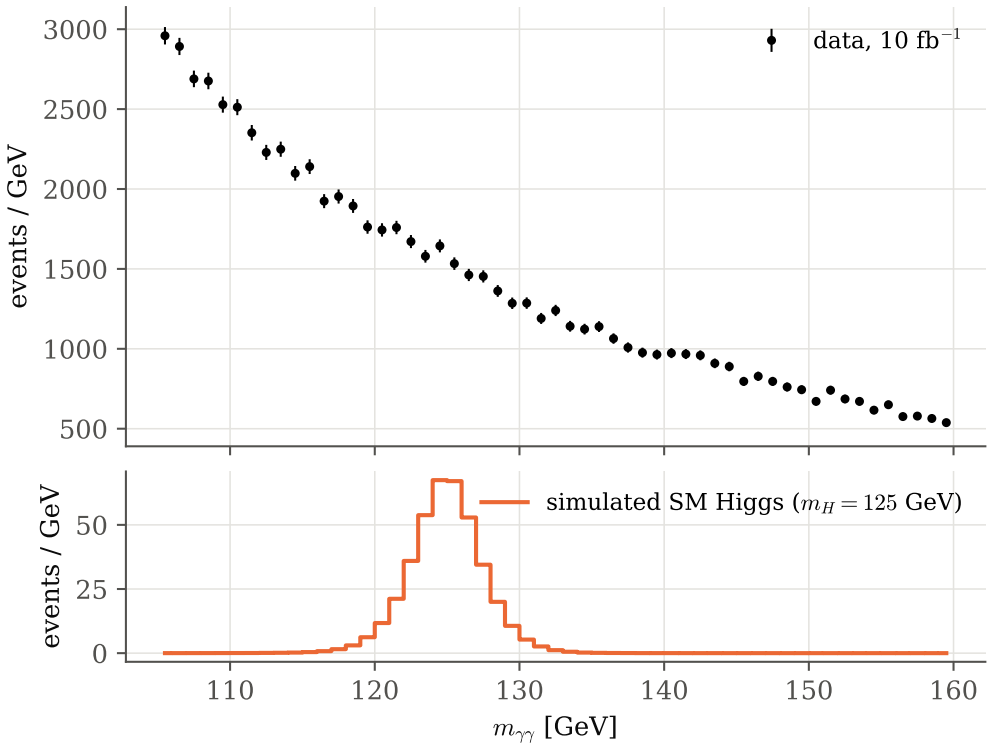

Figure 13.40: Top: the invariant mass of the 76394 selected photon pairs in 1 GeV bins, with Poisson error bars. Bottom: the Higgs signal expected in the same data from the simulation, 397.9 events in all, drawn on its own because on the scale of the top panel it would be a ripple of a few per cent.

categories only as an illustration (Section 13.25.3). The price is sensitivity, which Section 13.27 quantifies.

13.22 Shapes: the Higgs line and the background function

The likelihood of Section 4.15.1 needs two templates: the fraction f_i of the signal and the fraction g_i of the background expected in each bin i of the mass histogram, so that the mean count is $\nu_i = \mu S f_i + B g_i$ (4.88). In the pseudo-experiments of Chapter 4 both were handed to us. Here the signal template has to be extracted from the 397.9 simulated Higgs events of Section 13.21.1, and the background template has to be a smooth function whose parameters are fitted to the data. Both choices change the answer, and each has its own check.

13.22.1 The signal line shape

A Higgs boson is so narrow (its natural width is about 4 MeV, Chapter T4) that the width of the peak in $m_{\gamma\gamma}$ is entirely the detector's: the calorimeter measures each photon's energy with an error of one or two per cent, and by (13.44) $m_{\gamma\gamma} \propto \sqrt{E_1 E_2}$ inherits about half of each relative error. Many small independent errors add up to a Gaussian (the central limit theorem of Chapter 2), so the core of the peak is Gaussian. But some photons lose part of their energy before they reach the calorimeter, by converting into an electron–positron pair in the material in front of it or by leaking out of the back. Such losses only ever lower the measured mass. The peak therefore has a tail on its low side, and a Gaussian, which is symmetric, misses it.

The Crystal Ball function. The standard description, met in Section T4.3.3, is a Gaussian core glued to a power-law tail. With $t = (m - \bar{m})/\sigma$ the distance from the peak in units of the core width,

$$f_{\mathrm{CB}}(m) \propto \begin{cases} e^{-t^2/2}, & t > -\alpha, \\ A\,(B - t)^{-n}, & t \le -\alpha, \end{cases} \tag{13.46}$$

with four shape parameters: the peak position $\bar{m}$, the core width σ, the point $t = -\alpha$ where the tail takes over, and the power n of the tail. The constants A and B are not free. *The question:* what must they be for the two pieces to join smoothly at $t = -\alpha$, with the same value and the same slope? Equal slopes first, in logarithmic form (the log of each piece has a simple derivative):

$$\frac{\mathrm{d}}{\mathrm{d}t}\Big(-\frac{t^2}{2}\Big)\Big|_{t=-\alpha} \overset{(1)}{=} \frac{\mathrm{d}}{\mathrm{d}t}\big(\ln A - n\ln(B-t)\big)\Big|_{t=-\alpha} \implies \alpha = \frac{n}{B+\alpha} \implies B \overset{(2)}{=} \frac{n}{\alpha} - \alpha,$$
$$e^{-\alpha^2/2} \overset{(3)}{=} A\,(B+\alpha)^{-n} \implies A \overset{(4)}{=} \Big(\frac{n}{\alpha}\Big)^n e^{-\alpha^2/2}. \tag{13.47}$$

(1) Equal values and equal slopes means equal logarithmic slopes. On the left the derivative is $-t = \alpha$; on the right it is $n/(B - t) = n/(B + \alpha)$.
(2) Solve for B.
(3) Equal values at $t = -\alpha$.
(4) $B + \alpha = n/\alpha$ by the previous line.

For the normalisation we need the area of each piece, in units of σ. The core is a piece of a Gaussian, $\int_{-\alpha}^{\infty} e^{-t^2/2}\mathrm{d}t = \sqrt{\pi/2}\,[1 + \mathrm{erf}(\alpha/\sqrt{2})]$. The tail is a power law, which integrates in one line:

$$\int_{-\infty}^{-\alpha} A(B-t)^{-n}\mathrm{d}t \overset{(1)}{=} A\Big[\frac{(B-t)^{1-n}}{n-1}\Big]_{-\infty}^{-\alpha} \overset{(2)}{=} \frac{A}{n-1}\Big(\frac{n}{\alpha}\Big)^{1-n} \overset{(3)}{=} \frac{n}{\alpha(n-1)}\,e^{-\alpha^2/2}. \tag{13.48}$$

(1) The antiderivative of $(B - t)^{-n}$ is $(B - t)^{1-n}/(n - 1)$; the minus signs from the chain rule and from $1 - n$ cancel.
(2) For $n > 1$ the term at $t \to -\infty$ vanishes; at $t = -\alpha$, $B - t = n/\alpha$.
(3) Insert A from (13.47): $(n/\alpha)^n(n/\alpha)^{1-n} = n/\alpha$.

The tail needs $n > 1$ to have a finite area at all. As $n \to \infty$ the tail area $\to e^{-\alpha^2/2}/\alpha$, which is the large-$\alpha$ estimate of the Gaussian's own tail beyond $-\alpha$ (Chapter 4): a very steep power law is a Gaussian tail again. The library `code/ch13/lib_hyy.py` writes the cumulative distribution of (13.46) from these two areas, so that the expected signal in every bin is an exact difference of two cumulative values.

Fitting it to the simulation. The simulated events carry the weights w_j of (13.45). A weighted maximum-likelihood fit maximises $\sum_j w_j \ln p(m_j \mid \bar{m}, \sigma, \alpha, n)$, where p is (13.46) normalised over the window 105–160 GeV: each simulated event counts as many times as the real events it stands for. The fit to all production modes together gives

$$\bar{m} = 125\,\mathrm{GeV}, \qquad \sigma = 2.467\,\mathrm{GeV}, \qquad \alpha = 1.88, \qquad n = 10.3,$$

and a plain Gaussian fitted the same way has width 2.6 GeV (Figure 13.42). The Gaussian is wider because it has to stretch its symmetric shape to cover the low tail, which also makes it too wide at the top. The Crystal Ball puts 3.3% of the signal more than 2σ below the peak, against 2.3% for a Gaussian. Above the peak the simulation shows a small tail of its own, which the one-sided function misses; later analyses use a Crystal Ball with a power law on both sides. Its effect here is a few events out of 397.9.

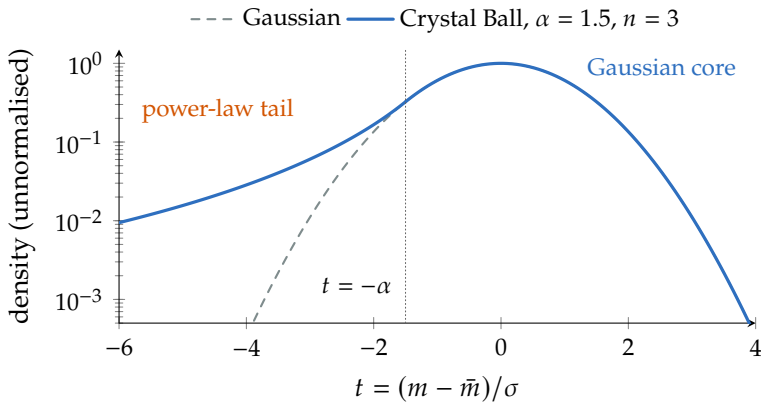

Figure 13.41: The Crystal Ball line shape on a logarithmic scale. To the right of $t = -\alpha$ it is the Gaussian; to the left it continues as a power law that joins with the same value and slope, (13.47), and falls far more slowly than the Gaussian (dashed). The excess area on the left is the events whose photons lost energy before being measured.

Example: the full width at half maximum. A peak is often quoted by its full width at half maximum (FWHM), because it can be read off a histogram without a fit. For a Gaussian, half maximum is where $e^{-t^2/2} = \frac{1}{2}$, so $t = \pm\sqrt{2\ln 2} = \pm 1.177$ and

$$\text{FWHM} = 2\sqrt{2\ln 2}\,\sigma = 2.355\,\sigma.$$

The Crystal Ball has the same half-maximum points as long as the tail starts beyond them, $\alpha > 1.177$, as it does here. The numerical FWHM of our fit is 5.81 GeV, $2.35\,\sigma$. ATLAS in 2012 quoted a FWHM of 3.9 GeV with $\sigma_{\text{CB}} = 1.6$ GeV for its inclusive sample [AadHiggs2012 §5.4]: a ratio of 2.4, slightly above 2.355 because their model adds a wider Gaussian (under 10% of the events) to the Crystal Ball and the inclusive sample mixes categories of different widths; for single categories they quote a ratio of typically 2.3. Their peak was narrower than ours by a factor $2.467/1.6 \approx 1.5$, a difference we return to in Section 13.27.

Example: the resolution depends on the photons. Fitted separately, the pairs in which both photons are central ($|\eta| < 0.75$) and unconverted have $\sigma = 1.825$ GeV, the rest $\sigma = 2.58$ GeV. Central unconverted photons cross the least material and land in the best part of the calorimeter. Section 13.25.3 uses this difference.

Other masses. The search tests masses m_H from 110 to 150 GeV, but the simulation exists only at 125 GeV. The calorimeter's relative resolution changes little over this range, so we scale both the peak position and the width with the mass, $\bar{m}(m_H) = \bar{m}\, m_H/125$ and $\sigma(m_H) = \sigma\, m_H/125$, and keep α and n. ATLAS interpolates between simulations at several masses [113].

13.22.2 Choosing the background function: the spurious signal

The background is mostly pairs of real photons from quark–antiquark annihilation and gluon fusion, plus photon–jet and jet–jet events where a jet passed as a photon [AadHiggs2012 §5]. No calculation predicts their sum after our cuts to a fraction of a per cent, which is the precision 76394 events demand. So the background is described by a smooth function with free parameters, fitted to the data together with the signal. The plain claim is: *any function that fits the data well will do*. The everyday question behind it is "does the function fit the data?", and we can answer it with the goodness-of-fit test of Section 4.8.

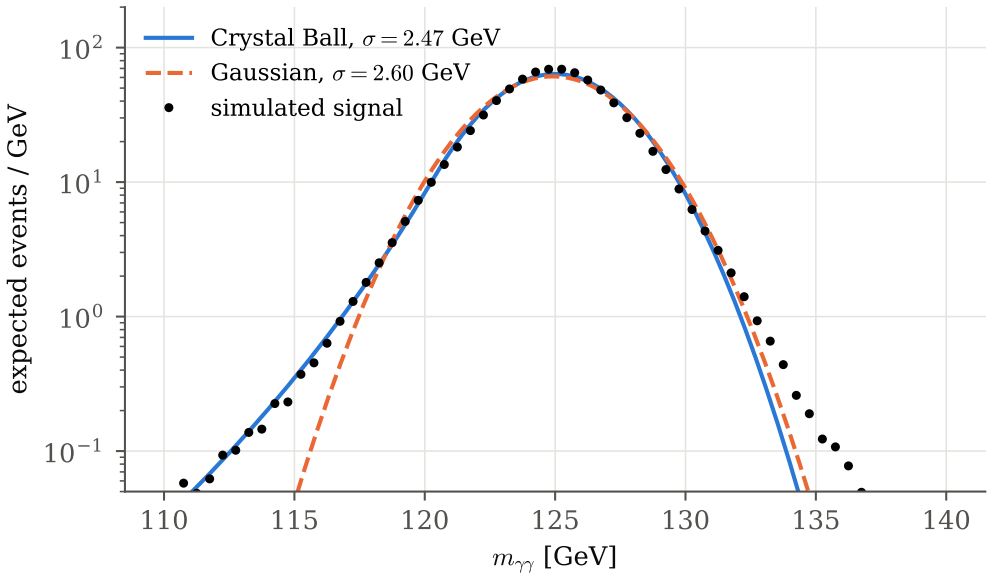

Figure 13.42: The simulated Higgs signal (points, expected events per GeV for 10 fb^{-1}, logarithmic scale) with the fitted Crystal Ball (solid) and Gaussian (dashed). The Gaussian falls far too fast below 118 GeV, where the photons that lost energy end up; the Crystal Ball's power law follows them.

Does each function fit? The script `code/ch13/32_hyy_model.py` fits eight families to the spectrum with no signal: exponentials of polynomials of degree one to four (Exp1 to Exp4, $g(m) \propto \exp \sum_{k=1}^{K} a_k u^k$ with u the mass mapped onto $[-1, 1]$), a power law m^{-a} (Pow) and Bernstein polynomials of degree three to five (Bern3 to Bern5, $g \propto \sum_{j=0}^{K} c_j \binom{K}{j} x^j (1-x)^{K-j}$ with x the mass mapped onto $[0, 1]$). The deviance $D = 2\sum_i [v_i - n_i + n_i \ln(n_i/v_i)]$ in 1 GeV bins is the likelihood-ratio goodness-of-fit statistic of Section 4.8.3, approximately χ^2 with $55 - 1 - K$ degrees of freedom.

	Exp1	Pow	Exp2	Bern3	Exp3	Bern4	Exp4	Bern5
free shape parameters K	1	1	2	3	3	4	4	5
deviance	78.3	63.2	58.4	54.7	54.5	54.2	54.3	53.4
p-value	0.013	0.16	0.252	0.337	0.342	0.318	0.315	0.308
max $\lvert S_{\text{spur}} \rvert$ (events)	707.9	245.8	273.8	98.1	218.6	79.3	40.8	15.6
max $\lvert S_{\text{spur}} \rvert / \sigma_S$	4.43	2.17	2.42	0.71	1.19	0.41	0.29	0.06

Only the single exponential is rejected at the one-per-cent level. Every other family fits.

The hidden assumption. "Fits the data" answers a question about all 55 bins at once. The question that matters for a search is narrower: *if there were no signal at all, would this function, fitted together with a signal template, return a signal of zero?* A function can follow the data within the errors everywhere and still be wrong by a few hundred events in a way that looks like a peak, because a deviation spread over a 6 GeV wide region of 1527 background events per GeV is a fraction of a per cent of the background there, below what the goodness of fit can see. The test that asks the right question is the **spurious-signal** test.

Working definition 13.3 (spurious signal)

Take a background spectrum with no signal in it, as realistic as possible (a "truth"). Fit it with the candidate background function plus a signal at mass m_H. The fitted signal $S_{\text{spur}}(m_H)$ [events the function invents, or hides when negative] is the spurious signal. ATLAS required $|S_{\text{spur}}|$ below 20% of the statistical error σ_S of the fitted signal at every m_H in 110–150 GeV [AadHiggs2012 §5.5]. *Operationally:* fit the truth's exact expectation (an Asimov spectrum), so that the result is the bias alone, with no fluctuation.

Where does a truth come from? ATLAS used large samples of simulated background. The open-data release has none for this selection, so we take as truths the two most flexible families, Bern5 and Exp4, each fitted to the whole data spectrum *together with* a 125 GeV signal, and keep only their background part. (Fitted without the signal they would have absorbed the real Higgs boson in the data, which is what we must not call background; their fitted signals were 496 and 462 events.) Each candidate is then fitted, with a signal, to each truth's Asimov spectrum scaled to 76394 events, at every m_H from 110 to 150 GeV in 1 GeV steps, skipping the truth's own family.

Example: the exponential of a quadratic. Exp2 fits the data with $p = 0.252$. Against the truths it invents up to 273.8 events, 2.42 times the statistical error σ_S of the signal: a function that passes the goodness-of-fit test would, on a background-only spectrum, produce a bump of more than two standard deviations by its shape alone. Figure 13.43 shows why: its spurious signal oscillates with m_H, positive where the truth bends above the Exp2 shape and negative where it bends below. A rigid function cannot follow a bend, so it uses the signal template to do it.

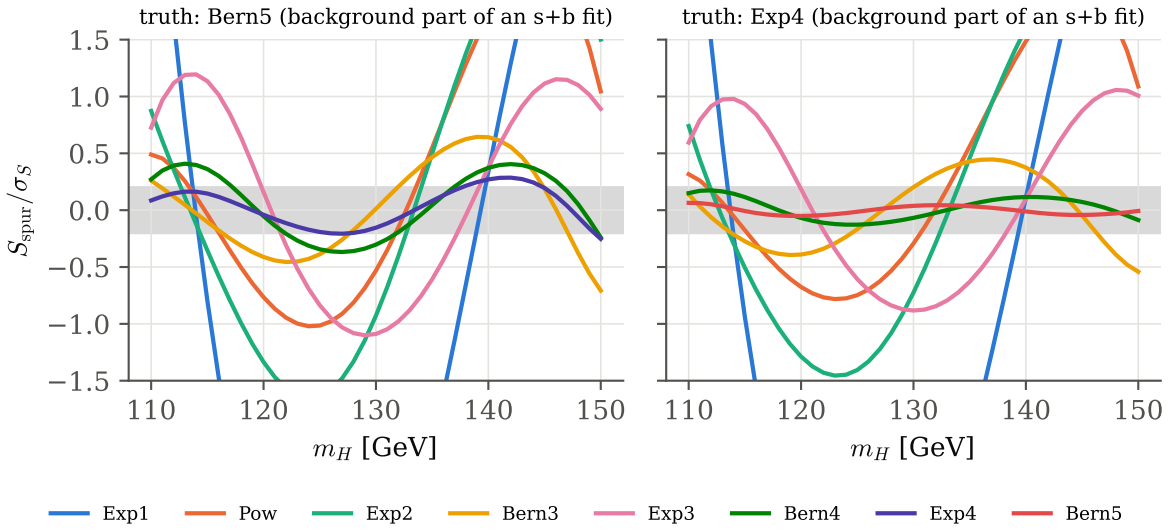

Figure 13.43: The spurious signal of each candidate background family, in units of the statistical error of the fitted signal, against the hypothesised Higgs mass. Left: the truth is the background part of a Bern5 fit to the data; right: of an Exp4 fit. The grey band is the ±20% criterion. The rigid families (Exp1, Pow, Exp2) swing far outside it; only the most flexible ones stay close to zero everywhere.

The verdict, and its limits. Only Bern5 passes, with $|S_{\text{spur}}| \leq 15.6$ events, $0.06\,\sigma_S$; Bern4 reaches $0.41\,\sigma_S$ against the Bern5 truth. We use Bern5 from here on. Two honest caveats.

The truths are themselves fits to the same data, so the test checks the families against each other rather than against an independent truth, and Bern5 has been tested only against Exp4. And with only the data, a more flexible truth would always make the next family fail. So, as ATLAS did, the spurious signal also enters the likelihood as a nuisance parameter: a term $\theta_{ss} S_{spur} f_i(m_H)$ added to the mean, with $S_{spur} = 15.6$ events and a unit Gaussian constraint on θ_{ss}. "The background model might be wrong by this much" becomes a systematic uncertainty of the signal.

The price of flexibility. A flexible function invents no signal, but it can also absorb part of a real one: a fifth-degree polynomial over 55 GeV can make a broad wiggle that resembles a 6 GeV-wide peak. How much sensitivity does that cost? *The question in words:* how much smaller is the expected q_0 when the background shape is fitted than when it is known? By Wald's approximation (Section 4.16.2), the expected q_0 for a signal μ is $q_{0,A} = \mu^2/V_{\mu\mu}$, with $V_{\mu\mu}$ the variance of $\hat{\mu}$ when the background parameters are fitted too. With the background known, the variance is the smaller $1/F_{\mu\mu}$, where F is the Fisher matrix. Then

$$\frac{q_{0,A}^{\text{fitted}}}{q_{0,A}^{\text{known}}} \overset{(1)}{=} \frac{\mu^2/V_{\mu\mu}}{\mu^2 F_{\mu\mu}} \overset{(2)}{=} \frac{1}{F_{\mu\mu}(\mathbf{F}^{-1})_{\mu\mu}} \overset{(3)}{=} 1 - \rho^2, \tag{13.49}$$

(1) The Asimov q_0 with the profiled and with the conditional variance.
(2) The variance of $\hat{\mu}$ with all parameters fitted is the $\mu\mu$ element of the inverse Fisher matrix (Chapter 10).
(3) The identity $1/F_{\mu\mu} = V_{\mu\mu}(1 - \rho^2)$ of Chapter 3, used in (4.93), with ρ^2 the fraction of the variance of $\hat{\mu}$ shared with the background parameters.

The background parameters play exactly the role the systematic uncertainty played in (4.93): whatever part of the signal's information they share is lost. On the Asimov data set of our spectrum with a $\mu = 1$ Higgs signal at 125 GeV (`code/ch13/33_hyy_search.py`):

background	known	Bern1	Bern2	Bern3	Bern4	Bern5	Bern6
expected $Z = \sqrt{q_{0,A}}$	3.39	2.88	2.87	2.51	2.5	2.16	2.01
$1 - \rho^2$	1	0.79	0.74	0.55	0.55	0.41	0.35

The expected significance falls with every added degree, and the second row explains the first: each Z is close to the known-background value times $\sqrt{1 - \rho^2}$. This is the trade-off ATLAS describes as a "compromise between limiting the size of a potential bias while retaining good statistical power" [AadHiggs2012 §5.5]: rigid functions bias the signal, flexible ones dilute it. The narrower the peak, the less a smooth polynomial can imitate it, which is one reason good mass resolution is worth so much.

13.23 Is there a peak? The discovery test

The spectrum of Figure 13.40 holds 76394 photon pairs, and a Standard Model Higgs boson would add about 397.9 of them, piled within a few GeV of 125 GeV. The general problem is old and simple to state: a small number of extra events is spread over a few bins of a histogram that already contains many events; how should the counts be combined to decide whether the extra events are there? Before writing the full likelihood, the smallest version of the problem shows what matters.

The smallest example: one window. Count the events in a mass window and compare the count with the background expected in it. If the window holds s signal and b background events with b large, the count fluctuates by $\sqrt{b}$, and the excess is worth about $s/\sqrt{b}$ standard deviations (Eq. (4.108) with $s \ll b$). The window's width is the only dial, and it acts on both numbers at once. *The naive choice:* use the whole window 105–160 GeV, which certainly contains all the signal. Then $s \approx 398$ and $b \approx 76\,000$, so

$$\frac{s}{\sqrt{b}} \approx \frac{398}{\sqrt{76\,000}} = \frac{398}{276} = 1.44.$$

Most of those 76 000 events are far from 125 GeV and carry no information about the peak, but each adds its fluctuation. *A better choice:* keep only $m_H \pm k\sigma$ around the peak, with $\sigma = 2.467$ GeV the width of the signal from Section 13.22.1. A Gaussian peak puts a fraction $\mathrm{erf}(k/\sqrt{2})$ of its events inside, while the background in the window is its density β times the width $2k\sigma$. Near 125 GeV the background density is $\beta = 1527$ events per GeV. The ratio $\mathrm{erf}(k/\sqrt{2})/\sqrt{2k}$ is largest near $k = 1.4$, where the window keeps 84% of the signal, so

$$\frac{s}{\sqrt{b}} = \frac{0.84 \times 398}{\sqrt{1527 \times 2.8 \times 2.47}} = \frac{334}{103} = 3.25.$$

Cutting away the empty regions more than doubled the significance. *The price:* the number b under the peak must now be known, and it is not measured inside the window, where the signal sits; it has to be interpolated from the sidebands with a background function. Every uncertainty of that interpolation lowers the 3.25. The lesson in one line: *the events near the peak carry the information, and the background under the peak is what we pay to know.* A likelihood does better than any window: it weights every bin by how much signal it can hold, fits the background under the peak together with the signal, and can ask the discovery question of Section 4.16 at every mass from 110 to 150 GeV.

13.23.1 The likelihood of the spectrum

The mean count in each bin. The histogram now has 220 bins of 0.25 GeV between 105 and 160 GeV, fine enough that the shape of the peak (about ten bins wide) is not smeared by the binning. Each count n_i is Poisson, as in Section 4.15.1, with a mean built from four pieces:

$$\nu_i = \underbrace{\mu\,(1+\delta_y)^{\theta_y}\, s_i(m_H;\theta_\sigma,\theta_m)}_{\text{Higgs signal}} + \underbrace{\theta_{\text{ss}}\, S_{\text{spur}}\, f_i(m_H)}_{\text{spurious signal}} + \underbrace{\sum_{j=0}^{5} c_j\, b_{j,5}(m_i)}_{\text{background}}. \tag{13.50}$$

Each piece, one at a time:

- $s_i(m_H)$ is the number of Higgs events the simulation predicts in bin i for a Standard Model Higgs boson of mass m_H: the 397.9 events of Section 13.21.1 distributed with the Crystal Ball shape of (13.46). The **signal strength** μ [the observed signal divided by the Standard Model prediction] is the parameter of interest: $\mu = 0$ is no Higgs boson, $\mu = 1$ is the Standard Model.
- θ_y moves the expected number of signal events by a relative $\delta_y = 10\%$ per unit. It stands for everything that scales the signal as a whole: the luminosity, the photon identification and isolation efficiencies. ATLAS quoted 8–11% for the identification and 1.8–3.6% for the luminosity [AadHiggs2012 §5.6]. The power form $(1+\delta_y)^{\theta_y}$ keeps the yield positive for any θ_y.

- θ_σ changes the width of the peak by a factor $(1+\delta_\sigma)^{\theta_\sigma}$ with $\delta_\sigma = 14\%$, the resolution uncertainty of the 2012 analysis [AadHiggs2012 §5.6].
- θ_m shifts the peak by a relative $\delta_m \theta_m$, with $\delta_m = 0.0086$, the photon energy-scale uncertainty that the release stores for every photon, averaged over the selected signal events (a 1% shift of both photon energies moves $m_{\gamma\gamma} \propto \sqrt{E_1 E_2}$ by 1%).
- $\theta_{\text{ss}} S_{\text{spur}} f_i$ is the spurious signal of Section 13.22.2: a signal-shaped term of size $S_{\text{spur}} = 15.6$ events, with f_i the signal shape normalised to one.
- $b_{j,5}(m)$ are the six Bernstein basis polynomials of degree five chosen in Section 13.22.2, and the c_j are free. They describe the background everywhere, under the peak included, without any separate sideband.

Constraints. The four θ's are calibrations measured outside this spectrum. As in Section 4.15.2, each one comes with an auxiliary measurement a_k whose likelihood is a Gaussian of unit width, so that $\theta_k = \pm 1$ is one standard deviation of that calibration, and $a_k = 0$ for the real data. The whole likelihood is (4.89), and the function we minimise is

$$-2\ln \mathcal{L}(\mu, \boldsymbol{c}, \boldsymbol{\theta}) = 2\sum_{i=1}^{220}\left[\nu_i - n_i \ln \nu_i\right] + \sum_k \left(\theta_k - a_k\right)^2 + \text{const}, \tag{13.51}$$

with eleven parameters: μ, six c_j and four θ_k. The first sum is -2 times the log of the Poisson probabilities, without the $\ln n_i!$ that does not depend on the parameters; the second is -2 times the log of the four Gaussian constraints. `code/ch13/lib_hyy.py` codes (13.50) and (13.51) in its class `Search` and minimises with MINUIT through `iminuit`.

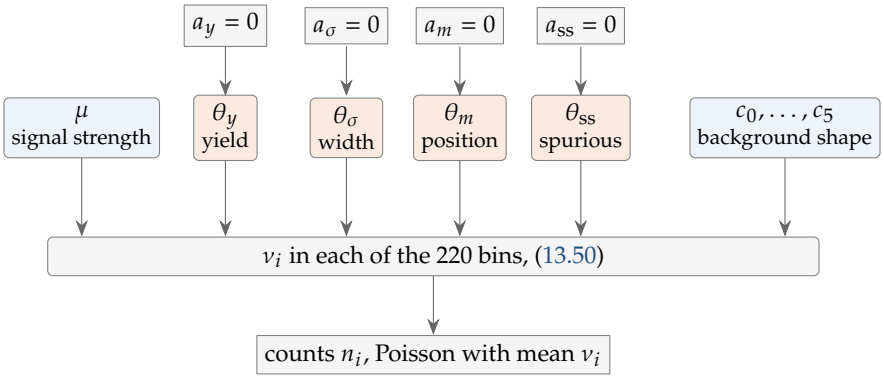

Figure 13.44: The structure of the diphoton likelihood. The parameter of interest μ and the six background coefficients are free; each of the four nuisance parameters (orange) is tied to an auxiliary measurement a_k by a unit Gaussian. All eleven parameters together set the mean count of every bin, and the observed counts are Poisson about those means.

13.23.2 The scan: local significance

The question at one mass. Fix a mass, say $m_H = 125\,\text{GeV}$. *If there were no Higgs boson ($\mu = 0$), would an excess like the one in the data, or a larger one, be something we would reasonably expect?* The null hypothesis is "background only", because its sampling distribution is the one we can work out: with $\mu = 0$, the statistic q_0 of (4.98) follows the half-χ^2_1 law of (4.101) for a large sample. So the procedure is: fit (13.51) twice, once with μ free and once with $\mu = 0$, the background and nuisance parameters re-fitted each time; take q_0 as twice the difference of the two minima of $-\ln \mathcal{L}$ when $\hat{\mu} > 0$ (and 0 otherwise); then

$$p_0 = \text{P}(q_0 \geq q_{0,\text{obs}} \,|\, \mu = 0) = 1 - \Phi\left(\sqrt{q_{0,\text{obs}}}\right), \qquad Z = \Phi^{-1}(1 - p_0) = \sqrt{q_{0,\text{obs}}}, \tag{13.52}$$

from (4.101) with $\mu' = 0$. The significance Z is simply the square root of q_0: that is what makes q_0 convenient.

The scan. We do not know m_H, so `code/ch13/33_hyy_search.py` repeats the test at every m_H from 110 to 150 GeV in steps of 0.5 GeV. Figure 13.46 shows the result. The largest excess is at $m_H = 124.5$ GeV, with

$$q_{0,\mathrm{obs}} = 7.6, \qquad Z_{\mathrm{loc}} = 2.77, \qquad p_0 = 0.002846, \qquad \hat{\mu} = 1.28.$$

The word *local* is a warning: this is the p-value of a test made at one mass chosen in advance, while we chose 124.5 GeV after looking at all of them. The correction is the subject of Section 13.24. With all four nuisance parameters held at their nominal values the largest Z is 2.77: the calibrations cost almost nothing here, because a 10% uncertainty on the yield or a 14% uncertainty on the width changes q_0 only at second order when the signal is a small fraction of the data. Away from the largest excess the two curves of Figure 13.46 do separate, most visibly near 140 GeV. There the energy-scale parameter θ_m can slide the signal template a few GeV towards the excess at 143 GeV, paying for it with its constraint term θ_m^2. A nuisance parameter that moves the peak competes with the scanned mass itself; at the top of an excess it has nowhere better to go, which is why the largest q_0 is unchanged. The other excesses in the scan are what background fluctuations look like: the largest one more than 8 GeV away from the peak is at 143 GeV with $Z = 2.71$.

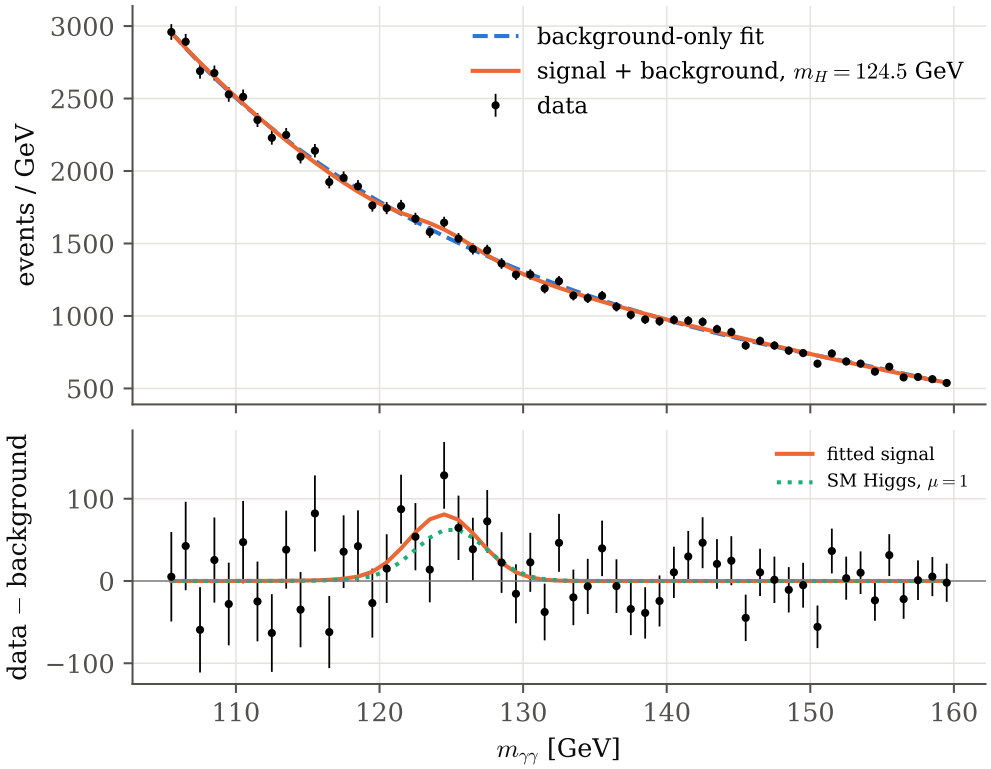

Figure 13.45: Top: the data in 1 GeV bins with the background-only fit (dashed) and the best signal-plus-background fit at $m_H = 124.5$ GeV (solid). Bottom: the same data with the fitted background subtracted. The fitted signal (orange) and the Standard Model expectation (dotted) are of similar size; the residuals far from the peak scatter about zero as Poisson noise of about $\pm\sqrt{1600} = \pm 40$ events per GeV.

Example: the excess in events. At 124.5 GeV the fit gives $\hat{\mu} = 1.28$, that is $1.28 \times 397.9 \approx 510$ extra events spread over the peak, against a background of about 1527 events per GeV. The bottom panel of Figure 13.45 shows them as a bump of about 80 events per GeV at its top on residuals that scatter by ±40: a bump no single bin could establish, which the likelihood finds by adding the evidence of all the bins it covers.

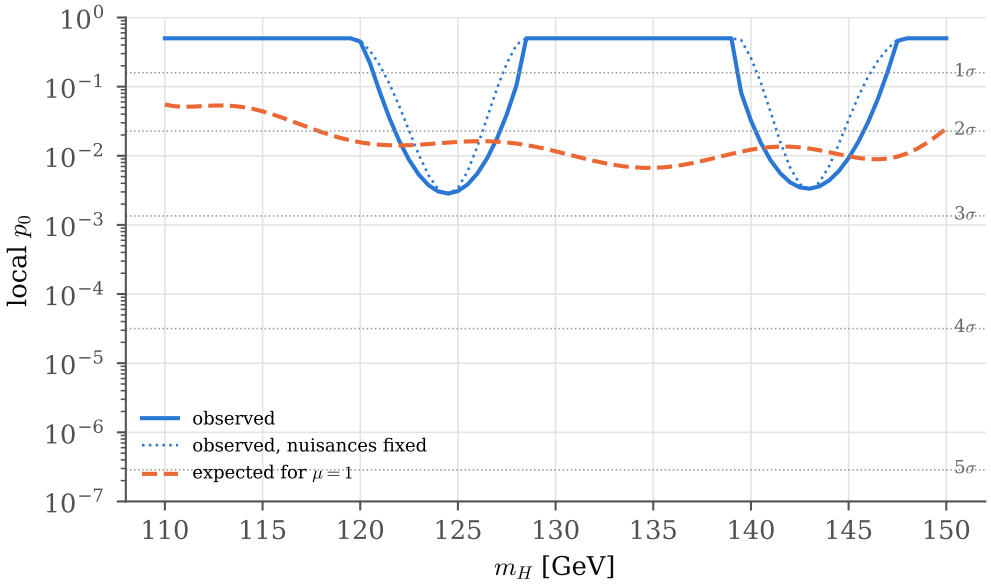

Figure 13.46: The local p-value p_0 of the background-only hypothesis against the tested mass (solid), with the nuisance parameters fixed at their nominal values (dotted) and the median expected for a Standard Model Higgs boson at each mass (dashed, from Asimov data sets). The horizontal lines mark 1σ to 5σ. The observed curve dips where the data have an excess, and the expected curve says how deep the dip should be if the Standard Model Higgs boson were at that mass.

13.23.3 How large an excess should we expect?

The question. A local Z of 2.77 is neither a discovery nor nothing. To judge it we need to know what a Standard Model Higgs boson would typically produce in this data set. *If the truth were $\mu = 1$ at 125 GeV, what q_0 would we typically see?* The answer is the Asimov data set of Section 4.16.3: replace the counts by their expected values $n_i = b_i + s_i$, with b_i the fitted background, and compute q_0 on them. By (4.107) the result $q_{0,\mathrm{A}}$ is the median of q_0 under $\mu = 1$, so $\sqrt{q_{0,\mathrm{A}}}$ is the median significance. The script does this at each mass, which gives the dashed curve of Figure 13.46; at 125 GeV,

$$Z_{\mathrm{exp}} = \sqrt{q_{0,\mathrm{A}}} = 2.15.$$

The data show 2.74 at 125 GeV, and $\hat{\mu} = 1.28$ at the peak: a little more signal than the Standard Model predicts, within the fluctuations Section 13.25 quantifies.

Where the expected significance comes from. *The question:* which features of the data set the number 2.15? Start from the simplest case, the background known exactly and no nuisance parameters. The bins are independent, so $\ln \mathcal{L}$ is a sum over bins and so is q_0. In each bin the

Asimov value is the counting result (4.108). With $x_i = s_i/b_i$, which is below 0.1 in every bin,

$$q_{0,\mathrm{A}} \overset{(1)}{=} 2\sum_i \left[(s_i+b_i)\ln\!\left(1+\frac{s_i}{b_i}\right) - s_i\right] \overset{(2)}{=} 2\sum_i \left[b_i(1+x_i)\left(x_i - \frac{x_i^2}{2} + \frac{x_i^3}{3} - \cdots\right) - b_i x_i\right]$$
$$\overset{(3)}{=} 2\sum_i b_i\left[\frac{x_i^2}{2} - \frac{x_i^3}{6} + \cdots\right] \overset{(4)}{\approx} \sum_i \frac{s_i^2}{b_i}. \tag{13.53}$$

(1) (4.108) applied bin by bin and summed, since q_0 is a sum of independent bins when the background is known.
(2) Write $s_i = b_i x_i$ and expand $\ln(1+x) = x - x^2/2 + x^3/3 - \cdots$.
(3) Multiply out: $(1+x)(x - x^2/2 + x^3/3) = x + x^2/2 - x^3/6 + \cdots$, and the leading x cancels against $-b_i x_i$.
(4) Keep the first term, $b_i x_i^2 = s_i^2/b_i$; the next is smaller by a factor $x_i/3$.

Each bin contributes the square of its own counting significance $s_i/\sqrt{b_i}$, and squares add. This is the window of the opening example with every bin given its own weight: a bin with no signal contributes nothing (instead of adding noise), and the bins at the top of the peak contribute most. On our spectrum $\sqrt{\sum_i s_i^2/b_i} = 3.41$.

The same in closed form. A peak of S events with a Gaussian shape of width σ, on a background of density β events per GeV that is nearly flat across it, has $s_i = S\,\varphi(m_i)\,\Delta$ and $b_i = \beta\Delta$ in bins of width Δ, with φ the Gaussian density. For bins much narrower than σ the sum becomes an integral:

$$q_{0,\mathrm{A}} \overset{(1)}{=} \sum_i \frac{S^2\varphi(m_i)^2\Delta^2}{\beta\Delta} \overset{(2)}{=} \frac{S^2}{\beta}\int \varphi(m)^2\,\mathrm{d}m \overset{(3)}{=} \frac{S^2}{\beta}\cdot\frac{1}{2\pi\sigma^2}\int e^{-(m-m_H)^2/\sigma^2}\mathrm{d}m$$
$$\overset{(4)}{=} \frac{S^2}{\beta}\cdot\frac{\sqrt{\pi}\,\sigma}{2\pi\sigma^2} = \frac{S^2}{2\sqrt{\pi}\,\sigma\,\beta}. \tag{13.54}$$

(1) Insert s_i and b_i into (13.53).
(2) One factor Δ is left: $\sum_i g(m_i)\Delta \to \int g\,\mathrm{d}m$.
(3) The square of $\varphi(m) = e^{-(m-m_H)^2/2\sigma^2}/(\sqrt{2\pi}\sigma)$.
(4) The Gaussian integral $\int e^{-u^2/a^2}\mathrm{d}u = \sqrt{\pi}\,a$ with $a = \sigma$.

Equation (13.54) says the peak acts like a counting window of effective width $2\sqrt{\pi}\,\sigma = 3.54\,\sigma$ holding all S events: $Z^2 = S^2/(\beta \times 3.54\sigma)$. It shows the three dials of every resonance search at once. The significance grows like the signal S, falls like the square root of the background density, and falls like the square root of the mass resolution. Halving σ is worth as much as halving the background density β: either one doubles Z^2.

Example: our numbers. With $S = 397.9$ events in the window, $\sigma = 2.467$ GeV and $\beta = 1527$ per GeV,

$$q_{0,\mathrm{A}} \approx \frac{398^2}{2\times 1.772\times 2.467\times 1527} = \frac{158\,400}{13\,350} = 11.9, \qquad Z \approx 3.44,$$

the value 3.44 printed by the script, against 3.41 from the exact sum with the Crystal Ball shape. The tail of the Crystal Ball puts a few per cent of the signal where the background is large, which costs a little.

From 3.4 to 2.15: what the fit costs. The full Asimov value at 125 GeV is 2.15, well below 3.41. The difference is the price paid at the end of the opening example: the background under the peak is not known but fitted. By (13.49), fitting six background coefficients together with μ keeps a fraction $1 - \rho^2 = 0.41$ of $q_{0,\mathrm{A}}$, and

$$3.41 \times \sqrt{0.41} \approx 2.16,$$

the expected significance with the degree-five background in the table of Section 13.22.2. The nuisance parameters take the rest of the way to 2.15. So most of the loss is the background function, and very little is the calibrations. A real analysis fights this loss by splitting the events into categories with different σ and β (Section 13.25.3) and by using a background function no more flexible than the spurious-signal test demands.

Watch out

Z_{exp} is the *median* significance under $\mu = 1$, not a prediction of what this data set will show. The observed q_0 fluctuates about $q_{0,\mathrm{A}}$ with a spread of about $2\sqrt{q_{0,\mathrm{A}}}$ (Eq. (4.100): $\sqrt{q_0} = \hat{\mu}/\sigma_\mu$ is Gaussian with unit width), so with $Z_{\mathrm{exp}} = 2.15$ a true Standard Model Higgs boson gives Z anywhere between about 1.2 and 3.2 in two thirds of repetitions.

13.24 Anywhere in the range: checking the formulas and looking elsewhere

Two claims of Section 13.23 rest on formulas rather than on the data. The local p-value 0.002846 came from the half-χ^2 law (4.101), which Wald's approximation guarantees only for a large sample and a well-behaved fit, and here the fit has eleven parameters and a background that bends. And the excess at 124.5 GeV was picked as the largest of 81 tested masses, so its local p-value is not the probability that background alone produces such an excess *somewhere*. Both are questions about the sampling distribution of q_0 under the background-only hypothesis, and both can be answered by simulating the experiment many times.

What we saw in the toy bump hunt, and what is different now. In Section 4.14.3 a simulated spectrum of 3000 events with a known exponential background was scanned for a Gaussian peak of width 1.5 GeV over 50 GeV. Its largest bump had $Z_{\mathrm{loc}} = 3.28$; 20000 background-only scans made that a global 2.15σ, a trials factor of 31.3, and the Gross–Vitells formula (4.85), calibrated on 100 scans, reproduced it. The method is the same now. Three things differ, and each changes the size of the correction. The peak is wider, $\sigma = 2.467$ GeV against 1.5, and the range is shorter, 40 GeV against 50: there are fewer independent places for a fluctuation to appear, roughly $40/2.5 = 16$ against $50/1.5 = 33$. The background shape is fitted in every toy, with six coefficients, so a toy that fluctuates in a smooth, broad way is absorbed by the background rather than counted as a bump. And the local significance is lower, 2.77 against 3.28, and by (4.86) the trials factor grows with the local significance. All three point to a smaller trials factor than the 31.3 of the toy.

How the toys are made. `code/ch13/34_hyy_toys.py` draws each background-only toy as 220 Poisson counts whose means are the background-only fit to the data, b_i. Every toy is then analysed exactly as the data: the degree-five Bernstein background is refitted, and q_0 is computed at all 81 masses. Fitting 81 masses for each of thousands of spectra with MINUIT would take hours, but the model with the four nuisance parameters fixed is linear in its seven free parameters (μ and the six c_j). For a mean linear in the parameters, $\ln \mathcal{L} = \sum_i (n_i \ln \nu_i - \nu_i)$

is concave, so Newton's method converges from any reasonable start, and it can be run on 250 spectra at once as matrix operations. At the largest excess the nuisance parameters changed Z by less than 0.01 (Section 13.23.2), and the largest q_0 of a scan is what the global p-value counts, so fixing them in the toys leaves it unchanged. Scanned with this fitter, the data give $q_{0,\mathrm{obs}} = 7.7$ at 124.5 GeV, essentially the 7.6 of the full fit.

13.24.1 Is the half-χ^2 law right?

The question: if there were no Higgs boson, how would q_0 at one fixed mass, 125 GeV, be distributed over repetitions of the experiment? The half-χ^2 law makes three checkable predictions. Half of the toys should have $\hat{\mu} \le 0$ and so $q_0 = 0$ exactly; the toys give 0.508. The fraction with $q_0 > 4$ (a local 2σ) should be $\Phi(-2) = 0.0228$; the toys give 0.0228. The fraction with $q_0 > 9$ (a local 3σ) should be $\Phi(-3) = 0.0013$; the toys give 0.0012. With 4000 toys the statistical error of a fraction p is $\sqrt{p(1-p)/4000}$, about 0.002 at 0.023 and 0.0006 at 0.0013, so the agreement is as good as the toys can tell. Figure 13.47 (left, blue) shows the whole tail.

The same question under the signal hypothesis tells us whether the Asimov expected significance is the median, as (4.107) says. Toys drawn with $\mu = 1$ at 125 GeV have a median $\sqrt{q_0}$ of 2.15, against the Asimov value 2.16, and the central 68% lie between 1.14 and 3.13: a spread of one unit in Z, as the pitfall of Section 13.23.3 said. Only a fraction 0.002 of experiments of this size would see a Standard Model Higgs boson at 5σ. With 76 000 events the asymptotic formulas are doing exactly what they promise; they were derived for this situation.

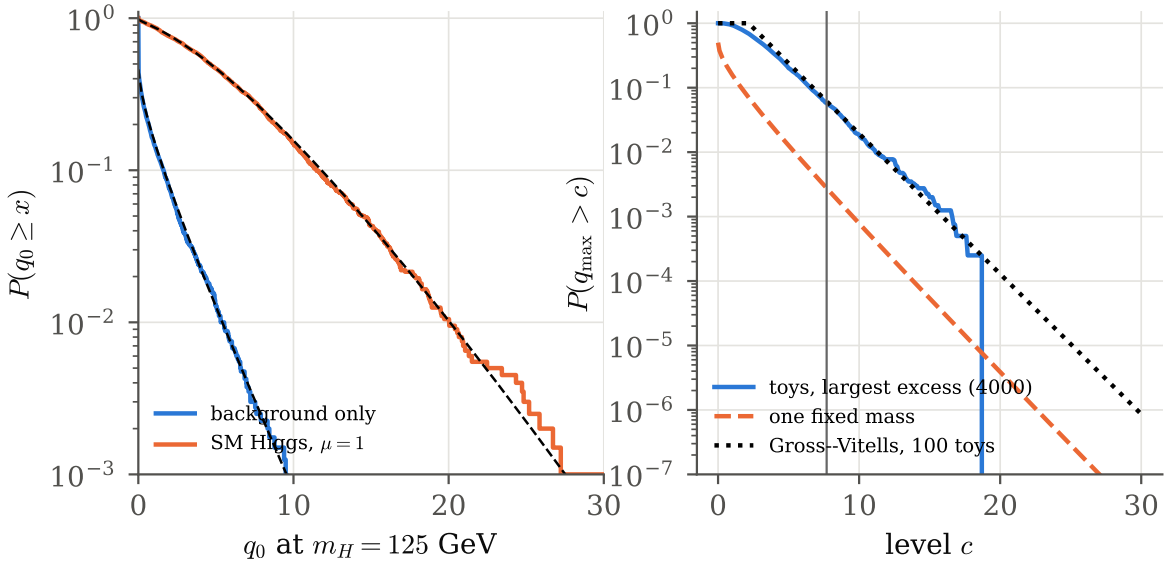

Figure 13.47: Left: the probability that q_0 at 125 GeV exceeds x, from toys with background only (blue) and with a Standard Model Higgs boson (orange), against the asymptotic formulas (black dashed). The step at $x = 0$ in the blue curve is the half of the toys with $\hat{\mu} \le 0$. Right: the probability that the largest q_0 anywhere in 110–150 GeV exceeds a level c (blue, 4000 toys), the probability at one fixed mass (orange dashed), and the Gross–Vitells formula calibrated on the first 100 toys (black dotted). The vertical line is the excess in the data.

13.24.2 The global p-value

The question. *If there were no Higgs boson, how often would an excess as large as the one we saw appear somewhere between* 110 *and* 150 *GeV?* The event is now "the largest q_0 in the scan is at

least $q_{0,\mathrm{obs}} = 7.7''$. Each toy gives one largest q_0, so the answer is a count: 229 of the 4000 background-only toys have $q_{\max} \geq 7.7$, so

$$p_{\mathrm{glob}} = 0.0572 \pm 0.0037,$$

with the binomial error $\sqrt{p(1-p)/N}$ of Chapter 4.

The same from a hundred toys. For a stronger excess the counting would need millions of toys. The Gross–Vitells formula (4.85) needs only the mean number of upcrossings of a low level, which a few scans measure well. Counting how often each of the first 100 toy scans crosses $c_0 = 0.5$ upwards gives $\mathbb{E}[N(c_0)] = 2.14$ (all 4000 toys: 2.06). Then, at $c = q_{0,\mathrm{obs}}$,

$$\begin{aligned} p_{\mathrm{glob}} &\overset{(1)}{=} p_{\mathrm{loc}}(c) + \mathbb{E}[N(c_0)]\, e^{-(c-c_0)/2} \overset{(2)}{=} \Phi\big(-\sqrt{7.7}\big) + 2.14\, e^{-(7.7-0.5)/2} \\ &\overset{(3)}{=} 0.0613, \qquad Z_{\mathrm{glob}} = 1.54. \end{aligned} \tag{13.55}$$

(1) The Gross–Vitells formula (4.85): the chance of being above c at the start of the range plus the expected number of upward crossings of c, scaled down from the reference level c_0 by $e^{-(c-c_0)/2}$.
(2) Insert the observed q_0 and the measured $\mathbb{E}[N(c_0)]$.
(3) Evaluate, and convert to a significance with $Z = \Phi^{-1}(1-p)$.

The two routes agree within the error of the toy count, and the right panel of Figure 13.47 shows that they agree over the whole curve, not only at the observed value. With the full likelihood (all nuisance parameters free) the local significance is 2.77, and the same formula gives $Z_{\mathrm{glob}} = 1.53$.

The trials factor. The ratio of the two p-values is $p_{\mathrm{glob}}/p_{\mathrm{loc}} = 22.2$. Its asymptotic form (4.86), $1 + \sqrt{2\pi}\, \mathcal{N}_1 Z$ with $\mathcal{N}_1 = \mathbb{E}[N(c_0)]e^{c_0/2} = 2.75$, gives 20.1. Both are below the 31.3 of the toy bump hunt, for the three reasons met there: a wider peak and a shorter range, a fitted background and a lower local significance. The number $\mathcal{N}_1 = 2.75$, against 3.60 in Section 4.14.3, measures how many independent places the scan offers. It is smaller, as expected, but not half as small as the crude count of range over width (16 against 33) suggested: that count is only a rough guide, and the upcrossings measure the real number directly.

Example: how often background alone gives a local 3σ somewhere. At a fixed mass a local 3σ excess has probability 0.0013. Somewhere in the range it is far more common: the toys give 0.032 and the formula 0.032, so roughly one search in thirty of this size shows a local 3σ bump with no Higgs boson at all. That is why particle physics asks for 5σ before it says "discovery": a 3σ excess in a scan is a reason to look again with more data, not a result.

The data's second bump. The scan of Figure 13.46 has a second excess, at 143 GeV with local $Z = 2.71$, almost as large as the one at the Higgs mass. Nothing is expected there, and the global p-value is exactly the tool that tells us not to be impressed: an excess of that size somewhere in the range happens in about 0.0572 of background-only experiments. The data alone cannot say which of the two bumps is the Higgs boson. What singles out 125 GeV is outside this spectrum: the 2012 discovery in this and other decay channels, and the expected size of the signal.

Which range? The global p-value depends on the range searched, and the range has to be fixed before the data are seen. In 2012 ATLAS quoted both: a global 5.1σ for 110–600 GeV and

5.3σ for 110–150 GeV, from a local 5.9σ in all channels combined [AadHiggs2012 §9]. For us, in 2016 data, the mass was already known to a fraction of a GeV, and the honest test is the local one at 125 GeV: $Z = 2.74$. Had we searched only 120–130 GeV, the expected number of upcrossings would be a quarter of that for 40 GeV, and the formula gives $Z_{\text{glob}} = 2.1$.

How this is used in real research: Toys in a real analysis

The LHC experiments compute local significances with the asymptotic formulas, check them with toys at a few masses as above, and quote global significances from the Gross–Vitells formula or a variant with several search dimensions (mass and width) [15, 27]. Toys are run in full only where the formulas are in doubt: few events, a parameter near a boundary, or a statistic far in its tail. Each toy there is a full fit with every nuisance parameter, and the auxiliary measurements a_k are drawn afresh in each toy, which our statistics-only toys skip.

13.25 How strong, and where? Measuring μ and m_H

Once a signal is taken to be present, the question changes from "is it there?" to "how much of it is there, and where?". The first is a test with one answer, yes or no at a chosen level; the second is a measurement with an interval. The data are the same 76394 masses, the likelihood is the same (13.51), and the tool is the profile likelihood ratio $\lambda(\mu)$ of (4.92) read as a curve rather than at one point.

13.25.1 The signal strength

The question. *Which values of μ at $m_H = 125$ GeV are compatible with the data?* For each trial μ we fit everything else (the six background coefficients and the four nuisance parameters) and record how much worse the best fit is than the overall best: $-2\ln\lambda(\mu)$. By Wald's approximation (4.100), $-2\ln\lambda(\mu) \approx (\mu - \hat{\mu})^2/\sigma_\mu^2$, a parabola that reaches 1 at $\hat{\mu} \pm \sigma_\mu$. So the values where the curve crosses 1 bound the 68% interval, and this remains true when the curve is not a parabola, because a reparametrisation that would make it one does not move the crossing points (Section 4.11.5).

The result. Figure 13.48 (left) shows the curve. It crosses 1 at

$$\hat{\mu} = 1.28\,^{+0.55}_{-0.49} \qquad (m_H = 125\,\text{GeV}).$$

The Standard Model value $\mu = 1$ lies inside; $\mu = 0$, no Higgs boson, is at $-2\ln\lambda = 2.74^2 \approx 7.5$, which is the q_0 of Section 13.23.2 read from the other side. The interval is wider above than below. The yield enters as $\mu(1+\delta_y)^{\theta_y}$, so the uncertainty it carries is a fixed fraction of μ: for large μ it is larger in absolute terms.

How much of it is statistics? Repeating the scan with the four nuisance parameters fixed at their nominal values gives the dashed curve, crossing 1 at ± 0.46. That is the uncertainty we would have with perfect calibrations: the statistical part. If the statistical and the systematic fluctuations of $\hat{\mu}$ are independent and Gaussian, their variances add, and the systematic part follows by subtraction:

$$\sigma_{\text{tot}}^2 \overset{(1)}{=} \sigma_{\text{stat}}^2 + \sigma_{\text{syst}}^2 \quad\Longrightarrow\quad \sigma_{\text{syst}} \overset{(2)}{=} \sqrt{\sigma_{\text{tot}}^2 - \sigma_{\text{stat}}^2} = \sqrt{0.52^2 - 0.46^2} \approx 0.24. \tag{13.56}$$

(1) The variance of a sum of independent fluctuations is the sum of their variances.
(2) Solve for the systematic part, with $\sigma_{\text{tot}} = 0.52$ the half-width of the total interval.

So $\hat{\mu} = 1.28 \pm 0.46\,(\text{stat}) \pm 0.24\,(\text{syst})$. A 10% yield uncertainty alone would give $0.10 \times 1.28 \approx 0.13$; the width and the position of the peak add the rest, because a wider or shifted template changes how many events the fit assigns to the peak. Statistics dominate: this measurement would improve with more data long before better calibrations mattered.

What the nuisance parameters did. At the best fit the four nuisance parameters sit at $\hat{\theta}_y = 0.00$ and $\hat{\theta}_{\text{ss}} = 0.00$ (to two decimals), $\hat{\theta}_\sigma = 0.03$ and $\hat{\theta}_m = -0.3$, all well within one standard deviation of their calibrations. The data cannot distinguish a larger yield from a larger μ, so they leave θ_y where its constraint puts it. Only θ_m moves: the data's peak sits a little below the simulated one. A nuisance parameter that the fit pushes far from zero would be a sign that a calibration and the data disagree, and would have to be investigated before quoting anything.

Example: compared with the Standard Model and with 2012. Our $\hat{\mu} = 1.28 \pm 0.52$ differs from the Standard Model value by $(1.28 - 1)/0.52 \approx 0.5$ standard deviations. ATLAS measured $\hat{\mu} = 1.8 \pm 0.5$ in the diphoton channel in 2012 [AadHiggs2012 Table 7], a value 1.6 standard deviations above one. The two results differ by $(1.8 - 1.28)/\sqrt{0.5^2 + 0.52^2} \approx 0.7$ standard deviations: entirely compatible. The high 2012 value was partly the luck of the experiment that made the discovery: a search that happens to fluctuate upwards is the one that crosses 5σ first.

13.25.2 The mass

The question. *Which Higgs masses are compatible with the data?* The same recipe applies with m_H in the place of μ: for each trial m_H from 120 to 130 GeV, fit everything else, μ included, and plot $-2\ln\lambda(m_H)$ (Figure 13.48, right). It crosses 1 at

$$\hat{m}_H = 124.5 \pm 1.4\,\text{GeV} \quad \text{(all nuisances)}, \qquad \hat{m}_H = 124.5\,^{+0.8}_{-0.9}\,\text{GeV} \quad \text{(nuisances fixed)}.$$

Here the systematic part is larger than for μ. The photon energy scale is known to $\delta_m = 0.0086$, which at 125 GeV is ± 1.07 GeV, and a shift of the energy scale moves the peak exactly as a shift of m_H does, so the data cannot separate them. In quadrature, $\sqrt{0.85^2 + 1.07^2} = 1.37$, the total.

How precisely should a peak locate a mass? The statistical ± 0.85 GeV is far smaller than the width $\sigma = 2.467$ GeV of the peak. *The question:* how does the position error depend on the peak? The Fisher information on the position m_0 of a peak with $s_i = S\varphi(m_i - m_0)\Delta$ on a flat background $b_i = \beta\Delta$ is $\sum_i (\partial s_i/\partial m_0)^2/b_i$, the same kind of sum as (13.53) with the derivative of the signal in the place of the signal (Chapter 10). For a Gaussian peak, $\partial\varphi/\partial m_0 = \big((m - m_0)/\sigma^2\big)\varphi$:

$$\begin{aligned}\frac{1}{\sigma_m^2} &\overset{(1)}{=} \frac{S^2}{\beta}\int \frac{(m-m_0)^2}{\sigma^4}\,\varphi(m-m_0)^2\,\mathrm{d}m \overset{(2)}{=} \frac{S^2}{\beta}\cdot\frac{1}{2\pi\sigma^6}\int u^2 e^{-u^2/\sigma^2}\mathrm{d}u \\ &\overset{(3)}{=} \frac{S^2}{\beta}\cdot\frac{1}{2\pi\sigma^6}\cdot\frac{\sqrt{\pi}\,\sigma^3}{2} = \frac{S^2}{4\sqrt{\pi}\,\sigma^3\beta} \overset{(4)}{=} \frac{q_{0,\text{A}}}{2\sigma^2}.\end{aligned} \tag{13.57}$$

(1) The sum over narrow bins becomes an integral, as in (13.54).
(2) Write $u = m - m_0$ and square $\varphi = e^{-u^2/2\sigma^2}/(\sqrt{2\pi}\sigma)$.
(3) The second moment of a Gaussian: $\int u^2 e^{-u^2/a^2}\mathrm{d}u = \sqrt{\pi}\,a^3/2$ with $a = \sigma$.
(4) Compare with $q_{0,\text{A}} = S^2/(2\sqrt{\pi}\sigma\beta)$ of (13.54).

So $\sigma_m = \sqrt{2}\,\sigma/Z$, with $Z = \sqrt{q_{0,\mathrm{A}}}$ the significance of the peak: a peak located to a fraction of its width, and the fraction is $\sqrt{2}$ over its significance. A barely significant peak locates nothing; a 5σ peak locates its mass to 0.28 of its width. For the signal the data show, $\hat{\mu} = 1.28$ times the known-background $Z = 3.39$, this gives $\sqrt{2} \times 2.467/(1.28 \times 3.39) \approx 0.80\,\mathrm{GeV}$, close to the ± 0.85 of the profile. (The fitted background costs little here: a smooth polynomial cannot imitate the antisymmetric change that shifting a peak makes.)

Example: the 2012 mass. For the diphoton channel in 2012, $\sigma_{\mathrm{CB}} = 1.6\,\mathrm{GeV}$ and a local $Z = 4.5$ [AadHiggs2012 Table 7] give $\sigma_m \approx \sqrt{2} \times 1.6/4.5 = 0.50\,\mathrm{GeV}$; the statistical error ATLAS quoted for the combined mass, dominated by the diphoton and four-lepton channels, was 0.4 GeV [AadHiggs2012 §9]. Their peak was narrower and more significant, so their statistical error was smaller than our $\pm 0.85\,\mathrm{GeV}$ by almost a factor of two.

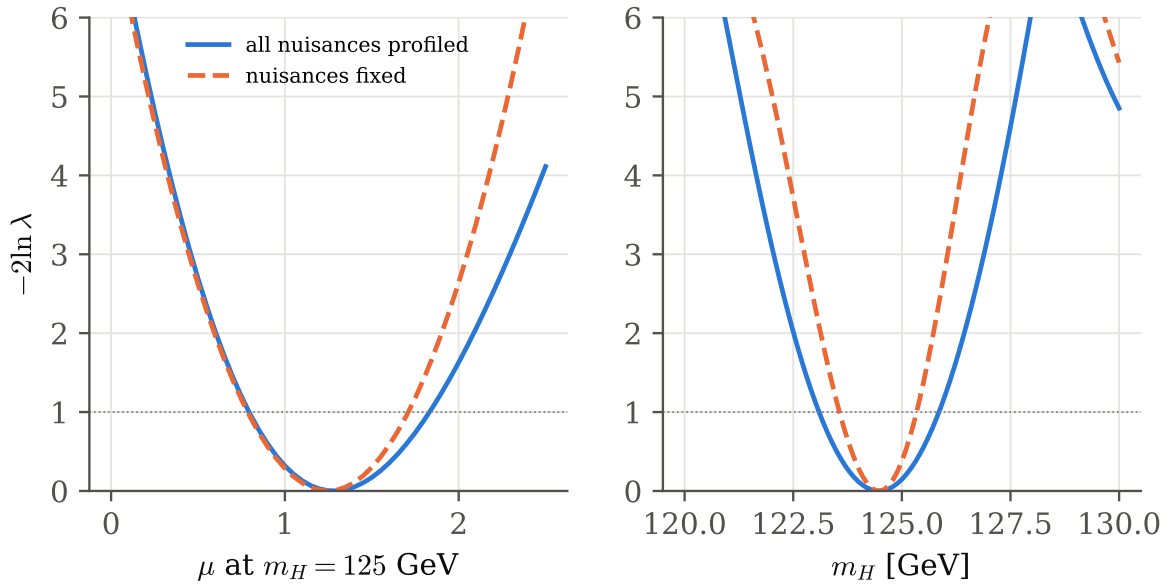

Figure 13.48: Left: $-2\ln\lambda$ as a function of the signal strength at $m_H = 125\,\mathrm{GeV}$, with all nuisance parameters profiled (solid) and fixed (dashed). The crossings of the dotted line at 1 bound the 68% intervals. Right: the same for the Higgs mass. The solid curve is much wider than the dashed one for the mass, because the photon energy scale shifts the peak exactly as a different mass would; for μ the two curves are close, because the measurement is limited by statistics.

13.25.3 Splitting the events into categories

The opening example of Section 13.23 showed that bins with more signal per background carry more information. The same holds for groups of events. In Section 13.22.1 the pairs with both photons central and unconverted had a narrower peak, $\sigma = 1.825\,\mathrm{GeV}$, than the rest, $\sigma = 2.58\,\mathrm{GeV}$. If we fit the two groups as separate spectra, each with its own background, the narrow peak is no longer diluted by the wide one.

Why splitting cannot hurt. *The question:* if two independent spectra share one μ, how do their significances combine? The likelihood is the product of the two (the rule by which Junk combined the LEP search channels [30, (1)]), so $\ln\mathcal{L}$ and q_0 are sums, and (13.53) becomes a sum over categories c and their bins. Take two categories with S_1, S_2 signal and B_1, B_2 background in comparable windows. Split, $Z^2 = S_1^2/B_1 + S_2^2/B_2$; merged, $Z^2 = (S_1 + S_2)^2/(B_1 + B_2)$. Their

difference is

$$\frac{S_1^2}{B_1}+\frac{S_2^2}{B_2}-\frac{(S_1+S_2)^2}{B_1+B_2} \overset{(1)}{=} \frac{S_1^2B_2(B_1+B_2)+S_2^2B_1(B_1+B_2)-(S_1+S_2)^2B_1B_2}{B_1B_2(B_1+B_2)}$$
$$\overset{(2)}{=} \frac{S_1^2B_2^2-2S_1S_2B_1B_2+S_2^2B_1^2}{B_1B_2(B_1+B_2)} \overset{(3)}{=} \frac{(S_1B_2-S_2B_1)^2}{B_1B_2(B_1+B_2)} \geq 0. \tag{13.58}$$

(1) Bring the three terms to the common denominator $B_1B_2(B_1+B_2)$.
(2) Expand: the terms $S_1^2B_1B_2$ and $S_2^2B_1B_2$ cancel against those of $-(S_1^2+2S_1S_2+S_2^2)B_1B_2$.
(3) A perfect square.

Splitting gains exactly when the categories have different signal-to-background ratios, $S_1/B_1 \neq S_2/B_2$, and never loses (as long as the background in each category is determined as well as before, which with fitted backgrounds is only approximately true).

Example: two categories in our data. The central unconverted category holds 8582 events and 58.8 expected Higgs events with $\sigma = 1.825\,\text{GeV}$; the rest holds 67812 events and 339.1 Higgs events with $\sigma = 2.58\,\text{GeV}$. Near 125 GeV the fitted background densities are about $\beta_1 \approx 171$ and $\beta_2 \approx 1360$ events per GeV (the signal yields 58.8 and 339.1 divided by β are 0.344 and 0.25 GeV). With (13.54) for each,

$$Z_1^2 = \frac{58.8^2}{2\times 1.772\times 1.825\times 171} = 3.1, \qquad Z_2^2 = \frac{339.1^2}{2\times 1.772\times 2.58\times 1360} = 9.2,$$

so $Z = \sqrt{12.4} = 3.52$ split, against 3.44 merged. The full fit with fitted backgrounds (statistical part only) gives an expected 2.26 split against 2.16 merged, and on the data 2.99 against 2.71, with $\hat{\mu} = 1.31$ against 1.25 (Figure 13.49). The gain is small because only one Higgs event in seven lands in the good category. ATLAS in 2012 used ten categories built from the photon positions, conversions and the transverse momentum of the pair, and Section 13.27 shows what that bought.

13.26 Where can a Higgs boson be excluded?

Before July 2012 the main output of every Higgs search was not a significance but a list of excluded masses. By then the searches at LEP, the Tevatron and the first LHC data had excluded a Standard Model Higgs boson at 95% confidence everywhere below 600 GeV except for some regions between 116 and 127 GeV [AadHiggs2012 §1]. An exclusion answers the opposite question to a discovery. The hypothesis under test is now the signal: *if a Higgs boson with strength μ existed at mass m_H, would data as background-like as ours, or more so, be something we would reasonably expect?* If not, that μ is excluded at that mass.

What we saw in Chapter 4, and what is new. In Section 4.13.4 the question was asked of a single count, with CL_{s+b} and CL_s computed from Poisson sums. In Sections 4.16.4 and 4.16.5 the same ideas were carried to a binned likelihood with nuisance parameters: the statistic $\tilde{q}_\mu$ (4.99), its asymptotic distribution (4.104), the CL_s upper limit (4.111) and the expected band (4.112), all computed on a simulated spectrum. The formulas are the same now. What is new is a scan of 41 masses on real data, where the observed limit can be compared with what the experiment should have achieved, and a check of the asymptotic CL_s limit against toys.

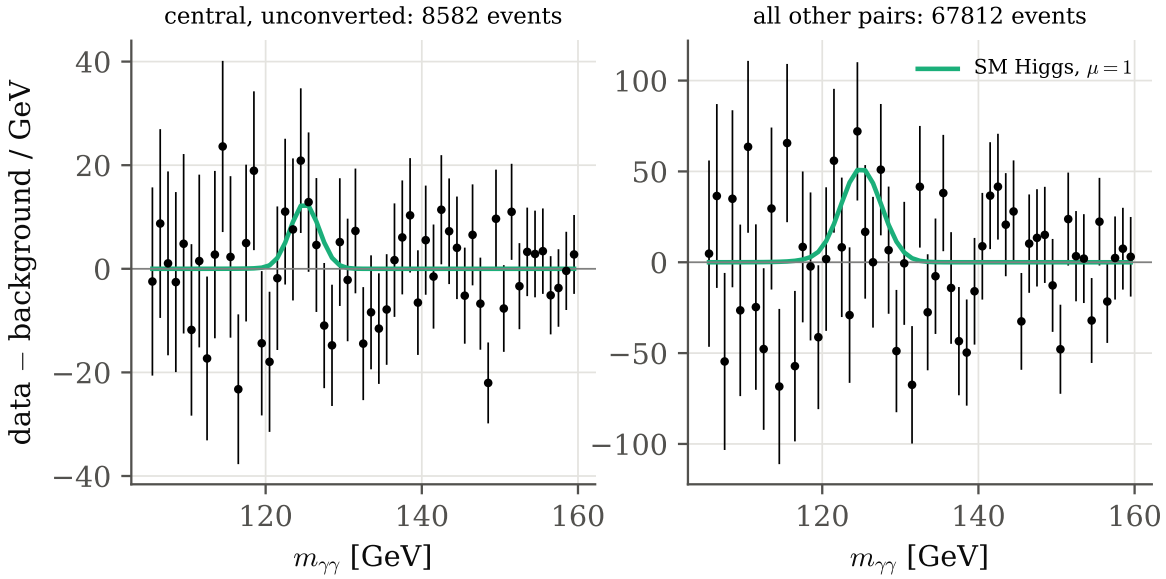

Figure 13.49: The data minus the fitted background in the two categories, with the Standard Model Higgs signal expected in each (orange). The central unconverted pairs (left) are fewer, but their peak is narrower and stands higher above the noise relative to its size; the rest (right) holds most of the signal on a much larger background.

The statistic and the two p-values. At each mass m_H and each trial μ the script computes $\tilde{q}_\mu$ from two fits of (13.51): with μ fixed and with μ free (or at 0 if the free fit gives $\hat{\mu} < 0$). It is large when the data have too few events for a signal of strength μ, and zero when they have more than μ predicts, because an upper limit should not be strengthened by an excess. Two p-values follow from the observed value, one under each hypothesis:

- $\mathrm{CL}_{s+b} = \mathrm{P}(\tilde{q}_\mu \geq \tilde{q}_{\mu,\mathrm{obs}} \,|\, \mu)$: how often a world with the signal gives data at least this background-like;
- $\mathrm{CL}_b = \mathrm{P}(\tilde{q}_\mu \geq \tilde{q}_{\mu,\mathrm{obs}} \,|\, 0)$: how often a world without it does.

Both come from (4.104), with $\mu' = \mu$ and $\mu' = 0$. Excluding μ whenever $\mathrm{CL}_{s+b} < 0.05$ would be a valid test, but it has a flaw that Read described with two experiments [31]: when the background fluctuates down, an experiment can exclude signals so small that it could never have seen them, and an experiment with more background can then quote the stronger limit. The CL_s method divides by CL_b,

$$\mathrm{CL}_s = \frac{\mathrm{CL}_{s+b}}{\mathrm{CL}_b} < \alpha = 0.05, \tag{13.59}$$

which leaves the test unchanged where the two hypotheses predict very different data ($\mathrm{CL}_b \approx 1$) and makes exclusion harder where they predict nearly the same data (CL_b small) [30, 31]. The price is over-coverage: a true signal is excluded in fewer than 5% of experiments, as Figure 4.35 showed for counts.

The one number the formulas need. The asymptotic distributions contain one unknown, the standard deviation σ of $\hat{\mu}$. *The question:* how is it found without simulation? By (4.107), with the background-only Asimov data set ($n_i = b_i$, the true $\mu' = 0$), $\sigma_{\mathrm{A}}^2 = \mu^2/\tilde{q}_{\mu,\mathrm{A}}$: fit the expected background spectrum with μ fixed, see how much worse it fits than with μ free, and read off the width. Because σ depends a little on μ (the nuisance parameters scale with the signal), the

script computes it at $\mu = 0.25, 0.5, 1$ and 2 and interpolates. At 125 GeV, $\sigma_A = 0.491$ at $\mu = 1$; the statistical-only estimate of Section 13.25.1 was 0.46, and the difference is the systematic part. The observed limit μ_{up} is then the μ at which (13.59) becomes an equality, found by root finding.

What should we have excluded? An observed limit means little without the limit the experiment expected. *The question:* if there is no Higgs boson at this mass, what limit would the experiment typically report, and in what range? Without signal, $\hat{\mu} \sim \mathcal{N}(0, \sigma^2)$, and the CL_s limit is an increasing function of $\hat{\mu}$; so its quantiles are the limits at the quantiles of $\hat{\mu}$, which is (4.112):

$$\mu_{up}(N) = \sigma_A \left[N + \Phi^{-1}\big(1 - \alpha\, \Phi(N)\big) \right], \qquad N = -2, -1, 0, 1, 2.$$

The median $N = 0$ gives $\sigma_A \Phi^{-1}(1 - \alpha/2) = 1.96\, \sigma_A$. At 140 GeV, $\sigma_A = 0.477$ and the expected median limit is $0.93 = 1.94\, \sigma_A$, the small difference from 1.96 coming from the change of σ_A with μ.

Example: the $+1\sigma$ edge of the band. For $N = 1$: $\Phi(1) = 0.841$, so $1 - 0.05 \times 0.841 = 0.958$ and $\Phi^{-1}(0.958) = 1.73$. The edge is at $\sigma_A(1 + 1.73) = 2.73\, \sigma_A$, which at 140 GeV is about $2.73 \times 0.477 = 1.30$. Without the division by CL_b the edge would be at $\sigma_A(1 + 1.645) = 2.65\, \sigma_A$: when the data fluctuate up, CL_s and CL_{s+b} differ little. For $N = -2$ the difference is large. $\Phi(-2) = 0.0228$, so $\Phi^{-1}(1 - 0.05 \times 0.0228) = \Phi^{-1}(0.99886) = 3.05$ and the edge is at $1.05\, \sigma_A$, where CL_{s+b} alone would give $(-2 + 1.645)\sigma_A < 0$, an exclusion of every signal including zero. That negative limit is exactly what CL_s was built to forbid.

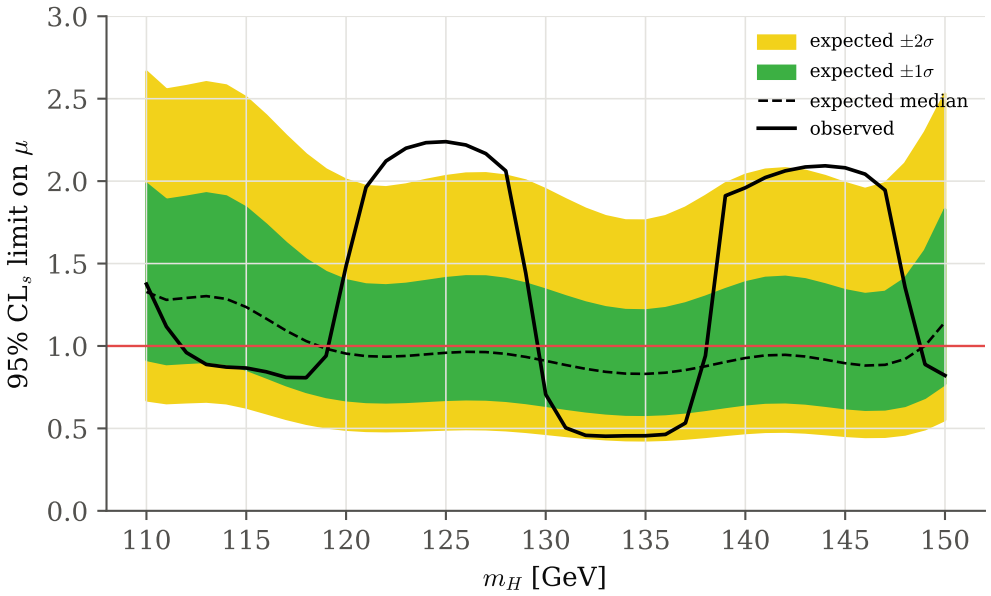

Figure 13.50: The 95% CL_s upper limit on the signal strength μ against the Higgs mass. The dashed line is the median expected without a Higgs boson, the green and yellow bands the ranges expected in 68% and 95% of background-only experiments, and the solid line the observed limit. Where the solid line is below the red line at $\mu = 1$, a Higgs boson with the expected signal is excluded. The observed limit leaves the band upwards near 125 GeV, where the data contain the Higgs boson, and near 143 GeV, where they contain a fluctuation.

The result. Figure 13.50 shows the observed limit and the expected band from 110 to 150 GeV. The median expected limit lies between 0.83 and 1.33, highest at the low end of the range,

where the background is largest, and at the edges of the fitted window, where the polynomial background is most flexible. So with 10 fb^{-1} at 13 TeV the diphoton channel alone expects to exclude a Higgs boson of the Standard Model size over most of the range, but only barely: the median is close to one. The observed limit excludes $\mu = 1$ at 19 of the 41 masses, in the ranges 112–119, 130–138, 149–150 GeV, and leaves a gap around 125 GeV where the observed limit, 2.24, is more than twice the expected 0.96. That gap is the excess of Section 13.23 seen from the other side: a limit cannot exclude a signal that is there. The other gap, near 143 GeV, is the second bump of Section 13.24.2; there the observed limit at 140 GeV is 1.96 against an expected 0.93. A limit curve on real data is read with the p-value scan beside it: the first says what the data rule out, the second what they might contain.

What "$\mu = 1$ at another mass" means here. The simulation exists only at 125 GeV, so at every mass we used the same expected yield, 397.9 events, with the shape scaled as in Section 13.22.1. The true Standard Model yield changes with mass: above about 130 GeV both the production cross section and the diphoton branching ratio fall. Our μ away from 125 GeV is therefore measured relative to a signal of the 125 GeV size, not to the Standard Model at that mass; ATLAS used simulations at many masses [AadHiggs2012 §5.4] and expected to exclude 110–140 GeV in 2012, observing 112–123 and 132–143 GeV [AadHiggs2012 Table 7]. The pattern is the same as ours: an exclusion on both sides of the peak and a hole where the boson is.

13.26.1 Are the asymptotic limits right?

The question: does the CL$_s$ computed from the half-χ^2-type formulas agree with CL$_s$ computed from the actual distribution of $\tilde{q}_\mu$? At 140 GeV, `code/ch13/34_hyy_toys.py` draws 1000 spectra with signal strength μ and 1000 with background only, for each μ on a grid, computes $\tilde{q}_\mu$ for each with the background refitted, and counts the fractions above the observed value: those fractions are CL$_{s+b}$ and CL$_b$ directly [30, (3)–(6)]. (These toys hold the four nuisance parameters fixed, as in Section 13.24; the statistical-only σ_A at 140 GeV is 0.438.)

Figure 13.51 (left) compares the two distributions of $\tilde{q}_\mu$ for $\mu = 0.5$ with the asymptotic curves of (4.104): under the signal hypothesis the half-χ^2 for small values and a shifted Gaussian tail for large ones, under background only a distribution pushed to larger values. The toys follow the curves. The right panel shows CL$_s$ as a function of μ; the toy points scatter about the asymptotic line, and the 95% limits are

$$\mu_{\text{up}}^{\text{toys}} = 1.05, \qquad \mu_{\text{up}}^{\text{asymptotic}} = 1.07.$$

The two agree to within the scatter of the toy points. Both are about half the limit 1.96 that the full likelihood gives at the same mass. That difference is not an error of the formulas but the energy-scale parameter: with θ_m free, a signal hypothesised at 140 GeV can slide towards the excess at 143 GeV (Section 13.23.2), so the data look less background-like for it and its exclusion is weaker. A comparison of toys with asymptotics must use one and the same likelihood, as it does here. With 76 000 events, about 1500 per GeV under the peak, the asymptotic formulas are accurate to the precision a few thousand toys can measure. They would not be for a search with a handful of events in the signal region, which is where the toy method of [30, 31] came from: the LEP Higgs searches, with a few candidates each.

13.27 Reproducing the 2012 diphoton result

The 2012 ATLAS paper has met us before. In Section T4.6.2 its Table 4 gave the number of expected diphoton events, and from $N_S = 110.5$, $\sigma \times \text{BR} = 50$ fb and $L = 5.9$ fb^{-1} we

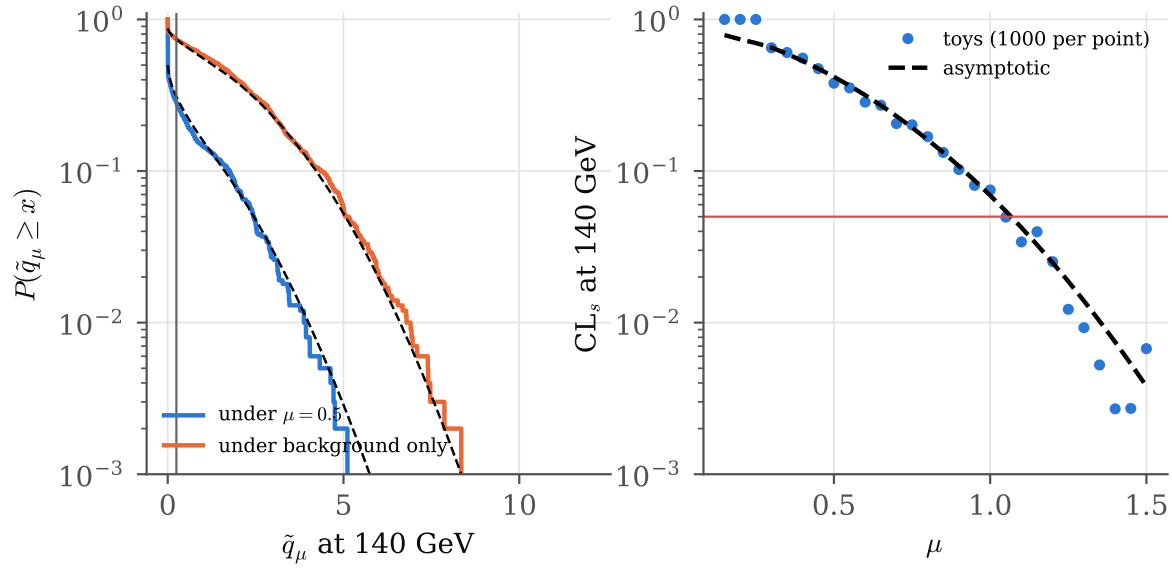

Figure 13.51: Left: the distribution of $\tilde{q}_\mu$ at 140 GeV for $\mu = 0.5$, from toys with that signal (blue) and with background only (orange), against the asymptotic formulas (black dashed); the vertical line is the value in the data. Right: CL_s against μ from the toys (points, 1000 toys per hypothesis and μ) and from the asymptotic formulas (dashed); the limit is where they cross 0.05 (red line).

recomputed a selection efficiency of 0.375 at 8 TeV; Section T4.6.4 went through its local and global significances; and Section T4.6.5 noted that the open-data files store a gluon-fusion $\sigma \times \mathrm{BR}(\gamma\gamma)$ twice as large as the 2012 value. Those were counts of events. The same table now answers a different question, how significant those events were expected to be, and it lets us set the 2012 result and ours side by side ingredient by ingredient. The efficiency below combines both collision energies, so it differs slightly from the 8 TeV value.

13.27.1 Their question

In the first half of 2012 the Higgs boson was the last missing particle of the Standard Model, and only a narrow window of masses near 125 GeV had not yet been excluded (Section 13.26). ATLAS asked whether the diphoton spectrum, combined over the 2011 data at 7 TeV and the first 2012 data at 8 TeV, showed a peak in that window that the background could not explain, and if so how strong it was [113]. Their answer in the diphoton channel alone was a local excess of 4.5σ at 126.5 GeV where 2.5σ was expected, with $\hat{\mu} = 1.8 \pm 0.5$ [AadHiggs2012 Table 7]. Ours, from 10 fb^{-1} of 2016 data at 13 TeV, is 2.74σ at 125 GeV where 2.15 was expected, with $\hat{\mu} = 1.28 \pm 0.52$. *Why did a search with about the same luminosity, at a higher energy where the Higgs boson is produced more than twice as often, expect less?* The answer is in the ingredients, and one formula can compare them.

13.27.2 Their setup

The 2012 analysis used 4.8 fb^{-1} at 7 TeV and 5.9 fb^{-1} at 8 TeV. The photon selection is close to ours (two isolated photons, relative momentum cuts of 0.35 and 0.25), with a fit range of 100–160 GeV. The essential difference is that the events were split into ten categories, by where the photons hit the calorimeter (central, rest, the transition region), whether they converted, the transverse momentum p_{Tt} of the pair relative to its thrust axis, and a category with two forward jets for vector-boson fusion [AadHiggs2012 §5.3]. For each category they published three

numbers per collision energy in their Table 4: the number of data events N_D in 100–160 GeV, the expected number of signal events N_S at $m_H = 126.5$ GeV, and the full width at half maximum of the signal. Their sums are:

	7 TeV	8 TeV	together
luminosity (fb^{-1})	4.8	5.9	10.7
$\sigma \times \mathrm{BR}(H \to \gamma\gamma)$ (fb)	39	50	
data events N_D, 100–160 GeV	23 788	35 251	59039
expected signal N_S	79.6	110.5	190.1
FWHM, inclusive (GeV)	3.9		$\sigma \approx 1.66$

The background in each category was a fourth-order Bernstein polynomial, an exponential of a second-order polynomial or an exponential, chosen by the spurious-signal test of Section 13.22.2 [AadHiggs2012 §5.5].

13.27.3 Their key equation, derived

ATLAS computed their expected significance $E(Z_l)$ from Asimov data sets with the full likelihood. With only Table 4 in hand we cannot redo that, but everything needed for the leading-order expected significance is there. *The question:* what expected significance do the published numbers imply? Three results already derived combine into one formula:

1. a Gaussian peak of S events and width σ on a background of density β per GeV has $q_{0,\mathrm{A}} = S^2/(2\sqrt{\pi}\,\sigma\beta)$, (13.54);
2. independent categories (and independent collision energies) add their $q_{0,\mathrm{A}}$, Section 13.25.3;
3. fitting the background shape keeps a fraction $1 - \rho^2$ of it, (13.49).

So

$$Z^2_{\mathrm{exp}} \approx (1-\rho^2) \sum_c \frac{S_c^2}{2\sqrt{\pi}\,\sigma_c\,\beta_c}, \qquad \sigma_c = \frac{\mathrm{FWHM}_c}{2\sqrt{2\ln 2}}, \tag{13.60}$$

with the sum over the ten categories at each energy, twenty terms in all.

The symbol map. Their N_S is our S_c. Their FWHM becomes our σ_c through the Gaussian relation of Section 13.22.1; we use it for both energies, since Table 4 gives it only at 8 TeV. Their N_D counts events in the whole 60 GeV window, while β_c is the density *under the peak*. *How do we get one from the other?* The spectrum falls roughly exponentially, by a factor of about 3.9 from 100 to 160 GeV in their Fig. 4, so its decay length is $\lambda = 60/\ln 3.9 \approx 44$ GeV. For an exponential the ratio of the density at the peak, 26.5 GeV into the window, to the mean density is

$$\frac{\beta(126.5)}{N_D/60} \overset{(1)}{=} \frac{e^{-26.5/\lambda}}{\frac{1}{60}\int_0^{60} e^{-x/\lambda}\mathrm{d}x} \overset{(2)}{=} \frac{60\,e^{-26.5/\lambda}}{\lambda\,(1-e^{-60/\lambda})} \overset{(3)}{=} \frac{60\times 0.548}{44\times 0.744} = 1.00. \tag{13.61}$$

(1) Density at $x = 26.5$ GeV over the mean density of the window, both for $e^{-x/\lambda}$; the normalisation cancels.
(2) The integral of an exponential.
(3) $e^{-26.5/44} = 0.548$ and $1 - e^{-60/44} = 1 - 1/3.9 = 0.744$.

The peak happens to sit where the density equals the window's mean, so $\beta_c = N_{D,c}/60$ GeV to within a per cent. Finally their $E(Z_l)$ is our $Z_{\mathrm{exp}} = \sqrt{q_{0,\mathrm{A}}}$, and their μ is ours.

The background factor. The last ingredient, $1 - \rho^2$, depends on the background function and the window. The script computes it from the Fisher matrix (13.49) for a Gaussian peak of the inclusive width on an exponential background: for their fourth-order Bernstein polynomial over 60 GeV it is 0.7, and for our fifth-order one over 55 GeV with our wider peak, 0.41. A narrower peak is harder for a polynomial to imitate, so it loses less.

13.27.4 What we compute

`code/ch13/35_hyy_atlas2012.py` types in Table 4, evaluates each of the twenty terms of (13.60) and the inclusive version (one category with the totals), and evaluates the same formula on our spectrum with $S = 397.9$, the FWHM of our fitted Crystal Ball, 5.81 GeV, and $\beta = 1527$ per GeV. It also reads the cross section times branching ratio stored in our four simulation files, to separate the signal per fb^{-1} into "how many Higgs bosons decayed to two photons" and "what fraction of them we selected".

13.27.5 Side by side

	ATLAS 2012 (7 + 8 TeV)	open data (13 TeV)
luminosity (fb^{-1})	10.7	10.06
$\sigma \times \mathrm{BR}(H \to \gamma\gamma)$ (fb)	39, 50	114
Higgs bosons to $\gamma\gamma$ produced	482	1149
selection efficiency	0.39	0.35
expected signal S per fb^{-1}	17.8	39.5
background under the peak, per GeV per fb^{-1}	92	152
mass resolution σ (GeV)	1.66	2.467
categories	10 per energy	1
$1 - \rho^2$ of the background fit	0.7	0.41
Z_{exp}, formula, inclusive, $1 - \rho^2 = 1$	2.5	3.44
Z_{exp}, formula, categories, $1 - \rho^2 = 1$	2.93	
Z_{exp}, formula with $1 - \rho^2$	2.45	2.21
Z_{exp}, full Asimov fit	2.5 (quoted)	2.15
Z_{obs} (local)	4.5	2.74
$\hat{\mu}$	1.8 ± 0.5	1.28 ± 0.52

The expected significance. From nothing but Table 4, (13.60) gives 2.45 for ATLAS against the 2.5 they quoted, and 2.21 for us against our full Asimov value 2.15. The leading-order formula with the background factor captures what the full likelihood does to within a few per cent. The comparison of the two "inclusive" entries, 2.5 against 2.93, shows what the ten categories were worth to ATLAS; for us, two categories gained only from 2.16 to 2.26 (Section 13.25.3).

Growth with luminosity. At a fixed analysis, S and β both grow in proportion to the luminosity L, so by (13.54) $Z_{\mathrm{exp}} \propto S/\sqrt{\beta} \propto \sqrt{L}$. A 5σ expected significance needs $L(5/Z_{\mathrm{exp}})^2$: 43 fb^{-1} with the 2012 diphoton analysis, 54 fb^{-1} with ours. Figure 13.52 shows both lines with the two observations. ATLAS did not wait for 43 fb^{-1}: the discovery came from combining the diphoton excess with the four-lepton and WW channels, 5.9σ locally from 4.9σ expected [AadHiggs2012 Table 7], and from an upward fluctuation that made the diphoton excess 1.6 standard deviations larger than the Standard Model predicted.

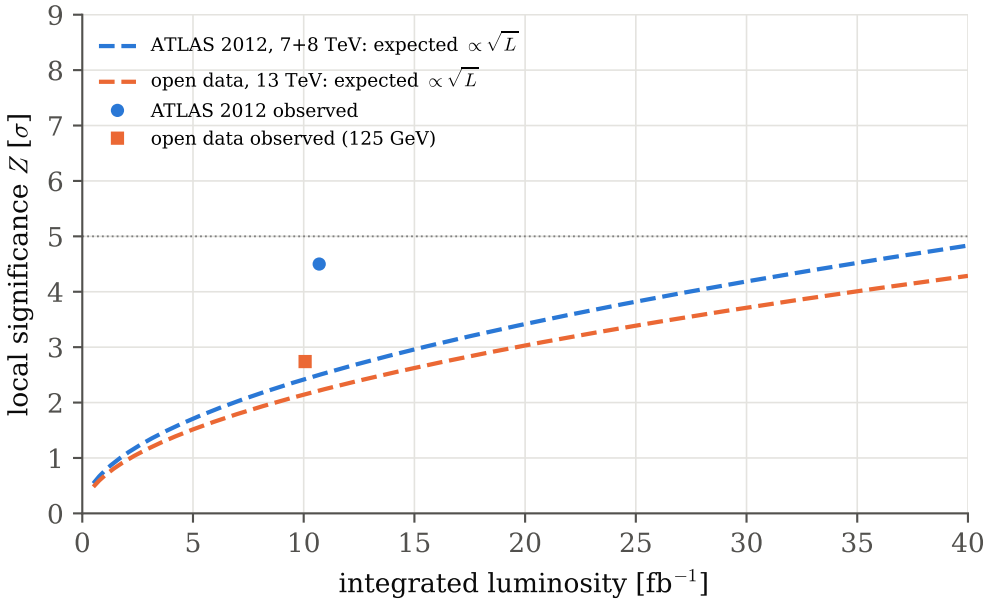

Figure 13.52: The expected local significance of the diphoton search against integrated luminosity, for the 2012 ATLAS analysis (blue dashed, scaled from its quoted 2.5σ at $10.7\,\text{fb}^{-1}$) and for ours (orange dashed, from 2.15σ at $10.06\,\text{fb}^{-1}$), both growing as $\sqrt{L}$. The points are the observed local significances. Both observations lie above their expectation: in 2012 by two units of Z, in our data by about half a unit.

13.27.6 Why they differ

Each ingredient of (13.60) can be compared separately, and the formula says how much each one matters: $Z \propto \sqrt{1-\rho^2}\, S/\sqrt{\sigma\beta}$ for one category. Compared at equal luminosity, ours over theirs, one factor at a time:

- *More Higgs bosons per* fb^{-1}*: a factor* $39.5/17.8 = 2.22$. At 13 TeV the cross section times branching ratio of all four production modes together is 114 fb, 2.5 times that at 7–8 TeV (gluon fusion alone is 102 fb, Section T4.6.5), because at a higher energy a Higgs boson of fixed mass needs gluons carrying a smaller fraction of the proton's momentum, and such gluons are more numerous (Chapter T4). Our selection keeps a fraction 0.35 of the produced diphoton decays against ATLAS's 0.39 (they quote about 40% [AadHiggs2012 §5.4]), which takes back a little.
- *More background per* fb^{-1}*: a factor* $(152/92)^{-1/2} = 0.78$. The diphoton continuum grows with energy as well, and the open-data photons pass a looser isolation: the calorimeter energy is summed in a cone of $\Delta R < 0.2$ and compared with 6.5% of p_T, where the 2012 analysis used a cone of 0.4 and a fixed 4 GeV [AadHiggs2012 §5.1], and a smaller cone lets more jets that fake photons through.
- *A wider peak: a factor* $(2.467/1.66)^{-1/2} = 0.82$. Our width is what the released simulation gives; the release does not document the photon energy calibration in enough detail to trace the difference further.
- *No categories: a factor* $2.5/2.93 = 0.85$. The ten categories raised ATLAS's leading-order Z by separating the few events with a narrow peak and little background from the many with a wide peak and much background, exactly as (13.58) promises.
- *A more flexible background: a factor* $\sqrt{0.41/0.7} = 0.77$. A degree-five polynomial over 55 GeV

against a degree-four one over 60 GeV, and a wider peak that the polynomial imitates more easily (Section 13.22.2).

The product is $2.22 \times 0.78 \times 0.82 \times 0.85 \times 0.77 = 0.93$. The two predictions of (13.60) per unit of luminosity, $2.21/\sqrt{10.06} = 0.70$ against $2.45/\sqrt{10.7} = 0.75$, are in exactly that ratio, and so, to the precision of the formula, are the quoted expectations. The budget explains the opening puzzle: the higher energy more than doubled the signal, and four smaller losses, each between 15 and 25%, took all of it back. The two largest, the background function and the background density, are the cheapest to recover: categories with less background and a narrower peak would improve both.

The *observed* values differ for a different reason. ATLAS's diphoton excess was a 1.6σ upward fluctuation of the signal on top of an expected 2.5σ; ours is a fluctuation of about half a standard deviation.

The lesson. Reading the paper gives one number, 2.5σ expected; rebuilding it shows that the number is the product of five ingredients, each of which can be measured separately and traded against the others: signal per luminosity, background density under the peak, mass resolution, how finely the events are sorted by their quality, and how flexible the background function has to be. A resonance search is designed by improving the weakest of these, and the formula $Z^2 \approx (1-\rho^2)\sum_c S_c^2/(2\sqrt{\pi}\sigma_c\beta_c)$ tells which one that is before any data are taken.

13.28 The full analysis, and what our shortcuts cost

Every number of this search came from a laptop-sized computation: 1.9 GB of files read once, a few thousand toy spectra fitted by Newton's method, and each script ran within minutes on four cores. The statistics is the same as in the collaboration's analysis, but several pieces were simplified. Each simplification has a cost we can name, and for most of them the cost was measured along the way.

	full analysis	ours, and the cost
events	all channels, full photon calibration, many times more data in later years	10 fb^{-1} of released data, diphoton only; $Z \propto \sqrt{L}$ (Figure 13.52)
categories	ten in 2012, more later, each with its own background function	one (two as an example); the ten categories were worth 2.5 → 2.93 in 2012
signal shape	Crystal Ball plus Gaussian, simulated at many masses	Crystal Ball at 125 GeV, scaled to other masses; μ away from 125 GeV relative to a fixed yield
background choice	spurious-signal test on large simulated background samples	truths fitted to the same data (Section 13.22.2); the test only compares families
nuisance parameters	dozens: each efficiency, energy scale and resolution term, theory	four, with sizes taken from 2012 and from the release
toys	full fits with all nuisance parameters, auxiliary measurements redrawn	statistical part only, linear fits; nuisances changed Z by less than 0.01 here
global significance	Gross–Vitells in mass (and width), combined channels	Gross–Vitells in mass, checked with 4000 toys

Verification and research. Two kinds of simulation appeared in this search, and they did different jobs. The toys of Sections 13.24.1 and 13.26.1 *verified* known analytic results: the half-χ^2 law of q_0, the Asimov median, the asymptotic CL_s. With 76 000 events the formulas passed, so the toys added confidence but no new number. The background-only scans of Section 13.24.2 were the *research instrument*: no closed formula gives the global p-value of a scan over a fitted, bending background, and the Gross–Vitells formula itself needs the upcrossing count that only simulated scans provide. The same division runs through every capstone of this chapter: simulation checks a formula where one exists and replaces it where none does.

Recap

- From the released 13 TeV files, the HyyAnalysis selection keeps 76394 photon pairs in 105–160 GeV, where a Standard Model Higgs boson would add 397.9 events; the invariant mass $2p_{T1}p_{T2}[\cosh\Delta\eta - \cos\Delta\phi]$ is where it would appear as a peak.
- The signal is a Crystal Ball of width 2.467 GeV fitted to weighted simulation; the background a fifth-order Bernstein polynomial, the least flexible family whose spurious signal stays below 20% of the statistical error. Flexibility costs a fraction ρ^2 of $q_{0,\mathrm{A}}$, here more than half.
- The expected significance of a peak is $Z^2 \approx (1-\rho^2)\sum_c S_c^2/(2\sqrt{\pi}\sigma_c\beta_c)$, and its mass precision $\sigma_m = \sqrt{2}\,\sigma/Z$; splitting into categories never loses, by $(S_1B_2 - S_2B_1)^2/(B_1B_2(B_1+B_2))$.
- The data show a local 2.77σ excess at 124.5 GeV where 2.15σ was expected at 125 GeV; toys confirm the asymptotic laws, and the global significance over 110–150 GeV is about 1.54σ, with a trials factor of 22.2 and a background bump of similar local size at 143 GeV.
- $\hat{\mu} = 1.28 \pm 0.46\,(\mathrm{stat}) \pm 0.24\,(\mathrm{syst})$ and $\hat{m}_H = 124.5 \pm 1.4$ GeV, the mass error dominated by the photon energy scale.
- CL_s excludes a signal of the Standard Model size at 112–119, 130–138, 149–150 GeV and not near 125 GeV, where the observed limit is 2.24 against an expected 0.96.
- Rebuilt from its Table 4, the 2012 ATLAS expected 2.5σ follows from the same formula; our larger signal per fb^{-1} is outweighed by more background, a wider peak, the absence of categories and a more flexible background function.

13.29 A small twist in the polarization of the sky

In Section 13.1 we took the SMICA temperature map and asked how strong its fluctuations are on each angular scale. The pipeline we built for that question handles a great deal: the mask that hides our Galaxy, the beam and pixels that blur the map, the noise, which drops out when the two half-mission maps are cross-correlated, and simulated skies that tell us how much every number would scatter. All of it was aimed at a spectrum whose *size* we wanted to know, and whose value is large: thousands of $\mu\mathrm{K}^2$ at the acoustic peaks.

Now the question is different. The same SMICA files also contain the polarization of the sky, and in the polarization there is a spectrum that the standard model says must vanish on average. If something turned the polarization of every CMB photon by the same small angle on its way to us, that spectrum would no longer vanish: it would become a faint copy of a spectrum we know well, about one per cent of it for an angle of a third of a degree. We are no longer measuring how big something is. We are looking for a faint copy of a known pattern in a place where nothing should be, and asking how much of that pattern is there.

A picture on the wall. Picture a wall covered in wallpaper with vertical stripes, some bold and some faint, and a photograph of it taken with the camera turned slightly. In the photograph every stripe leans a little to one side. The lean is obvious where the stripes are bold and invisible where the wall is plain, because a plain wall has nothing to lean. So the way to measure the tilt is to compare two pictures: the pattern of "lean" and the pattern of "stripe". If the first is a scaled copy of the second, the scale factor is the tilt. Notice also what the photograph cannot tell us. A crooked camera and crooked wallpaper give the same photograph. Only something in the picture that we know was hung straight, a door frame say, can tell the two apart: the door frame leans only if the camera is crooked.

The same picture on the sky. Recall from Chapter T1 the physics in one breath. CMB photons are linearly polarized, and at each point of the sky the polarization is a short headless stick (Section T3.3), described by the Stokes parameters Q and U with $Q + iU = Pe^{2i\psi}$, where ψ is the angle of the stick. The pattern of sticks splits into two kinds. **E modes** are patterns that look the same in a mirror (sticks lined up along or across the direction in which the polarization changes, like the stripes). **B modes** are patterns with a handedness (sticks at 45° to that direction, like swirls). The physics of the early Universe, as far as we know, does not prefer left to right, so on average there is no correlation between E and B, or between temperature and B: $C_\ell^{EB} = C_\ell^{TB} = 0$. Now suppose every stick is turned by the same angle β between the last scattering surface and us, as a slowly varying pseudoscalar field coupled to photons would do [57]. That is our crooked wallpaper. Some of every E pattern becomes B, and Chapter T1 derives what happens to the spectra:

$$C_\ell^{EB,o} = \tfrac{1}{2}\sin(4\beta)\,\big(C_\ell^{EE} - C_\ell^{BB}\big), \qquad C_\ell^{TB,o} = \sin(2\beta)\,C_\ell^{TE}, \tag{13.62}$$

where "o" means observed and the spectra on the right are those before the rotation. The crooked camera is a detector whose polarization directions are all turned by an angle α from where we think they are: it turns every stick in the map, CMB or not, and its effect on (13.62) is identical, with β replaced by $\alpha + \beta$. The door frame is the polarized emission of our own Galaxy, which is turned by α but not by β, because it has not travelled across the Universe [71].

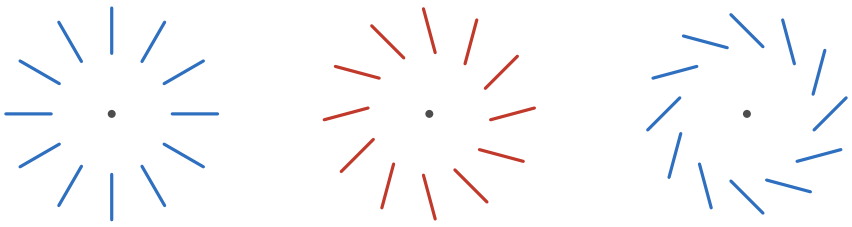

Figure 13.53: Polarization sticks on a ring around a point. Left: a pattern of E type, sticks pointing away from the centre, which looks the same in a mirror. Right: a pattern of B type, every stick at 45°, which has a handedness. Middle: the E pattern with every stick turned by the same angle (exaggerated here to 15°): it has become mostly E with a little B, the fraction $\sin 2\beta$ of the amplitude that (13.62) turns into the EB correlation.

The story in symbols. Take the smallest case: one multipole ℓ, a sky with E and no B, and a rotation by β. For each m the rotation mixes the two coefficients as $E' = \cos 2\beta\, E - \sin 2\beta\, B$ and $B' = \sin 2\beta\, E + \cos 2\beta\, B$ (Chapter T1), so with $B = 0$,

$$\big\langle E'B'^{*}\big\rangle \overset{(1)}{=} \cos 2\beta\, \sin 2\beta\, \big\langle |E|^2 \big\rangle \overset{(2)}{=} \tfrac{1}{2}\sin 4\beta\, C_\ell^{EE} \;\approx\; 2\beta\, C_\ell^{EE}. \tag{13.63}$$

(1) Substitute $E' = \cos 2\beta\, E$ and $B' = \sin 2\beta\, E$ (the terms in B vanish) and take the mean.

(2) $2\sin x\cos x = \sin 2x$ with $x = 2\beta$, and $\langle|E|^2\rangle = C_\ell^{EE}$; for a small angle $\sin 4\beta \approx 4\beta$.

The numbers make the difficulty plain. At $\ell = 1000$ the fiducial E spectrum is $D_\ell^{EE} = 42.1\,\mu\mathrm{K}^2$ (with $D_\ell = \ell(\ell+1)C_\ell/2\pi$ as always), so an angle of 0.3° makes $D_\ell^{EB} = 0.44\,\mu\mathrm{K}^2$, about one per cent of it. The dial is the angle, and the obvious estimator is the ratio at one multipole, $\hat\beta_\ell = \widehat{C}_\ell^{EB}/2\widehat{C}_\ell^{EE}$. It is hopeless. At $\ell = 1000$ the noise power of one SMICA half-mission map in polarization is about 4 times the E signal, the multipole has about 1766 independent modes on the kept sky, and the scatter of that single ratio is about 3° (the estimate is made in `44_angle.py` from the variance of a product of two Gaussian coefficients, the formula of Section 13.31). The good choice is the wallpaper's: compare the whole pattern of $\widehat{C}_\ell^{EB}$ across a thousand and more multipoles with the whole pattern of $\widehat{C}_\ell^{EE} - \widehat{C}_\ell^{BB}$, giving most weight where E is strong and the noise is weak. That buys a factor of order $\sqrt{1000}$ and more, and its price is that we need the covariance of the $\widehat{C}_\ell^{EB}$ across multipoles, which only simulated skies supply. Lesson: a tiny effect that is a known pattern times one number is measured by fitting the pattern, never by reading one point.

A picture: a projection onto a template. Write the measured EB spectrum, bin by bin, as one long list $\boldsymbol{e}$, and the pattern it should copy, $C^{EE} - C^{BB}$, as a second list $\boldsymbol{D}$. If the sky is rotated, $\boldsymbol{e} \approx 2\beta\,\boldsymbol{D}$ plus noise. Estimating β is asking how much of the direction $\boldsymbol{D}$ is in $\boldsymbol{e}$: a projection, with the noise deciding which components of the projection to trust. The same estimator wears many names. It is the linear least-squares fit of one amplitude (Section 3.10.2); it is the matched filter that finds a gravitational-wave chirp of known shape in noisy data (Section 10.8.3); it is template fitting wherever a signal's shape is known and its strength is not. Linear algebra is the natural language because spectra, templates and weights are lists of numbers and the estimator is a weighted dot product.

The route is then clear. The polarization maps are brought to laptop size and their spectra computed through the SMICA confidence mask; the mask turns out to be unable to fake a rotation; the estimator is tested on six hundred simulated skies in which a known angle was hidden, then applied to the real sky and compared with the published measurements. The same spectra finally answer a second question: do they show the one B-mode signal that the standard model guarantees, the lensing of E into B?

The event. The data are the SMICA Q and U maps of the 2018 release [19, 159], from the same files as the temperature map of Section 13.1.1, in their two half-mission versions. Our event is a number computed from them: the angle $\hat\beta$ that best turns the measured $\widehat{C}_\ell^{EE} - \widehat{C}_\ell^{BB}$ and $\widehat{C}_\ell^{TE}$ into the measured $\widehat{C}_\ell^{EB}$ and $\widehat{C}_\ell^{TB}$.

What could have produced a nonzero angle? Before computing it, we list the situations that could make $\hat\beta$ differ from zero, one at a time, each with its reason.

1. *A rotation β of the CMB polarization in flight.* This is the effect we are after. It produces exactly the pattern (13.62).

2. *A miscalibration α of the detectors' polarization angles.* Each *Planck* polarimeter's orientation on the sky was measured on the ground, to about 0.3° [187]. A common offset turns every stick in the map, so it produces the same pattern, with $\alpha + \beta$ in place of β. SMICA combines many detectors and frequencies with fixed weights, so the map carries one effective α, a weighted average of theirs.

3. *Polarized dust in our Galaxy with an EB correlation of its own.* If the dust filaments are slightly twisted relative to the magnetic field that aligns them, the dust has $C^{EB} \neq 0$ [57, 67]. SMICA removes most of the dust, but not all of it near the plane.
4. *Leakage of temperature into polarization by the beams.* An asymmetric beam turns some of the bright temperature map into spurious polarization, which can correlate with T and E.
5. *Leakage of E into B by the mask.* Cutting the sky mixes E and B. It adds scatter but cannot produce the pattern (13.62) on average.
6. *Chance.* With no rotation at all, the noise and the CMB itself make $\widehat{C}_\ell^{EB}$ scatter around zero, and some realisations lean one way. This is the explanation whose sampling distribution we can produce, by simulating skies.

The first two cannot be told apart with one CMB map, whatever we do: they make the same pattern from the same sky. The third is tested by changing how much of the sky near the Galactic plane we keep; the fifth and sixth by simulations; the fourth we can only bound by quoting the published analyses.

The questions, in words.

(a) What are the EE, BB, EB, TE and TB cross-spectra of the two half-mission maps through the SMICA polarization mask, and can the mask fake a rotation?

(b) If the sky were not rotated, how much would an estimate of the angle scatter? If it were rotated by a known angle, would the estimator find it, on average, and would its error bar cover the truth as often as it claims?

(c) Which angle does the real sky prefer, and would an angle that large, or larger, be something we would reasonably expect if the true angle were zero?

(d) How does it compare with the published measurements, and what exactly has been measured?

(e) Do the same spectra show the B modes that lensing must make?

The inputs, and what would break them. Two inputs are *physical*. (i) Outside the mask, the polarization is a Gaussian CMB with the fiducial spectra, possibly rotated by one angle, plus noise; dust residuals would break this, and would show up as an angle that depends on the mask. (ii) The noise of the two halves is independent, so the cross-spectra carry no noise bias. Two are *observational*: (iii) the beam is the same for E and B and for every direction on the sky, so it multiplies each coefficient by a number and cannot rotate anything; (iv) the angle is the same everywhere on the sky. One is *mathematical*: (v) the angle is small, so $\sin 4\beta \approx 4\beta$; at $\beta = 1^\circ$ the error of this approximation is $1 - \sin(4^\circ)/(4^\circ \cdot \pi/180) \approx 8 \times 10^{-4}$ of the angle, far below anything we can measure.

13.29.1 The polarization maps at laptop size

The SMICA files of Table 13.1 hold, besides the temperature, the Stokes Q and U maps (columns `Q_STOKES` and `U_STOKES`) and two confidence masks, one for temperature and one for polarization (`PMASK`, field 4 of the full-mission file). SMICA builds its polarization map the way it builds the temperature map: it combines the frequency maps multipole by multipole, separately for E and for B, with weights chosen so that the CMB passes and the Galaxy is suppressed [19, §3]. The confidence mask marks the pixels where that cleaning is trusted. It is

generous: it keeps a fraction 0.929 of the sky, far more than the temperature common mask of Section 13.2.

Noise first. The polarization maps differ from the temperature map in one way that shapes everything below. Outside the mask, the root mean square of Q and U in a pixel of the full-mission map is 28.6 μK, and 41.7 μK in a half-mission map, while the CMB polarization itself has a root mean square of a few μK. Pixel by pixel, the maps are noise. The CMB polarization is there only statistically, in the spectra, where thousands of modes are averaged. That is why Figure 13.54a looks like static and why the polarized intensity becomes structured only after smoothing over a degree (Figure 13.54b), where the noise averages down.

The degrade. We bring the maps to $N_{\mathrm{side}} = 512$ exactly as in (13.1), with one change: Q and U are transformed together with the spin-2 harmonic transform, which turns them into the E and B coefficients, and the pixel window used is the polarization one. A HEALPix pixel averages Q and U over its area in the local frame of each point, and the window this produces for E and B differs slightly from the temperature window; `hp.pixwin(..., pol=True)` returns both. At $\ell = 1000$ the polarization window of $N_{\mathrm{side}} = 512$ is 0.835 and the beam is 0.826; the beam supplied for polarization (`POL_BEAM`) is the same 5′ effective beam as for temperature.

Filling the holes with zeros. In Section 13.1.1 the holes of the temperature map were filled with the inpainted CMB before the transform, because the Galactic plane and the point sources in the temperature map are thousands of μK bright and the band limit would ring them out over the kept sky. In polarization the masked pixels are not much brighter than the kept ones: the largest polarized intensity inside the holes of the full map is 356 μK, against 306 μK outside, both set by noise spikes. So the danger of ringing is small, and we simply set $Q = U = 0$ in the masked pixels at full resolution before the transform. That guarantees that nothing from the regions SMICA does not trust can be carried into the kept sky. The mask is degraded as in Section 13.1.1: a pixel at $N_{\mathrm{side}} = 512$ is kept only if all sixteen of its small pixels are kept, which leaves a fraction 0.925.

Listing 13.10: The spin-2 degrade: zero the masked pixels, transform Q and U to E and B, swap the polarization pixel windows, synthesise (`code/ch13/41_pol_data.py`)

```
fl[2:] = pw512[2:] / pw2048[2:]
out = {}
for kind in ("full", "hm1", "hm2"):
    src = lp.raw_path(kind)
    q = hp.read_map(src, field=1, dtype=np.float64) * 1e6
    u = hp.read_map(src, field=2, dtype=np.float64) * 1e6
    p = np.hypot(q, u)
    tag = {"full": "Full", "hm1": "HmOne", "hm2": "HmTwo"}[kind]
    nums[f"ThirteenEPmaxIn{tag}"] = f"{p[hole].max():.0f}"
    nums[f"ThirteenEPmaxOut{tag}"] = f"{p[~hole].max():.0f}"
    nums[f"ThirteenEPrmsOut{tag}"] = f"{np.sqrt(np.mean(p[~hole] ** 2) / 2):.1f}"
    q[hole] = 0.0
    u[hole] = 0.0
    alm = hp.map2alm([np.zeros_like(q), q, u], lmax=L, iter=1, pol=True)
    del q, u, p
    aE, aB = hp.almxfl(alm[1], fl), hp.almxfl(alm[2], fl)
    _, Q, U = hp.alm2map([alm[0] * 0, aE, aB], N, lmax=L, pol=True)
    out[f"{kind}_Q"], out[f"{kind}_U"] = Q.astype(np.float32), U.astype(np.float32)
    print(f"{kind}: done ({time.time() - t0:.0f} s)", flush=True)
```

For each map the loop converts Q and U from K to μK, records the largest polarized intensity inside and outside the mask, zeroes the masked pixels, and calls `hp.map2alm` with `pol=True`,

which returns the T, E and B coefficients (the temperature slot is filled with zeros because the temperature maps of Section 13.1.1 are reused). `hp.almxfl` multiplies E and B by the ratio of polarization pixel windows, and `hp.alm2map` with `pol=True` synthesises Q and U at $N_{\rm side} = 512$. The three maps took 65 s on the cluster and are cached in `data/ch13/`.

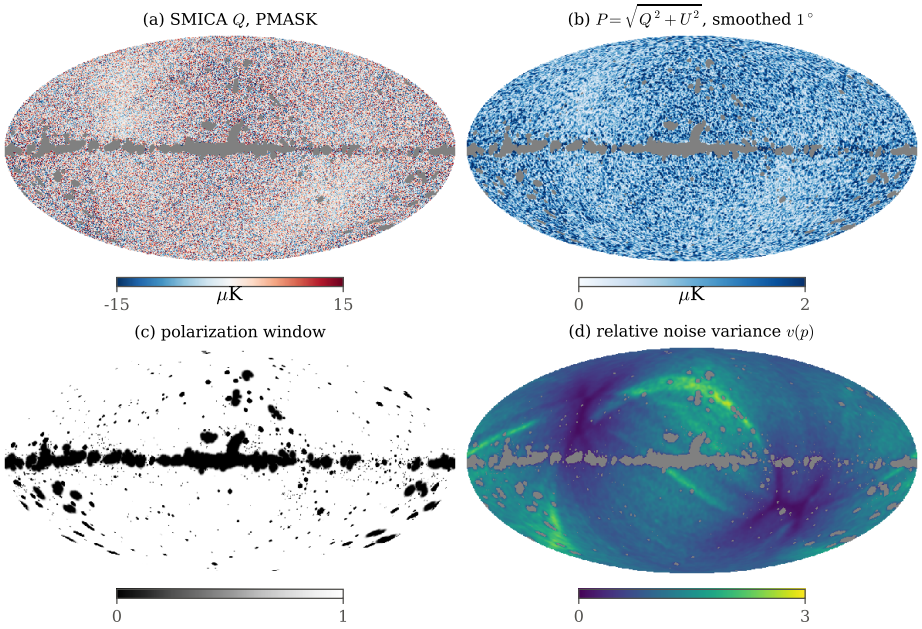

Figure 13.54: (a) The SMICA Q map at $N_{\rm side} = 512$, outside the polarization confidence mask (grey): at the pixel level it is dominated by noise. (b) The polarized intensity after smoothing Q and U over 1°, where the noise has averaged down and the CMB polarization becomes visible. (c) The window of the analysis, the confidence mask with tapered edges (Section 13.30.1). (d) How the noise variance varies over the sky relative to its mean, measured from the half-difference map (Section 13.30.4): the scanning strategy of *Planck* leaves the regions near the ecliptic poles less noisy.

13.30 Polarization spectra through a mask

For the temperature map of Section 13.3 the route from a masked map to a spectrum had three steps: multiply by a tapered window, transform, and undo on average what the window did, with the MASTER coupling matrix. A polarization map adds a complication that temperature does not have. A window does not only move power from one multipole to another; it also moves it from E to B. Since the angle we want is measured precisely by how much E has turned into B, this looks like a disaster. It is not: the toy skies of Section 10.17 showed why, and the same one-line reason makes the whole analysis simpler than the temperature one.

13.30.1 The window

The degraded confidence mask has 1009 holes, of which 25 are larger than 20 deg^2; we split them as in Section 13.2.1 and taper the Galactic holes over 2° and the small ones over 0.5° with the cosine profile (13.2) (Figure 13.54c). The window keeps $f_{\rm sky} = 0.925$ of the sky; the mean of W^2 is 0.873 and the effective sky fraction that counts modes, $\langle W^2\rangle^2/\langle W^4\rangle$ (Section 8.9), is 0.882. The temperature spectra TE and TB use the temperature window of Section 13.2.2 for T and this window for E and B; nothing below requires the two windows to be equal.

For the Galactic check we also build a *strict* window, the product of the polarization window

and the temperature window. It removes in addition everything the temperature common mask removes, a broader band around the plane and many more source holes, and keeps $f_{\rm sky} = 0.757$ ($\langle W^2\rangle^2/\langle W^4\rangle = 0.683$). Dust residuals, if they matter, are stronger in the main window.

13.30.2 Why a mask turns E into B

The toy skies of Section 10.17 met this problem first. Whether the sticks around a point form a spoke-and-ring pattern (E) or a swirl (B) is not a property of one pixel; it depends on how the sticks change across a neighbourhood, so cutting the map changes the answer near every edge. The picture there was a field of wheat combed in neat rows and photographed through a window frame: a row that stops abruptly at the frame is, for anyone who describes the photograph by its waves, a bundle of waves pointing in slightly different directions, and for those directions part of the combed pattern reads as a swirl, although nothing in the field has changed. Cutting one E wave with a straight edge gave the size of the effect (Eq. (10.105)): a sharp edge reads as B a strip about one wavelength wide along the cut, a smooth taper spreads the cut over its own width and leaks far less at wavelengths shorter than that width, and in neither case is the leaked B correlated with E on average. On a band-shaped mask the simulated skies there showed exactly this: the 5° taper pushed the leak well below the lensing B at $\ell \approx 300$, while the sharp band still leaked a sizeable fraction of it (Figure 10.46). The B created this way is the **E-to-B leakage**. Because E is a hundred times stronger than the lensing B in the sky, even a small leaked fraction can be larger than the real B. What the band mask cannot tell us is how much leaks through the SMICA window, with its narrow Galactic cut and hundreds of small holes; that we measure.

Example: how much leaks? The simulated skies of Section 13.31.2 let us measure it, because there we can observe the E part of a sky alone, with no B and no noise, and look at the B that comes out. Through the *binary* confidence mask the leaked B power is, in the median bin, 0.7% of the E power; through the tapered window it is 0.43% (Figure 13.55). The taper helps here by only a factor of about 2, much less than for the temperature coupling of Section 8.10.4, and at the lowest multipoles not at all (in the first bin, $50 \le \ell < 80$, the two are 2.2% and 2.41%). The reason is the geometry of this mask: it removes only a narrow Galactic band and a few hundred small holes, so most of the leakage comes from long edges and from the large-scale shape of the cut, which a taper of 2° does not smooth. The cut-wave estimate of Section 10.17 puts numbers on this: a taper of width $\theta_{\rm apo}$ multiplies the leak of a sharp edge by $\pi^2/(2k\theta_{\rm apo})$ (Eq. (10.107)), about a fifth near $\ell \approx 750$ for the 2° Galactic taper but about three quarters for the 0.5° tapers of the small holes, and it gains nothing on scales longer than the taper; with hundreds of small holes, the overall gain stays small. Even so, a leaked half per cent of E is comparable to the lensing B itself, which is why the leaked power must be subtracted before B modes can be measured (Section 13.34). Research codes go further and use *pure* B estimators, which build the window's derivatives into the transform so that a pure E pattern gives no B at all on the cut sky [188]. The angle does not need them, because a rotation passes through the mask unchanged.

13.30.3 A rotation passes through the mask unchanged

The question. The window mixes E and B, and the rotation mixes E and B. Can the first fake or spoil the second? The toy skies of Section 10.17.1 settled it, and the reason carries over to any window. The window multiplies $Q + iU$ at each pixel by its own real weight W; a uniform rotation multiplies it by $e^{2i\beta}$, the same number at every pixel; and two multiplications can be done in either order. So rotating the sky and then masking it gives the same map as masking

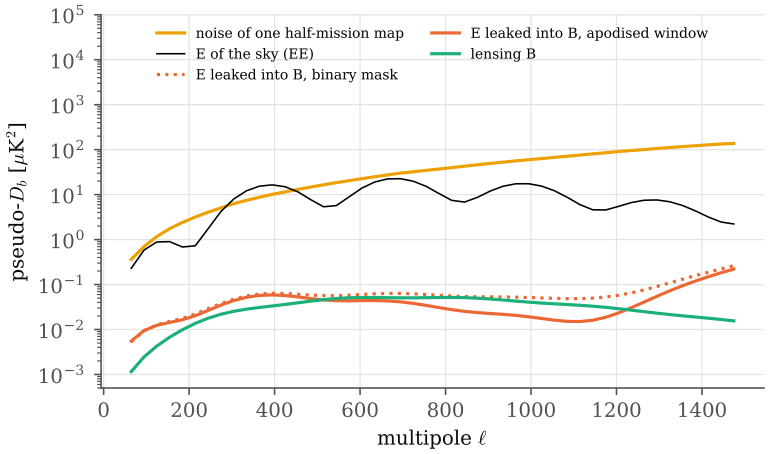

Figure 13.55: What a pseudo-BB spectrum of one half-mission map is made of, averaged over the simulated skies. The noise (yellow) is above everything else except the E power of the sky (black) near its first peak, $\ell \approx 400$. Far below, the share of E that the binary mask turns into B (dotted orange), the smaller share left by the tapered window (solid orange; the two differ little below $\ell \approx 600$), and the B modes made by lensing (green), seen through the same window.

it and then rotating (Figure 13.56). The spin-2 transform is linear, so the constant $e^{2i\beta}$ goes straight through it, and the coefficients $\widetilde{E}_{\ell m}$, $\widetilde{B}_{\ell m}$ of the masked map, the **pseudo-coefficients**, turn exactly as the full-sky coefficients do (Chapter T1):

$$\widetilde{E}'_{\ell m} = \cos 2\beta\, \widetilde{E}_{\ell m} - \sin 2\beta\, \widetilde{B}_{\ell m}, \qquad \widetilde{B}'_{\ell m} = \sin 2\beta\, \widetilde{E}_{\ell m} + \cos 2\beta\, \widetilde{B}_{\ell m}. \tag{13.64}$$

The beam and the pixel window multiply E and B by the same number T_ℓ (input (iii)), so they commute with the rotation as well. Whatever the window has done, the rotation acts on the pseudo-coefficients as if there were no window.

The pseudo-spectra, $\widetilde{C}_\ell^{XY} = \frac{1}{2\ell+1}\sum_m \mathrm{Re}\,\widetilde{X}_{\ell m}\widetilde{Y}^*_{\ell m}$, therefore obey the rotation formulas of Chapter T1, now with tildes: substituting (13.64) into the definition and multiplying out, exactly as for the full sky, gives

$$\widetilde{C}_\ell^{EB\prime} = \tfrac{1}{2}\sin 4\beta\,\left(\widetilde{C}_\ell^{EE} - \widetilde{C}_\ell^{BB}\right) + \cos 4\beta\, \widetilde{C}_\ell^{EB}, \qquad \widetilde{C}_\ell^{TB\prime} = \sin 2\beta\, \widetilde{C}_\ell^{TE} + \cos 2\beta\, \widetilde{C}_\ell^{TB}, \tag{13.65}$$

the second because T is not rotated. These are the formulas (13.62) again, but for the *pseudo*-spectra, and they hold sky by sky.

The last term on average. What remains is $\widetilde{C}_\ell^{EB}$ of the unrotated sky. As on the toy skies, the masked EB is fed by the true EB alone, never by EE or BB [142]: the leak adds B power but no correlation with E. A sky with $C_\ell^{EB} = 0$ therefore has $\langle\widetilde{C}_\ell^{EB}\rangle = 0$, and likewise for TB. Combining,

$$\left\langle\widetilde{C}_\ell^{EB\prime}\right\rangle = \tfrac{1}{2}\sin 4\beta\,\left\langle\widetilde{C}_\ell^{EE} - \widetilde{C}_\ell^{BB}\right\rangle, \qquad \left\langle\widetilde{C}_\ell^{TB\prime}\right\rangle = \sin 2\beta\,\left\langle\widetilde{C}_\ell^{TE}\right\rangle. \tag{13.66}$$

We check this on six hundred simulated skies in Section 13.31.3: with no rotation, the estimated angle averages to zero.

This is why no spin-2 version of the MASTER correction of Section 13.3.4 appears in the angle measurement: the leaked E sits in both $\widetilde{C}_\ell^{EE}$ and $\widetilde{C}_\ell^{BB}$ of the template, and the angle is read from pseudo-spectra directly. The leakage does still cost something: the leaked E in $\widetilde{B}$ adds to the variance of $\widetilde{C}_\ell^{EB}$, in the same way that noise does. On the toy skies this mattered only for a map deep enough to see below the lensing B (Section 10.17.3); SMICA's polarization is far noisier, and Figure 13.55 shows that its noise is so much larger than the leakage through the tapered window that the leakage costs essentially nothing.

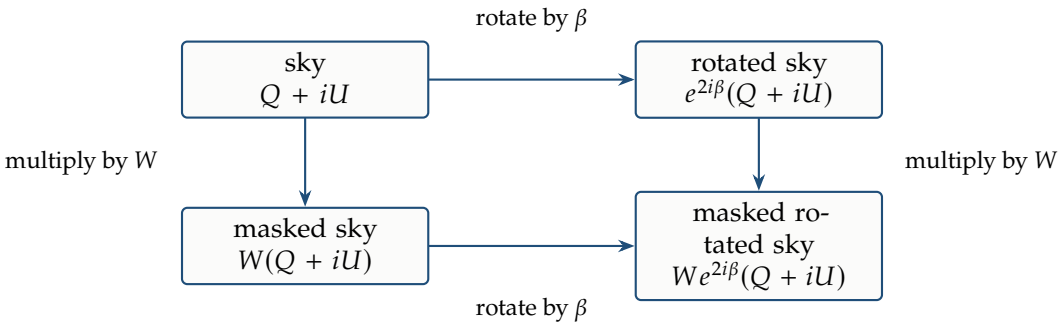

Figure 13.56: Both routes from the sky (top left) to the masked rotated sky (bottom right) give the same map, because the rotation multiplies every pixel by the same number $e^{2i\beta}$ and the window multiplies every pixel by its own real weight. On the bottom row the rotation therefore acts on the pseudo-coefficients exactly as it acts on the full-sky coefficients.

13.30.4 Cross-spectra of the halves, and the noise

No noise bias. As in Section 13.3.2, the noise of the two half-mission maps is independent, so a spectrum formed from one coefficient of each half has no noise term on average. For a parity-odd spectrum there are two such products, $\widetilde{E}^{(1)}\widetilde{B}^{(2)*}$ and $\widetilde{E}^{(2)}\widetilde{B}^{(1)*}$, and both have the same mean. We average them,

$$\widehat{C}_\ell^{EB} = \frac{1}{2\ell+1}\sum_m \tfrac{1}{2}\,\mathrm{Re}\big(\widetilde{E}^{(1)}_{\ell m}\widetilde{B}^{(2)*}_{\ell m} + \widetilde{E}^{(2)}_{\ell m}\widetilde{B}^{(1)*}_{\ell m}\big), \tag{13.67}$$

and the same for TE and TB; for EE and BB there is only one product. Each half is rotated by the same angle, so (13.65) holds term by term for (13.67). All spectra are then binned in 48 bins of $\Delta\ell = 30$ between $\ell = 50$ and 1489, as plain averages of D_ℓ over the bin. The range follows the published analyses, which start at $\ell = 51$ because the largest scales of the *Planck* polarization maps carry systematic residuals, and stop near $\ell = 1500$ [57]; at $N_{\mathrm{side}} = 512$ we cannot go much further anyway.

Listing 13.11: The symmetrised cross-spectra of two half-mission maps (`code/ch13/lib_biref.py`)

```
def xcl(a, b):
    """Symmetrised cross-spectrum 1/2 (a1 b2* + b1 a2*) given pairs a=(a1,a2), b=(b1,b2)."""
    return 0.5 * (hp.alm2cl(a[0], b[1]) + hp.alm2cl(b[0], a[1]))

def cross_spectra(h1, h2):
    """h = (T, E, B) pseudo-a_lm of one half.  Binned cross-spectra of the two halves."""
    T, E, B = zip(h1, h2)
    return {"EE": binned(hp.alm2cl(E[0], E[1])), "BB": binned(hp.alm2cl(B[0], B[1])),
            "EB": binned(xcl(E, B)), "TE": binned(xcl(T, E)), "TB": binned(xcl(T, B))}
```

`xcl` forms the average of the two cross products in (13.67), and `cross_spectra` returns the five binned spectra from the pseudo-coefficients (T, E, B) of each half. The pseudo-coefficients themselves come from `hp.map2alm` with `pol=True` applied to WQ and WU.

The noise model. We build it as in Section 13.4.1, now for Q and U. The half-difference $d = (\mathrm{hm1} - \mathrm{hm2})/2$ contains no sky. Its local variance $v(p)$, the average of d_Q^2 and d_U^2 smoothed over 2° and divided by its mean over the kept sky, says how the noise level varies over the sky (Figure 13.54d; at most 2.7 times the mean). The E and B spectra of $d/\sqrt{v}$, divided by $\langle W^2\rangle$ and averaged over 31 neighbouring multipoles, say how it varies with scale. A simulated

half-mission noise map is then $\sqrt{2}\sqrt{v}$ times a Gaussian polarization field with those two spectra, the $\sqrt{2}$ derived in Section 13.4.1. The noise is almost the same in E and in B (their ratio is 0.96 at $600 < \ell < 900$), as it should be for noise that knows nothing about the patterns on the sky.

Example: the noise level in familiar units. Noise that is white on the sky has a flat spectrum, $N_\ell = \sigma_{\text{pix}}^2 \Omega_{\text{pix}}$, and experiments quote $\sqrt{N_\ell}$ in μK arcmin: the noise in a pixel of one square arcminute. Dividing the measured noise spectrum of one half-mission map by the squared beam and pixel window and averaging over $600 < \ell < 900$ gives 91 μK arcmin. For comparison, the temperature noise of Section 13.4.1 stayed below the sky at every multipole we used; here the noise power of one half is above the E signal at almost every multipole we use (the exception is the first E peak near $\ell \approx 400$), and about 1471 times the lensing B near $\ell = 980$ (Figure 13.55). Every result below is limited by this noise.

13.31 The estimator, tested on skies where we know the angle

A carpenter who is handed a new ruler measures something of known length before trusting it on the table she is building. The estimator of the angle is our ruler, and the object of known length is a simulated sky: we rotate it by an angle we choose, pass it through everything the real sky went through, and see what the estimator says. One such sky tells us little, because one estimate scatters. Hundreds of them tell us three things: whether the estimator is right on average (its *bias*), how much it scatters (its *error*), and whether the error bar it reports for each sky contains the truth as often as it should (its *coverage*). The estimator comes first, from least squares; six hundred skies then give the three numbers.

The same carpentry was done once already, on a toy. In Section 10.15 a Fisher forecast told us how the error on the angle shrinks with lower noise, more sky and more multipoles, before any sky existed; in Section 10.17 simulated toy skies checked that forecast and the estimator's bias, scatter and coverage, mask leakage included. What is new here is that every ingredient is the real one: SMICA's noise, measured from its own half-missions, SMICA's mask, and a covariance that has to be estimated rather than written down. So the toy's conclusions are a prediction, and the simulated skies below test whether they survive contact with the real pipeline.

13.31.1 Least squares for one angle

The model. Stack the binned parity-odd spectra into one list, $\boldsymbol{e} = (\widehat{D}_b^{EB}, \widehat{D}_b^{TB})$, with 2×48 entries, and the spectra they should copy into a second list of the same length, $\boldsymbol{D} = (\widehat{D}_b^{EE} - \widehat{D}_b^{BB}, \widehat{D}_b^{TE})$. For a small angle, (13.66) says that on average $\boldsymbol{e} = 2\beta \boldsymbol{D}$, since $\frac{1}{2}\sin 4\beta \approx 2\beta$ and $\sin 2\beta \approx 2\beta$. The data scatter around that mean with a covariance $\mathbf{C}$, so we write

$$\boldsymbol{e} = 2\beta\, \boldsymbol{D} + \boldsymbol{n}, \qquad \boldsymbol{n} \sim \mathcal{N}(\mathbf{0}, \mathbf{C}). \tag{13.68}$$

This is the linear model with one parameter of Section 3.10.2. The template $\boldsymbol{D}$ is made of the *measured* spectra, not of a theory curve, as in the term of [57] that carries the rotation of everything in the map: it is then automatically seen through the same window, beam and pixels as $\boldsymbol{e}$, and no theory enters at all.

The best angle. The likelihood of (13.68) is largest where $\chi^2(\beta) = (\boldsymbol{e} - 2\beta\boldsymbol{D})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{e} - 2\beta\boldsymbol{D})$ is smallest. Setting its derivative to zero,

$$0 = \frac{\mathrm{d}\chi^2}{\mathrm{d}\beta} \overset{(1)}{=} -4\,\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\big(\boldsymbol{e} - 2\beta\boldsymbol{D}\big)$$

$$\Longrightarrow \qquad \hat{\beta} \overset{(2)}{=} \frac{\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{e}}{2\,\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}}. \tag{13.69}$$

(1) Differentiate the quadratic form: $\mathrm{d}(\boldsymbol{r}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r})/\mathrm{d}\beta = 2(\mathrm{d}\boldsymbol{r}/\mathrm{d}\beta)^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{r}$ for the symmetric $\mathbf{C}^{-1}$, with $\boldsymbol{r} = \boldsymbol{e} - 2\beta\boldsymbol{D}$ and $\mathrm{d}\boldsymbol{r}/\mathrm{d}\beta = -2\boldsymbol{D}$.
(2) Expand, $\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{e} = 2\beta\,\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}$, and divide by $2\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}$.

Its error. $\hat{\beta}$ is a fixed linear combination $\boldsymbol{w}^{\mathsf{T}}\boldsymbol{e}$ of the data, with $\boldsymbol{w} = \mathbf{C}^{-1}\boldsymbol{D}/(2\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D})$, so

$$\operatorname{Var}\hat{\beta} \overset{(1)}{=} \boldsymbol{w}^{\mathsf{T}}\mathbf{C}\,\boldsymbol{w} \overset{(2)}{=} \frac{\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{C}\,\mathbf{C}^{-1}\boldsymbol{D}}{4\,(\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D})^2} \overset{(3)}{=} \frac{1}{4\,\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}}, \qquad \sigma_\beta = \frac{1}{2\sqrt{\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}}}. \tag{13.70}$$

(1) The variance of a linear combination $\boldsymbol{w}^{\mathsf{T}}\boldsymbol{e}$ of a vector with covariance $\mathbf{C}$ (Section 3.6.1); $\boldsymbol{D}$ is treated as fixed.
(2) Substitute $\boldsymbol{w}$; $\mathbf{C}^{-1}$ is symmetric.
(3) $\mathbf{C}^{-1}\mathbf{C} = \mathbb{1}$, and one factor $\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}$ cancels.

The template is itself measured and noisy, which (13.70) ignores. Whether that matters is one of the things the simulated skies decide, since they carry a noisy template too.

Example: one bin, then two. With a single bin, $\boldsymbol{e} = e$, $\boldsymbol{D} = D$ and $\mathbf{C} = \sigma^2$, (13.69) is $\hat{\beta} = e/2D$, the naive ratio of Section 13.29, and its error is $\sigma/2|D|$. With two independent bins,

$$\hat{\beta} \overset{(1)}{=} \frac{D_1 e_1/\sigma_1^2 + D_2 e_2/\sigma_2^2}{2\,(D_1^2/\sigma_1^2 + D_2^2/\sigma_2^2)} \overset{(2)}{=} \frac{w_1\hat{\beta}_1 + w_2\hat{\beta}_2}{w_1 + w_2}, \qquad w_b = \frac{D_b^2}{\sigma_b^2}, \tag{13.71}$$

(1) (13.69) with $\mathbf{C} = \operatorname{diag}(\sigma_1^2, \sigma_2^2)$.
(2) Write $D_b e_b = D_b^2 \cdot e_b/D_b = 2D_b^2\hat{\beta}_b$, with $\hat{\beta}_b = e_b/2D_b$ the angle from bin b alone.

The estimator is the weighted mean of the single-bin angles of Section 3.7, each weighted by one over its own variance, $(2|D_b|/\sigma_b)^2$: a bin counts in proportion to the square of how much E it has, compared with its noise. The wallpaper of Section 13.29 again: bold stripes count, a plain wall does not.

Example: the scatter of a cross-spectrum. The single-multipole numbers of Section 13.29 came from the variance of one cross product. Take one coefficient $x = E^{(1)}_{\ell m}$ from the first half and one $y = B^{(2)}_{\ell m}$ from the second, independent, with zero mean and variances $\sigma_x^2 = C_\ell^{EE} + N_\ell$ and $\sigma_y^2 = C_\ell^{BB} + N_\ell$ (sky plus the noise of one half). Then

$$\operatorname{Var}(xy) \overset{(1)}{=} \mathbb{E}[x^2y^2] - \big(\mathbb{E}[xy]\big)^2 \overset{(2)}{=} \mathbb{E}[x^2]\,\mathbb{E}[y^2] - 0 \overset{(3)}{=} \sigma_x^2\sigma_y^2. \tag{13.72}$$

(1) The definition of the variance.
(2) For independent x and y the mean of a product is the product of the means, applied to x^2, y^2 and to x, y (whose means are zero).
(3) Both means are zero, so $\mathbb{E}[x^2]$ is the variance.

Averaging over the $(2\ell+1)$ values of m, of which a fraction $f_{\text{sky}}^{\text{eff}}$ is effectively independent on the cut sky, divides this by $(2\ell+1)f_{\text{sky}}^{\text{eff}}$. With the noise far above C_ℓ^{BB}, the error of $\widehat{C}_\ell^{EB}$ is set by the noise times the E power plus noise: which is why the leakage, a small addition to σ_y^2, costs so little.

The covariance. The bins of $\widehat{D}^{EB}$ and $\widehat{D}^{TB}$ are correlated with each other, because both use the same B coefficients, and neighbouring bins are weakly correlated through the window. No formula gives this covariance exactly for our window and our noise, so we take it from simulated skies with no rotation, as in Section 13.4.3, and multiply its inverse by the Hartlap factor $(n-p-2)/(n-1)$ of Section 8.13.2. With $p = 2\times 48$ and $n = 400$ skies the factor is 0.76. The remaining 200 skies are kept apart and used only to test the estimator: a sky that helped build **C** would be a slightly too easy test object.

13.31.2 The simulated skies

The rule of Section 13.4.2 holds: whatever is done to the data is done to every simulated sky.

Drawing T and E together. The temperature and E polarization of the CMB are correlated: both are made by the same density waves at last scattering, and $C_\ell^{TE} \neq 0$. So for each (ℓ, m) we need two Gaussian coefficients with variances C_ℓ^{TT} and C_ℓ^{EE} and covariance C_ℓ^{TE}. With two independent unit Gaussians z_1, z_2 (complex for $m>0$, real for $m=0$, as in Section 8.5), set

$$a^T = \sqrt{C_\ell^{TT}}\, z_1, \qquad a^E = \frac{C_\ell^{TE}}{\sqrt{C_\ell^{TT}}}\, z_1 + \sqrt{C_\ell^{EE} - \frac{(C_\ell^{TE})^2}{C_\ell^{TT}}}\, z_2. \tag{13.73}$$

It has the right second moments:

$$\begin{aligned} \left\langle a^T a^{E*} \right\rangle &\overset{(1)}{=} \sqrt{C_\ell^{TT}}\, \frac{C_\ell^{TE}}{\sqrt{C_\ell^{TT}}} \left\langle |z_1|^2 \right\rangle \overset{(2)}{=} C_\ell^{TE}, \\ \left\langle |a^E|^2 \right\rangle &\overset{(3)}{=} \frac{(C_\ell^{TE})^2}{C_\ell^{TT}} + C_\ell^{EE} - \frac{(C_\ell^{TE})^2}{C_\ell^{TT}} \overset{(4)}{=} C_\ell^{EE}. \end{aligned} \tag{13.74}$$

(1) Multiply out; the term with $\langle z_1 z_2^* \rangle$ vanishes because z_1, z_2 are independent with zero mean.
(2) $\langle |z_1|^2 \rangle = 1$.
(3) The two squared coefficients, since the cross term vanishes for the same reason.
(4) The two fractions cancel.

This is the Cholesky factor of the 2×2 covariance matrix, the recipe of Section 2.12.1. B is drawn independently from the lensing B spectrum C_ℓ^{BB} of the fiducial model; EB and TB are zero.

One simulated sky.

1. Draw a^T, a^E, a^B for $\ell \le 1535$ from the CAMB fiducial spectra [8] with (13.73), multiply by the transfer functions, and make the temperature map and two polarization maps, one from E alone and one from B alone.
2. Make two half-mission noise maps for T (the model of Section 13.4.1) and for Q, U (Section 13.30.4).

3. Compute the pseudo-coefficients of the signal maps and of the noise maps separately, through the same windows as the data.
4. For each injected angle $\beta \in \{0, 0.3^\circ, 1^\circ\}$, rotate the signal pseudo-coefficients with (13.64), add the noise, and compute the five binned cross-spectra.

Step 4 is where Section 13.30.3 pays off a second time. Rotating the pseudo-coefficients is *exactly* the same as rotating the sky before observing it, so one simulated sky yields three rotated skies for the price of one, with identical CMB and noise: the differences between them are due to the rotation alone. The noise is not rotated. Keeping the E part and the B part of the sky apart costs one more transform and gives, for free, the leakage and the lensing spectra of Figure 13.55, and a version of every sky with the lensing B removed.

Listing 13.12: One simulated polarized sky, observed like the real one, rotated three ways (`code/ch13/43_pol_sims.py`)

```
def one_sky(rng, with_binary):
    aT, aE, aB = lb.correlated_alm(cls, L, rng)
    tsky = hp.alm2map(hp.almxfl(aT, TT_), N, lmax=L)
    qE, uE = spin_synth(hp.almxfl(aE, TP), zero)
    qB, uB = spin_synth(zero, hp.almxfl(aB, TP))
    sT = hp.map2alm(WT * tsky, lmax=L, iter=0)
    sE = spin_anal(WP, qE, uE)                  # pseudo (E, B) of the E part: B here is leakage
    sB = spin_anal(WP, qB, uB)                  # pseudo (E, B) of the lensing B part
    cE, cB = spin_anal(WC, qE + qB, uE + uB)      # the stricter window, beta = 0
    cEl = spin_anal(WC, qE, uE)
    noise, cnoise = [], []
    for _ in range(2):
        nt = sqvT * np.sqrt(2.0) * hp.alm2map(cs.synalm(ngT, L, rng), N, lmax=L)
        nq, nu = spin_synth(cs.synalm(ngE, L, rng), cs.synalm(ngB, L, rng))
        nq, nu = np.sqrt(2.0) * sqvP * nq, np.sqrt(2.0) * sqvP * nu
        nE, nB = spin_anal(WP, nq, nu)
        noise.append((hp.map2alm(WT * nt, lmax=L, iter=0), nE, nB))
        cnoise.append(spin_anal(WC, nq, nu))
    out = {}
    sigE, sigB = sE[0] + sB[0], sE[1] + sB[1]
    for i, beta in enumerate(BETAS):
        rE, rB = lb.rotate(sigE, sigB, beta)
        h = [(sT + n[0], rE + n[1], rB + n[2]) for n in noise]
        s = lb.cross_spectra(*h)
        for k, v in s.items():
            out[f"b{i}_{k}"] = v
    h = [(sT + n[0], sE[0] + n[1], sE[1] + n[2]) for n in noise]     # no lensing B in the sky
    for k, v in lb.cross_spectra(*h).items():
        out[f"nolens_{k}"] = v
```

`lb.correlated_alm` implements (13.73); `spin_synth` and `spin_anal` are healpy's spin-2 transforms. The variables `sE` and `sB` hold the pseudo-coefficients (E and B) of the E part and of the B part of the sky; their sum is the observed sky. The loop over `BETAS` is step 4. One sky takes 6.2 s on eight cores; we ran 600 of them, in chunks of 25 cached in `data/ch13/`.

13.31.3 What the simulations say

Is the estimator unbiased? On the 200 test skies with no rotation the joint estimator averages 0.000°, with a Monte Carlo error of 0.004° on that average (the scatter divided by $\sqrt{200}$). With an injected 0.3° the average error is $0.000^\circ \pm 0.004^\circ$, and with 1° it is $0.001^\circ \pm 0.004^\circ$ (Figure 13.57). In each case the question is whether an average as far from zero as this one, or farther, would

be something we would reasonably expect from an unbiased estimator with this Monte Carlo error; the answer is read off by comparing each bias with its error. With no rotation, this also confirms (13.66): the mask leaks E into B, but no EB appears on average.

Is the error bar right? For EB alone, the scatter of the estimate over the test skies with no rotation is 0.048°, and the error bar the estimator reports, (13.70) averaged over the skies, is 0.048°: a ratio of 1.00. TB alone scatters by 0.087°, almost twice as much: both copy their template with the same factor 2β, but the TB template, the TE correlation, is small compared with the scatter of $\widehat{C}_\ell^{TB}$, which is the polarization noise multiplied by the large temperature power. For the joint estimate the reported error is 0.045°, smaller than that of EB alone, as adding information should make it. But the joint estimate actually scatters by 0.050°, a ratio of 1.11, and no better than EB alone. Each of these scatters is itself estimated from 200 skies, so it carries a Monte Carlo error of $1/\sqrt{2(200-1)}$, about five per cent; a ratio is meaningful only when it differs from one by more than that.

Why the joint error bar is too small. Formula (13.70) assumes that $\mathbf{C}$ is the true covariance. Ours is estimated from $n = 400$ skies, and its inverse, although corrected on average by the Hartlap factor, is noisy element by element. Noisy weights are not the optimal weights, and an estimator with slightly wrong weights scatters more than the optimal one: the extra variance is a factor of about $1 + p/n$ for p bins [254]. For the joint estimate, $p = 2 \times 48$ and $\sqrt{1 + p/n} = 1.11$, which the measured ratio matches within its five per cent Monte Carlo error; for EB alone the factor is 1.06, too close to one for two hundred skies to resolve. With four hundred skies, doubling the number of bins costs about as much as the TB information gains. So for the real sky we quote the joint angle with the error the test skies give it, their scatter 0.05°, not the formula's.

Does the interval cover the truth? A 68% interval $\hat\beta \pm \sigma_\beta$ should contain the true angle in 68% of the skies, and $\hat\beta \pm 1.96\sigma_\beta$ in 95%. With 200 skies a coverage fraction has a binomial error of about 3 percentage points near 68% and 2 near 95%. For EB alone the reported intervals cover the truth in 68% and 95% of the skies, as they should. For the joint estimate with the formula's error bar they cover it in 65%, 65% and 64% of the skies for the three angles, and in 92%, 92% and 92% at $1.96\sigma_\beta$. An error bar that is too small by the factor 1.11 expected from the noise of the covariance should cover the truth in the fraction of a Gaussian within $1/1.11 = 0.90$ of its standard deviation, 63%, and within $1.96/1.11 = 1.76$, 92%; the measured fractions are to be read against those two numbers and against 68 and 95, with the binomial errors just quoted. Two hundred skies make coverage a blunt instrument: it can expose an error bar that is wrong by a tenth only at the edge of its resolution, which is why the direct comparison of the scatter with the reported error, above, is the sharper test.

Lensing B: variance, not bias. Every simulated sky also exists without its lensing B, with the same CMB E and the same noise. Lensing B is a parity-even signal: on average it adds to C^{BB} and nothing to C^{EB}. In the cross-spectrum example above it is a small addition to σ_y^2, so it can only add variance, and next to the noise, which is more than a thousand times larger near $\ell = 1000$, the addition is tiny. The skies agree. With lensing the joint estimate averages 0.000°, without it −0.000°, both within the Monte Carlo error of zero; the scatters, 0.0496° and 0.0499°, are equal to within a per cent, and which of the two comes out larger depends on the particular skies drawn; and the sky-by-sky difference between the two estimates, which cancels the shared CMB and noise, scatters by only 0.0033°. So lensing B leaves the angle unbiased and adds variance too small for this noise level to show, as the parity argument says.

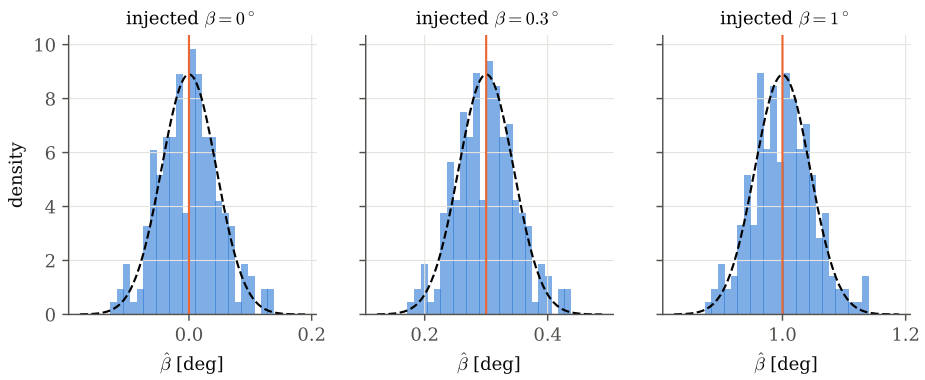

Figure 13.57: The joint estimator on the 200 held-out simulated skies, for three injected angles (orange lines). The histograms are the estimates; the dashed curves are Gaussians centred on the injected angle with the mean error bar the estimator reports. The three panels are the same skies rotated three ways, so their shapes match.

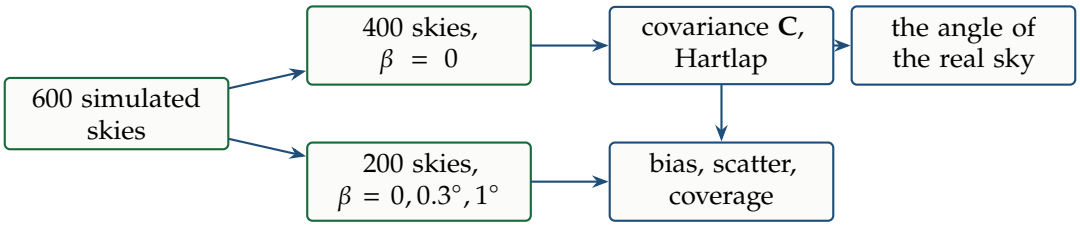

Figure 13.58: How the simulated skies are used. Two thirds build the covariance of the parity-odd spectra; the other third, never used for the covariance, tests the estimator with known angles. The same covariance is then used on the real sky.

13.32 What the SMICA sky says

The ruler has been checked on skies whose angle we chose. It is unbiased, and on four hundred skies' worth of covariance its honest error for the joint estimate is the scatter of the test skies, 0.05°. Now we lay it on the one sky whose angle nobody chose.

Listing 13.13: The estimator (13.69) and its formal error (13.70) (`code/ch13/lib_biref.py`)

```
def estimate_beta(s, Cinv, which="joint"):
    """Least squares for e = 2 beta D + noise:  beta = D C^-1 e / (2 D C^-1 D),  sigma = 1/(2 sqrt(D C^-1 D))."""
    e, D = vectors(s, which)
    F = D @ Cinv @ D
    return (D @ Cinv @ e) / (2 * F), 1.0 / (2 * np.sqrt(F))
```

`vectors` stacks the binned spectra into $\boldsymbol{e}$ and $\boldsymbol{D}$ as in (13.68), the two dot products are $\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{e}$ and $\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}$, and the function returns (13.69) and (13.70). The data spectra go in exactly as the simulated ones did.

The event. The SMICA half-mission cross-spectra give

$$\hat{\beta}_{EB} = 0.28^\circ \pm 0.048^\circ, \qquad \hat{\beta}_{TB} = 0.37^\circ \pm 0.092^\circ, \qquad \hat{\beta} = 0.31^\circ \pm 0.05^\circ \ \text{(EB and TB together)}, \tag{13.75}$$

where the first two errors are the formula's, which the test skies confirmed for EB and TB alone, and the last is the scatter of the test skies (Section 13.31.3). The two separate angles agree: their difference is about one TB error. Figure 13.59 shows what was fitted. Above $\ell \approx 500$ the

measured $\widehat{D}_b^{EB}$ wander around zero with error bars larger than the curve $2\hat{\beta}(\widehat{D}_b^{EE} - \widehat{D}_b^{BB})$, which follows the acoustic wiggles of the E spectrum. Below $\ell \approx 500$ the noise is smallest and the error bars shrink, and there the points follow the first rise of the curve. Those bins carry most of the weight, but the fit does not rest on any one of them: it adds up 48 bins of EB and as many of TB, which on balance lean in the direction the template predicts. The wallpaper again.

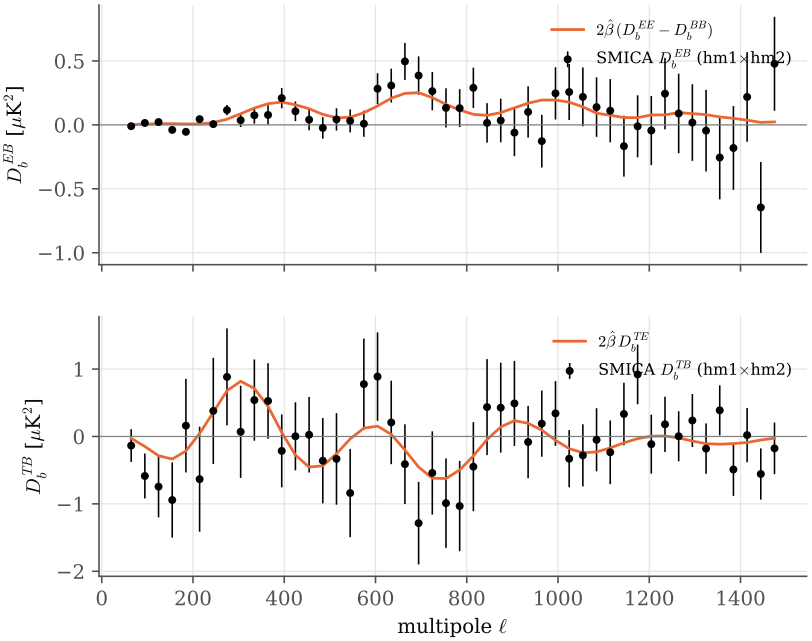

Figure 13.59: The SMICA half-mission cross-spectra that measure the angle, with error bars from the simulated skies. Top: $\widehat{D}_b^{EB}$ (points) and the rotation model $2\hat{\beta}(\widehat{D}_b^{EE} - \widehat{D}_b^{BB})$ for the joint angle (orange). Bottom: $\widehat{D}_b^{TB}$ and $2\hat{\beta}\,\widehat{D}_b^{TE}$. Above $\ell \approx 500$ the model is smaller than one error bar; the angle is measured by the coherent lean of all bins together, with most weight in the low-noise EB bins below $\ell \approx 500$.

What could have produced it? We return to the candidates of Section 13.29, now with a number to explain.

1. *Chance, with no rotation at all.* This is the one candidate whose sampling distribution we know, so it is our null hypothesis. If the true angle were zero, would an estimate of 0.31°, or one even farther from zero, be something we would reasonably expect? The angle is 6.3 times its error. A cleaner way to ask, which does not lean on the Gaussian shape of the estimate, is to compare how much better the rotated model fits than the unrotated one, $\Delta\chi^2 = \chi^2(0) - \chi^2(\hat{\beta})$, with the same quantity on the test skies with no rotation. On the data $\Delta\chi^2 = 48.2$. On the skies it follows the χ^2 distribution with one degree of freedom that Wilks' theorem predicts (Section 4.7), and none of the 200 skies comes anywhere near the data (Figure 13.60a). With 200 skies the simulations alone can only say that the probability is below about 1/200; the χ^2_1 tail, which the skies follow, puts it many orders of magnitude lower. Chance is ruled out.

2. *A leak of E into B through the mask.* Ruled out by (13.66) and by the test skies, whose mask leaks exactly as the data's does and whose angle averages to $0.000° \pm 0.004°$.

3. *Galactic dust with an EB of its own.* Dust residuals are strongest near the plane, so if they made the angle, removing more sky near the plane would change it. With the strict window the angle is $0.32° \pm 0.05°$. The two windows share most of the sky, so the right yardstick for

their difference is not either error bar but the scatter of the difference over the test skies, each analysed through both windows: 0.03°. The data's shift, −0.01°, is −0.2 times that scatter (Figure 13.60b). No sign of a dust-made angle; but dust whose twist is the same everywhere would not change with the mask, and this test cannot exclude it.

4. *A miscalibration α or a cosmic rotation β.* Both remain. Both produce exactly the pattern we fitted, and Section 13.33 explains why no test on this map can tell them apart.

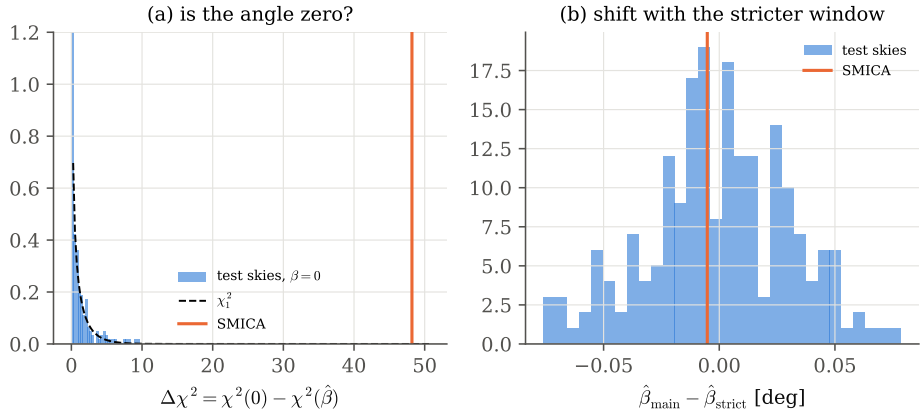

Figure 13.60: Two checks against the simulated skies. (a) How much the rotated model improves the fit, on the test skies with no rotation (histogram, following the χ^2_1 curve) and on the data (orange line). (b) The change of the angle between the main and the strict window, over the test skies and on the data: the data sit in the middle of the distribution.

13.32.1 Is the rotation model enough?

A model can win against no rotation and still be wrong. Three more questions test whether one angle explains the parity-odd spectra.

Does one angle fit all the bins? With the best angle, the remaining $\chi^2 = (\boldsymbol{e} - 2\hat{\beta}\boldsymbol{D})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{e} - 2\hat{\beta}\boldsymbol{D})$ is 95.6 for 95 degrees of freedom (96 numbers, one parameter). The test skies, fitted the same way, give a χ^2 larger than this in a fraction 0.51 of cases. Nothing in the EB and TB spectra calls for more than one angle.

Do low and high multipoles agree? The angle from the bins with $\ell < 770$ is $0.32° \pm 0.05°$, and from $\ell \geq 770$ it is $0.25° \pm 0.12°$ (formal errors). Their difference is less than one standard error of the difference. Most of the weight sits below $\ell \approx 800$, where the E spectrum is large compared with the noise. A rotation must be the same at every scale; an EB made by dust or by a beam effect would generally not be.

Does the template matter? The template $\boldsymbol{D}$ was made of the measured spectra. Replacing it by the mean of the simulated spectra, a noiseless version of the fiducial model seen through the same window, gives 0.31°. The two agree because the measured E spectrum is close to the fiducial one: in the first twenty bins their ratio is 1.008.

The answer. The SMICA polarization is turned, relative to the directions the instrument assumes, by

$$\hat{\beta}_{\rm SMICA} = 0.31° \pm 0.05° \quad (68\%,\ \text{statistical}), \tag{13.76}$$

an effect that chance does not explain, that the mask cannot produce, that does not move when we cut away more of the Galaxy and that has the same size at large and small scales. What it is an angle *of* is a separate question, and the published measurements, made with a different kind of map, answer it.

13.33 The published angle, and what one map can measure

Their question. By 2016 the *Planck* team had measured the rotation of the CMB polarization from the foreground-cleaned maps of its 2015 release and found $0.31^\circ \pm 0.05^\circ$ [187]. The statistical error was small, but next to it stood a second one, $\pm 0.28^\circ$: the uncertainty of the ground measurement of the detectors' polarization directions. That second error swallowed the first, and it could not be reduced by more data, because every CMB measurement of the angle measures the same sum $\alpha + \beta$. Minami and Komatsu asked whether the sky itself could calibrate the detectors, so that β could be separated from α [57, 71]. That is the door frame of Section 13.29: something in the picture that is known to hang straight.

13.33.1 Their setup, in plain terms

Instead of one cleaned map they used the four polarized frequency maps of the High Frequency Instrument (100, 143, 217 and 353 GHz), each in its two half-mission versions, and all their cross-spectra, so that no noise bias enters. Each frequency was allowed its own miscalibration α_ν, because different detectors can be misaligned differently, and the sky one common β. The frequency maps still contain the Galaxy, and that is the point: the dust emission, bright at 353 GHz, travels only a few hundred parsecs and is rotated by α_ν but not by β. They masked only bright CO regions, bright sources and unobserved pixels, keeping most of the sky, tapered the masks by 0.5°, computed the spectra with NaMaster [142] between $\ell = 51$ and 1500 in bins of $\Delta\ell = 20$, and sampled the posterior of the five angles with emcee. The baseline assumes that the dust itself has no EB correlation (Table 13.12).

13.33.2 Their key equation

Chapter T1 derives the relation behind their method from the rotated spectra. Its content, with the reason for each step in a sentence, is short. Take one frequency and write the sky in it as the CMB plus the Galactic foreground. On the way to the detector the CMB is rotated by β and then everything by α; the foreground is rotated only by α. Assume, as their baseline does, that neither component has an EB of its own and that the two are uncorrelated, so their cross terms vanish on average. Each component then contributes to the observed spectra as in (13.62), with its own angle and its own $\Delta_\ell = C_\ell^{EE} - C_\ell^{BB}$ before rotation:

$$\begin{aligned} C_\ell^{EB,\mathrm{o}} &= \tfrac{1}{2}\sin\big(4(\alpha+\beta)\big)\,\Delta_\ell^{\mathrm{cmb}} + \tfrac{1}{2}\sin(4\alpha)\,\Delta_\ell^{\mathrm{fg}}, \\ C_\ell^{EE,\mathrm{o}} - C_\ell^{BB,\mathrm{o}} &= \cos\big(4(\alpha+\beta)\big)\,\Delta_\ell^{\mathrm{cmb}} + \cos(4\alpha)\,\Delta_\ell^{\mathrm{fg}}. \end{aligned} \tag{13.77}$$

The second line follows by multiplying out as in (13.65): a rotation by θ multiplies the $EE - BB$ of a component with no EB by $c^2 - s^2 = \cos 4\theta$. We do not know $\Delta_\ell^{\mathrm{fg}}$, so we eliminate it: subtracting $\frac{1}{2}\tan 4\alpha$ times the second line from the first cancels the foreground, because $\tan 4\alpha \cos 4\alpha = \sin 4\alpha$, and the sine subtraction formula $\sin A \cos B - \cos A \sin B = \sin(A - B)$, with $A = 4(\alpha + \beta)$ and $B = 4\alpha$, collects what is left of the CMB:

$$C_\ell^{EB,\mathrm{o}} - \tfrac{1}{2}\tan(4\alpha)\big(C_\ell^{EE,\mathrm{o}} - C_\ell^{BB,\mathrm{o}}\big) = \frac{\sin 4\beta}{2\cos 4\alpha}\,\Delta_\ell^{\mathrm{cmb}}. \tag{13.78}$$

Figure 13.61 draws the two paths. This is the single-frequency form of their equation [57, (2)], derived in [71]. Read it as a fit with two templates. The *observed* $C^{EE,\mathrm{o}} - C^{BB,\mathrm{o}}$, CMB and foreground together, enters with the coefficient $\frac{1}{2}\tan 4\alpha$; the *theoretical* CMB $\Delta_\ell^{\mathrm{cmb}}$ enters with a coefficient set by β. Symbol map to ours: their $C_\ell^{XY,\mathrm{o}}$ are our binned cross-spectra $\widehat{D}_b^{XY}$; their Δ^{cmb} is the fiducial $C^{EE} - C^{BB}$ through beam and pixels; our single β in (13.68) is their $\alpha + \beta$.

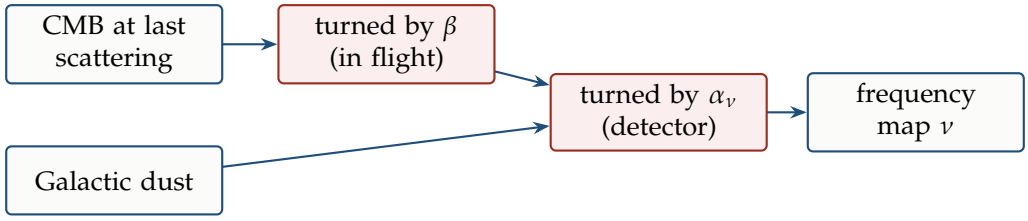

Figure 13.61: The two rotations of (13.77). The CMB is turned twice, once on its way across the Universe and once by the detector; the dust of our Galaxy is turned only by the detector. In a map that still contains the dust the two components carry different angles, and the fit (13.79) can tell α_ν from β; in a map from which the dust has been removed only $\alpha_\nu + \beta$ is left.

Why the two angles separate, and when they do not. For small angles the first line of (13.77) reads

$$C_\ell^{EB,\mathrm{o}} \approx 2(\alpha + \beta)\,\Delta_\ell^{\mathrm{cmb}} + 2\alpha\,\Delta_\ell^{\mathrm{fg}}, \tag{13.79}$$

a sum of two known shapes with two unknown amplitudes. Two amplitudes can be fitted separately only if the two shapes are different. They are: the dust spectrum is a smooth power law, large at low ℓ, while the CMB spectrum has acoustic peaks. So the fit finds α from the foreground shape and $\alpha + \beta$ from the CMB shape, and their difference is β. Now remove the foreground: $\Delta^{\mathrm{fg}} = 0$, and (13.79) contains α and β only through their sum. Any pair with the same sum fits equally well. This is exactly the situation of a component-separated map: SMICA was built to suppress the Galaxy, so it removed the door frame along with the dust. The degeneracy is not a weakness of our estimator. It is a property of the map.

13.33.3 What we compute

With the SMICA map, (13.78) collapses to our model (13.68), and our angle is

$$\hat{\beta}_{\mathrm{SMICA}} = \widehat{\alpha_{\mathrm{eff}} + \beta}, \tag{13.80}$$

where α_{eff} is the miscalibration that the SMICA combination inherits from its input channels. SMICA forms its B map from the channels' B maps with harmonic weights, and its E map from their E maps with other weights. If channel ν is turned by a small α_ν, its B map contains $2\alpha_\nu$ times its E map, so the B map of SMICA contains $2\sum_\nu w_{\ell\nu}^B \alpha_\nu$ times the CMB E map. The effective angle is the average of the channel angles weighted by the SMICA B-mode weights, which favour the cleanest CMB channels, 143 and 217 GHz [19].

13.33.4 Side by side

Our SMICA angle sits on top of the two other measurements of $\alpha + \beta$, within a fraction of their statistical errors, and inside the range of the β measurements. Given how different the data and the pipelines are, the agreement is the first thing to explain.

analysis	data	what it measures	angle [deg]
Planck XLIX [187]	2015 cleaned maps, EB+TB	$\alpha + \beta$	$0.31 \pm 0.05\,(\text{stat}) \pm 0.28\,(\text{syst})$
Minami & Komatsu, $\alpha_\nu = 0$ [57]	PR3 HFI channels	$\alpha + \beta$	0.289 ± 0.048
Minami & Komatsu [57]	PR3 HFI channels	β	0.35 ± 0.14
Diego-Palazuelos et al. [74]	PR4 HFI, $f_{\text{sky}} = 0.93$	β	0.30 ± 0.11
Eskilt & Komatsu [75]	PR4 LFI+HFI, WMAP	β	$0.342^{+0.094}_{-0.091}$
SMICA, here	PR3 SMICA halves, EB+TB	$\alpha_{\text{eff}} + \beta$	$0.31 \pm 0.05\,(\text{stat})$

Table 13.12: The rotation of the CMB polarization in the literature and here. Errors are 68% intervals. The first, second and last rows can only measure the sum of the cosmic angle and the miscalibration; the middle rows use the Galactic foreground to calibrate α_ν and quote β alone.

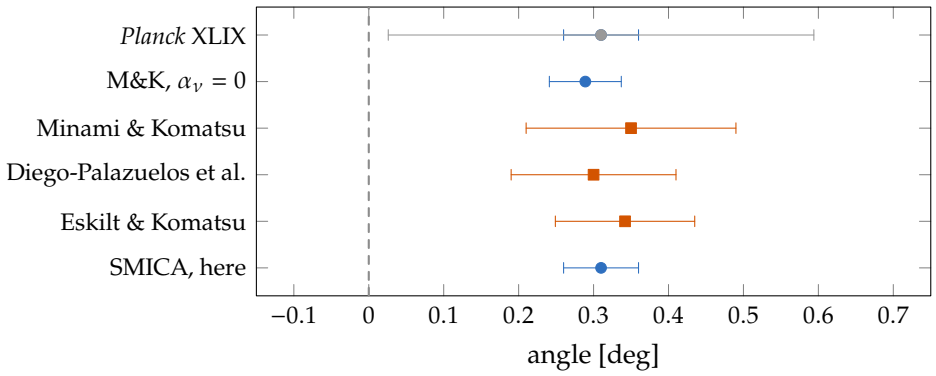

Figure 13.62: The angles of Table 13.12. Blue circles measure $\alpha + \beta$ with their statistical errors; the grey bar on the top row adds the 0.28° uncertainty of the ground calibration in quadrature. Orange squares are measurements of β alone, calibrated on the Galactic foreground.

13.33.5 Why they differ

Each row of Table 13.12 is a different estimate of a different combination from a different cut of the data, so agreement is expected only within the stated causes.

- *Different angles are measured.* Our number and the first two rows are $\alpha + \beta$, and the miscalibration in each is that of a different combination of detectors: the SMICA B-mode weights for us, the cleaning weights of 2015 for *Planck* XLIX, a single α forced on all four channels for the second row. Minami and Komatsu found channel angles between −0.28° and +0.07° [57, Table I], so the effective α of a combination can differ from one combination to the next by a tenth of a degree.
- *Different noise.* Our error is set by the half-mission noise of the SMICA map, 91 μK arcmin per half (Section 13.30.4). The frequency-channel analyses cross many more maps, but each channel is noisier than the combination and the foreground must be fitted at the same time; the end result is a statistical error on $\alpha + \beta$ of the same size as ours, and an error on β alone about three times larger, the price of separating the two angles.
- *The same sky.* All rows observe the same CMB, so their CMB fluctuations are shared and their differences are smaller than either error would suggest; the rows differ mostly through noise, sky fraction and foreground treatment.
- *What we left out.* We correct neither the temperature-to-polarization leakage of the beams nor the dust's own EB, and our noise model is Gaussian and approximate. Minami and Komatsu found the beam leakage to change β by less than 0.01° [57]; the dust EB is the leading open question, which Diego-Palazuelos et al. saw as an angle that drifts with the sky fraction [74], and which our strict-window check of Section 13.32.1 probes in the SMICA map.

The honest reading. Our $\hat{\beta}_{\rm SMICA} = 0.31^\circ \pm 0.05^\circ$ is a measurement of $\alpha_{\rm eff} + \beta$. To turn it into a statement about β we would subtract $\alpha_{\rm eff}$, and the only independent knowledge of it is the ground calibration, uncertain by 0.28° [187]. Added in quadrature to our statistical error, that gives about $\sqrt{0.05^2 + 0.28^2}$ degrees for β, and no claim about cosmic birefringence survives it. What the measurement does show is that the SMICA map contains a rotation of the size the frequency analyses attribute to β, and that a careful pipeline on a single public map finds it.

What the foreground method would need. Separating β from α takes, in order: maps that still contain the Galaxy, one per frequency (or per detector set), since each has its own α_ν; cross-spectra between all of them, half-missions crossed so that noise does not bias them; a foreground bright enough in at least one channel to fix α_ν, which for *Planck* is the dust at 353 GHz; a model of the dust's own EB correlation, since a twist of the dust filaments relative to the Galactic magnetic field makes $C^{EB,\rm dust} \neq 0$ and is degenerate with α [57, 74]; and end-to-end simulations of the instrument to show that no systematic effect makes EB. None of these is in a single component-separated map. The published value of β is therefore a measurement of the CMB *relative to the dust*: it is as good as the assumption about the dust's EB.

Lesson. Reproducing the number taught us what the number is. One CMB map, however carefully analysed, measures how much its polarization is turned relative to the instrument's idea of north; only a second, nearby source of polarization seen through the same instrument can tell the instrument's error from the Universe's.

13.34 The B modes that must be there: lensing

Everything so far asked about a B signal that might not exist. There is one B signal that must exist, and the same cross-spectra can look for it. Look at a tiled floor through a sheet of old, slightly wavy window glass. The grout lines were straight, but through the glass they wobble, and a pattern that was nothing but straight lines now has little bends and twists in it. Nothing was added to the floor; the light was bent on its way to us. The CMB is seen through such a glass: the matter between us and the last scattering surface deflects the photons by a few arcminutes, in directions that change from place to place (Chapter T1). The deflection rearranges the E pattern, and a rearranged mirror-symmetric pattern is no longer purely mirror-symmetric: some of it is B [47, 64]. The standard model predicts this lensing B spectrum precisely from the E spectrum and the matter distribution; it is the BB of our fiducial CAMB spectra, which are computed with lensing switched on, and near $\ell = 980$ it is $D_\ell^{BB} \approx 0.097\,\mu\mathrm{K}^2$, hundreds of times below the E spectrum.

Where else B comes from. The classification of B-mode sources in Chapter T1 sorts them by where they are made. In the early Universe: primordial gravitational waves, which at the current limits are far below lensing at these multipoles, and a rotation of the polarization, which turns a fraction $\sin^2 2\beta \approx (2\beta)^2$ of E into B, about 10^{-4} of the E power for a third of a degree, also far below lensing. On the way: lensing. In our Galaxy: dust and synchrotron emission, which have their own B, with roughly half as much B power as E power for dust [66]. In the instrument and the analysis: leakage of E into B by the mask (Section 13.30.2), leakage of temperature into polarization by the beams, and noise. Noise adds no B to a cross-spectrum of independent halves on average, but noise correlated between the halves would. Figure 13.63 sorts these by whether they can survive in the mean of our cross-spectrum.

The questions, in words. Do the SMICA cross-spectra contain B power, after the leakage is removed? Is its amount and shape that of lensing? And how sharp a test can this map make, at its noise level?

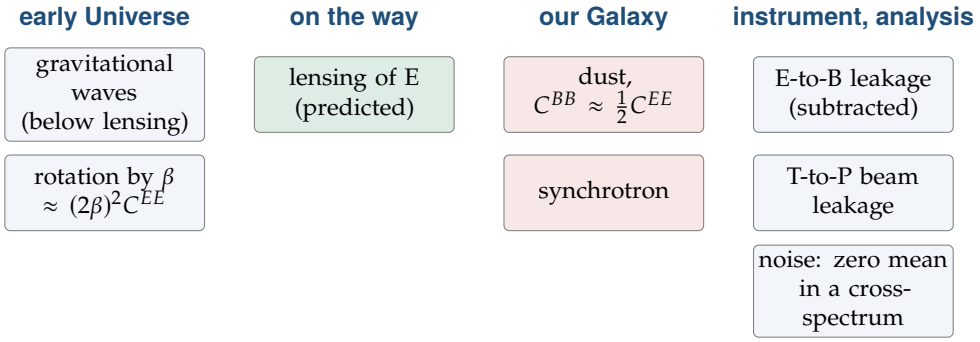

Figure 13.63: What can put B power into the mean of a half-mission cross-spectrum, sorted by where it is made. Lensing (green) is the signal we test for; the Galactic emission (red) is what SMICA tries to remove and what the confidence mask is meant to exclude; the E-to-B leakage of the mask is known from simulations and subtracted; independent noise averages out.

13.34.1 From a pseudo-BB spectrum to B power

What is in the mean of the data. In a simulated sky we kept the E part and the B part apart (Section 13.31.2), and their pseudo-coefficients add: $\widetilde{B} = \widetilde{B}[\text{E part}] + \widetilde{B}[\text{B part}] + \widetilde{B}[\text{noise}]$. The first term is the leakage. Taking the mean of the binned cross-spectrum of the halves,

$$\big\langle \widehat{D}_b^{BB} \big\rangle \overset{(1)}{=} \big\langle |\widetilde{B}[\text{E}]|^2 \big\rangle_b + \big\langle |\widetilde{B}[\text{B}]|^2 \big\rangle_b \overset{(2)}{=} L_b + F_b\, D_b^{BB}. \tag{13.81}$$

(1) Multiply out the cross-spectrum. The noise of one half has nothing to multiply in the other, the E and B parts of the sky are independent, so all cross terms have zero mean. Each half sees the same sky, so each sky term appears as its own power.

(2) Name the two pieces. L_b is the leaked E power, the mean pseudo-BB of an E-only sky. The B part through window, beam and pixels gives some multiple F_b of its true bandpower D_b^{BB}; F_b is a *transfer function*, measured as the mean pseudo-BB of the B-only skies divided by the fiducial lensing bandpower, the Monte Carlo transfer function of the MASTER method [140] in its simplest form.

So the estimator of the B bandpower, applied identically to the data and to every simulated sky, is

$$\widehat{\mathcal{B}}_b = \frac{\widehat{D}_b^{BB} - L_b}{F_b}. \tag{13.82}$$

It is unbiased if the leakage of the real sky equals that of the fiducial skies, which holds if the real E spectrum is the fiducial one; the comparison of Section 13.32.1 found them equal to about a per cent at the multipoles where the leakage matters. A spin-2 MASTER correction would do the same job with the coupling matrices of the window instead of simulated means [142]; for a single amplitude the Monte Carlo version is enough.

One number for the comparison. The lensing prediction is a known shape t_b, the binned fiducial BB. Write $\widehat{\mathcal{B}}_b = A\, t_b + \text{noise}$ and fit the one amplitude A by least squares: the algebra of (13.69) with $2\boldsymbol{D}$ replaced by $\boldsymbol{t}$ gives $\hat{A} = \boldsymbol{t}^{\mathsf{T}}\mathbf{C}_B^{-1}\widehat{\boldsymbol{\mathcal{B}}}/(\boldsymbol{t}^{\mathsf{T}}\mathbf{C}_B^{-1}\boldsymbol{t})$, with the covariance $\mathbf{C}_B$ of the 48 bandpowers from the 400 covariance skies. On the test skies with lensing, $\hat{A}$ averages 0.98 and scatters by 0.54; on the same skies with the lensing B removed it averages -0.02 and scatters by

0.54 (Figure 13.64b). That second distribution is the null: what this pipeline reports when there is no B in the sky.

What the comparison can and cannot show. The two distributions overlap. A sky with exactly the predicted lensing B gives an amplitude about 1/0.54 standard deviations from zero, a two-sigma effect at best. The reason is the noise: near $\ell = 980$ one bandpower has an error of $0.63\,\mu\mathrm{K}^2$ against a lensing signal of $0.097\,\mu\mathrm{K}^2$, and the noise power of one half is 1471 times the lensing power there. So SMICA can tell us whether the B power is far above lensing, and roughly how far; it cannot measure the shape of the lensing spectrum, and it cannot by itself detect lensing B with any confidence. (The simulated lensing B is a Gaussian field with the lensed BB spectrum; the real one is slightly non-Gaussian, which adds a little variance to $\hat{A}$, negligible beside this noise.) The experiments that measure lensing B, from the ground at a few μK arcmin, have noise twenty to thirty times lower in amplitude.

13.34.2 What the data say

The event. Through the main window the data give $\hat{A} = 7.01$, with an error of 0.54 from the test skies. None of the 200 null skies reaches it, and none of the skies *with* lensing does either (Figure 13.64). There is B power in the SMICA cross-spectra, and there is far too much of it to be lensing: the χ^2 of the bandpowers against the lensing prediction is 288.2 for 48 bins. Figure 13.64a shows where: above $\ell \approx 400$ almost every bin sits above the prediction.

What could have produced the excess? We take the candidates of Figure 13.63 one at a time.

1. *Lensing alone, larger than predicted.* An amplitude of 7.01 times the standard model's would contradict every lensing measurement made with lower noise; and lensing cannot depend on the mask, which the excess does (item 4).
2. *Noise correlated between the halves.* It would raise the cross-spectrum roughly uniformly over the sky. The half-difference map is our test of the noise model: its BB spectrum agrees with the simulated half-differences to 3% in every bin below $\ell = 1100$, and is up to 6% below them at the highest multipoles, where our smoothed noise model is slightly too high. That does not touch the cross-spectrum's mean, and item 4 argues against a sky-wide cause.
3. *The rotation itself.* It moves only $(2\beta)^2 \approx 10^{-4}$ of the E power into B, far less than what is seen.
4. *Galactic emission.* Compare the cross-spectra of the data with the mean of the simulated skies between $\ell = 800$ and 1400. Through the main window the data have an excess of $1.14 \pm 0.08\,\mu\mathrm{K}^2$ in pseudo-EE and $0.60 \pm 0.07\,\mu\mathrm{K}^2$ in pseudo-BB: about twice as much E as B, the ratio of polarized dust. Through the strict window, which also removes the region the temperature mask removes, the excesses drop to 0.21 ± 0.07 and $-0.01 \pm 0.06\,\mu\mathrm{K}^2$. The amplitude drops from 7.01 to 2.50, a change of 13.3 times the scatter of that change over the test skies, 0.34. An excess that lives in the sky near the Galactic plane and in the regions around bright sources, with twice as much E as B, is a residual of Galactic emission that the SMICA confidence mask lets through.

The strict window does not remove everything: $\hat{A} = 2.50$, with a scatter of 0.63 over the test skies, is still 2.4 of those errors above one. A stricter cut removes most of the residual, not all of it. Through the main window the excess grows with multipole, roughly as $D_\ell \propto \ell^{0.8}$ between $\ell \approx 650$ and 1250. That shape is set as much by the SMICA weights, which decide how much of each frequency channel, and so of the dust in it, survives at each multipole, as by the dust itself, and one map cannot tell the two apart.

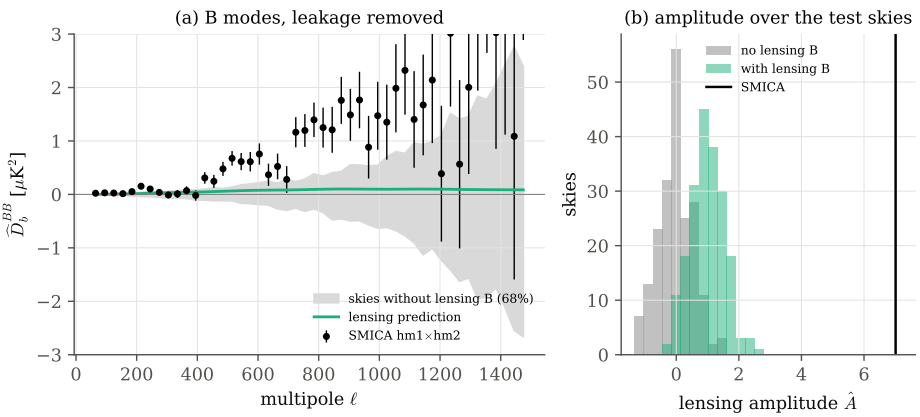

Figure 13.64: (a) The B bandpowers (13.82) of the SMICA half-missions through the main window (points, errors from the test skies), the lensing prediction (green), and the range in which 68% of the test skies without lensing B fall (grey). (b) The fitted lensing amplitude on the test skies without lensing (grey) and with lensing (green), and on the data (black line), far outside both.

What this means for the angle. The excess B is parity-even and sits in EE and BB. If it carried no EB of its own, it could not create an angle, and the angle did not move when the strict window removed most of the excess (Section 13.32.1). It enters the template $\widehat{D}^{EE} - \widehat{D}^{BB}$ as the difference of its E and B parts, about half a $\mu\mathrm{K}^2$ against an E spectrum tens of times larger.

Lensing B: variance, not bias. The same holds for lensing, and for a stronger reason. Lensing remaps the polarization pattern by a deflection that is the gradient of a potential, a mirror-symmetric operation, so a sky with no EB before lensing has none after it on average. Lensing therefore adds BB but no EB: it adds to the scatter of $\widehat{C}_\ell^{EB}$ through the B variance in the cross-spectrum example of Section 13.31.1, and nothing to its mean. The simulated skies with and without lensing confirmed it in Section 13.31.3: the mean angle is $0.000°$ with lensing and $-0.000°$ without, and the scatter is $0.0496°$ with lensing and $0.0499°$ without: equal to within a per cent, with the sign of the tiny difference set by the particular skies drawn, because the B variance is dominated by the noise. For a future experiment with noise below the lensing B, the lensing variance would be the floor of the angle's error, and removing it (*delensing*) would sharpen the angle.

Lesson. A B-mode spectrum from a component-separated map is a test of the component separation before it is a test of cosmology: the one B signal guaranteed by the standard model is, at SMICA's noise level, smaller than what the cleaning leaves behind near the Galaxy.

13.35 The full analysis, and what the laptop version gives up

Every step above was scaled down so that it runs in about an hour of computing, and each reduction has a price. Table 13.13 lists them side by side with what the published analyses do.

How good is our error bar itself? The variance of the angle is estimated from the scatter of 200 test skies, so its square root, the error bar, carries a relative Monte Carlo error of $1/\sqrt{2(n-1)}$ with $n = 200$ (Section 8.13.1), a few per cent. The covariance built from 400 skies is noisy too; the Hartlap factor removes the bias of its inverse on average, and the coverage test of Section 13.31.3

step	research version	here	what it costs
maps	frequency maps per detector set, $N_{\text{side}} = 2048$	SMICA halves, $N_{\text{side}} = 512$	only $\alpha + \beta$; $\ell \leq 1489$
mask	CO, sources, Galactic cuts of several sizes	SMICA confidence mask, one strict variant	a coarse dust check
spectra	NaMaster, beam leakage matrices	pseudo-spectra of the halves, no beam leakage	small, by the published tests
covariance	analytic, or from end-to-end simulations	400 Gaussian skies, Hartlap	error bar uncertain by a few per cent
noise	simulated time streams through the pipeline	Gaussian, modulated, from the half-difference	no stripes, no non-Gaussian tails
foreground	per-channel α_ν, dust EB models	none	no separation of α and β

Table 13.13: The angle measurement at research scale and at laptop scale.

checks the combined effect directly on skies that did not build it. A research analysis would add skies until both effects were well below a per cent.

Verification and research. Two jobs were done by the same simulations. The tests at known angles *verified* two statements we had derived: that the rotation passes through the mask unchanged (Section 13.30.3), and that least squares with the right covariance gives an unbiased angle with the stated error (Section 13.31.1). The covariance of the parity-odd spectra, the distribution of the $\Delta\chi^2$ under no rotation, the scatter of the shift between two windows on one sky, and the distribution of the lensing amplitude without lensing are *research* products: no formula gives them for this mask and this noise, and the simulations are the measurement.

Recap

- A uniform rotation of the polarization turns E into B: $C^{EB} = \frac{1}{2}\sin 4\beta\,(C^{EE} - C^{BB})$ and $C^{TB} = \sin 2\beta\, C^{TE}$; for a small angle, the parity-odd spectra are 2β times a known template.
- The rotation commutes with the mask, the beam and the pixels, so the same relation holds for pseudo-spectra; E-to-B leakage adds scatter but no EB on average, and no spin-2 MASTER is needed.
- Least squares gives $\hat{\beta} = \boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{e}/(2\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D})$ and $\sigma_\beta = 1/(2\sqrt{\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D}})$, with $\mathbf{C}$ from simulated skies; on held-out skies with known angles it is unbiased. For EB alone the formula's error is right; for EB and TB together a covariance from 400 skies makes the true scatter larger by about $\sqrt{1 + p/n}$, so the scatter of the held-out skies is quoted instead.
- The SMICA half-missions give $\hat{\beta} = 0.31^\circ \pm 0.05^\circ$ from EB and TB together. It measures $\alpha + \beta$: a miscalibrated instrument and a rotating Universe make the same pattern in a CMB map. Only a foreground rotated by α alone, in per-frequency maps, separates them.
- The same spectra contain B power far above lensing ($\hat{A} = 7.01 \pm 0.54$ times the prediction through the main window, 2.50 through the strict one), with twice as much E as B in the excess and a strong dependence on the mask: a Galactic residual. At SMICA's noise, lensing alone would be a two-sigma signal. Lensing adds BB but no EB, so it adds variance, not bias, to the angle.

Reading the literature

- *The CMB power spectrum on the real sky.* The *Planck* 2018 overview, power-spectrum and parameter papers [25, 70, 159]; the MASTER method [140]; the pseudo-C_ℓ and likelihood approximations of [16, 141]; a modern pseudo-C_ℓ code and its conventions [142]; HEALPix [7]; CAMB [8].
- *Topology of the real CMB sky. Planck* 2018 isotropy and statistics [109]; Minkowski functionals on the sphere [105]; Betti numbers of the CMB [5]; the bias of an inverted simulated covariance [6].
- *Galaxy clustering on a real survey.* The BOSS DR12 catalogues and weights [249]; the systematics behind the weights [250]; the first CMASS detection [235]; the DR12 correlation-function BAO [251] and the final BOSS distances [197]; the estimator [194] and weights [196]; the first detection [42]; DESI's analysis with blinding [101]; jackknife errors [252, 253].
- *A Higgs search on collider open data.* The discovery papers [113, 119], of which the ATLAS one documents the diphoton categories, background functions and spurious-signal test in detail; the 13 TeV open-data release and its samples [116, 118]; the asymptotic formulas for q_0, $\tilde{q}_\mu$ and the Asimov data set [27] and the structure of the likelihood with constraint terms [29]; the look-elsewhere effect and upcrossings [15]; the CL_s method [30, 31].
- *Cosmic birefringence in Planck polarization.* The SMICA maps and their confidence masks [19]; the first *Planck* angle and its ground-calibration error [187]; the use of the Galactic foreground to calibrate the detector angles [71] and its application to the 2018, PR4 and combined WMAP and *Planck* data [57, 74, 75]; the dust EB caveat [67] and the polarized foregrounds [66]; spin-2 pseudo-C_ℓ [142] and pure-B estimators [188]; lensing B modes [47, 64]; the cost of a noisy simulated covariance [254].

Chapter summary

Each capstone analysis runs the full pipeline on real data: a physical model, a field, catalogue or list of events, a summary, its sampling distribution, and an inference. The CMB power spectrum, the topology of the CMB sky, the clustering of CMASS galaxies, the diphoton search and the twist of the CMB polarization differ in what is observed and what is undone, and share the last three stages (Figure 13.65). In the first three the summary is a curve or a set of numbers and the question is a parameter or a consistency test; in the Higgs search the summary is a histogram and the question is first a test (is there a peak?), then a measurement (how strong, where?), then an exclusion (where is there none?), all from one likelihood. In the birefringence analysis the summary is a pair of spectra that must vanish on average, EB and TB, and the question is how much of a known template they contain; the answer is an angle, and what that angle is an angle *of* ($\alpha + \beta$, not β) is decided by the data used, not by the estimator.

concept	operational meaning	used later in
The CMB power spectrum of the real sky		
masked, apodised map	multiply the map by a smooth mask that hides the Galaxy and point sources (Section 8.10.4)	Chapter 14
pseudo-C_ℓ and MASTER	the masked sky's spectrum is $\sum_{\ell'} M_{\ell\ell'} C_{\ell'}$; invert the binned coupling matrix (Section 8.11)	Section 13.20.1, Chapter 14
beam and pixel window	divide the spectrum by $b_\ell^2 p_\ell^2$ (Section 8.2.1)	Section 13.10.1

concept	operational meaning	used later in
simulated covariance	push Gaussian skies of the fiducial model through the same mask and noise (Chapter 8)	Section 13.12.2
reduced parameter fit	sample (A_s, n_s) with the Metropolis–Hastings sampler of Chapter 9	Chapter 14
The topology of the real CMB sky		
one sky as one draw	test the sky against the simulated distribution of the Gaussian null (Section 13.9)	Chapter 14
degrading a map	multiply $a_{\ell m}$ by $b_\ell^{\text{new}} p_\ell^{\text{new}} / (b_\ell^{\text{old}} p_\ell^{\text{old}})$ (Section 13.10.1)	
functionals on a cut sphere	area, boundary length and $V - E + F$ inside the mask (Section 13.11.1)	Chapter 14
Mahalanobis χ^2 and Hartlap	quadratic form of the statistics with a simulated covariance, its inverse rescaled (Sections 13.12.1 and 13.12.2)	Section 13.18.2
rank p-value	fraction of simulations at least as extreme, with error $\sqrt{p(1-p)/n}$ (Section 13.12.3)	Section 13.24.2, Chapter 14
Betti numbers and persistence on the sphere	$\beta_1 = \beta_0 - \chi$ on a cut sphere; H_0 diagrams compared by W_1 (Section 13.13)	Section 13.20.2
Galaxy clustering of CMASS South		
positions from (RA, Dec, z)	comoving distance of the fiducial model, then Cartesian coordinates (Section 13.15.3)	Section 13.19.3
catalogue weights	$w_{\text{tot}} = w_{\text{systot}}(w_{\text{cp}} + w_{\text{noz}} - 1)$ for galaxies, times w_{FKP}; randoms carry w_{FKP} (Section 13.16)	Chapter 14
window in pair counts	$\langle DD \rangle / \langle RR \rangle = 1 + \xi(s)$ in each thin shell (Section 13.20.1)	Chapter 14
leave-one-region-out counts	$C_{-k} = C - C(k, \cdot) - C(\cdot, k) + C(k, k)$ (Section 13.17.2)	Section 13.18
jackknife covariance	$\frac{N-1}{N} \sum_k (\hat{\boldsymbol{\xi}}_{-k} - \bar{\boldsymbol{\xi}})(\cdots)^{\mathsf{T}}$; exact for a mean, biased upward otherwise (Section 13.18)	Chapter 14
α to a distance	$D_V / r_d = \alpha \, D_V^{\text{fid}} / r_d^{\text{tmpl}}$, with h cancelling (Section 13.19.3)	Chapter 14
detection and location	$\sqrt{\Delta\chi^2}$ for existence, rise of $\chi^2(\alpha)$ for position; $\sigma_\alpha \sqrt{\Delta\chi^2}$ fixed by the bump's shape (Sections 13.19.5 and 13.19.6)	Section 13.25.2, Chapter 14
subset against parent sample	$\text{Var}(\alpha_S - \alpha_{NS}) = \sigma_S^2 - \sigma_{NS}^2$ (Section 13.19.6)	Chapter 14
A Higgs search on collider open data		
invariant mass	$m_{\gamma\gamma}^2 = 2 p_{T1} p_{T2} [\cosh \Delta\eta - \cos \Delta\phi]$ from the stored photon momenta (Section 13.21.1)	Chapter 14
weighted simulation	each selected simulated event stands for $L \sigma w_j \text{SF}_j / \sum_k w_k$ real events (Section 13.21.1)	Section 13.22.1
Crystal Ball line shape	Gaussian core joined with equal value and slope to a power-law tail; tail area $\frac{n}{\alpha(n-1)} e^{-\alpha^2/2}$ (Section 13.22.1)	Section 13.23.1
spurious signal	fit a background-only truth with candidate background plus signal; keep the families inventing less than 20% of σ_S (Section 13.22.2)	Section 13.23.1
price of flexibility	fitted background parameters keep $1 - \rho^2 = 1/(F_{\mu\mu}(\mathbf{F}^{-1})_{\mu\mu})$ of $q_{0,\text{A}}$ (Section 13.22.2)	Sections 13.23.3 and 13.27

concept	operational meaning	used later in

CL_s limits and the Brazil band	$\mathrm{CL}_{s+b}/\mathrm{CL}_b < 0.05$; band $\sigma_{\mathrm{A}}[N + \Phi^{-1}(1 - \alpha\Phi(N))]$ from the background-only Asimov set (Section 13.26)	Chapter 14
Cosmic birefringence in Planck polarization		
spin-2 degrade	zero the masked Q, U, transform to E, B, swap the polarization pixel windows, synthesise (Section 13.29.1)	Chapter 14
E-to-B leakage	a cut E pattern is read partly as B along every edge (Section 10.17); measured on E-only skies and subtracted (Section 13.30.2)	Section 13.34.1
rotation commutes with the window	$We^{2i\beta}(Q + iU) = e^{2i\beta}W(Q + iU)$, so pseudo-spectra obey the rotation formulas; no spin-2 MASTER for the angle (Section 13.30.3)	Section 13.31.2
template fit for one angle	$\hat{\beta} = \boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{e}/(2\boldsymbol{D}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{D})$ with measured $EE - BB$ and TE as template (Section 13.31.1)	Chapter 14
noisy covariance, inflated error	a simulated $\mathbf{C}$ from n skies raises the scatter by $\sqrt{1 + p/n}$; quote the scatter of held-out skies (Section 13.31.3)	Chapter 14
α–β degeneracy	a cleaned map measures $\alpha + \beta$; only a foreground rotated by α alone separates them (Section 13.33.2)	Chapter 14
lensing-B amplitude	subtract leakage, divide by a Monte Carlo transfer function, fit A to the lensing template; null from skies without lensing B (Section 13.34.1)	Chapter 14

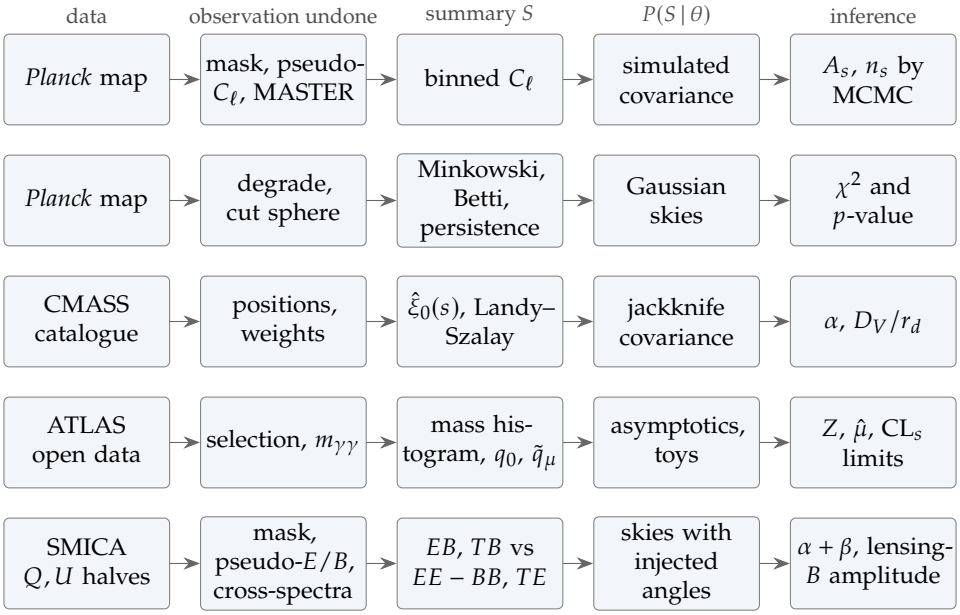

Figure 13.65: The five capstone analyses as rows of one pipeline: the CMB power spectrum (top), the topology of the CMB sky, the clustering of CMASS galaxies, the diphoton Higgs search, and the rotation of the CMB polarization (bottom). Each column is one stage of the pipeline.

Chapter 14

Synthesis: Which Idea, When

Where this chapter is going

Every analysis began with a question said in words, and the question chose the tool. The same few ideas came back in every experiment, from a coin to the *Planck* sky: a distribution that predicts, a likelihood that reads the prediction backwards, a sampling distribution built by simulation, a posterior, a forecast. Faced with a new data set, the quick way to the right one is to start from the question. Each question (is this a fluke, how big is the effect, which values survive, which model is better, how well could we do) is answered by one object, and the object fixes which distribution describes the number and which method turns that distribution into physics. Those choices are the stages of a single pipeline, from a physical model to an inference, and a collider, a CMB satellite, a gravitational-wave detector and a galaxy survey all run it, with different noise. The pipeline also shows where the errors enter. Each recurring trap is an object built for one question and used for another, and its size can be measured with a small computation.

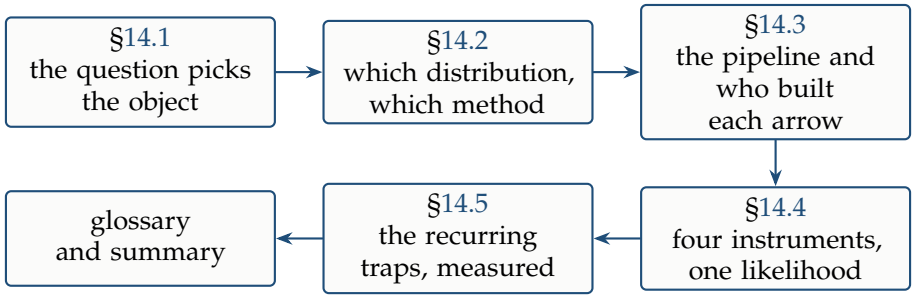

Figure 14.1: From question to inference. The top row is about choosing: the question, then the distribution and the method, then their place in the pipeline. The bottom row tests the choices: the same pipeline in four instruments, and the traps that appear when a quantity built for one question is used to answer another.

14.1 The question picks the object

A colleague at a collider stops us in the corridor. In a narrow window of invariant mass the background model predicts $b = 4$ events on average, and the detector recorded $n = 11$. "Is that something?" The honest reply is another question: *what exactly do you want to know?* Whether a fluctuation of the background could easily give eleven events? How large the signal is, and how uncertain? Which signal strengths are still believable? How much more data a discovery would need? Each of these is a different question about the same number, each has its own answer, and the answers are different numbers. Every one of them was built somewhere in the

book. The danger is never a lack of tools. It is answering one question with the object built for another.

Two directions, once more. All the objects fall into two families, and the family tells us what an object can claim. In the forward direction, prediction, we fix a hypothesis or a parameter value and ask what data it produces and how often (Section 0.1). The probability mass function of a count, the sampling distribution of an estimator, the p-value and the Fisher forecast all live here: each one starts from an assumed truth. In the backward direction, inference, the data are already in hand and we ask which hypotheses could have produced them, and how probable each one is in the light of what was seen (Section 5.1). The likelihood read as a function of the parameters, the posterior and the evidence live here. The habit that keeps the two apart is to say, before any symbol, which possible hypotheses could have produced the observation, and then how probable the observation would have been under each one (Section 5.6). Cowan puts the same split in terms of what a probability means [Cowan §1.2, pp. 4–6]. A forward probability can always be read as a long-run frequency over repeated experiments, which suits colliders, where collisions really are repeated. A statement such as "the electron mass lies in this interval with probability 95%" cannot: the mass is a constant, always inside or always outside, and the probability describes our state of knowledge. Every object of the backward direction needs that second reading, and with it a prior.

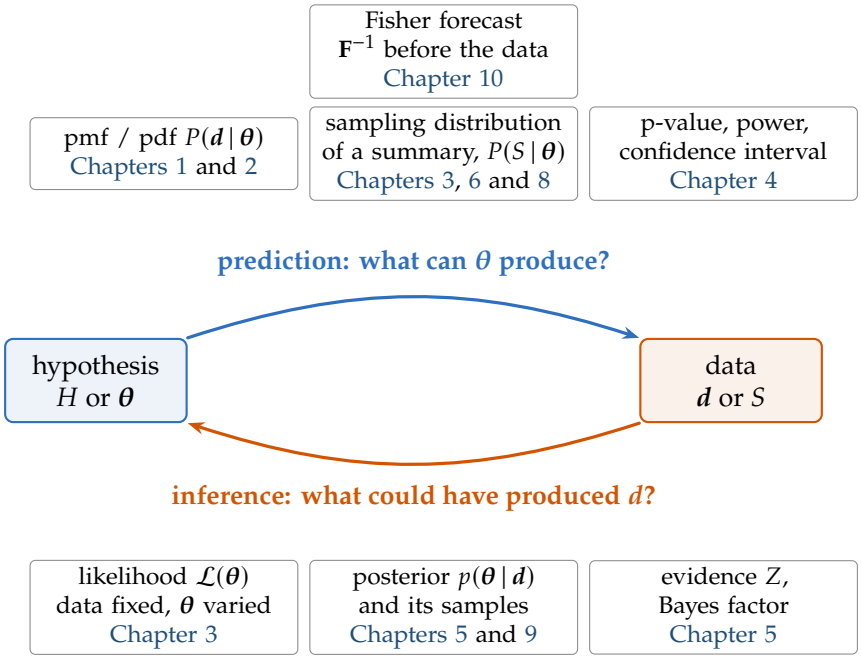

Figure 14.2: The objects of the book sorted by direction. Above, the forward direction: each object starts from an assumed $\boldsymbol{\theta}$ and describes the data it would produce; the confidence interval belongs here because it is built from such predictions and then inverted. Below, the backward direction: each object starts from the data actually recorded and weighs the possible $\boldsymbol{\theta}$; all of them except the likelihood need a prior.

The questions in words. Nine questions cover everything the book computed. Eight of them take a summary of the data as given; the ninth goes upstream and asks which summary to compute in the first place. Each comes with the object that answers it and the place where that object was built.

The ninth question is different in kind. A complicated field holds more information than any single summary, and which summary is right depends on what we want to know. If the

Taxonomy: which object answers which question

the question in words	the object that answers it	direction	built in
1. If this hypothesis holds, how often does this event happen?	$\mathrm{P}(E \mid H)$ from the rules of probability, trees, counting	forward	Chapter 1
2. How is this number distributed, and why?	a distribution derived from the machine that made the number	forward	Chapter 2
3. What value do the data point to, and how far off might it be?	an estimator, its sampling distribution, the likelihood and its curvature	both	Chapter 3
4. If only chance were at work, would a result like this, or one even more extreme in the same direction, be something we would reasonably expect?	a test statistic, its null distribution, the p-value; inverted, a confidence interval, or after a search that finds nothing an upper limit (CL_s)	forward	Chapter 4
5. Which parameter values could have produced the data, and how probable is each?	the posterior, summarised by its samples and credible intervals	backward	Chapters 5 and 9
6. Which of two models better predicted the data we got?	the evidence of each, their ratio (Bayes factor), posterior odds	backward	Chapter 5
7. The algebra is too hard: can we get any of these by drawing random numbers?	Monte Carlo: simulated data sets, simulated sampling distributions, chains	either	Chapters 6, 8 and 9
8. Before the experiment exists, how well could it measure $\boldsymbol{\theta}$?	the Fisher matrix at a fiducial model, checked by a chain on mock data	forward	Chapter 10
9. Which property of the field carries the physics and survives the nuisances of observation?	a chosen summary: C_ℓ, $\xi(r)$, peaks, Minkowski functionals, Betti numbers, persistence	upstream	Chapters 7 and 12

question is how much the field fluctuates on each scale, the power spectrum is the natural answer. If it is how likely the data are under a model, the likelihood is. If it is which parameter values survive, the posterior is. If it is whether a feature survives a whole class of smooth distortions, a topological invariant may be the answer, and if it is how features appear and disappear as a threshold is lowered, persistence is (Sections 12.1 and 12.9). Topology is therefore not an extra layer added after probability and inference. It is one answer to the first question of the whole pipeline: what should we measure from the raw data at all?

Example: eleven events where four were expected. Back to the corridor. The background in the window is known, $b = 4$, and a possible signal adds a mean $s \geq 0$, so the count is Poisson with mean $s + b$ (Section 2.4). The data are one number, $n = 11$. We put eight of the nine questions to it in turn; Figure 14.3 shows four of the answers.

Could the background alone do this? This is question 4. The hypothesis whose predictions we know is "background only", $s = 0$, and the result "in the same direction or further" means eleven events or more:

$$p \overset{(1)}{=} \mathrm{P}(N \geq n \mid s = 0) \overset{(2)}{=} 1 - \sum_{k=0}^{n-1} \frac{b^k e^{-b}}{k!} \overset{(3)}{=} 0.00284, \qquad Z = \Phi^{-1}(1 - p) = 2.77. \tag{14.1}$$

(1) The p-value of Section 4.1.3: the probability, under the null, of a count at least as large as the one observed, since an excess is what a signal would produce.
(2) The complement of the probability of $0, 1, \dots, 10$ events, with the Poisson probabilities of mean b.
(3) The sum evaluated by `scipy.stats.poisson.sf` for $b = 4$, $n = 11$.

The significance Z is the number of Gaussian standard deviations with the same one-sided tail (Section 4.9). Question 7, simulation, checks the sum: of 2×10^6 background-only experiments drawn by the script, a fraction 0.00282 ± 0.00004 gave eleven or more.

How big is the signal? This is question 3. Read the Poisson probability of the observed count as a function of s:

$$\ln \mathcal{L}(s) \overset{(1)}{=} n \ln(s+b) - (s+b) - \ln n!, \qquad \frac{\mathrm{d} \ln \mathcal{L}}{\mathrm{d}s} \overset{(2)}{=} \frac{n}{s+b} - 1, \qquad \frac{\mathrm{d}^2 \ln \mathcal{L}}{\mathrm{d}s^2} \overset{(3)}{=} -\frac{n}{(s+b)^2}. \tag{14.2}$$

(1) The logarithm of $(s+b)^n e^{-(s+b)}/n!$.
(2) Differentiate term by term; the constant $\ln n!$ drops out.
(3) Differentiate once more.

The first derivative vanishes at $\hat{s} = n - b = 7$. At that point $s + b = n$, so the curvature is $-1/n$ and the curvature error (Section 3.12) is $\hat{\sigma} = \sqrt{n} = 3.32$. The likelihood itself is not symmetric: the two values of s where $\ln \mathcal{L}$ has fallen by $\frac{1}{2}$ from its peak are 4.01 and 10.66, a little closer below $\hat{s}$ than above it (panel b of Figure 14.3).

Which signal strengths could have produced eleven events? This is question 5, and it needs a prior. With a flat prior on $s \geq 0$ the posterior is the likelihood cut at $s = 0$ and normalised (Section 5.7). Its median is 7.67, its mean 8.01, and 68% of its probability lies between 4.61 and 11.40. These numbers are statements about s given the one count we have. The likelihood interval of the previous paragraph is a statement about a procedure over repeated counts, and the two need not coincide (Section 14.5).

Is there a signal at all? This is question 6, and it asks the data to choose between two models. Model H_0 says $s = 0$. Model H_1 says the signal lies somewhere in $[0, s_{\max}]$ with $s_{\max} = 20$, every value equally likely beforehand. Each model's evidence is the probability it gave to the count actually seen (Section 5.15):

$$B_{10} \overset{(1)}{=} \frac{Z_1}{Z_0} \overset{(2)}{=} \frac{\frac{1}{s_{\max}} \int_0^{s_{\max}} \mathrm{P}(n \mid s+b)\, \mathrm{d}s}{\mathrm{P}(n \mid b)} \overset{(3)}{=} \frac{0.04983}{0.00192} = 25.9, \tag{14.3}$$

(1) The Bayes factor is the ratio of the two evidences.
(2) Z_0 is the Poisson probability of n with mean b; Z_1 averages the Poisson probability over the uniform prior of height $1/s_{\max}$.
(3) The integral done numerically by the script.

How large could B_{10} have been with a cleverer prior? An average never exceeds the maximum of what is averaged, so $Z_1 \leq \mathcal{L}(\hat{s})$ for every prior, and

$$B_{10} \overset{(1)}{\leq} \frac{\mathcal{L}(\hat{s})}{\mathcal{L}(0)} \overset{(2)}{=} \left(\frac{n}{b}\right)^n e^{-(n-b)} \overset{(3)}{=} 62. \tag{14.4}$$

(1) $Z_1 = \int \mathcal{L}(s)\pi(s)\,\mathrm{d}s \leq \mathcal{L}(\hat{s}) \int \pi(s)\,\mathrm{d}s = \mathcal{L}(\hat{s})$, and $Z_0 = \mathcal{L}(0)$.
(2) $\mathcal{L}(s) \propto (s+b)^n e^{-(s+b)}$ evaluated at $\hat{s} = n - b$ and at 0; the factor $1/n!$ cancels.
(3) $(11/4)^{11} e^{-7}$.

The bound is reached only by a prior that is a spike at $\hat{s}$, chosen after looking (Section 5.17.4). A wider honest prior lowers Z_1: doubling $s_{\max}$ roughly halves B_{10}, because the extra prior range is spent on signals the data rule out (Section 5.17.2).

How much more data would a discovery need? This is question 8, asked before new data exist. The forecast uses the *median experiment* (Section 10.13.1): the data are replaced by their expected value under the signal hypothesis, $n \to s+b$ with $s=\hat{s}$. The likelihood-ratio statistic for testing $s=0$ is

$$q_0 \overset{(1)}{=} -2\ln\frac{\mathcal{L}(0)}{\mathcal{L}(\hat{s})} \overset{(2)}{=} 2\Big[n\ln\frac{n}{b}-(n-b)\Big] \overset{(3)}{=} 2\Big[(s+b)\ln\Big(1+\frac{s}{b}\Big)-s\Big], \qquad Z_A=\sqrt{q_0}. \tag{14.5}$$

(1) The statistic of Section 4.7.3, whose square root is the significance.
(2) $\ln\mathcal{L}(\hat{s})-\ln\mathcal{L}(0)=n\ln(n/b)-(n-b)$, from the logarithm in (14.2) at $s+b=n$ and at $s+b=b$.
(3) Replace the observed n by its expected value $s+b$.

This Z_A is called the Asimov significance [27]. With $s=7$ and $b=4$ it is 2.87. Collecting k times more data multiplies both s and b by k, and the bracket in (14.5) by k, so $Z_A \propto \sqrt{k}$. Reaching 5σ needs $k=(5/2.87)^2=3.0$ times the present exposure, if the signal is real and has the size we estimated (panel d).

And if nothing had been seen? Had the detector recorded four events or fewer, the useful question would have been question 4 turned around: which signal strengths does the count exclude? The answer is an upper limit on s. Collider experiments compute it with the CL_s rule, which divides the p-value of the signal hypothesis by that of the background alone, so that a downward fluctuation of the background cannot exclude a signal the experiment was never sensitive to (Section 4.16).

What shape does it have? The ninth question has no meaning for a single number. It needs a field, and it was asked of simulated maps in Chapter 12 and of the real sky in Section 13.9.

What the example shows. None of the eight numbers is wrong, and none can replace another. The p-value of 0.00284 is not the probability that the background-only hypothesis is true; the Bayes factor of 25.9 depends on a prior range that the p-value never needed; the curvature error ±3.32 is a Gaussian summary of a likelihood that is lopsided; the forecast of 3.0 times the data assumes a signal that the data have only hinted at. Every trap collected in Section 14.5 is one of these objects asked to answer a question that belongs to another.

Key idea: the question first

Say the question in words before computing anything. The question fixes the direction (prediction or inference), and the direction fixes the object: a distribution, a p-value, a likelihood, a posterior, an evidence or a forecast. A number is only as meaningful as the match between the question asked and the object computed.

14.2 Which distribution, which method

Two choices come before any inference. The first is the distribution of the number we measured: the machine that made it fixes how it scatters, and the scatter is the likelihood. The second is the method that turns that distribution into an answer: a forecast, a test, an interval, a posterior or a model comparison. Making the first choice by fitting curves to a histogram, or the second by habit, is the commonest way an analysis goes wrong without anyone noticing. Both choices can

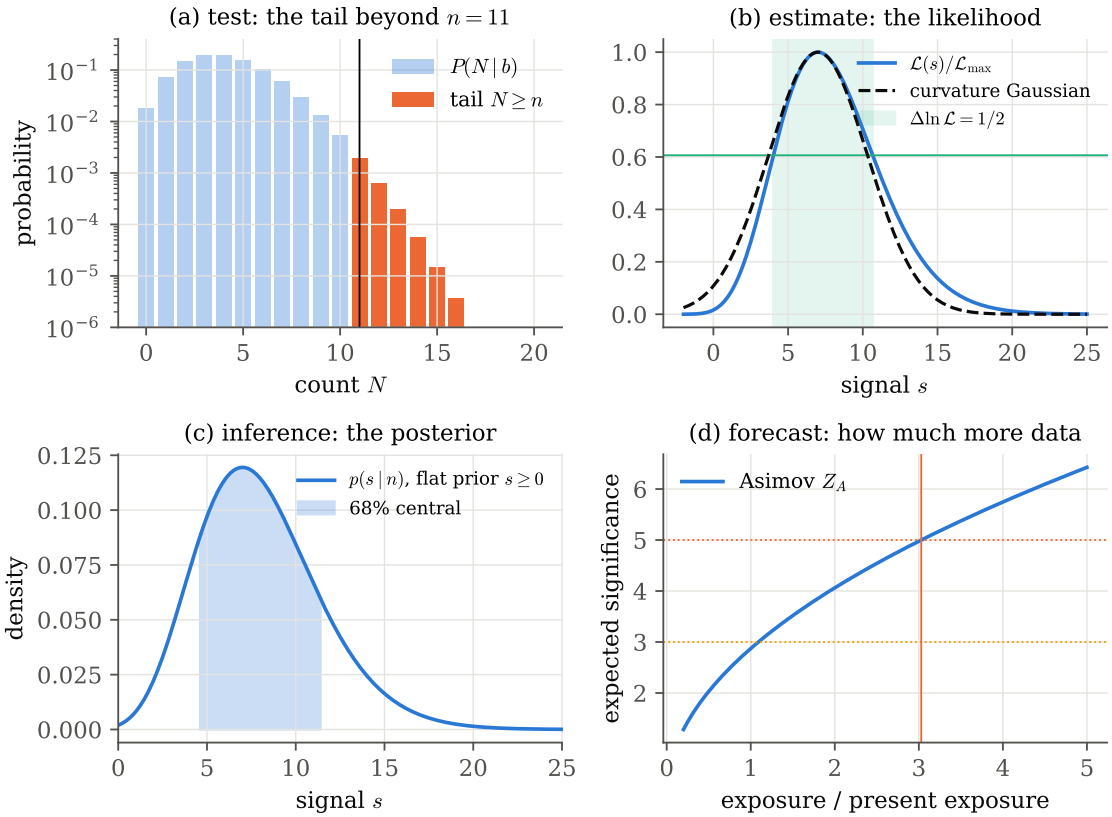

Figure 14.3: One count, four objects. (a) The prediction of the background alone; the orange bars are the outcomes at least as large as the eleven observed, and their total is the p-value. (b) The same Poisson probability read as a function of the signal s; the dashed Gaussian has the curvature at the peak, and the green band is where $\ln \mathcal{L}$ is within $\frac{1}{2}$ of its maximum. (c) The posterior for s with a flat prior on $s \geq 0$, with its central 68%. (d) The expected significance as the exposure grows; the vertical line marks the exposure that would give 5σ.

be made by asking a few questions in a fixed order, and both orders can be drawn as decision charts.

14.2.1 Which distribution: ask what made the number

Section 2.16 gave the rule: the question "which distribution?" is really "which machine made these numbers?", and the histogram comes afterwards, to check the answer in the tails, where the conclusion of a search rests. The machines met since then add a few branches to the family trees drawn there: estimated spectra, quadratic forms with simulated covariances, and summaries so elaborate that no machine can be written down. Figure 14.4 arranges all of them as a chart. Start at the left with the question *how was the number made?*, follow the branch that describes the operation, and read off the distribution.

Three recognitions show the chart at work. Each one is a number the book met, read off the chart and then checked with a short calculation.

Example: the matched filter with an unknown phase. A gravitational-wave search correlates the detector output with a template whose phase is unknown, so it uses two templates a quarter cycle apart and combines their outputs z_c and z_s (Section 10.8.3). In pure noise each output is a standard normal, and the two are independent. *How was the number made?* The detection

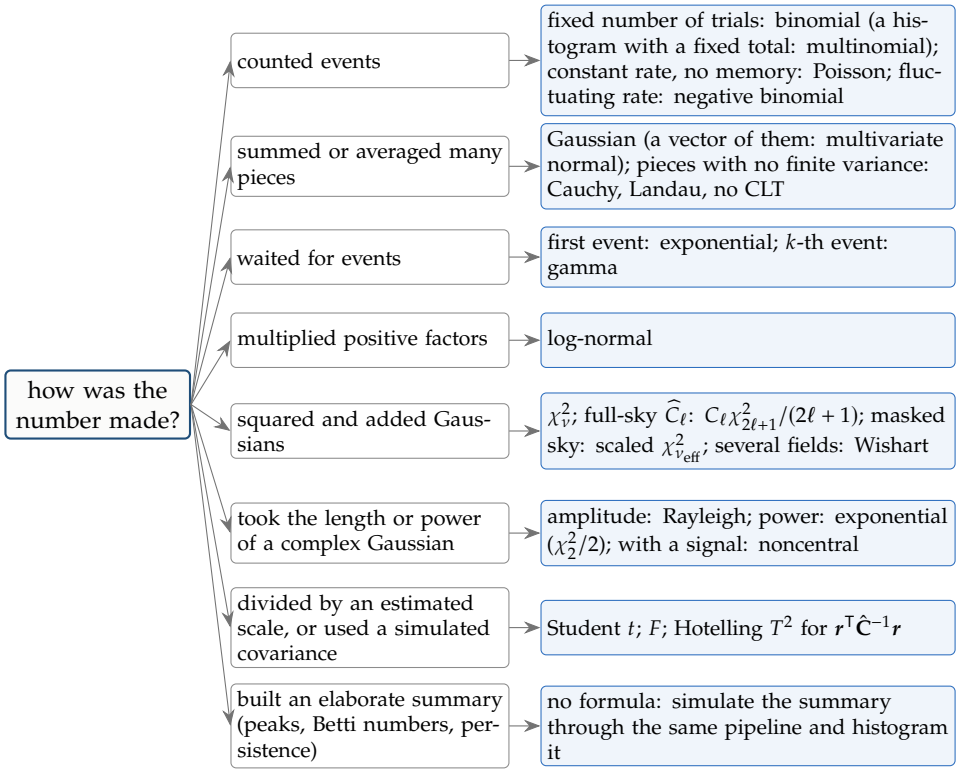

Figure 14.4: Which distribution, chosen by the operation that produced the number. The middle column names the operation, the right column the distribution it produces, with the variants that apply when the conditions change. The last row is where the book ended up most often: summaries for which no machine can be written, whose distribution is measured by simulation. Whatever the branch, the tails are checked separately, because that is where tests and discoveries live.

statistic $\rho^2 = z_c^2 + z_s^2$ is the power of a complex Gaussian, two squared Gaussians added. The chart gives χ^2_2, whose density is $\frac{1}{2}e^{-x/2}$ (Section 2.13). The false-alarm probability above a threshold x_* is then

$$\mathrm{P}(\rho^2 > x_* \,|\, \text{noise}) \overset{(1)}{=} \int_{x_*}^{\infty} \tfrac{1}{2} e^{-x/2}\, \mathrm{d}x \overset{(2)}{=} \left[-e^{-x/2}\right]_{x_*}^{\infty} \overset{(3)}{=} e^{-x_*/2}. \tag{14.6}$$

(1) The tail of the χ^2_2 density.
(2) The antiderivative of $\frac{1}{2}e^{-x/2}$ is $-e^{-x/2}$.
(3) At the upper limit the exponential vanishes.

A false-alarm probability of 10^{-3} per template therefore needs $\rho_* = \sqrt{2\ln 10^3} = 3.72$, not the 3.09 of a one-sided Gaussian: the unknown phase is a second chance for the noise to look like a signal.

Example: a χ^2 whose covariance came from simulations. In Section 13.12 thirty-six Minkowski-functional values of the sky were combined into one number $\boldsymbol{r}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\boldsymbol{r}$, with $\boldsymbol{r}$ the difference from the simulated mean and $\hat{\mathbf{C}}$ estimated from simulated skies. The chart sends this number not to χ^2_{36} but to the branch "used a simulated covariance". Its mean is $p(n-1)/(n-p-2)$ times too large for p bins and n simulations (Section 8.13.2), and even after that is corrected its tail is the Hotelling law, a scaled F distribution, rather than χ^2_p (Section 12.24.2). Section 14.5.5 measures the size of the error.

Example: a bandpower on a cut sky. On the full sky the estimate $\widehat{C}_\ell$ at one multipole is $C_\ell \chi^2_{2\ell+1}/(2\ell+1)$ (Section 7.10). With a mask the multipoles are mixed and no exact law is known, but the chart's branch "squared and added Gaussians" still suggests a scaled χ^2, $X = \langle X \rangle \chi^2_\nu / \nu$, with the number of degrees of freedom ν left free. It is fixed by matching the variance measured on simulations:

$$\operatorname{Var} X \overset{(1)}{=} \frac{\langle X \rangle^2}{\nu^2} \operatorname{Var} \chi^2_\nu \overset{(2)}{=} \frac{\langle X \rangle^2}{\nu^2} 2\nu \overset{(3)}{=} \frac{2\langle X \rangle^2}{\nu} \qquad \Longrightarrow \qquad \nu_{\text{eff}} = \frac{2\langle X \rangle^2}{\operatorname{Var} X}. \tag{14.7}$$

(1) A constant factor c multiplies a variance by c^2, here $c = \langle X \rangle / \nu$.
(2) The variance of χ^2_ν is 2ν (Section 2.13).
(3) Cancel one factor of ν, then solve for ν.

On the full sky this returns $\nu = 2\ell + 1$; on a cut sky ν_{eff} comes out close to $(2\ell+1) f_{\text{sky}}$ for smooth masks, and is measured, not assumed, for sharp ones (Section 8.12). The machine fixes the family, and the simulations fix the one number the machine could not.

14.2.2 Which method: ask what is known and what is wanted

With the distribution of the summary in hand, the method follows from three questions asked in order. *Do we have data yet?* If not, the only question that makes sense is how well a planned experiment could do, and the answer is a forecast. *Is the sampling distribution $P(S \mid \boldsymbol{\theta})$ known in closed form?* If not, it is built by simulation before anything else. *What do we want to know?* Whether the result could be chance, which parameter values are allowed, which of two models is better, or whether the model fits at all: four questions, four methods. Figure 14.5 draws the order.

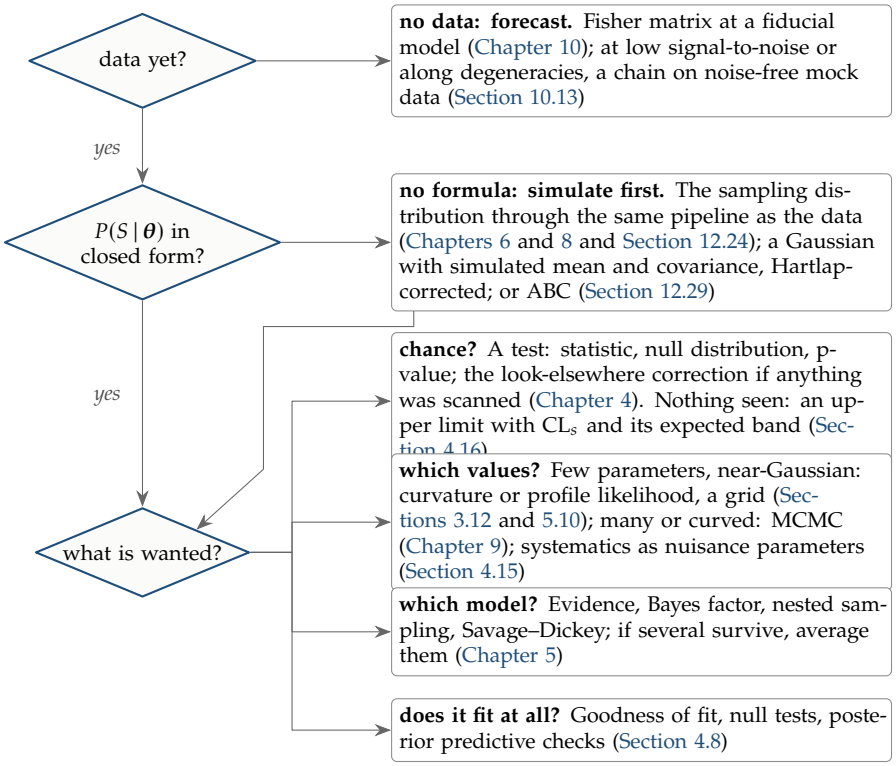

Figure 14.5: Which method, chosen by what is already known and what is wanted. A forecast needs no data; a simulated sampling distribution rejoins the main line as soon as it exists; the last decision splits by the question asked of the data, and each of the four branches has its own object.

Estimation and comparison ask different questions. Two of the four branches look alike and are not. "Which values?" and "which model?" can both be put to the question "is the effect zero?". The estimation branch looks at the whole posterior of the effect and asks whether the values near zero are among the credible ones. The comparison branch sets up a model in which the effect is exactly zero and asks whether that model predicted the data better than a model in which it is free. Kruschke's point is that both are legitimate and that they pose the question at different levels, so they need not agree [Kruschke §12.3, pp. 352–354]. The comparison is meaningful only if an exactly zero effect is physically plausible, and only if the alternative's prior is a real statement about the effect [Kruschke §12.4, p. 354]. In physics both conditions often hold: a massless photon, $f_{\mathrm{NL}} = 0$ from single-field inflation, a dark-matter environment that either exists or does not. Where they do not hold, the estimate is the more informative answer.

Example: a Bayes factor for the null with a wide posterior. A coin gives seven heads in fourteen tosses. Model H_0 says $\theta = \frac{1}{2}$; model H_1 says θ is uniform on $[0, 1]$. The binomial coefficient $\binom{14}{7}$ is common to both evidences and cancels, so

$$B_{01} \overset{(1)}{=} \frac{(\frac{1}{2})^{14}}{\int_0^1 \theta^7 (1-\theta)^7 \,\mathrm{d}\theta} \overset{(2)}{=} \frac{2^{-14}}{7!\,7!/15!} \overset{(3)}{=} 3.14. \tag{14.8}$$

(1) Each evidence is the probability of the observed sequence under the model, averaged over the model's prior (Section 5.15).

(2) The beta integral $\int_0^1 \theta^{a-1}(1-\theta)^{b-1}\mathrm{d}\theta = (a-1)!(b-1)!/(a+b-1)!$ with $a = b = 8$ (Section 2.15).

(3) $2^{-14} = 6.10 \times 10^{-5}$ and $7!\,7!/15! = 1.94 \times 10^{-5}$.

The data favour "exactly fair" by about three to one, yet the posterior of θ under H_1 is a Beta$(8, 8)$ whose 95% highest-density interval runs from 0.27 to 0.73 [Kruschke §12.2.1.1, p. 347]. Both statements are true. The first compares two predictions of the data. The second says how precisely θ is known, and it is not known well at all. Reporting only the Bayes factor would suggest a precision the data do not have. When several models survive a comparison, the parameter posteriors can be averaged with the posterior model probabilities as weights, so that no single model is pretended to be true (Section 5.18).

Sampling distributions keep two jobs. Within the inference branches a Bayesian never uses the cloud of data sets that were not observed. Kruschke stresses that this cloud is still the right tool for two jobs [Kruschke §11.5, pp. 329–330]: planning, where the experiment has not been run and its possible outcomes are exactly what we want to know about, and checking, where data simulated from the fitted model are compared with the real data to see whether the model is any good. The forecast and "does it fit?" boxes of Figure 14.5 are those two jobs.

Four walks through the chart. *Can LISA see a dark-matter spike around an intermediate-mass black hole?* No data exist, so the chart says forecast: the Fisher matrix of the waveform phase (Section 10.11). The environment's effect is weak and nearly degenerate with the chirp mass, which is exactly the situation in which the forecast must be checked by a chain on noise-free mock data; at the signal-to-noise ratios LISA expects, the chain's widths exceeded the Fisher widths by factors of up to two to four (Section 10.13.2). *Is the topology of the Planck temperature map that of a Gaussian field?* The data exist; no formula gives the sampling distribution of Betti numbers on a masked, beamed, noisy sphere, so the chart says simulate first; the question is "could it be chance?", so the method is a test with a simulated null and a p-value counted from the simulations (Section 13.9). *What are the amplitude and tilt of the primordial spectrum?* The data

exist; the bandpowers are close to Gaussian with a simulated covariance, so the likelihood is available once the covariance is simulated; the question is "which values?" with two curved, correlated parameters, so the method is a Markov chain (Section 13.7). *Is there a new particle decaying to two photons near* 125 *GeV?* The data exist: a histogram of the invariant mass of photon pairs (Chapter T4). Each bin is a Poisson count, so the sampling distribution is known in closed form, but the shape of the background is not predicted by theory: it is a smooth function fitted to the data, and its coefficients are nuisance parameters (Section 4.15). The question is "could it be chance?", so the method is a test with the profile likelihood ratio q_0, whose distribution under the background alone is known asymptotically; because the mass was scanned, the local p-value needs the look-elsewhere correction (Section 4.14.3). At masses where nothing is seen, the same likelihood answers the other question, which signal strengths are excluded, with CL_s and the band of limits the background alone would give (Section 4.16). The search was run on public ATLAS data in Sections 13.23 and 13.26.

Key idea: two charts, two questions

The distribution is fixed by the operation that made the number, not by the look of its histogram. The method is fixed by three questions in order: are there data yet, is the sampling distribution known in closed form, and what exactly do we want to know.

14.3 The pipeline, and who built each arrow

The very first chapter drew one chain, (0.5): a physical model makes a field or a data set; we choose which information in it matters; we compress the data into a summary; we derive how the summary scatters for each value of the parameters; and only then do we infer physics. At that point the chain was a promise. Every later chapter built one or more of its arrows, and many arrows were built twice, once where a formula exists and once where only simulation can do the job. Seeing the finished chain with each chapter in its place answers a practical question: faced with a new experiment, which parts of the book does each step need?

Reading the chain from left to right. The first stage is physics, and in the book it was borrowed: the cosmological model turns six numbers into the expected C_ℓ and $P(k)$ (Section T1.1), and a compact binary turns masses and an environment into a phase $\Psi(f)$ (Section T2.5), and a collision model turns a particle's mass and couplings into a cross section, a number of expected events and a peak in the invariant mass (Chapter T4). A model never predicts the data themselves, only their statistics, because the data are one draw from a random process (Section 7.1). The second stage is the instrument and the survey: what the beam smooths, where the noise is added, which part of the sky is hidden, which galaxies made it into the catalogue (Sections 8.2 and 13.16), and how a particle detector smears and loses the energies it records. That last effect is described by a response matrix measured on simulated events, and it can either be folded into the prediction or, with care, undone in the data (Section 6.14). The third stage is a decision rather than a calculation: which property of the field should carry the physics. The power spectrum is the natural choice for a Gaussian field, because it is then a sufficient summary (Section 3.16); for a field made non-Gaussian by gravity, or for a question about robustness, shapes and topology become candidates (Section 12.1).

The fourth stage turns the decision into an estimator. The fifth is where the probability of the book does most of its work: the sampling distribution $P(S \mid \boldsymbol{\theta})$. For a few summaries it has a closed form, the $\chi^2_{2\ell+1}$ of a full-sky $\widehat{C}_\ell$, the Gaussian of a matched filter in Gaussian noise, or the product of Poisson probabilities of a histogram of collision events. In the last case the predicted signal and background shapes are themselves uncertain, and each uncertainty

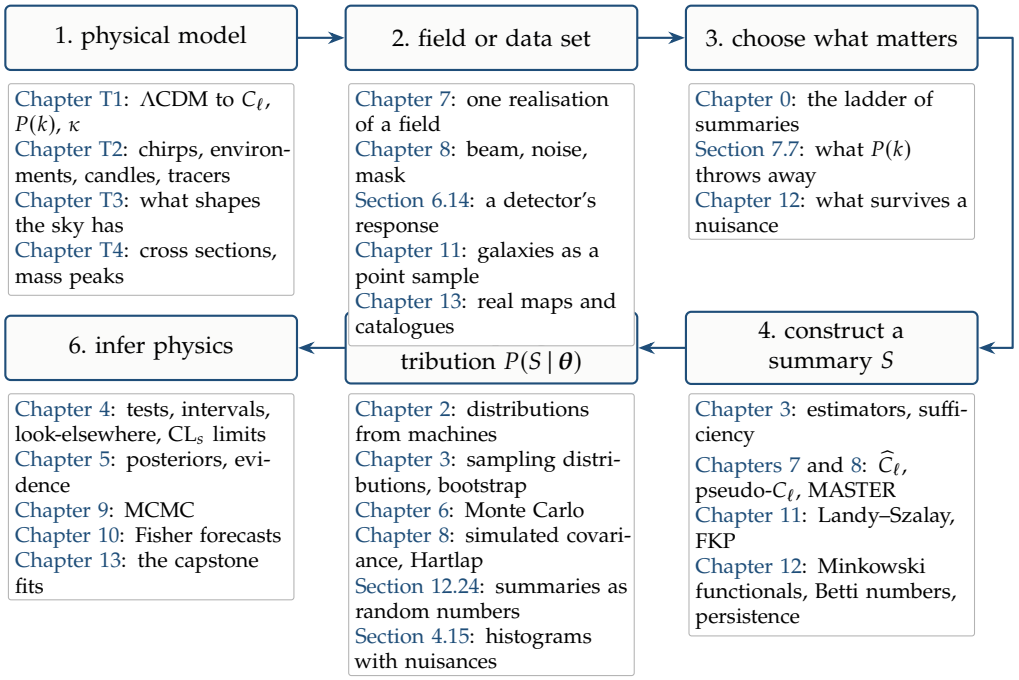

Figure 14.6: The pipeline of the book with the chapters that built each stage. The probability rules of Chapter 1 are the language of every arrow, and the Python of Chapter T0 is the tool of every arrow; neither is listed. The first three stages decide what is computed; the last three decide what it means.

enters as a nuisance parameter that is profiled or integrated away (Section 4.15). For most of the summaries a research analysis actually uses, the masked pseudo-C_ℓ, the jackknifed correlation function, the Betti numbers of a noisy map, it is measured by sending simulated data through exactly the same code as the real data. The sixth stage reads that distribution backwards. Tests and intervals do it in the frequentist way (Chapter 4), and a search that finds nothing turns the same test into an upper limit on the signal, protected by the CL_s construction against excluding a signal to which the experiment was not sensitive (Section 4.16); posteriors in the Bayesian way (Chapter 5), with chains when the parameters are many (Chapter 9); and forecasts do it before the data exist, by replacing the data with their expected value (Chapter 10).

Where formulas end and simulations begin. The same summary can be on either side of that line depending on what the instrument did to the data. On the full sky the mean, the variance and the shape of $\widehat{C}_\ell$ all have formulas, and simulations only verify them. With a mask, the mean can still be undone with a coupling matrix computed from the mask alone, but the covariance and the shape are measured on simulations (Section 8.12). That is the line between verification and research drawn in Section 8.8, and Figure 14.7 draws it for the summaries of the book.

Example: the whole chain for one CMB amplitude. How precisely could a perfect CMB experiment measure the overall amplitude A of the temperature spectrum, $C_\ell = A\, C_\ell^{\text{fid}}$? Follow the chain. The model gives C_ℓ^{fid} (stage 1). The sky is one realisation, seen on a fraction f_{sky} of the sphere up to ℓ_{max} without noise (stage 2). For a Gaussian sky the spectrum holds everything (stage 3), estimated by $\widehat{C}_\ell$ (stage 4), whose scatter is cosmic variance (stage 5). The forecast of

	mean	covariance	shape
counts in a bin (Poisson)	formula	formula	formula
full-sky $\widehat{C}_\ell$	formula	formula	formula
matched filter in Gaussian noise	formula	formula	formula
masked pseudo-C_ℓ (MASTER)	formula	simulated	simulated
galaxy $\hat{\xi}(s)$ with a survey window	formula	simulated	simulated
χ of a Gaussian field, no mask	formula	simulated	simulated
Betti numbers of a masked, noisy sky	simulated	simulated	simulated
peaks of a lognormal mass map	simulated	simulated	simulated

Figure 14.7: For each summary of the book, whether the mean, the covariance and the shape of its sampling distribution came from a formula (blue) or had to be measured on simulations (orange). Going down the list, the observation and the summary become more realistic, and the simulations take over, first for the scatter and then for everything.

stage 6 is the CMB Fisher matrix of Section 10.6.1, here with one parameter and no noise:

$$F_{AA} \overset{(1)}{=} \sum_{\ell=2}^{\ell_\text{max}} \frac{(2\ell+1)f_\text{sky}}{2}\left(\frac{\partial C_\ell/\partial A}{C_\ell}\right)^2 \overset{(2)}{=} \frac{f_\text{sky}}{2A^2}\sum_{\ell=2}^{\ell_\text{max}}(2\ell+1) \overset{(3)}{=} \frac{f_\text{sky}\,[(\ell_\text{max}+1)^2-4]}{2A^2} \equiv \frac{N_\text{modes}}{2A^2}, \quad (14.9)$$

(1) The CMB Fisher matrix with $N_\ell = 0$, for the single parameter A.
(2) $\partial C_\ell/\partial A = C_\ell^\text{fid} = C_\ell/A$, so each term of the bracket is $1/A^2$.
(3) $\sum_{\ell=0}^{L}(2\ell+1) = (L+1)^2$, the number of $a_{\ell m}$ up to L, minus the $1+3=4$ modes of $\ell = 0, 1$.

so $\sigma_A/A = \sqrt{2/N_\text{modes}}$: each independent mode measures the variance once, and a variance measured from N Gaussian numbers has a relative error $\sqrt{2/N}$ (Section 3.4.3). For $\ell_\text{max} = 2000$ and $f_\text{sky} = 0.6$, $N_\text{modes} = 0.6 \times (2001^2 - 4) \approx 2.4 \times 10^6$ and $\sigma_A/A \approx 9 \times 10^{-4}$. *Planck* measures $\ln(10^{10}A_s)$ to 0.014, an error of 1.4% on A_s [25], fifteen times larger. The difference is not noise: the temperature spectrum measures only the combination $A_s e^{-2\tau}$, and the error on the optical depth τ is passed on to A_s (Sections T1.3 and 9.22). Stage 6 is where degeneracies between parameters, not the count of modes, set the final error.

Example: the chain for a gravitational-wave amplitude. The detector records strain plus Gaussian noise with power spectral density $S_n(f)$ (stages 1 and 2, Section T2.7). Because the noise is Gaussian and its spectrum known, the data themselves are a sufficient summary and the likelihood is exact: $\mathcal{L} \propto e^{-(d-h|d-h)/2}$ with the noise-weighted inner product of Section 10.8 (stages 3 to 5). For the overall amplitude, $h = \mathcal{A}\,g$ with g fixed, the Fisher matrix of Section 10.9 gives

$$\Gamma_{\ln\mathcal{A}\,\ln\mathcal{A}} \overset{(1)}{=} \left(\frac{\partial h}{\partial \ln\mathcal{A}}\middle|\frac{\partial h}{\partial \ln\mathcal{A}}\right) \overset{(2)}{=} (h|h) \overset{(3)}{=} \rho^2, \qquad \sigma_{\ln\mathcal{A}} = \frac{1}{\rho}, \quad (14.10)$$

(1) The Gaussian-noise Fisher matrix, $\Gamma_{ij} = (\partial_i h|\partial_j h)$.
(2) $\partial h/\partial \ln\mathcal{A} = \mathcal{A}\,\partial h/\partial\mathcal{A} = \mathcal{A}g = h$.
(3) The squared signal-to-noise ratio is $\rho^2 = (h|h)$.

A source at $\rho = 20$ has its amplitude measured to 5%, independent of everything else about the waveform. Here the CMB example's lesson is reversed: the amplitude is the easy parameter, and the hard ones are those whose effect on the phase other parameters can imitate (Section 10.9.3).

Example: the chain for the topology of the sky. The model is a Gaussian ΛCDM sky, possibly with a small f_{NL} (stage 1, Section T3.2); the data are a masked, beamed, noisy temperature map (stage 2). The choice of stage 3 is to look at the shape of the excursion sets at thresholds set by the area fraction, which removes any monotone distortion of the temperature values (Section 12.4). Stage 4 counts areas, boundary lengths, Euler characteristics and Betti numbers inside the mask. For an unmasked Gaussian field the mean of the Euler characteristic has a formula (Section 12.5); for everything else in stage 5 there are only simulated skies sent through the same mask and code. Stage 6 is a test against the Gaussian null with a simulated covariance (Section 13.12). The chain is the same as for the amplitude; what moved is the line between formula and simulation in Figure 14.7.

What the chain buys us. A new problem can be placed on the chain before any calculation. Its stage 5 decides the cost: if the summary has a known sampling distribution, the analysis is a few lines; if not, the number of simulations sets the precision of everything after it (Section 8.13). Its stage 6 decides the dangers: the traps of Section 14.5 all live there.

How this is used in real research: the chain in a research collaboration

A large analysis divides the chain among teams: a theory team owns the Boltzmann or waveform code (stage 1), an instrument team the beam, noise and mask models and the end-to-end simulations (stages 2 and 5), and an analysis team the estimators and the likelihood (stages 4 and 6). The *Planck* likelihood, the LIGO–Virgo parameter estimation and the BOSS clustering analysis all have this shape. The weak points are the hand-overs: a covariance simulated with a different mask from the one in the data, or a template built at a different fiducial cosmology from the one used for the distances, each passes silently from one stage to the next.

14.4 Four instruments, one likelihood

A particle physicist scanning a diphoton spectrum, a cosmologist fitting the *Planck* temperature spectrum, a gravitational-wave astronomer estimating the masses of a binary and a survey astronomer measuring the clustering of galaxies read different journals and use different words. In Section 0.5 we saw that underneath all of them lies one question: for a trial value of the parameters, how probable is the noise realisation that would turn the model's prediction into the data actually recorded? The likelihood is the density of that required noise (0.9). At that point the claim rested on three short formulas. Now every stage of the pipeline has been built for each instrument, and the comparison can be made stage by stage. The interesting part is no longer that the idea is shared; it is *where* the four implementations differ, because each difference is a place where a method that works for one instrument fails for another.

The question in words. For each instrument: what is the noise that the data require, what is its distribution, and how do the parameters change it? The answers fill Table 14.1. Two of its rows deserve a derivation, because they are where the columns part company: the form of the likelihood for counts and for a Gaussian field with several components, and the place where the parameters enter.

	collider counts	**CMB**	**gravitational waves**	**LSS and topology**
data	events in bins of mass	a temperature (and polarization) map	a strain time series	a galaxy catalogue, a mass map
noise	Poisson counting	cosmic variance of a Gaussian field, plus detector noise	stationary Gaussian noise with spectrum $S_n(f)$	cosmic variance, shot noise, shape noise; non-Gaussian
summary	the counts themselves	$\widehat{C}_\ell$, pseudo-C_ℓ bandpowers	the data themselves, or the matched-filter output	$\hat{\xi}(s)$, $\hat{P}(k)$; peaks, Minkowski functionals, Betti numbers
its distribution	Poisson, exact	$\chi^2_{2\ell+1}$ (Wishart for several fields); simulated with a mask	Gaussian, exact	simulated (mocks, simulated maps)
$-2\ln\mathcal{L}$	$2\sum_i[\mu_i - n_i\ln\mu_i]$	sum over ℓ of $(2\ell+1)\big[\mathrm{Tr}(\mathbf{C}^{-1}\widehat{\mathbf{C}}) + \ln\det\mathbf{C}\big]$	$(d-h \mid d-h)$	$\boldsymbol{r}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\boldsymbol{r}$, $\boldsymbol{r} = \boldsymbol{S} - \hat{\boldsymbol{\mu}}$, Hartlap-corrected
$\boldsymbol{\theta}$ enters	the mean $\mu_i(\boldsymbol{\theta})$, with nuisance parameters for the shapes	the covariance $\mathbf{C}_\ell(\boldsymbol{\theta})$	the mean $h(\boldsymbol{\theta})$	mostly the mean; covariance fixed at a fiducial model
forecast	Asimov significance, $\sigma_s^2 = (s+b)$	Knox, CMB Fisher matrix	$\Gamma_{ij} = (\partial_i h \mid \partial_j h)$	Fisher with simulated derivatives and its noise bias
many tests	the look-elsewhere effect in a mass scan	anomalies chosen after looking	a bank of templates and arrival times	many thresholds and summaries: combine, do not pick
built in	Sections 3.11, 4.1, 4.14.3, 4.15, 4.16, 13.23 and 13.26 and Chapter T4	Chapters 7, 8 and 13 and Section 9.19	Chapter T2 and Sections 10.8 and 10.9	Chapters 11 and 12 and Section 12.24

Table 14.1: The same pipeline in four instruments. Each column is one kind of experiment and each row one stage of the analysis. The rows that differ, where the parameters enter and whether the distribution is known or simulated, decide which methods transfer from one column to another.

Example: counts in many bins. A spectrum of k independent bins with counts n_i and expected counts $\mu_i(\boldsymbol{\theta}) = s_i(\boldsymbol{\theta}) + b_i$ has the likelihood of Section 3.11:

$$-2\ln\mathcal{L}(\boldsymbol{\theta}) \overset{(1)}{=} -2\sum_{i=1}^{k}\ln\frac{\mu_i^{n_i}e^{-\mu_i}}{n_i!} \overset{(2)}{=} 2\sum_{i=1}^{k}\big[\mu_i - n_i\ln\mu_i\big] + 2\sum_{i=1}^{k}\ln n_i!$$
$$\overset{(3)}{=} 2\sum_{i=1}^{k}\big[\mu_i(\boldsymbol{\theta}) - n_i\ln\mu_i(\boldsymbol{\theta})\big] + \text{const.} \tag{14.11}$$

(1) Independent bins multiply, so their logarithms add.
(2) $\ln(\mu^n e^{-\mu}/n!) = n\ln\mu - \mu - \ln n!$, multiplied by -2.
(3) The data's own term $\sum\ln n_i!$ does not depend on $\boldsymbol{\theta}$.

This is Cash's statistic [20]. The parameters enter only through the mean. Nothing in it assumes many counts, which is why it, and not a χ^2 with $\sqrt{n_i}$ errors, is right for the sparse tails where new particles are sought. Its price is that the null distribution of the best bump, scanned over all masses, has no Wilks theorem behind it (Section 4.14.3). Panel (a) of Figure 14.8 shows one background-only spectrum of 40 bins scanned bin by bin. Its largest local excess, $Z = 2.95$, would be matched or beaten somewhere in 0.06 of all background-only spectra; a 3σ local excess, with local probability 0.00135, appears somewhere in 0.050 of them.

Example: a CMB multipole with temperature and polarization. At one multipole ℓ the temperature and the E-mode polarization give, for each m, a pair $\boldsymbol{a}_{\ell m} = (a^T_{\ell m}, a^E_{\ell m})$. Isotropy makes different m uncorrelated and gives every m the same 2×2 covariance

$$\mathbf{C}_\ell = \begin{pmatrix} C_\ell^{TT} & C_\ell^{TE} \\ C_\ell^{TE} & C_\ell^{EE} \end{pmatrix}$$

(Section 7.9). As in the one-field count of Section 7.10, the independent real numbers are the vector $\boldsymbol{x}_0 = \boldsymbol{a}_{\ell 0}$, which is real with covariance $\mathbf{C}_\ell$, and for each $m = 1, \dots, \ell$ the real and imaginary parts $\boldsymbol{x}_m$ and $\boldsymbol{y}_m$ of $\boldsymbol{a}_{\ell m} = \boldsymbol{x}_m + i\boldsymbol{y}_m$, each with covariance $\mathbf{C}_\ell/2$; the negative m are fixed by the reality condition $\boldsymbol{a}_{\ell,-m} = (-1)^m \boldsymbol{a}^*_{\ell m}$. *What is the probability of the observed $\boldsymbol{a}_{\ell m}$ if the spectra are $\mathbf{C}_\ell$?* It is the product of the Gaussian densities of these independent vectors, and each contributes $\boldsymbol{x}^\mathsf{T}\Sigma^{-1}\boldsymbol{x} + \ln\det\Sigma$ (plus a constant) to $-2\ln\mathcal{L}$:

$$\begin{aligned}
-2\ln\mathcal{L}(\mathbf{C}_\ell) &\overset{(1)}{=} \boldsymbol{x}_0^\mathsf{T}\mathbf{C}_\ell^{-1}\boldsymbol{x}_0 + \ln\det\mathbf{C}_\ell + \sum_{m=1}^{\ell}\Big[\boldsymbol{x}_m^\mathsf{T}\big(\tfrac{1}{2}\mathbf{C}_\ell\big)^{-1}\boldsymbol{x}_m + \boldsymbol{y}_m^\mathsf{T}\big(\tfrac{1}{2}\mathbf{C}_\ell\big)^{-1}\boldsymbol{y}_m + 2\ln\det\big(\tfrac{1}{2}\mathbf{C}_\ell\big)\Big] + c_1 \\
&\overset{(2)}{=} \boldsymbol{x}_0^\mathsf{T}\mathbf{C}_\ell^{-1}\boldsymbol{x}_0 + 2\sum_{m=1}^{\ell}\big[\boldsymbol{x}_m^\mathsf{T}\mathbf{C}_\ell^{-1}\boldsymbol{x}_m + \boldsymbol{y}_m^\mathsf{T}\mathbf{C}_\ell^{-1}\boldsymbol{y}_m\big] + (2\ell+1)\ln\det\mathbf{C}_\ell + c_2 \\
&\overset{(3)}{=} \sum_{m=-\ell}^{\ell}\boldsymbol{a}^\dagger_{\ell m}\mathbf{C}_\ell^{-1}\boldsymbol{a}_{\ell m} + (2\ell+1)\ln\det\mathbf{C}_\ell + c_2 \\
&\overset{(4)}{=} \mathrm{Tr}\Big[\mathbf{C}_\ell^{-1}\sum_{m=-\ell}^{\ell}\boldsymbol{a}_{\ell m}\boldsymbol{a}^\dagger_{\ell m}\Big] + (2\ell+1)\ln\det\mathbf{C}_\ell + c_2 \\
&\overset{(5)}{=} (2\ell+1)\Big[\mathrm{Tr}\big(\mathbf{C}_\ell^{-1}\widehat{\mathbf{C}}_\ell\big) + \ln\det\mathbf{C}_\ell\Big] + c_2 .
\end{aligned} \tag{14.12}$$

(1) The Gaussian density of each independent real vector; c_1 collects the factors of 2π, which do not depend on $\mathbf{C}_\ell$.

(2) $(\frac{1}{2}\mathbf{C}_\ell)^{-1} = 2\mathbf{C}_\ell^{-1}$, and for a 2×2 matrix $\det(\frac{1}{2}\mathbf{C}_\ell) = \frac{1}{4}\det\mathbf{C}_\ell$, so each $m \geq 1$ gives $2\ln\det\mathbf{C}_\ell$ plus a constant; with $m = 0$ that is $1 + 2\ell$ copies of $\ln\det\mathbf{C}_\ell$.

(3) For a real symmetric matrix M, $\boldsymbol{a}^\dagger M\boldsymbol{a} = \boldsymbol{x}^\mathsf{T}M\boldsymbol{x} + \boldsymbol{y}^\mathsf{T}M\boldsymbol{y}$: the cross terms $i\boldsymbol{x}^\mathsf{T}M\boldsymbol{y} - i\boldsymbol{y}^\mathsf{T}M\boldsymbol{x}$ cancel because $\boldsymbol{x}^\mathsf{T}M\boldsymbol{y} = \boldsymbol{y}^\mathsf{T}M\boldsymbol{x}$. By the reality condition $\boldsymbol{a}_{\ell,-m}$ gives the same value as $\boldsymbol{a}_{\ell m}$, so the factor 2 is the sum over $\pm m$.

(4) A number is its own trace, and the trace is cyclic: $\boldsymbol{a}^\dagger M\boldsymbol{a} = \mathrm{Tr}(M\boldsymbol{a}\boldsymbol{a}^\dagger)$.

(5) Define the estimated spectrum matrix $\widehat{\mathbf{C}}_\ell = \frac{1}{2\ell+1}\sum_m \boldsymbol{a}_{\ell m}\boldsymbol{a}^\dagger_{\ell m}$, the two-field version of $\widehat{C}_\ell$; it is real because the $\pm m$ terms are complex conjugates.

For one field, $\mathrm{Tr}(\mathbf{C}^{-1}\widehat{\mathbf{C}}) + \ln\det\mathbf{C}$ becomes $\widehat{C}_\ell/C_\ell + \ln C_\ell$ and (14.12) is the exact full-sky likelihood of Section 9.19. Read the other way, as a distribution of the data $(2\ell+1)\widehat{\mathbf{C}}_\ell$ for fixed $\mathbf{C}_\ell$, it is a Wishart distribution with $2\ell+1$ degrees of freedom, the matrix version of $\chi^2_{2\ell+1}$ and the same law that governs a covariance matrix estimated from simulations (Section 8.13.2). Here the parameters enter only through the *covariance*, and at low ℓ the likelihood is far from Gaussian in C_ℓ (panel b of Figure 14.8): at $\ell = 2$ there are only 5 modes, and the likelihood has a long tail to large C_ℓ. Detector noise adds $\boldsymbol{N}_\ell$ to $\mathbf{C}_\ell$, and a mask replaces $2\ell+1$ by an effective number of modes close to $(2\ell+1)f_{\mathrm{sky}}$ (Section 9.19).

Example: a gravitational-wave signal in Gaussian noise. For a detector with stationary Gaussian noise, the noise in different frequency bins is independent, with variance set by $S_n(f)$, and the likelihood is $\mathcal{L} \propto \exp[-\frac{1}{2}(d-h|d-h)]$ with the noise-weighted inner product

(Section 10.8). The parameters enter only through the *mean*, the waveform $h(\boldsymbol{\theta})$. When the phase is unknown the detection statistic is the χ^2_2 of (14.6) in noise and a noncentral χ^2_2 with a signal; at $\rho = 4$ a threshold set for a false-alarm probability of 10^{-3} ($\rho^2 > 13.82$) catches the signal with probability 0.66 (panel c).

Example: summaries with no formula. For a galaxy correlation function measured through a survey window, or for peak counts and Betti numbers of a lognormal mass map, nothing is known in closed form. The standard choice is a Gaussian likelihood whose mean $\hat{\boldsymbol{\mu}}(\boldsymbol{\theta})$ and covariance $\hat{\mathbf{C}}$ are both measured on simulations, the covariance at one fiducial model (Sections 11.6 and 12.24). The Gaussian form is an assumption, checked by histogramming the simulated summaries, and the estimated covariance changes the distribution of the χ^2 even when the data are exactly Gaussian. Panel (d) shows 10 summaries with a covariance from 40 simulations. After the Hartlap factor the mean of the χ^2 is right, 10.02 against 10, but the tail is heavier: the 5% critical value of χ^2_{10} is exceeded in 0.075 of trials.

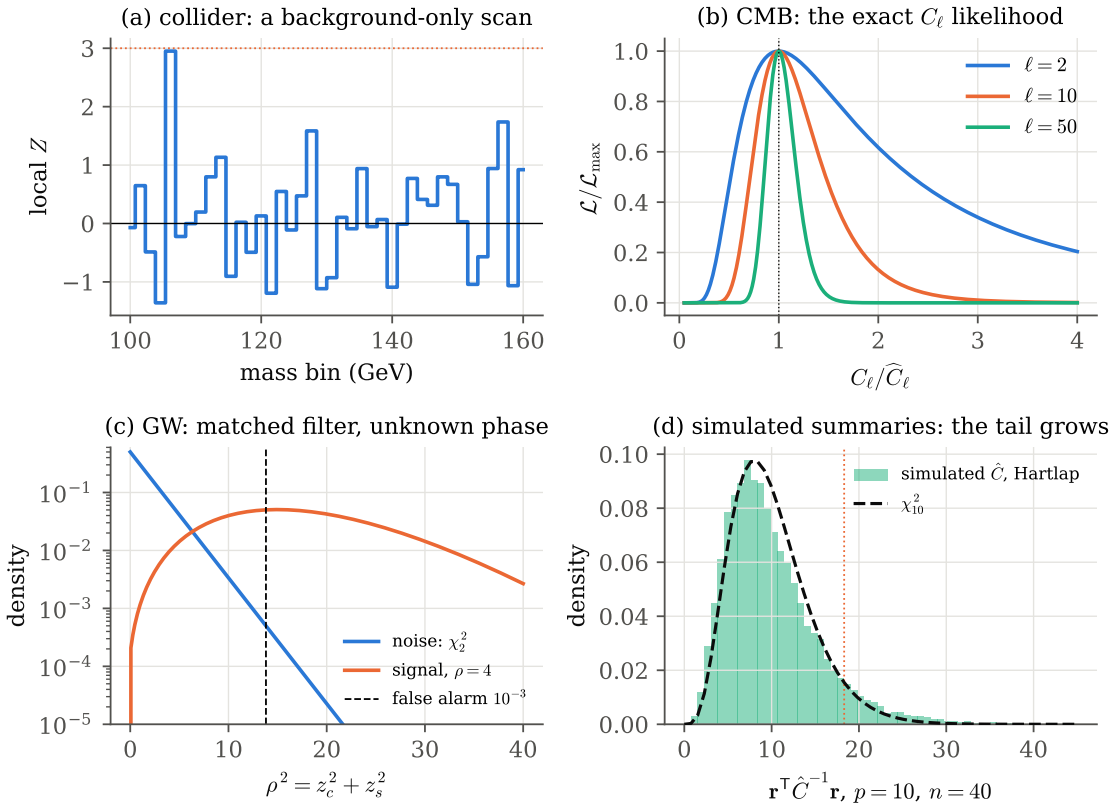

Figure 14.8: The distribution each instrument's inference rests on. (a) A background-only spectrum scanned bin by bin. When forty masses are tried, a local excess of two standard deviations somewhere is common; the largest in this spectrum is $Z = 2.95$. (b) The exact likelihood of a CMB spectrum at one multipole, when the measured $\widehat{C}_\ell$ equals the fiducial value: lopsided at $\ell = 2$, nearly Gaussian at $\ell = 50$. (c) The matched-filter statistic with an unknown phase, in noise and with a signal of $\rho = 4$; the dashed line is the threshold for a false-alarm probability of 10^{-3}. (d) A χ^2 built with a covariance estimated from forty simulations: after the Hartlap factor its mean is right but its tail is heavier than χ^2_{10}.

Where the parameters enter. All four likelihoods are, or are approximated by, a Gaussian in some data vector, with

$$-2\ln\mathcal{L}(\boldsymbol{\theta}) = \big[\boldsymbol{d} - \boldsymbol{\mu}(\boldsymbol{\theta})\big]^\mathsf{T}\mathbf{C}(\boldsymbol{\theta})^{-1}\big[\boldsymbol{d} - \boldsymbol{\mu}(\boldsymbol{\theta})\big] + \ln\det\mathbf{C}(\boldsymbol{\theta}) + \text{const},$$

the Poisson case joining through its Gaussian limit at large counts. The parameters can sit in the mean, in the covariance, or in both, and the Fisher matrix inherits the split: a mean part $\boldsymbol{\mu}_{,i}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\mu}_{,j}$ and a covariance part $\frac{1}{2}\,\mathrm{Tr}[\mathbf{C}^{-1}\mathbf{C}_{,i}\mathbf{C}^{-1}\mathbf{C}_{,j}]$ (Section 10.3). The consequences differ in practice. When the parameters sit in the mean, the likelihood is Gaussian in the data even at low signal-to-noise, and the danger is a curved, nonlinear model; this is the GW case, where the Fisher ellipse fails because the waveform is not linear in its parameters (Section 10.13). When they sit in the covariance, the likelihood is not Gaussian in the data until many modes are averaged; this is the CMB at low ℓ, where a Gaussian approximation in C_ℓ biases the answer (Section 9.19). When neither is known, simulations supply both, and their finite number becomes part of the error budget. Figure 14.9 collects the three cases.

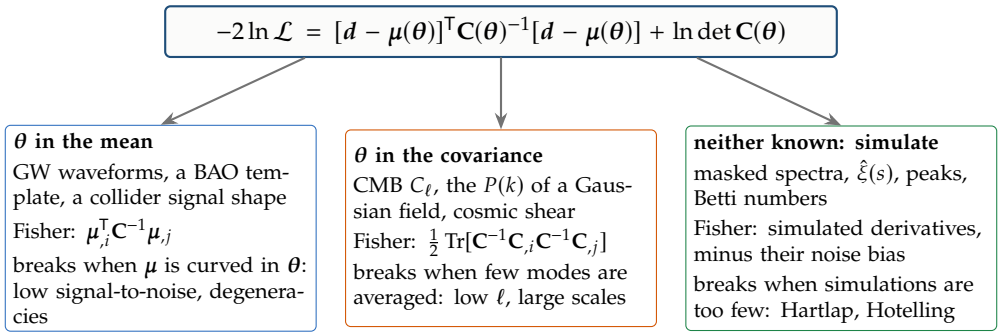

Figure 14.9: Where the parameters enter the likelihood decides how the analysis behaves. In the mean (left), the likelihood stays Gaussian in the data and the trouble is a nonlinear model. In the covariance (middle), the trouble is a non-Gaussian likelihood when few modes are available. Measured from simulations (right), the trouble is the finite number of simulations.

Which methods transfer, and which do not. The table and the three cases explain why some recipes travel and others do not. Inverting the Fisher matrix for a forecast transfers everywhere, but it is checked against a chain in the left and right columns of Figure 14.9 and against the exact likelihood at low ℓ in the middle one. A χ^2 with a known covariance is exact for the gravitational-wave matched filter and for Gaussian bandpowers at high ℓ, approximate for counts, and has the Hotelling tail for simulated summaries. The look-elsewhere correction is unavoidable in a mass scan, and has analogues wherever many places, templates or thresholds are tried. The safest habit for simulated summaries is to combine every threshold into one pre-declared statistic rather than to quote the most significant one (Section 12.25).

Key idea: same question, different noise

The likelihood of every instrument is the probability of the noise that the data require. What changes from one instrument to the next is where the parameters enter, in the mean or in the covariance, and whether the distribution of the summary is known or simulated. Those two facts decide which approximations hold and which checks are needed.

14.5 The traps that kept coming back

The same few mistakes appeared in chapter after chapter, in coins, in collider bumps, in CMB spectra and in gravitational waves. None of them is a mistake of arithmetic. Each is a number built to answer one question being read as the answer to another, exactly the mismatch the corridor example of Section 14.1 warned about. Each trap has the same anatomy: the statement as people make it, the everyday question it seems to answer, the assumption hidden inside

that question, a small simulated example that breaks the assumption (the numbers come from `code/ch14/02_pitfalls.py`), and the lesson in one line.

14.5.1 A p-value is not the probability that the null is true

The statement. "We found $p = 0.05$, so there is only a 5% chance that the effect is a fluke."

The question it seems to answer. Given what we saw, how probable is it that nothing is there?

The hidden assumption. The p-value runs in the forward direction: *if* the null were true, how often would a result this extreme or more appear (Section 4.1.3)? The question runs backwards: given the result, how probable is the null? Turning one into the other is Bayes' theorem, and Bayes' theorem needs two things the p-value never used: how readily the *alternative* would have produced the same result, and how often nulls are true to begin with (Section 4.4.4). The statement silently sets the first to one and ignores the second.

An example where the assumption fails. Picture a field in which half the hypotheses tested are true nulls and the other half have real effects of varied size: the true effect μ, in units of the measurement error, is drawn from $\mathcal{N}(0, \tau^2)$ with $\tau = 2$, and each experiment reports $z = \mu + \text{noise}$ with unit Gaussian noise and a two-sided p-value. Among the experiments that landed near $p = 0.05$, what fraction were true nulls? Under the null, $z \sim \mathcal{N}(0, 1)$. Under the alternative, z is the sum of two independent Gaussians, the effect and the noise, so it is Gaussian with the variances added, $z \sim \mathcal{N}(0, 1 + \tau^2)$ (Section 2.12). The Bayes factor for the null at the observed z is the ratio of these two densities:

$$B_{01} \overset{(1)}{=} \frac{e^{-z^2/2}/\sqrt{2\pi}}{e^{-z^2/2(1+\tau^2)}/\sqrt{2\pi(1+\tau^2)}} \overset{(2)}{=} \sqrt{1+\tau^2}\,\exp\!\left[-\frac{z^2}{2}\left(1-\frac{1}{1+\tau^2}\right)\right]$$
$$\overset{(3)}{=} \sqrt{1+\tau^2}\,\exp\!\left[-\frac{z^2}{2}\,\frac{\tau^2}{1+\tau^2}\right] \overset{(4)}{=} 0.481. \tag{14.13}$$

(1) The two Gaussian densities at the observed z, variance 1 under H_0 and $1 + \tau^2$ under H_1.
(2) The $\sqrt{2\pi}$ cancels; the two exponentials combine into one.
(3) $1 - 1/(1 + \tau^2) = \tau^2/(1 + \tau^2)$.
(4) $z = 1.96$ (the two-sided $p = 0.05$) and $\tau = 2$: $\sqrt{5}\,e^{-1.92\times0.8}$.

With equal prior probabilities the posterior probability of the null is $B_{01}/(1 + B_{01}) = 0.325$. The simulation of 4×10^6 experiments agrees: of the 61737 that gave $0.045 < p < 0.055$, a fraction 0.322 ± 0.002 were nulls (Figure 14.10a). A different spread of effects gives a different number, but there is a floor. Over every alternative that is symmetric about zero and falls away from it, the most a p-value can support is the odds $\bar{B}_{10} = -1/(e\,p \ln p)$ (Section 5.17.4), which at $p = 0.05$ is 2.46, so the null keeps at least 0.289 of its probability.

The lesson. A p-value is a prediction made from the null; the probability of the null is an inference that needs the alternative and the prior, and at $p = 0.05$ it is nearer one third than one twentieth.

14.5.2 A confidence interval is not a credible interval

The statement. "The 90% interval is $[a, b]$, so the true value lies in $[a, b]$ with probability 90%."

The question it seems to answer. How sure can we be that the parameter is in this range, given the data we have?

The hidden assumption. A confidence interval is a recipe whose output covers the fixed true value in 90% of repeated experiments (Section 4.12). The probability belongs to the recipe, not to the one interval in hand. "The value lies in $[a, b]$ with probability 90%" is a statement about

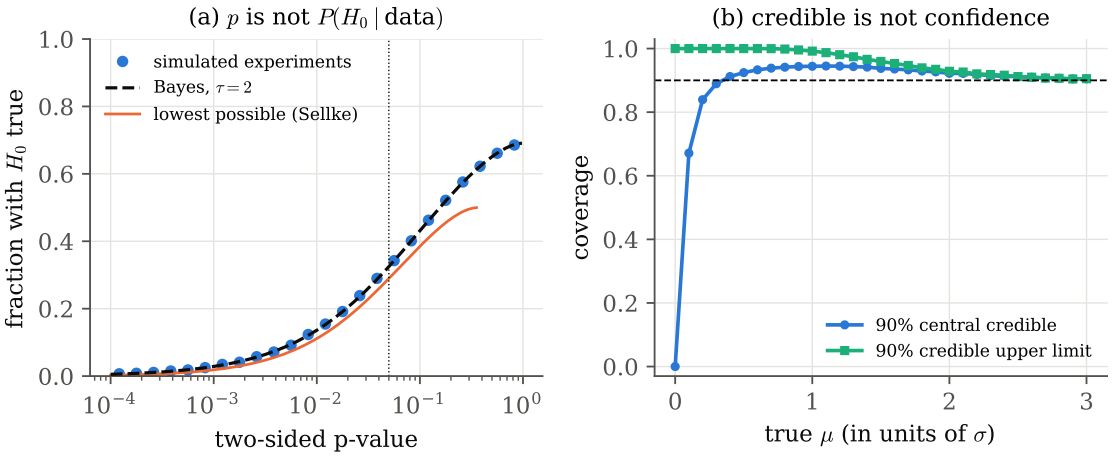

Figure 14.10: (a) Among simulated experiments, half of them true nulls, the fraction of nulls at each p-value. The dots are the simulation, the dashed curve the Bayes factor of (14.13), and the orange curve the lowest value any symmetric, decreasing alternative can produce. At $p = 0.05$ (dotted line) about a third are nulls. (b) How often a 90% credible interval for a non-negative mean contains the truth, as a function of the truth. The central interval never contains $\mu = 0$; the upper limit always does; neither has 90% coverage near the boundary.

the parameter given these data, which is a credible interval and needs a prior (Section 4.17). The two coincide for a Gaussian mean far from any boundary with a flat prior, which is where the habit is learned.

An example where the assumption fails. A mass $\mu \geq 0$ is measured once with Gaussian error $\sigma = 1$, and the reading is $x = -1.5$, below zero by a downward fluctuation. The central 90% confidence interval is $x \pm 1.645 = [-3.145, 0.145]$. The recipe is valid: it covers the truth in 90% of repetitions, whatever μ is. But how much posterior probability does this particular interval hold? With a flat prior on $\mu \geq 0$ the posterior is the Gaussian $\mathcal{N}(x, 1)$ cut at zero and renormalised, and the interval's physical part is $[0, 0.145]$:

$$\mathrm{P}(0 \leq \mu \leq x + 1.645 \mid x) \overset{(1)}{=} \frac{\Phi(1.645) - \Phi(-x)}{1 - \Phi(-x)} \overset{(2)}{=} \frac{0.950 - 0.933}{1 - 0.933} \overset{(3)}{=} 0.25. \tag{14.14}$$

(1) The probability of the Gaussian $\mathcal{N}(x, 1)$ between 0 and $x + 1.645$, in units of standard deviations from x, divided by its total probability above zero.
(2) $-x = 1.5$, and $\Phi(1.5) = 0.933$.
(3) The script's value.

So this "90%" interval holds a quarter of the posterior probability. The reverse also fails. The central 90% credible interval, with 5% of the posterior on each side, never reaches down to zero, so if the true mass is zero it covers it in 0.000 of experiments; at $\mu = 0.5$ it covers in 0.924, and only far from the boundary, at $\mu = 3$, does it settle at 0.905. The credible upper limit covers $\mu = 0$ every time (1.000, Figure 14.10b). A further difference is what each depends on. For the same seven heads in twenty-four tosses, Kruschke's one-tailed p-value, and with it the confidence interval, is 0.032 if the plan was to toss twenty-four times and 0.017 if the plan was to stop at the seventh head [Kruschke §§11.1.2–11.1.3, pp. 302–308]; the posterior is the same in both cases, because the likelihoods are proportional (Section 4.2.2).

The lesson. Coverage is a property of the recipe over repeated experiments, credibility a property of the parameter given these data and a prior; check which one the question asks for.

14.5.3 A Fisher forecast is not the posterior

The statement. "The Fisher matrix gives $\sigma = 0.45$, so the experiment will measure the parameter to ± 0.45."

The question it seems to answer. When the data come in, how wide will the posterior be?

The hidden assumption. The Fisher matrix is the average curvature of the log-likelihood at the true parameters (Section 10.1.1). Its inverse is the covariance of the posterior only if the log-likelihood is a quadratic in the parameters, which is exact for a model linear in the parameters with Gaussian noise and approximately true when the data are many (Section 10.2.3). Away from that limit the posterior can be skewed, wider, or bounded, and the Gaussian of the Fisher matrix cannot show it.

An example where the assumption fails. N unstable particles decay at times t_i drawn from $e^{-t/\tau}/\tau$, and we want the lifetime τ. Write $S = \sum_i t_i$. The log-likelihood and the Fisher information are

$$\ln \mathcal{L}(\tau) \overset{(1)}{=} -N \ln \tau - \frac{S}{\tau}, \qquad I(\tau) \overset{(2)}{=} -\mathbb{E}\Big[\frac{N}{\tau^2} - \frac{2S}{\tau^3}\Big] \overset{(3)}{=} -\frac{N}{\tau^2} + \frac{2N\tau}{\tau^3} \overset{(4)}{=} \frac{N}{\tau^2}, \tag{14.15}$$

(1) The product of N exponential densities, $\tau^{-N} e^{-S/\tau}$, in logarithms.
(2) The Fisher information is minus the expected second derivative; differentiate $-N \ln \tau - S/\tau$ twice.
(3) Each decay time has mean τ, so $\mathbb{E}\, S = N\tau$.
(4) Collect the two terms.

so the forecast is $\sigma_\tau = \tau/\sqrt{N}$. With a flat prior in τ the posterior is the likelihood itself, $p(\tau \mid S) \propto \tau^{-N} e^{-S/\tau}$. That is the inverse-gamma shape $\tau^{-\alpha-1} e^{-\beta/\tau}$ with $\alpha = N - 1$ and $\beta = S$, whose mean is $\beta/(\alpha - 1) = S/(N - 2)$. Take the median experiment, $S = N\tau$ with $\tau = 1$. For $N = 5$ the Fisher interval is $[0.553, 1.447]$; the posterior's central 68% is $[0.847, 2.389]$, with median 1.362 and mean 1.667. The posterior is shifted up, more than twice as wide above the peak as below it, and excludes the short lifetimes that the Fisher interval allows. For $N = 50$ the two are $[0.859, 1.141]$ and $[0.894, 1.189]$: the posterior is approaching its Gaussian limit (Figure 14.11a).

The lesson. The Fisher matrix is the large-data limit of the posterior; whenever the signal is weak, the model nonlinear or a parameter near a boundary, check the forecast with a chain on mock data (Section 10.13).

14.5.4 A chain forgets where it started, not what it was told

The statement. "We ran the chain long enough for the initial choices to wash out."

The question it seems to answer. Does the answer still depend on anything we chose before seeing the data?

The hidden assumption. Two choices are made before the first step: the point where the walker starts and the prior. Only the first is part of the walk. An ergodic chain forgets its start geometrically fast (Section 9.5), but the prior is part of the target density $\mathcal{L} \times p$ that the chain samples (Section 9.14). A longer run only samples the posterior of that prior more precisely.

An example where the assumption fails. N Gaussian readings of unit error have mean $\bar{x} = 1$, the true value. The prior, wrong and confident, is $\mathcal{N}(-2, 0.3^2)$. The posterior is Gaussian (Section 5.8), with mean

$$\mathbb{E}(\mu \mid \boldsymbol{d}) \overset{(1)}{=} \frac{\mu_p/s_p^2 + N\bar{x}/\sigma^2}{1/s_p^2 + N/\sigma^2} \overset{(2)}{=} \frac{-2/0.09 + 10}{1/0.09 + 10} \overset{(3)}{=} -0.579 \quad (N = 10), \tag{14.16}$$

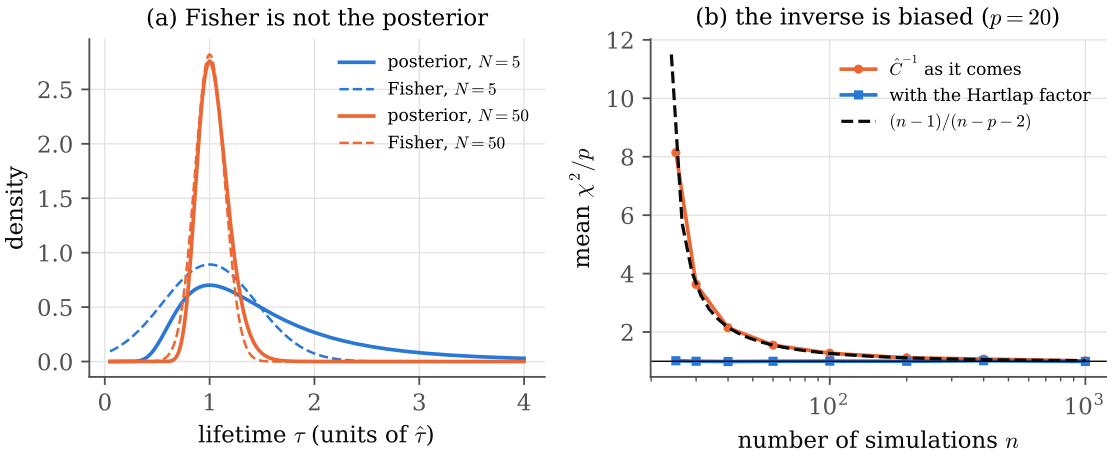

Figure 14.11: (a) Posterior for a lifetime from $N = 5$ and $N = 50$ decays (solid), with the Gaussian of the Fisher forecast (dashed), both for the median experiment. With five decays the posterior is skewed towards long lifetimes and the forecast misplaces it; with fifty the two nearly agree. (b) The mean of $\boldsymbol{r}^{\mathsf{T}}\hat{\mathbf{C}}^{-1}\boldsymbol{r}$ divided by the number of bins $p = 20$, for covariances estimated from n simulations: the raw inverse inflates it by $(n-1)/(n-p-2)$ (dashed), and the Hartlap factor removes the inflation.

(1) The inverse-variance weighted mean of the prior centre μ_p and the data mean $\bar{x}$ (the Normal–Normal update).
(2) $\mu_p = -2$, $s_p = 0.3$, $\bar{x} = 1$, $\sigma = 1$, $N = 10$.
(3) $-12.2/21.1$.

Three Metropolis chains of 20000 steps, started at -20, 0 and $+20$, give after a burn-in of 1000 steps the means -0.582, -0.577 and -0.579: the start is gone, and all three agree on the wrong answer (Figure 14.12a). More data do what more steps cannot. The data's weight N/σ^2 grows while the prior's $1/s_p^2$ stays fixed, and the posterior mean moves from -1.75 at $N = 1$ through 0.70 at $N = 100$ to 0.967 at $N = 1000$ (Figure 14.12b, and Section 5.13).

The lesson. Steps remove the start, only data remove the prior; diagnose the first with $\hat{R}$ and burn-in, and the second by rerunning with another prior.

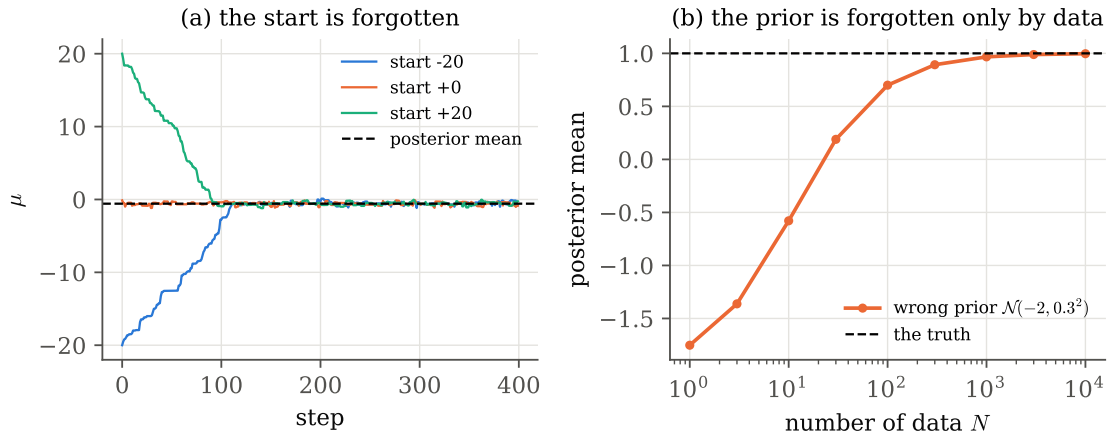

Figure 14.12: (a) The first four hundred steps of three Metropolis chains started far apart, for ten data points and a confident wrong prior: within about a hundred steps all three wander around the same posterior mean (dashed), which is far from the truth $\mu = 1$. (b) The posterior mean with the same prior as the number of data grows: only data pull it to the truth.

14.5.5 The inverse of an estimated covariance is biased

The statement. "The sample covariance from simulations is unbiased, so its inverse gives the right χ^2."

The question it seems to answer. Is the scatter of my data vector properly weighted?

The hidden assumption. That the inverse of an unbiased estimate is an unbiased estimate of the inverse. Inversion is a convex operation, so a fluctuation of a variance towards zero raises its inverse more than an equal fluctuation away from zero lowers it, and the average inverse is too large. For one bin and n simulations the factor is $(n-1)/(n-3)$ (8.76); for p bins it is $(n-1)/(n-p-2)$ (Section 8.13.2).

An example where the assumption fails. Take $p = 20$ Gaussian summaries with unit covariance, estimate the covariance from $n = 30$ simulations, and compute the χ^2 of an independent data vector, 4000 times. The mean should be 20; it is 72.6, against the prediction $20 \times 29/8 = 72.5$. At a nominal 5% threshold of χ^2_{20} the test rejects 0.88 of perfectly good data sets. The Hartlap factor $(n-p-2)/(n-1)$ brings the mean to 20.0, but the false-alarm rate is still 0.134, because the tail of the corrected statistic is the Hotelling law, not χ^2_p (Section 12.24.2). With $n = 100$ the raw rate is 0.225 and the corrected one 0.077 (Figure 14.11b).

The lesson. Correct the inverse, use the Hotelling (or a Student-type) likelihood for the tail, and plan many more simulations than bins (Section 8.13).

14.5.6 Where we looked changes how surprising it is

The statement. "A 3σ excess: a chance of one in seven hundred and forty."

The question it seems to answer. If there is nothing new, how often would we see something this striking?

The hidden assumption. That the excess was the only place we looked. If a bump at any of M masses would have been reported, the null distribution that answers the question is that of the *largest* excess among all M (Section 4.14).

An example where the assumption fails. Let the M search windows be independent, each with local significance $Z_j \sim \mathcal{N}(0,1)$ under the background. The largest is below a threshold c only if every one of them is:

$$p_{\text{glob}} \overset{(1)}{=} 1 - \mathrm{P}\big(\max_j Z_j < c\big) \overset{(2)}{=} 1 - \prod_{j=1}^{M} \mathrm{P}(Z_j < c) \overset{(3)}{=} 1 - (1 - p_{\text{loc}})^M \overset{(4)}{\approx} M p_{\text{loc}}. \tag{14.17}$$

(1) The complement of "no window exceeds c".
(2) Independent windows: the probability that all stay below c is a product.
(3) Each factor is $1 - p_{\text{loc}}$ with $p_{\text{loc}} = \mathrm{P}(Z > c)$.
(4) The binomial expansion to first order, valid while $M p_{\text{loc}} \ll 1$.

With $M = 20$ and $c = 3$, $p_{\text{loc}} = 0.00135$ becomes $p_{\text{glob}} = 0.0267$ (simulated: 0.0266), a global significance of 1.93σ and a trials factor of 19.7. Real windows overlap and are correlated, which lowers the effective number of trials; the scan of Section 4.14.3 counted them with the Gross–Vitells formula. Where the number of places looked at cannot be counted, as for CMB anomalies noticed after the map was made (Section T3.5), no global p-value can be computed at all.

The lesson. The null distribution must describe the whole procedure, including every place we would have been happy to find something.

14.5.7 A shared calibration does not average down

The statement. "With a hundred independent measurements the error is ten times smaller."

The question it seems to answer. How precise is the average?

The hidden assumption. That the errors are independent. When every measurement is multiplied or shifted by the same borrowed number, a zero point, the absolute magnitude of a supernova, the sound horizon of a BAO analysis, that part of the error is the same in all of them (Section 11.20).

An example where the assumption fails. Each of K measurements is $x_i = \theta + c + e_i$, with independent errors e_i of size σ and a common offset c of size σ_c. The average is $\bar{x} = \theta + c + \frac{1}{K}\sum_i e_i$, so

$$\operatorname{Var}\bar{x} \overset{(1)}{=} \operatorname{Var} c + \operatorname{Var}\Big(\frac{1}{K}\sum_{i=1}^{K} e_i\Big) \overset{(2)}{=} \sigma_c^2 + \frac{\sigma^2}{K}. \tag{14.18}$$

(1) The offset and the individual errors are independent, so their variances add.
(2) The variance of a mean of K independent errors is σ^2/K (Section 3.3.1).

With $\sigma = 2\%$ and $\sigma_c = 1\%$, one measurement has an error of 2.24% and a hundred have 1.02% (simulated: 1.02%), not 0.2%. For the Hubble constant from supernovae, an offset δM in the absolute magnitude moves every distance together, $\delta H_0/H_0 = (\ln 10/5)\,\delta M$, and the whole Hubble tension is an offset of 0.18 mag, about 8% in H_0 (Sections 3.17 and 11.20).

The lesson. Find the factor that every measurement shares before averaging; its error is a floor that no amount of data removes.

What the machinery assumes. The seven traps are special cases of a short list of assumptions that run through the whole book. Each holds in the examples where a method was first derived, and each fails somewhere in research. The table names the assumption, the place it breaks, and what the data show when it does.

Taxonomy: assumptions, where they break, and the symptom

assumption	where it breaks	symptom, and the check
the likelihood is Gaussian in the parameters	few counts, low ℓ, weak signals, nonlinear models	skewed chains; Fisher errors too small (Sections 9.19 and 10.13)
the data points are independent	a shared calibration, correlated bins, overlapping windows	errors that stop shrinking; χ^2 per degree of freedom far from one (Section 3.7)
the covariance is known	covariances from simulations or jackknife	inflated χ^2, too many rejections (Sections 8.13.2 and 13.18.2)
one test was made	mass scans, many thresholds, anomalies found by looking	excesses that fade with more data (Section 4.14)
the chain has converged	multiple modes, long correlation times	$\hat{R} > 1$, different answers from different starts (Section 9.13)
the prior is harmless	few data, wide prior ranges in model comparison	answers that move when the prior moves (Sections 5.13 and 5.17.2)
the sample is the population	flux limits, survey masks, fibre collisions	biased distances and clustering (Sections T2.13 and 13.16)
the model is right	any real data	poor goodness of fit; posterior predictive checks fail (Section 4.8)

14.6 The words, and the routes through them

Statistics reuses ordinary words for precise things, and two words that sound alike can belong to opposite directions of reasoning. "Likely" and "probable", "error" and "uncertainty", "confidence" and "credibility" are interchangeable in conversation and not interchangeable in a paper. Every trap measured in Section 14.5 began with one of these swaps. Pinning each word to a plain sentence and to the place where it was built removes the ambiguity. The words fall into the groups the pipeline of Section 14.3 uses: the language of probability, the estimate and its likelihood, tests and intervals, the Bayesian objects, simulation and chains, and the fields, forecasts and summaries of research analyses.

One word needs its two meanings stated before any table, because the others inherit them. A **probability** can be a long-run frequency: the fraction of repeated experiments in which something happens. That is the only reading the frequentist school allows, and with it a parameter, being a fixed constant, has no probability at all [Wasserman p. 175]. Or it can be a degree of belief: how strongly the information we hold supports a statement, including a statement about a constant such as the electron mass [Cowan §1.2, pp. 5–6]. Both obey the same rules of Section 1.2. The forward objects of Figure 14.2 can be read either way; the backward ones need the second reading. In large samples with a well-behaved model the two schools give nearly the same numbers, and in general they need not [Wasserman p. 185], which is why every entry below says which question its object answers.

The language of probability

word	what it means here	built in
conditional probability	the probability after keeping only the cases in which B happened, $\mathrm{P}(A \mid B) = \mathrm{P}(A \cap B)/\mathrm{P}(B)$	Section 1.4
independence	knowing that B happened does not change the probability of A	Section 1.6
random variable	a number attached to each outcome of an experiment	Section 1.8
pmf, pdf	probability of each value of a count; probability per unit length of a continuous number	Section 1.9
marginal distribution	the distribution of one variable with the nuisance variables averaged out of the joint distribution	Section 1.10.2
expectation, variance	the probability-weighted average; the average squared distance from it	Section 1.12
covariance, correlation	how two numbers move together; the same scaled to lie between -1 and 1	Section 1.13
Bernoulli, binomial	a single yes–no trial; the number of successes in many successive trials	Sections 2.1 and 2.2
Poisson	the count of rare, independent events at a constant rate in a fixed window	Section 2.5.1
central limit theorem	a sum of many independent pieces with finite variance is close to Gaussian	Section 2.10
χ^2_ν	the sum of ν squared independent standard Gaussians	Section 2.13
multivariate normal	Gaussian numbers with a covariance matrix; every marginal and conditional is again Gaussian	Section 2.12

The estimate and its likelihood

word	what it means here	built in
estimator	a recipe that turns data into a guess of a parameter; itself a random number	Section 3.1.2
sampling distribution	how the estimator scatters over repeated experiments at a fixed true value	Section 3.1.3
bias, MSE	the average offset of the estimator from the truth; bias squared plus variance	Section 3.2.1
standard deviation, standard error	the scatter of one measurement; the scatter of their mean, smaller by $\sqrt{N}$	Section 3.3.1
likelihood	for a trial $\boldsymbol{\theta}$, the probability of the noise needed to turn the prediction into the data seen; a function of $\boldsymbol{\theta}$, not a density in $\boldsymbol{\theta}$	Sections 3.8 and 3.8.3
maximum-likelihood estimate	the $\boldsymbol{\theta}$ under which the observed data were most probable	Section 3.9
Fisher information	the expected curvature of $-\ln \mathcal{L}$; large curvature means a sharp estimate	Section 3.12.3
Cramér–Rao bound	no unbiased estimator scatters less than the inverse Fisher information	Section 3.13.3
nuisance parameter	a parameter we must model but do not want, removed by profiling or integrating	Sections 3.14 and 4.15.2
profile likelihood	the likelihood of the wanted parameter with the nuisance parameters at their best value for it	Section 3.14
sufficient statistic	a summary that keeps every piece of information the data carry about $\boldsymbol{\theta}$	Section 3.16.2
least squares	maximum likelihood when the noise is Gaussian with known widths	Section 3.10.1
bootstrap	the sampling distribution estimated by resampling the data themselves	Section 3.15

Tests and intervals

word	what it means here	built in
null hypothesis	the hypothesis whose sampling distribution we know, usually "it happened by chance"	Section 4.1.1
p-value	if the null were true, the probability of a result like this one or further in the same direction	Section 4.1.3
significance Z	the p-value restated as the number of Gaussian standard deviations with the same one-sided tail	Section 4.9.1
size, power	the rate of false alarms we accept; the probability of detecting a real effect of given size	Sections 4.3 and 4.3.1
likelihood ratio, Wilks	best fit under the null over best fit overall; $-2\ln$ of it is χ^2 for large samples	Sections 4.7 and 4.7.1
confidence interval	a procedure whose intervals contain the true value in a stated fraction of repetitions	Section 4.10.1
coverage	that fraction, measured by simulation at each true value	Section 4.12
Feldman–Cousins	a confidence belt ordered by likelihood ratio, which moves smoothly from limits to two-sided intervals	Section 4.13.3
look-elsewhere effect	the extra chance of a large fluctuation somewhere when many places were searched	Section 4.14
CL_s	the p-value of signal plus background divided by that of background alone; excludes only signals the experiment could see	Section 4.16.4
Asimov data, Brazil band	the data replaced by their expected values; the band of limits expected from background alone	Sections 4.16.3 and 4.16.5
goodness of fit	whether the best model is an acceptable description at all	Section 4.8

The Bayesian objects

word	what it means here	built in
prior	how probable each parameter value was before these data	Section 5.12
posterior	the prior reweighted by how readily each value could have produced the data, then normalised	Section 5.7
conjugate prior	a prior whose posterior has the same family, so the update is a change of two numbers	Section 5.8
credible interval, HDI	a region holding a stated posterior probability; the narrowest such region	Sections 4.17.1 and 4.17.3
Bernstein–von Mises	with enough data the posterior forgets a smooth prior and becomes the Gaussian of the likelihood	Section 5.13
evidence	the probability a model gave to the data actually seen, averaged over its prior	Section 5.15.1
Bayes factor	the ratio of two evidences: which model predicted the data better	Section 5.15.2
Occam factor	the fraction of a model's prior range that the data allow; the price of flexibility	Section 5.16
Savage–Dickey ratio	for nested models, posterior over prior density at the null value	Section 5.18.1
model averaging	posteriors of several models combined with their posterior probabilities as weights	Section 5.18.2

Simulation and chains

word	what it means here	built in
pseudo-random numbers, seed	a deterministic sequence that passes tests of randomness; the number that fixes it	Section 6.5
Monte Carlo error	the scatter of a simulated average, falling as $1/\sqrt{N}$	Section 6.11.2
importance sampling	drawing from a convenient density and reweighting, with thicker tails than the target	Section 6.12
response matrix, unfolding	the probability that a true bin lands in each measured bin, learned by simulation; its regularised inversion	Section 6.14
stationary distribution	the distribution a Markov chain keeps once it has reached it	Section 9.4
detailed balance	equal probability flow each way between any two states; enough for stationarity	Section 9.4.2
Metropolis–Hastings	a random walk biased by an accept–reject step to spend more time where the probability is higher	Section 9.9.1
burn-in	the early steps that still remember the starting point	Section 9.12.1
autocorrelation time	how many steps the chain needs to produce one independent draw	Section 9.12.2
$\hat{R}$	chains from different starts compared; values above one mean they have not met	Section 9.13

Fields, forecasts and summaries

word	what it means here	built in
random field	a field whose values are random, described by their joint distribution at all points	Section 7.1
homogeneity, isotropy	the statistics do not change from place to place, or with direction	Section 7.1.2
C_ℓ, $\widehat{C}_\ell$	the variance of the harmonic coefficients at multipole ℓ; its estimate from one sky	Section 7.10
cosmic variance	the scatter of $\widehat{C}_\ell$ because only $2\ell + 1$ modes exist at each ℓ	Section 7.10.2
pseudo-C_ℓ, MASTER	the spectrum of a masked sky; its mean undone with a mode-coupling matrix	Sections 8.9.3 and 8.11
Hartlap factor	the correction for the bias of the inverse of a covariance estimated from simulations	Section 8.13.2
jackknife	a covariance from the data by leaving out one region at a time	Section 13.18
Fisher forecast	the curvature of the expected log-likelihood at a fiducial model, before any data	Section 10.1.1
noise spectrum, matched filter	the variance of the noise per frequency; the correlation of the data with a template, weighted by it	Sections 10.8.3 and 10.8.6
excursion set, Minkowski functionals	the region above a threshold; its area, boundary length and Euler characteristic	Sections 12.2 and 12.4
Betti numbers, persistence	the numbers of pieces and holes; the thresholds at which each is born and dies	Sections T3.6.2 and 12.9
ABC	inference that keeps the parameter draws whose simulated summary lands near the observed one	Section 12.29

Routes through the book. A glossary answers "what does this word mean?". A new analysis asks a different question: which chapters does it need, and in what order? The pipeline of Figure 14.6 answers by stage. A shorter answer comes from following the four instruments

of Section 14.4 through the book, one route each (Figure 14.13). The routes share their first stops, the rules of probability and the distributions that come from machines, and part ways at the stage where the instrument decides what the noise is. Each route starts from the Python of Chapter T0, which every chapter uses. Its section on numerical trust (Section T0.10) asks a question that every number in this book had to answer before it was printed: is the result a property of the data, or of the rounding, the step size and the random seed that produced it?

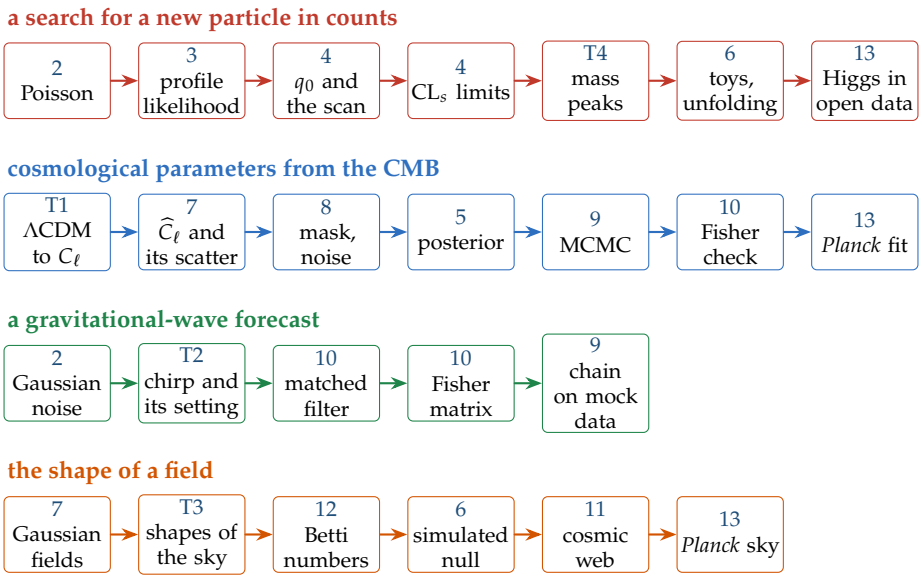

Figure 14.13: Four routes through the book, one for each instrument of Table 14.1. Each box names a chapter and what the route takes from it. All four start after the probability rules of Chapter 1 and the code of Chapter T0; they differ where the instrument fixes the noise, and they meet again in the machinery of tests, posteriors and simulations.

Recap

- The question, said in words before any symbol, fixes the direction: prediction (what can this hypothesis produce?) or inference (which hypotheses could have produced what we saw?). The direction fixes the object: a distribution, a p-value, an interval, a likelihood, a posterior, an evidence or a forecast (Section 14.1). One count of eleven events on a background of four gave eight different, correct numbers.
- The distribution of a number is chosen by the operation that made it; the method by three questions in order: are there data yet, is the sampling distribution known in closed form, and what do we want to know (Section 14.2).
- Every analysis runs the same pipeline: model, data, choice of what matters, summary, sampling distribution, inference. Formulas give the sampling distribution in the simplest cases; simulations through the same code as the data give it in research (Section 14.3).
- The likelihood is always the probability of the noise the data require. For counts it is Poisson and the parameters move the mean; for a Gaussian field the parameters move the covariance and the likelihood is Wishart; for detector noise they move the mean against a known spectrum; for elaborate summaries the distribution is simulated (Section 14.4).
- Seven traps recur: a p-value read as the probability of the null, a confidence interval read as a credible one, a Fisher forecast read as a posterior, a prior confused with a starting point, an inverted simulated covariance, a scan without a look-elsewhere correction, and

a shared calibration averaged as if it were independent (Section 14.5).

Reading the literature

- **The two schools side by side.** Kruschke, *Doing Bayesian Data Analysis*, Chapter 11 (how the stopping and testing intentions change a p-value, confidence against highest-density intervals, what sampling distributions remain good for) and Chapter 12 (estimation against model comparison for a null value). Wasserman, *All of Statistics*, §11.1 and §11.9 [Wasserman pp. 175–176, 185–189], for the postulates of each school and examples where they part.

- **The physicist's view.** Cowan, *Statistical Data Analysis*, Chapter 1 for the two meanings of probability, and the whole book as a compact reference for the frequentist toolkit of colliders.

- **Searches at colliders.** Cowan, Cranmer, Gross and Vitells on the asymptotic formulae for q_0, $\tilde{q}_\mu$ and the Asimov data set [27]; Read and Junk on CL_s [30, 31]; Gross and Vitells on the look-elsewhere effect [15]; Feldman and Cousins on unified intervals [28]; Cranmer's lectures on practical statistics for the LHC [29]; the statistics review of the Particle Data Group [114].

- **Calibrating evidence.** Sellke, Bayarri and Berger on how much a p-value can support an alternative [35]; Kass and Raftery on Bayes factors [33]; Trotta's review of Bayesian methods in cosmology [32].

- **Simulated covariances.** Hartlap, Simon and Schneider on the bias of the inverse [6]; Taylor, Joachimi and Kitching on how many simulations a covariance needs [137]; Sellentin and Heavens on the likelihood that replaces the Gaussian when the covariance is estimated [245].

- **The likelihoods of the four instruments.** Cash on Poisson fits [20]; Hamimeche and Lewis on the CMB likelihood beyond the Gaussian approximation [16]; Cutler and Flanagan on the matched-filter likelihood and Fisher matrix for inspirals [82]; Hivon et al. on pseudo-C_ℓ [140].

Chapter summary

The machinery of the book was assembled one piece at a time. Laid side by side, the pieces answer one practical question, when is each one the right one, and the answer comes in a fixed order. Say the question in words; read off the direction and the object; pick the distribution from the machine that made the number and the method from what is known and what is wanted; place the step in the pipeline; and check that the object was not built to answer a different question. The same ideas ran four very different instruments, and the same seven traps waited in all of them.

concept	operational meaning	built in
the question first	say in words what is wanted; it fixes prediction or inference	Sections 0.2 and 14.1
two directions	forward objects start from an assumed $\boldsymbol{\theta}$; backward objects start from the data and need a prior, except the likelihood	Sections 0.1 and 5.1
one count, eight answers	$n = 11$ on $b = 4$: p-value, Z, $\hat{s}$ and its error, likelihood interval, posterior, B_{10} and its bound, Asimov exposure	Section 14.1
upper limit, CL_s	when nothing is seen, the signal strengths the count excludes, protected against downward fluctuations	Section 4.16
which distribution	the operation that made the number: counted, summed, waited, multiplied, squared, divided by an estimate, or simulated	Sections 2.16 and 14.2.1
ν_{eff}	$2\langle X\rangle^2/\mathrm{Var}\,X$: a scaled χ^2 matched to simulated variance	Sections 8.12 and 14.2.1
which method	no data: forecast; no formula: simulate; then test, estimate, compare or check	Section 14.2.2
estimation vs comparison	a posterior for the effect against a model with the effect exactly zero; they need not agree	Sections 5.18.5 and 14.2.2
the pipeline	model, data, what matters, summary, $P(S \mid \boldsymbol{\theta})$, physics; each chapter builds an arrow	Sections 0.3 and 14.3
formula vs simulation	mean, covariance and shape of a summary: each either derived or measured on simulations	Sections 8.8 and 14.3
the likelihood across instruments	the probability of the noise the data require: Poisson, Wishart, Gaussian with a spectrum, simulated	Sections 0.5 and 14.4
where $\boldsymbol{\theta}$ enters	the mean (counts, waveforms, most summaries) or the covariance (a Gaussian field)	Section 14.4
p vs $\mathrm{P}(H_0 \mid d)$	at $p = 0.05$ about a third of the nulls survive; at least 0.289 for any symmetric alternative	Section 14.5.1
confidence vs credible	a procedure's coverage against a statement about this data set; they differ near boundaries	Section 14.5.2
Fisher vs posterior	Fisher is the Gaussian at the peak; the posterior is wider and skewed with few data	Section 14.5.3
start vs prior	a chain forgets its start; only data overwhelm a wrong prior	Section 14.5.4
inverse covariance	$\hat{\mathbf{C}}^{-1}$ is biased high; Hartlap fixes the mean, Hotelling gives the tail	Section 14.5.5
look-elsewhere	$1-(1-p)^M$ for M independent places; the null must describe the whole search	Section 14.5.6
shared calibration	$\sigma_c^2 + \sigma^2/K$: the common offset is a floor	Section 14.5.7
assumptions	Gaussian likelihood, independence, known covariance, one test, convergence, a harmless prior, a fair sample, a right model: each with its symptom	Section 14.5
routes	the chapters each kind of analysis needs, in order	Section 14.6
