
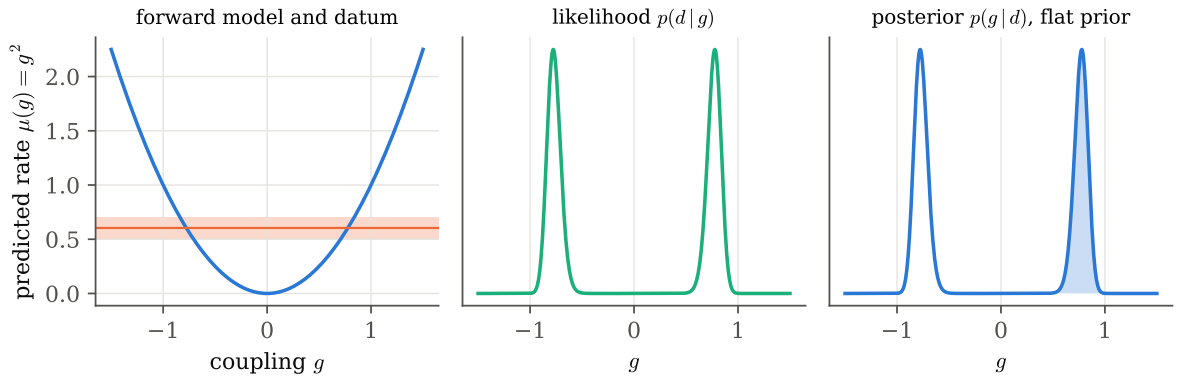

Figure 5.21: Inferring a coupling from a rate proportional to its square. Left: the forward model g^2 and the measured rate with its noise band. Two ranges of g, one on each side of zero, predict rates inside the band. Middle: the likelihood as a function of g has a peak at each of them. Right: with a flat prior the posterior has the same two peaks, and the shaded half, $g > 0$, holds exactly half the probability.

5.7.3 Many data points

A real experiment gives many readings. Let the model predict a whole data vector $\boldsymbol{m}(\lambda) = (m_1(\lambda), \ldots, m_N(\lambda))$ and let the measured values be $\boldsymbol{d} = (d_1, \ldots, d_N)$ with independent Gaussian noise of sizes σ_i. Independence means the joint density of all readings is the product of the single-reading densities [Wasserman p. 177], so

$$\ln \mathcal{L}(\lambda) \overset{(1)}{=} \ln \prod_{i=1}^{N} \frac{1}{\sqrt{2\pi\sigma_i^2}} \exp\left[-\frac{(d_i - m_i(\lambda))^2}{2\sigma_i^2}\right]$$

$$\overset{(2)}{=} -\frac{1}{2}\sum_{i=1}^{N} \frac{(d_i - m_i(\lambda))^2}{\sigma_i^2} - \frac{1}{2}\sum_{i=1}^{N} \ln(2\pi\sigma_i^2) \;=\; -\frac{1}{2}\chi^2(\lambda) + \text{const.} \tag{5.26}$$

(1) The likelihood of independent readings is the product of (5.22) over i.
(2) The log of a product is the sum of the logs, and $\ln e^x = x$.

Here $\chi^2(\lambda) = \sum_i (d_i - m_i(\lambda))^2/\sigma_i^2$ is the sum of squared residuals, each measured in units of its error bar, and the constant does not depend on λ. With correlated noise of covariance matrix $\mathbf{C}$ the product is replaced by one multivariate Gaussian and $\chi^2 = (\boldsymbol{d}-\boldsymbol{m})^{\mathsf{T}}\mathbf{C}^{-1}(\boldsymbol{d}-\boldsymbol{m})$ (Chapter 3). Either way the posterior is

$$p(\lambda \mid \boldsymbol{d}) \propto e^{-\chi^2(\lambda)/2}\, p(\lambda), \tag{5.27}$$

and nothing in the logic has changed. The observed event is now the whole vector $\boldsymbol{d}$. Each hypothesis λ is judged by how plausible the whole vector of fluctuations $\boldsymbol{d} - \boldsymbol{m}(\lambda)$ that it requires would be. Only the model for the probability of the data changes from problem to problem. With a flat prior, $p(\lambda)$ is a constant, so the peak of the posterior is where χ^2 is smallest: the least-squares estimate. Least squares is therefore the special case "flat prior, Gaussian noise" of Bayesian estimation [Sivia §3.5].

The same reasoning works at the scale of a whole survey; only the space of hypotheses grows. In cosmology $\boldsymbol{d}$ may be thousands of band powers of the CMB and λ the handful of parameters of the standard cosmological model (see the cosmology notes). What we observed is the whole data vector $\boldsymbol{d}$, every band power at once. The candidate explanations are the possible values of λ, each one a different cosmological model. For each of them the likelihood asks: had nature picked this model, how plausible would it have been for exactly the data we hold to come out? Bayes' theorem combines these likelihoods with the prior distribution and returns a posterior distribution over the models.

5.7.4 The posterior on a grid

For one or two parameters the safest way to compute a posterior is to evaluate it on a grid of values and look [Sivia §3.4, "brute force and ignorance"]. The grid works whether the posterior is skewed, has several peaks, or has a sharp edge where the prior stops. Its one trap is numerical: a product of many likelihoods is too large or too small for a computer to store.

Example: a lifetime from 2000 readings. A source decays with lifetime τ. We record the signal at $N = 2000$ times, $d_i = e^{-t_i/\tau} + \epsilon_i$ with $\sigma = 0.05$, and put a flat prior on τ. The obvious code multiplies the N Gaussian densities for each grid value of τ. Each density near the curve is about $1/(\sqrt{2\pi}\,\sigma) \approx 8$, and 8^{2000} is far beyond the largest floating-point number, so the product comes out as ∞. Now quote the same data in per cent. Every density is a hundred times smaller, about 0.08, and the product underflows to 0. The posterior cannot depend on the units the data are quoted in, so neither answer means anything. The cure is to work with logarithms [Sivia p. 34]:

1. compute $L_j = \ln \mathcal{L}(\tau_j) + \ln p(\tau_j)$ on the grid, as a *sum* of logs;
2. subtract the largest value, $L_j \to L_j - L_{\max}$, so that the largest is 0;
3. exponentiate, $w_j = e^{L_j - L_{\max}}$, which lies between 0 and 1;
4. normalise, $p(\tau_j \mid \boldsymbol{d}) = w_j / \sum_k w_k \Delta\tau$.

Step 2 is legitimate because it multiplies every w_j by the same constant $e^{-L_{\max}}$, and a common constant cancels in the normalisation of step 4. For our data $L_{\max} = 3149$: the likelihood at the peak is e^{3149}, a number no computer stores, but the *ratios* of likelihoods between grid points are perfectly ordinary numbers.

Listing 5.6: The lifetime posterior on a grid: the raw product fails, the log-sum with the maximum subtracted works (`code/ch05/08_grid_posterior.py`)

```
A, TAU_TRUE, N, SIGD = 1.0, 2.0, 2000, 0.05
t = np.sort(rng.uniform(0, 6, N))
data = A * np.exp(-t / TAU_TRUE) + SIGD * rng.standard_normal(N)
tau = np.linspace(1.9, 2.1, 801)
dtau = tau[1] - tau[0]
model = A * np.exp(-t[None, :] / tau[:, None])                  # (n_tau, N)
dens = np.exp(-(data - model) ** 2 / (2 * SIGD**2)) / np.sqrt(2 * np.pi * SIGD**2)
with np.errstate(over="ignore", under="ignore"):
    raw_max = np.prod(dens, axis=1).max()                       # overflows to inf
    # the same data quoted in per cent: every density is 100 times smaller
    raw_max_pct = np.prod(dens / 100.0, axis=1).max()           # underflows to 0
logL = np.sum(-(data - model) ** 2 / (2 * SIGD**2) - 0.5 * np.log(2 * np.pi * SIGD**2),
    axis=1)
logL_max = logL.max()
w = np.exp(logL - logL_max)                                     # flat prior on tau
post_tau = w / (w.sum() * dtau)
mean_tau = np.sum(tau * post_tau) * dtau
sd_tau = np.sqrt(np.sum((tau - mean_tau) ** 2 * post_tau) * dtau)
```

Line 63 builds the model prediction for every grid value of τ at every time at once, as an 801×2000 array, and line 64 the Gaussian density of every reading. Lines 65–68 form the raw products and show them overflow and, in per cent, underflow. Line 69 is the log-likelihood as a sum, line 71 subtracts the maximum and exponentiates, line 72 normalises, and lines 73–74 compute the posterior mean and standard deviation by summing over the grid. The result is $\tau = 1.996 \pm 0.007948$ (Figure 5.22), consistent with the true value 2 used in the simulation.

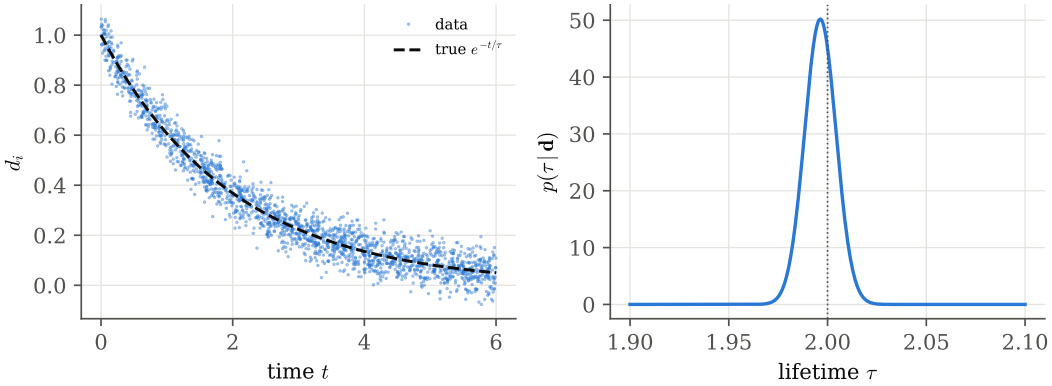

Figure 5.22: A lifetime from 2000 noisy readings. Left: the readings (dots) and the true decay curve (dashed). Right: the posterior for the lifetime computed on a grid of 801 values by summing log-likelihoods and subtracting their maximum. The dotted line marks the value used to simulate the data.

Watch out: Never multiply raw likelihoods

The product of many densities overflows or underflows depending only on the units the data are quoted in. Always sum log-likelihoods and subtract the maximum before exponentiating. The same rule applies to every sampler of Chapter 9: they compare $\ln p$ values, never p values.

A grid fails in many dimensions, because its cost grows as a power of the number of parameters. With n points per axis, a posterior in D parameters needs n^D evaluations: 100 points per axis is 10^4 evaluations in two dimensions and 10^{12} in six, the size of a minimal cosmological model. That cost, and the evidence integral it makes impossible, are what drive us to sampling methods (Chapters 6 and 9).

5.8 Conjugate priors: posteriors on the back of an envelope

For the likelihoods physicists meet most often, the product "likelihood times prior" can be worked out on paper. These are counts of successes, counts of events and Gaussian readings. A grid (Section 5.7) also gives the posterior, but only as a table of numbers. On paper the posterior comes out in the same family of curves as the prior, with a few constants shifted by the data. We can then see at a glance how much of the answer comes from the data and how much from the prior. Updating becomes bookkeeping: add the number of heads here, the number of counts there.

The question is: for which pairs of likelihood and prior does the product have the same functional form as the prior, and what are the update rules?

Working definition 5.3 (conjugate prior)

A family of prior densities is **conjugate** to a likelihood if, for every data set, prior from the family × likelihood is again a member of the family [same functional form in the parameter, different values of its constants] [Wasserman p. 179]. Conjugacy is a property of the *pair*: a prior is conjugate only with respect to a particular likelihood [Kruschke §6.2]. *Operationally:* write the likelihood as a function of the parameter, drop every factor that does not contain it, and look for a density with the same θ-dependence.

5.8.1 Coins: the Beta–Binomial pair

A coin, or any process with two outcomes, has unknown probability θ of "success". One toss $y \in \{0, 1\}$ has the Bernoulli probability $\theta^y(1-\theta)^{1-y}$, and N independent tosses with z successes have [Kruschke (6.2)]

$$p(\{y_i\} \mid \theta) \overset{(1)}{=} \prod_{i=1}^{N} \theta^{y_i}(1-\theta)^{1-y_i} \overset{(2)}{=} \theta^{\sum_i y_i}(1-\theta)^{\sum_i (1-y_i)} = \theta^z(1-\theta)^{N-z}.$$

(1) Independent tosses: the joint probability is the product.
(2) Powers of the same base multiply by adding exponents.

As a function of θ this is a power of θ times a power of $1-\theta$. A prior of the same shape is the **Beta distribution** (Chapter 2),

$$p(\theta) = \mathrm{Beta}(\theta \mid a, b) = \frac{\theta^{a-1}(1-\theta)^{b-1}}{B(a,b)}, \qquad B(a,b) = \int_0^1 \theta^{a-1}(1-\theta)^{b-1}\mathrm{d}\theta = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}, \tag{5.28}$$

with $a, b > 0$ [Kruschke (6.3)–(6.4)]. The Beta function $B(a,b)$ is only a normalising number. Recall $\Gamma(n) = (n-1)!$ for integers and $\Gamma(x+1) = x\Gamma(x)$ in general. The flat prior is $\mathrm{Beta}(1,1)$. Multiply prior and likelihood:

$$\begin{aligned} p(\theta \mid z, N) &\overset{(1)}{=} \frac{\theta^z(1-\theta)^{N-z}\ \theta^{a-1}(1-\theta)^{b-1}/B(a,b)}{p(z,N)} \overset{(2)}{=} \frac{\theta^{(z+a)-1}(1-\theta)^{(N-z+b)-1}}{B(a,b)\,p(z,N)} \\ &\overset{(3)}{=} \frac{\theta^{(z+a)-1}(1-\theta)^{(N-z+b)-1}}{B(z+a,\ N-z+b)} = \mathrm{Beta}(\theta \mid z+a,\ N-z+b). \end{aligned} \tag{5.29}$$

(1) Bayes' theorem with the Bernoulli likelihood and the Beta prior.
(2) Collect the powers of θ and of $1-\theta$.
(3) The numerator is the θ-dependence of a Beta density with parameters $z+a$ and $N-z+b$. A density must integrate to one, and there is only one constant that makes this one do

so, $B(z+a, N-z+b)$. So the denominator must be that constant, and no integral was needed [Kruschke §6.3].

The update rule is: *add the successes to a and the failures to b*. Adding is done in any order, so the result is the same whether the tosses arrive one at a time or all at once, as sequential updating requires (Section 5.5). The rule also tells us how to read a prior. Beta(a, b) behaves like the posterior we would hold after seeing about a successes and b failures. So $\kappa = a + b$ counts how many tosses' worth of information the prior carries [Kruschke §6.2.1].

The posterior mean is a compromise. The mean of a Beta density is

$$\mathbb{E}[\theta] \overset{(1)}{=} \frac{1}{B(a,b)} \int_0^1 \theta^a (1-\theta)^{b-1} \mathrm{d}\theta \overset{(2)}{=} \frac{B(a+1,b)}{B(a,b)} \overset{(3)}{=} \frac{\Gamma(a+1)\,\Gamma(a+b)}{\Gamma(a)\,\Gamma(a+b+1)} \overset{(4)}{=} \frac{a}{a+b}.$$

(1) Definition of the mean, $\int \theta\, p(\theta) \mathrm{d}\theta$, with one extra power of θ.
(2) The integral is the Beta function with $a \to a+1$.
(3) Write both Beta functions with Gammas. $\Gamma(b)$ cancels.
(4) $\Gamma(a+1) = a\Gamma(a)$ and $\Gamma(a+b+1) = (a+b)\Gamma(a+b)$.

For the posterior (5.29) this gives [Kruschke (6.9)], [Wasserman p. 179]

$$\frac{z+a}{N+a+b} \overset{(1)}{=} \frac{z}{N} \cdot \frac{N}{N+a+b} + \frac{a}{a+b} \cdot \frac{a+b}{N+a+b}. \tag{5.30}$$

(1) Multiply out the right side: the N and the $a+b$ cancel, leaving $(z+a)/(N+a+b)$.

The posterior mean is a weighted average of two numbers: the observed fraction z/N (the maximum likelihood estimate) and the prior mean $a/(a+b)$. Their weights are proportional to the number of tosses N and to the prior's worth in tosses, $\kappa = a+b$. So the data win once $N \gg \kappa$. For a flat prior, $a = b = 1$, it is $(z+1)/(N+2)$, Laplace's rule of succession [Wasserman p. 178, (11.5)–(11.6)]. For example, Kruschke's prior Beta$(5,5)$ with $z = 1$ success in $N = 10$ gives posterior mean $(1+5)/(10+10) = 0.3$, exactly halfway between the prior mean 0.5 and the data fraction 0.1, because $N = \kappa$ [Kruschke Fig. 6.3].

Example: the same data, three priors. *The event.* A two-outcome process is tried 20 times and gives 17 successes, 85%. *The question.* What should we now believe about its success probability θ? The answer depends on what we knew before, that is, on what the process is [Kruschke §6.4.1]. *Three cases in turn.* If it is a freshly minted government coin, we are confident it is fair: prior Beta$(100, 100)$, worth 200 tosses of evidence for 0.5. If a success is a professional basketball player making a free throw, we know such players make about 75% of them: prior Beta$(18.25, 6.75)$, mode 0.75 and $\kappa = 25$. If it is the colour of samples of a substance on a distant planet, we know only that both outcomes are possible: Beta$(1,1)$. *Only then the numbers.* Adding 17 to a and 3 to b, the three posteriors are Beta$(117, 103)$, Beta$(35.25, 9.75)$ and Beta$(18, 4)$, with modes 0.5321, 0.7965 and 0.85 (Figure 5.23). The 17 successes barely move the government coin, pull the basketball player just above his league's typical rate, and fully determine the planetary substance. None of the three analysts is wrong. They started from different knowledge, and twenty tosses are not enough to overwhelm a prior worth two hundred.

Example: predicting the next two tosses. Conjugacy also gives predictions in closed form. A coin gave 10 heads in 14 tosses. What is the probability that the next two tosses are both heads [Padilla §2.3, §3.1]? With a flat prior, Beta$(1,1)$, the posterior is Beta$(1+10, 1+4)$ = Beta$(11, 5)$. If

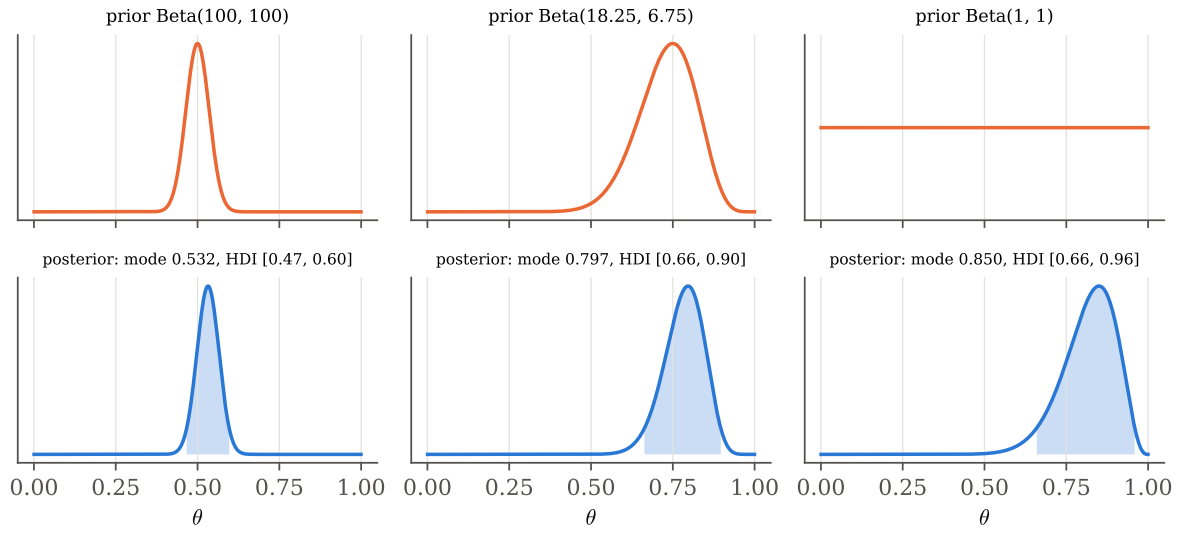

Figure 5.23: Seventeen heads in twenty tosses, analysed with three priors. Top row: a confident fair-coin prior, a basketball league's free-throw rate, and a flat prior. Bottom row: the three posteriors, each a Beta density, with the shaded 95% highest density interval (Section 5.9). The same data move the three beliefs by very different amounts.

we knew θ, two heads would have probability θ^2. We do not know θ, so we average θ^2 over the posterior, that is, we marginalise θ:

$$\mathrm{P}(\mathrm{HH} \mid \boldsymbol{d}) \overset{(1)}{=} \int_0^1 \theta^2 \, \frac{\theta^{10}(1-\theta)^4}{B(11,5)} \, \mathrm{d}\theta \overset{(2)}{=} \frac{B(13,5)}{B(11,5)} \overset{(3)}{=} \frac{12 \cdot 11}{17 \cdot 16} = 0.4853.$$

(1) Sum over the paths "θ, then two heads": the probability of HH given θ times the posterior density of θ.
(2) The integral is a Beta function with the first argument raised by two.
(3) $B(13,5)/B(11,5) = \Gamma(13)\Gamma(16)/[\Gamma(11)\Gamma(18)]$, and $\Gamma(13)/\Gamma(11) = 12 \cdot 11$, $\Gamma(18)/\Gamma(16) = 17 \cdot 16$.

Plugging in the single best value $\hat{\theta} = 10/14$ instead gives $(10/14)^2 = 0.5102$. The posterior predictive is smaller, and it is the honest answer. It remembers that θ might be lower than 10/14; the plug-in pretends that 14 tosses fixed θ exactly.

5.8.2 Counts: the Gamma–Poisson pair

A detector counts cosmic-ray muons in one-minute windows. The counts $n_1, \dots, n_M$ are Poisson with unknown rate λ per minute, so the likelihood is [Lambert (9.8)]

$$p(\{n_i\} \mid \lambda) \overset{(1)}{=} \prod_{i=1}^{M} \frac{\lambda^{n_i} e^{-\lambda}}{n_i!} \overset{(2)}{=} \frac{\lambda^{\sum_i n_i} \, e^{-M\lambda}}{\prod_i n_i!} \;\propto\; \lambda^{S} e^{-M\lambda}, \qquad S = \sum_i n_i .$$

(1) Independent windows: the product of Poisson probabilities.
(2) Add the exponents of λ, and M copies of $e^{-\lambda}$ make $e^{-M\lambda}$. The factorials do not contain λ.

A power of λ times a decaying exponential in λ is the shape of the **Gamma distribution**, $\mathrm{Gamma}(\lambda \mid \alpha, \beta) = \beta^{\alpha} \lambda^{\alpha-1} e^{-\beta\lambda} / \Gamma(\alpha)$ for $\lambda > 0$, with mean α/β and variance α/β^2 (Chapter 2). Multiplying,

$$p(\lambda \mid \{n_i\}) \overset{(1)}{=} \lambda^{S} e^{-M\lambda} \cdot \lambda^{\alpha-1} e^{-\beta\lambda} \overset{(2)}{=} \lambda^{(\alpha+S)-1} e^{-(\beta+M)\lambda} \;\Rightarrow\; \lambda \mid \{n_i\} \sim \mathrm{Gamma}(\alpha + S,\ \beta + M). \tag{5.31}$$

(1) Posterior $\propto$ likelihood $\times$ prior, dropping constants.
(2) Collect powers and exponents. The normalisation follows as in the Beta case.

The rule is: *add the total count to α and the number of windows to β* [Lambert (9.11)]. So Gamma(α, β) is like having already seen about α counts in β windows, and the posterior mean $(\alpha + S)/(\beta + M)$ is again a weighted average, of the prior mean α/β and the observed mean S/M.

Example: the muon rate. A previous run suggested "about 3 per minute, not very sure": prior Gamma$(3, 1)$, mean 3, standard deviation $\sqrt{3} \approx 1.7$. Five windows gave $3, 5, 7, 4, 9$ counts, total $S = 28$, observed mean 5.6. The posterior is Gamma$(31, 6)$ with mean 5.167 and standard deviation 0.928: pulled a little from the data's 5.6 towards the prior's 3, since the prior is worth one window against the data's five (Figure 5.24, middle).

5.8.3 Gaussian readings: inverse-variance weighting emerges

Several laboratories measure the same quantity μ with different instruments. Reading x_k has Gaussian error σ_k, and we have a Gaussian prior $\mathcal{N}(a, b^2)$ of mean a and width b. We work with the logarithm, because the log of a product of Gaussians is a sum of squares, which is easy to collect. Up to constants that do not contain μ,

$$\begin{aligned} -2\ln p(\mu \mid \{x_k\}) &\overset{(1)}{=} \sum_k \frac{(x_k-\mu)^2}{\sigma_k^2} + \frac{(\mu-a)^2}{b^2} \\ &\overset{(2)}{=} \mu^2\Big(\sum_k w_k + \frac{1}{b^2}\Big) - 2\mu\Big(\sum_k w_k x_k + \frac{a}{b^2}\Big) + \text{const} \\ &\overset{(3)}{=} P\,(\mu - m)^2 + \text{const}, \qquad P = \sum_k w_k + \frac{1}{b^2}, \quad m = \frac{\sum_k w_k x_k + a/b^2}{P}. \end{aligned} \tag{5.32}$$

(1) Log of Gaussian likelihoods times a Gaussian prior, multiplied by -2.
(2) Expand the squares and write $w_k = 1/\sigma_k^2$. Terms without μ go into the constant.
(3) Complete the square: $P\mu^2 - 2\mu P m = P(\mu - m)^2 - Pm^2$, and Pm^2 is a constant.

The posterior is therefore Gaussian, $\mu \mid \{x_k\} \sim \mathcal{N}(m, 1/P)$ [Wasserman p. 179, (11.7)]. Two rules have appeared by themselves.

- *Precisions add.* The precision (inverse variance) of the posterior is the sum of the precisions of the measurements and of the prior.
- *Means are precision-weighted.* Each measurement counts in proportion to $1/\sigma_k^2$, and the prior counts as one more measurement, of value a and error b.

With a very broad prior, $b \to \infty$, we get the familiar inverse-variance weighted mean $\bar{\mu} = \sum_k w_k x_k / \sum_k w_k$ with error $(\sum_k w_k)^{-1/2}$ [Sivia (2.30)–(2.31)]. For N equal errors this is the sample mean with error $\sigma/\sqrt{N}$. Wasserman writes the same result as $m = w\bar{X} + (1 - w)a$ with $w = (1/\mathrm{se}^2)/(1/\mathrm{se}^2 + 1/b^2)$ and $\mathrm{se} = \sigma/\sqrt{n}$ [Wasserman p. 179].

Example: three laboratories. Three simulated measurements are 10.2 ± 0.5, 9.936 ± 1.0 and 10.07 ± 2.0, and a vague earlier estimate gives the prior $\mathcal{N}(8, 3^2)$. The posterior is $\mu = 10.1 \pm 0.4319$. Without the prior, the inverse-variance weighted mean is 10.15 ± 0.4364. The prior counts as one more measurement, of error 3. It shifts the answer by a tenth of its error bar and shrinks the error bar slightly (Figure 5.24, right).

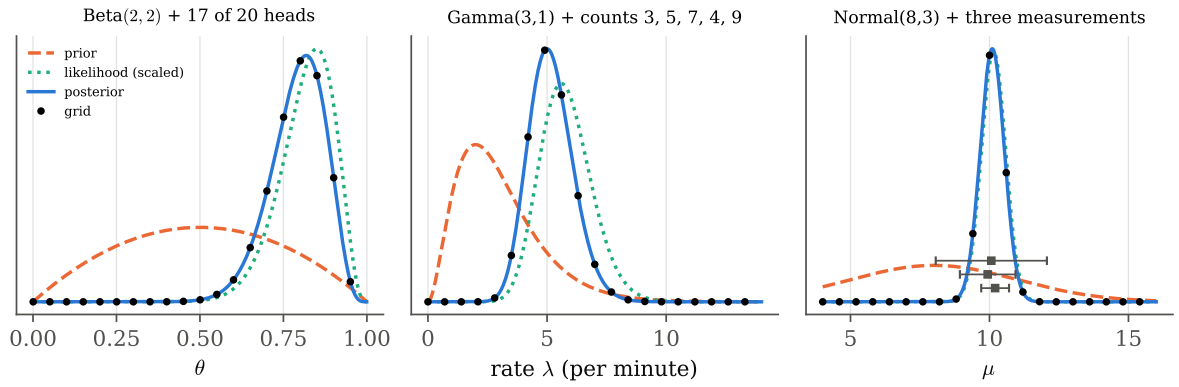

Figure 5.24: The three conjugate pairs. In each panel the dashed curve is the prior, the dotted curve the likelihood (scaled to unit area), the solid curve the closed-form posterior and the dots the posterior computed by brute force on a grid. Left: a Beta prior and 17 heads in 20. Middle: a Gamma prior and five minutes of muon counts. Right: a Gaussian prior and three measurements with different error bars (squares with bars). The dots lie on the curves, to a relative accuracy of 10^{-11}.

The update rules are exact, and the grid check in Figure 5.24 confirms it. The largest relative difference between the brute-force and closed-form posteriors is 1.247×10^{-11} for the Beta case, 1.018×10^{-11} for the Gamma case and 2.260×10^{-14} for the Gaussian case: pure round-off.

Taxonomy: common conjugate pairs

likelihood (data)	conjugate prior	posterior
Bernoulli/binomial (z of N)	Beta(a, b)	Beta$(a + z,\ b + N - z)$
Poisson (total S in M windows)	Gamma(α, β)	Gamma$(\alpha + S,\ \beta + M)$
multinomial (counts $\boldsymbol{n}$)	Dirichlet$(\boldsymbol{\alpha})$	Dirichlet$(\boldsymbol{\alpha} + \boldsymbol{n})$
Gaussian, known σ_k	$\mathcal{N}(a, b^2)$	$\mathcal{N}(m, 1/P)$, (5.32)
Gaussian, known mean, variance v	Inv-Gamma(α, β)	Inv-Gamma$\left(\alpha + \frac{N}{2},\ \beta + \frac{1}{2}\sum(x_i - \mu)^2\right)$

Sources: [Lambert Table 9.1], [Wasserman pp. 178–179]. The last row is the one used for a power-spectrum amplitude below.

The limits of conjugacy. Conjugate pairs exist only for a handful of simple likelihoods, and even then only priors of one particular shape are allowed. A coin factory that makes coins biased either near 0.25 or near 0.75 has a two-humped prior that no Beta density can represent. Its posterior after 14 heads in 27 has three bumps, a compromise between the two humps of the prior and the single peak of the likelihood, and must be computed on a grid [Kruschke §6.4.2]. Likewise, replacing a Gaussian likelihood by a more robust Student-t destroys conjugacy altogether [Lambert §9.7]. The lesson is not to bend the model to fit a conjugate prior. Conjugacy is a source of exact test cases and of intuition. Realistic models are handled by grids in low dimension and by sampling (Chapter 9) in high dimension.

5.8.4 One calculation, three instruments

The same few lines of algebra appear in three very different corners of physics. Only the likelihood changes: counts at a collider are Poisson, a CMB map is a Gaussian random field, and a gravitational-wave strain is a known waveform in Gaussian noise described by a power spectral density (Figure 5.25).

A collider search with no background. A search for a rare process expects s signal events and, after cuts, essentially no background. The number observed is Poisson with mean s. Suppose nothing is seen. How large could s be? The flat prior on $s \geq 0$ is the Gamma$(1,0)$ limit, and the search is a single window, so the Gamma update (5.31) with n events gives $s \mid n \sim \text{Gamma}(n+1,1)$. For $n=0$ the posterior is e^{-s}. The 95% credible upper limit s_{95} is the value below which s lies with probability 95%, so it solves

$$0.95 \overset{(1)}{=} \int_0^{s_{95}} e^{-s}\,\mathrm{d}s \overset{(2)}{=} 1 - e^{-s_{95}} \quad \Rightarrow \quad s_{95} = \ln 20 = 2.996.$$

(1) The posterior probability that s is below the limit is 95%.
(2) Elementary integral.

This is the famous "three events" upper limit for an empty search. With one or three events observed the limits are 4.744 and 7.754.

The CMB: a power-spectrum amplitude from $2\ell+1$ numbers. The temperature map is expanded in spherical harmonics, and at multipole ℓ the coefficients $a_{\ell m}$ amount to $2\ell+1$ independent real Gaussian numbers of zero mean and variance C_ℓ (see the cosmology notes, and Chapter 7). Their likelihood is

$$p(\{a_{\ell m}\} \mid C_\ell) \overset{(1)}{=} \prod_{m=-\ell}^{\ell} \frac{e^{-|a_{\ell m}|^2/2C_\ell}}{\sqrt{2\pi C_\ell}} \;\propto\; C_\ell^{-(2\ell+1)/2} \exp\!\left[-\frac{(2\ell+1)\widehat{C}_\ell}{2C_\ell}\right], \qquad \widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2.$$

(1) $2\ell+1$ independent Gaussians of variance C_ℓ, and the sum of their squares written through the estimator $\widehat{C}_\ell$.

As a function of C_ℓ this is an inverse power times $e^{-\text{const}/C_\ell}$. That is the shape of an inverse-Gamma density, the last row of the table. With the scale-invariant prior $p(C_\ell) \propto 1/C_\ell$ (Section 5.12) the posterior is Inv-Gamma$\big(\frac{2\ell+1}{2}, \frac{(2\ell+1)\widehat{C}_\ell}{2}\big)$. For the quadrupole, $\ell=2$, only five numbers exist in the whole sky. The posterior of $C_\ell/\widehat{C}_\ell$ has its mode at 0.7143, its mean at 1.667, and its central 68% interval from 0.6303 to 2.421. So five numbers cannot pin the quadrupole power to better than a factor of about two, however good the telescope. This is cosmic variance seen as a posterior. At $\ell = 50$ the interval has shrunk to $[0.8776, 1.162]$ and the posterior is nearly Gaussian.

A gravitational-wave amplitude. A detector records $d = A\,h_0 + n$, where h_0 is a known waveform, A an unknown amplitude and n stationary Gaussian noise with power spectral density $S_n(f)$. The likelihood is $\mathcal{L} \propto \exp[-\tfrac{1}{2}(d - Ah_0 \mid d - Ah_0)]$ with the noise-weighted inner product $(a|b) = 4\,\mathrm{Re}\int_0^\infty \tilde{a}\tilde{b}^*/S_n\,\mathrm{d}f$ (Chapter 3). The inner product is linear in each slot, so

$$(d - Ah_0 \mid d - Ah_0) \overset{(1)}{=} (d|d) - 2A\,(d|h_0) + A^2\,(h_0|h_0) \overset{(2)}{=} (h_0|h_0)\,\big(A - \hat{A}\big)^2 + \text{const},$$
$$\hat{A} = \frac{(d|h_0)}{(h_0|h_0)}.$$

(1) Expand, using $(h_0|d) = (d|h_0)$ for the real inner product.
(2) Complete the square in A.

The posterior for A with a flat or Gaussian prior is Gaussian, centred on the matched-filter estimate $\hat{A}$, with standard deviation $1/\sqrt{(h_0|h_0)}$. For our toy chirp in coloured noise, normalised to $(h_0|h_0) = 100$, the posterior is $A = 1.06 \pm 0.1$ for true $A = 1$, and over 4000 independent noise realisations the estimate $\hat{A}$ scatters by 0.1008, the posterior width, as it should.

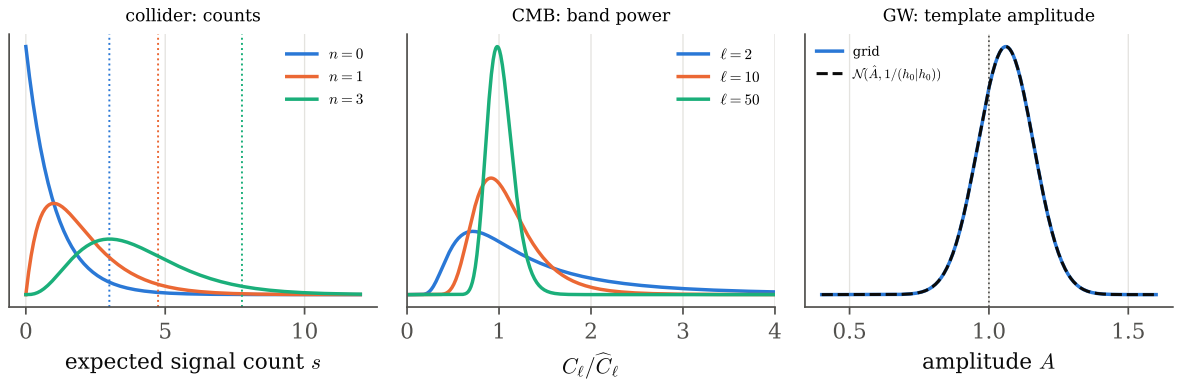

Figure 5.25: One posterior calculation in three instruments. Left: a background-free collider search, posterior for the expected signal after 0, 1 and 3 observed events, with the 95% upper limits dotted. Middle: the posterior of a CMB band power relative to its estimate, for $\ell = 2$, 10 and 50. The quadrupole's posterior is broad and skewed. Right: the amplitude of a known gravitational-wave template in coloured noise, computed on a grid (solid) and from the closed form (dashed).

How this is used in real research: closed forms inside large analyses

Conjugate results survive as building blocks inside big pipelines. Collider limits for counting experiments are routinely quoted as Bayesian upper limits with a flat prior on the signal rate, exactly the Gamma calculation above, and physicists check them against frequentist constructions (Chapter 4). CMB likelihoods at low ℓ use the exact inverse-Gamma shape rather than a Gaussian, because the quadrupole's posterior is far from Gaussian (Chapter 7). Gravitational-wave pipelines marginalise analytically over parameters that enter linearly, such as an amplitude or a phase, before sampling the rest (Chapter 9). Everywhere, the closed forms are also the test cases that a new sampler must reproduce.

5.9 Summarising a posterior: best values and credible intervals

The posterior is the complete answer: every statement we can make about the parameter is an integral of it. But papers quote only a handful of numbers, such as "$\theta = 0.28 \pm 0.08$" or "$s < 3$ events at 95%". A decision, such as building the next detector or claiming a discovery, also needs one number or one interval. So which numbers should we quote, and what exactly does each one mean?

Our running example is the posterior of the CMB quadrupole power C_2 from Section 5.8. There the five numbers a_{2m} ($m = -2, \dots, 2$) measured over the whole sky gave an inverse-Gamma posterior. Write it in terms of the ratio $x = C_2/\widehat{C}_2$ of the power to its estimate $\widehat{C}_2 = \frac{1}{5}\sum_m |a_{2m}|^2$. Then its parameters are $\alpha = \beta = 5/2$, and it is strongly skewed, with a long tail to large x (Figure 5.27, left).

5.9.1 Three best values, three losses

There are three standard point summaries [Lambert §7.6]: the **posterior mean** $\mathbb{E}[\theta \mid \boldsymbol{d}] = \int \theta\, p(\theta \mid \boldsymbol{d}) \mathrm{d}\theta$ [Wasserman p. 177, (11.4)], the **posterior median** (half the probability on each side), and the **posterior mode** or MAP, *maximum a posteriori*, the highest point of the density. For a

symmetric single-peaked posterior they coincide. For the quadrupole they are

$$\text{mode } 0.7143, \qquad \text{median } 1.149, \qquad \text{mean } 1.667.$$

Which one is "right"? Each is the best answer to a different question: what does it cost us to be wrong? Suppose we must announce one number M, and we pay a penalty $\text{loss}(\theta - M)$ if the truth turns out to be θ. We do not know θ, so we average the penalty over the posterior. The expected penalty is $R(M) = \int \text{loss}(\theta - M)\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta$, and the best M is the one that makes it smallest [Kruschke §4.3.3]. We take three penalties in turn.

Squared loss gives the mean. With $\text{loss} = (\theta - M)^2$,

$$\frac{\mathrm{d}R}{\mathrm{d}M} \overset{(1)}{=} \int \frac{\partial}{\partial M}(\theta - M)^2\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta \overset{(2)}{=} -2 \int (\theta - M)\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta \overset{(3)}{=} -2\big(\mathbb{E}[\theta \mid \boldsymbol{d}] - M\big),$$

(1) Differentiate under the integral, since the limits do not depend on M.
(2) $\partial_M(\theta - M)^2 = -2(\theta - M)$.
(3) Split the integral: $\int \theta p\, \mathrm{d}\theta$ is the mean and $\int M p\, \mathrm{d}\theta = M$ because p is normalised.

which vanishes at $M = \mathbb{E}[\theta \mid \boldsymbol{d}]$. A large miss costs the square of its size, so the rare values far out in a long tail weigh heavily, and they drag the answer towards that tail.

Absolute loss gives the median. With $\text{loss} = |\theta - M|$,

$$\frac{\mathrm{d}R}{\mathrm{d}M} \overset{(1)}{=} \int_{-\infty}^{M} p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta - \int_{M}^{\infty} p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta \overset{(2)}{=} \mathrm{P}(\theta < M \mid \boldsymbol{d}) - \mathrm{P}(\theta > M \mid \boldsymbol{d}),$$

(1) $\partial_M|\theta - M|$ is $+1$ for $\theta < M$ and -1 for $\theta > M$.
(2) Each integral of the density over a half-line is a probability.

which vanishes when half the probability lies on each side: the median.

"All or nothing" gives the mode. If we win only when M lands within a tiny window $\pm\delta$ of the truth, the expected reward is $\int_{M-\delta}^{M+\delta} p\, \mathrm{d}\theta \approx 2\delta\, p(M \mid \boldsymbol{d})$, largest where the density is highest: the MAP.

The mode is the easiest to compute. The evidence does not depend on θ, so the mode is simply the maximum of likelihood times prior, and no normalisation is needed. With a flat prior it is the maximum-likelihood estimate. But it is the most fragile of the three, for two reasons. First, it depends on the parametrisation: a density changes shape when the axis is stretched (Section 5.12). Second, for a skewed posterior it can sit far from the bulk of the probability. For the quadrupole, 78% of the posterior probability lies *above* the mode.

The median does not have the first weakness. If $y = g(\theta)$ is increasing, the median of y is g of the median of θ. The reason is that "half the probability lies below" is a statement about the probabilities of corresponding intervals, and a change of variable does not alter those. Lambert ranks the mean first, the median second and the MAP last [Lambert §7.6]. Whichever is quoted, say which one it is, and give an interval with it.

5.9.2 Credible intervals

A **credible interval** of level $1 - \alpha$ is any region holding posterior probability $1 - \alpha$. Many regions do so, and two conventions pick one of them.

The **equal-tailed interval** (ETI) puts probability $\alpha/2$ in each tail: find a, b with $\int_{-\infty}^{a} p\,\mathrm{d}\theta = \int_{b}^{\infty} p\,\mathrm{d}\theta = \alpha/2$ [Wasserman p. 178]. It is the interval between two quantiles, easy to compute from a cumulative distribution or from samples (Section 5.14), and, like the median, it maps onto itself under any increasing change of variable.

The **highest density interval** (HDI) instead takes the most credible values first [Kruschke §4.3.4]. Picture the posterior curve as a landscape, with a water level W that is lowered from above. The HDI is the set of θ that stick out above the water, $p(\theta \mid \boldsymbol{d}) > W$, with W lowered until that set holds probability $1 - \alpha$ (Figure 5.26).

Working definition 5.4 (highest density interval)

The $(1-\alpha)$ **HDI** is the set $\{\theta : p(\theta \mid \boldsymbol{d}) > W\}$, where the level W is chosen so that $\int_{p>W} p(\theta \mid \boldsymbol{d})\,\mathrm{d}\theta = 1 - \alpha$. Every point inside has higher density than every point outside [so it contains the most credible values]. For a single-peaked posterior it is the *shortest* interval with probability $1 - \alpha$ [Sivia (2.21)]. For a posterior with several peaks it can be several disjoint intervals. *Operationally:* on a grid, sort the grid values by density and accumulate them from the top until the probability reaches $1 - \alpha$. From samples, take the shortest interval that contains a fraction $1 - \alpha$ of the sorted samples.

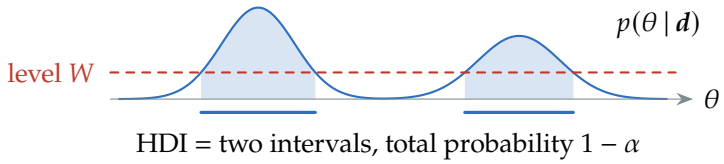

Figure 5.26: The highest density interval as a water level. The level W is lowered until the parts of the posterior above it (shaded) hold probability $1 - \alpha$. Every value inside the shaded region is more credible than every value outside. With two peaks, the HDI is two separate intervals.

Why the HDI is the shortest interval. For a single-peaked density, look for the shortest interval $[a, b]$ with fixed probability $F(b) - F(a) = 1 - \alpha$, where F is the cumulative distribution. Minimise $b - a$ with a Lagrange multiplier η for the constraint:

$$0 \overset{(1)}{=} \frac{\partial}{\partial a}\Big[(b-a) - \eta\big(F(b) - F(a) - (1-\alpha)\big)\Big] \overset{(2)}{=} -1 + \eta\, p(a), \qquad 0 \overset{(3)}{=} \frac{\partial}{\partial b}\Big[\cdots\Big] = 1 - \eta\, p(b),$$

(1) Stationarity of the Lagrangian with respect to the lower end.
(2) $\partial_a F(a) = p(a)$, the density at the lower end.
(3) The same with respect to the upper end.

So $p(a) = p(b) = 1/\eta$: the shortest interval has the same density at both ends. That is exactly the water level picture, with the level at height $1/\eta$. For a skewed posterior the two conventions therefore differ. The HDI is shifted towards the peak and has unequal tails. The ETI has equal tails and unequal densities at its ends.

Example: the quadrupole. Recall that $x = C_2/\widehat{C}_2$ is the quadrupole power relative to its estimate. Its 95% ETI is $[0.3896, 6.015]$ and its 95% HDI is $[0.2294, 4.389]$, at water level $W = 0.02375$ (Figure 5.27, left). The HDI is shorter and starts lower. Why? Values of x between 0.2294 and 0.3896 have higher density than values near 6.015, yet the ETI leaves out the former and keeps the latter [Kruschke §12.1.2.2]. From 10^5 posterior samples, the shortest interval containing 95% of them is $[0.2275, 4.356]$, the same up to sampling noise.

The HDI has a price: it depends on the variable it is computed in. Compute the HDI of the same posterior in the variable $y = \ln x$ and map its ends back to x. It becomes $[0.348, 5.054]$, a different interval. The reason is that the HDI is built from density heights, and heights change when the axis is stretched. The ETI is built from probabilities of intervals, so it is the same whichever variable it is computed in. Kruschke still prefers the HDI whenever the parameter has a natural scale, because on that scale it is the interval of the most credible values.

Example: two peaks. The coupling posterior of Section 5.7 has two peaks at $g = \pm 0.7772$. Its 68% HDI is two intervals, $[-0.8394, -0.7096] \cup [0.7096, 0.8394]$ (Figure 5.27, right). Its posterior mean is 0.000, in the gap between the peaks, where the posterior density is essentially zero. So the mean is the one value of g that the data rule out most firmly [Sivia §2.2, Fig. 2.6]. When a posterior has several peaks, no single number is an honest summary. Quote each peak with its own interval, or show the curve. Lambert's pirate makes the same point with money: if treasure is buried along a beach with a two-humped posterior, digging up the split HDI costs less than digging the whole central interval for the same chance of finding the gold [Lambert §7.7.2].

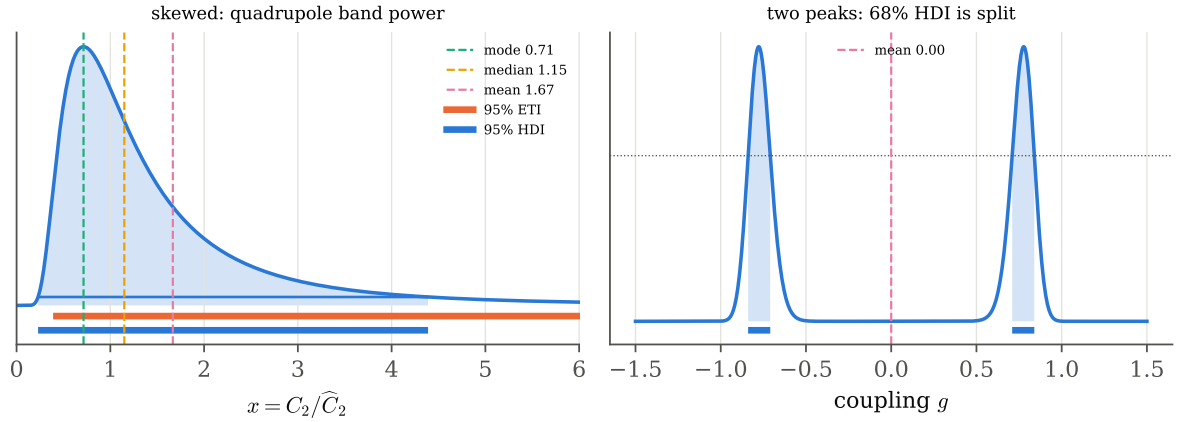

Figure 5.27: Summaries of two posteriors. Left: the skewed posterior of the quadrupole power relative to its estimate, with its mode, median and mean (vertical dashed lines), the 95% equal-tailed interval (upper bar, orange) and the 95% HDI (lower bar, blue, shaded, with its water level). Right: the two-peaked coupling posterior. Its 68% HDI is two intervals, and its mean falls in the gap between the peaks.

5.9.3 What a credible interval says, and what a confidence interval says

A 95% credible interval makes a direct statement about the parameter: given these data and this prior, the probability that θ lies in the interval is 0.95. A 95% confidence interval (Chapters 3 and 4) makes a statement about a procedure: if the experiment were repeated many times, intervals built this way would cover the fixed true value in 95% of the repetitions [Lambert §7.7]. The two are different statements and need not agree. Often, though, the numbers are the same. For a Gaussian likelihood and a flat or broad prior the posterior is $\mathcal{N}(\bar{\theta}, \tau^2)$ with $\bar{\theta} \approx \hat{\theta}$ and $\tau \approx \mathrm{se}$, where $\hat{\theta}$ is the maximum-likelihood estimate and se its standard error. So the 95% credible interval $\bar{\theta} \pm 1.96\tau$ is approximately the frequentist $\hat{\theta} \pm 1.96\,\mathrm{se}$ [Wasserman p. 179]. For large samples this agreement is general (Section 5.10). For small samples, skewed posteriors, parameters near a physical boundary, or informative priors, they can differ substantially, and in high dimensions a 95% credible region need not cover the truth 95% of the time [Wasserman p. 189].

Watch out: Credible is not confidence

"The parameter lies in $[a, b]$ with 95% probability" is a correct reading of a credible interval and an incorrect reading of a confidence interval. Conversely, "this interval covers the truth in 95% of repeated experiments" is guaranteed for a confidence interval and not, in general, for a credible interval. When a result is quoted, say which kind it is, and for a credible interval say which prior was used and whether it is an HDI or an equal-tailed interval.

5.10 The Gaussian approximation: a peak and its curvature

Most posteriors in a mature experiment look like a single smooth bump. Then two numbers describe the whole curve well: where the bump is and how wide it is. The result is quoted as "$\theta = \theta_0 \pm \sigma$". Where do these two numbers come from, in one parameter and in many? And when does this description mislead?

5.10.1 One parameter

We work with the logarithm of the posterior, $L(\theta) = \ln p(\theta \mid \boldsymbol{d})$, for two reasons. It turns products of likelihoods into sums. And near a peak it varies much more gently than the posterior itself, so a short Taylor series describes it well [Sivia (2.10)]. Let θ_0 be the peak, so $L'(\theta_0) = 0$ and $L''(\theta_0) < 0$, and Taylor-expand about it:

$$\begin{aligned} L(\theta) &\overset{(1)}{=} L(\theta_0) + L'(\theta_0)(\theta - \theta_0) + \tfrac{1}{2}L''(\theta_0)(\theta - \theta_0)^2 + \dots \\ &\overset{(2)}{=} L(\theta_0) - \frac{(\theta - \theta_0)^2}{2\sigma^2} + \dots, \qquad \sigma \equiv \left(-L''(\theta_0)\right)^{-1/2}. \end{aligned} \tag{5.33}$$

(1) Taylor's theorem to second order about θ_0.
(2) The linear term vanishes at a maximum, and $L''(\theta_0)$ is negative, so we may write it as $-1/\sigma^2$.

Exponentiate and drop the higher terms. The exponential of $-(\theta - \theta_0)^2/2\sigma^2$ is a Gaussian, so $p(\theta \mid \boldsymbol{d}) \approx \mathcal{N}(\theta_0, \sigma^2)$ [Sivia (2.13)–(2.15)]. This is the **Gaussian** or **Laplace approximation**. In words: the error bar is one over the square root of the curvature of the log-posterior at its peak. A sharply curved peak means a small error bar. Within the approximation, $\theta_0 \pm \sigma$ holds 68% of the probability and $\theta_0 \pm 2\sigma$ holds 95%.

Example: Gaussian readings. For N readings of equal error σ_x and a flat prior, $L = \text{const} - \sum_k (x_k - \mu)^2/2\sigma_x^2$. Then $L' = \sum_k (x_k - \mu)/\sigma_x^2 = 0$ gives $\mu_0 = \bar{x}$, and $L'' = -N/\sigma_x^2$ gives $\sigma = \sigma_x/\sqrt{N}$ [Sivia (2.28)–(2.29)]. Here the expansion is exact, because L is a quadratic and all higher derivatives vanish.

Example: the coin. With a flat prior and R heads in N tosses, $L = \text{const} + R\ln\theta + (N-R)\ln(1-\theta)$ [Sivia (2.17)]. Then

$$\begin{aligned} L'(\theta) &\overset{(1)}{=} \frac{R}{\theta} - \frac{N-R}{1-\theta} = 0 \;\Rightarrow\; \theta_0 = \frac{R}{N}, \\ L''(\theta_0) &\overset{(2)}{=} -\frac{R}{\theta_0^2} - \frac{N-R}{(1-\theta_0)^2} \overset{(3)}{=} -\frac{N}{\theta_0} - \frac{N}{1-\theta_0} \overset{(4)}{=} -\frac{N}{\theta_0(1-\theta_0)}, \end{aligned}$$

(1) Differentiate the logs, and solve $R(1-\theta_0) = (N-R)\theta_0$.

(2) Differentiate once more.
(3) Substitute $R = N\theta_0$ and $N - R = N(1-\theta_0)$.
(4) Common denominator: $\frac{1}{\theta_0} + \frac{1}{1-\theta_0} = \frac{1}{\theta_0(1-\theta_0)}$.

so $\sigma = \sqrt{\theta_0(1-\theta_0)/N}$ [Sivia (2.19)–(2.20)], the familiar binomial error. The width shrinks like $1/\sqrt{N}$. At fixed N it is largest for $\theta_0 = \frac{1}{2}$, so it is easier to show that a coin is strongly biased than to show that it is fair.

How good is the approximation? It depends on the data. For 9 heads in 32 tosses it gives $\theta = 0.2812 \pm 0.07948$. The exact posterior is a Beta density (Section 5.8) with mean 0.2941 and standard deviation 0.07702, so the two agree well (Figure 5.28, left). For 1 head in 10 the approximation gives 0.1 ± 0.09487. It puts 0.1459 of its probability at $\theta < 0$, which is impossible. The exact posterior is squeezed against the boundary $\theta = 0$ and skewed, with mean 0.1667. So near a physical boundary, and with few data, an error bar is the wrong summary: quote an interval from the posterior itself (Section 5.9).

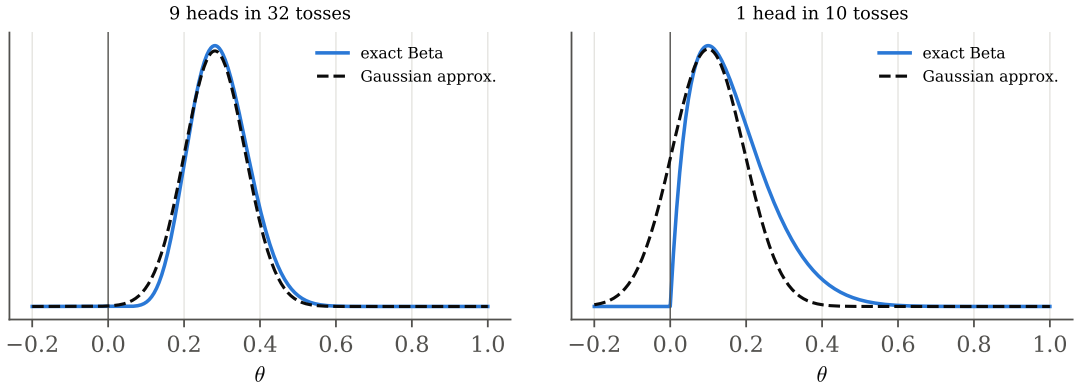

Figure 5.28: The Gaussian approximation (dashed) against the exact posterior (solid) for a coin with a flat prior. Left: 9 heads in 32 tosses, where the two nearly agree. Right: 1 head in 10 tosses, where the exact posterior is pressed against the boundary $\theta = 0$ and the Gaussian spills probability into the impossible region to its left.

5.10.2 Several parameters: the Hessian and its inverse

With parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$ the same expansion about the peak $\boldsymbol{\theta}_0$ reads [Sivia (3.30)–(3.31)]

$$L(\boldsymbol{\theta}) \approx L(\boldsymbol{\theta}_0) + \tfrac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\theta}_0)^{\mathsf{T}} \mathbf{H} (\boldsymbol{\theta} - \boldsymbol{\theta}_0), \qquad H_{ij} = \left.\frac{\partial^2 L}{\partial\theta_i\,\partial\theta_j}\right|_{\boldsymbol{\theta}_0}, \tag{5.34}$$

where the linear term has again vanished because $\boldsymbol{\theta}_0$ is the peak. The matrix $\mathbf{H}$ of second derivatives is the **Hessian**. Exponentiating, the posterior is approximately a multivariate Gaussian with covariance matrix $\mathbf{C} = -\mathbf{H}^{-1}$ [Sivia (3.32)], just as $\sigma^2 = -1/L''$ in one dimension. Its contours are ellipses (ellipsoids in more dimensions). Their axes point along the eigenvectors of $\mathbf{H}$, and their lengths are proportional to $|h_i|^{-1/2}$, where h_i are the eigenvalues of $\mathbf{H}$ [Sivia Fig. 3.6]. The peak really is a maximum only if all eigenvalues are negative.

Example: two parameters, done by hand. Write the second derivatives at the peak as $A = \partial_X^2 L$, $B = \partial_Y^2 L$, $C = \partial_X \partial_Y L$ [Sivia (3.19)]. A maximum needs $A < 0$, $B < 0$ and $AB > C^2$. The inverse of

a 2×2 matrix is $\left(\begin{smallmatrix} A & C \\ C & B \end{smallmatrix}\right)^{-1} = \frac{1}{AB-C^2}\left(\begin{smallmatrix} B & -C \\ -C & A \end{smallmatrix}\right)$, so

$$\mathbf{C} = -\mathbf{H}^{-1} \overset{(1)}{=} \frac{1}{C^2 - AB}\begin{pmatrix} B & -C \\ -C & A \end{pmatrix}, \qquad \sigma_X^2 \overset{(2)}{=} \frac{B}{C^2-AB}, \quad \sigma_Y^2 = \frac{A}{C^2-AB}, \quad \sigma_{XY} \overset{(3)}{=} \frac{C}{AB-C^2}. \tag{5.35}$$

(1) The 2×2 inverse, with the overall minus sign absorbed into the denominator.
(2) The diagonal entries are the variances. Both B and $C^2 - AB$ are negative, so $\sigma_X^2 > 0$ [Sivia (3.21)–(3.22)].
(3) The off-diagonal entry is the covariance [Sivia (3.27)].

The correlation coefficient is $\rho = \sigma_{XY}/(\sigma_X\sigma_Y) = C/\sqrt{AB}$.

There are two different error bars for X, and they answer different questions. The **marginal** error σ_X of (5.35) answers: how far can X move if Y may be anything the data permit (Section 5.11)? The **conditional** error answers: how far can X move if Y is held fixed at its best value? With Y fixed, only the curvature in X matters, so $\sigma_{X|Y} = (-A)^{-1/2}$. How much smaller is the second? Their ratio is

$$\frac{\sigma_X^2}{\sigma_{X|Y}^2} \overset{(1)}{=} \frac{B}{C^2-AB}(-A) \overset{(2)}{=} \frac{AB}{AB-C^2} \overset{(3)}{=} \frac{1}{1-\rho^2} \geq 1.$$

(1) Divide (5.35) by $1/(-A)$.
(2) Multiply numerator and denominator by -1.
(3) Divide numerator and denominator by AB and use $\rho^2 = C^2/(AB)$.

So holding a correlated parameter fixed always makes the error bar look smaller, by a factor $\sqrt{1-\rho^2}$. With $\rho = 0.95$ the conditional error is a third of the honest one [Sivia Fig. 3.8]. Figure 5.29 shows the geometry. The conditional error is the width of a horizontal slice through the centre of the ellipse. The marginal error is the width of the ellipse's shadow on the X axis.

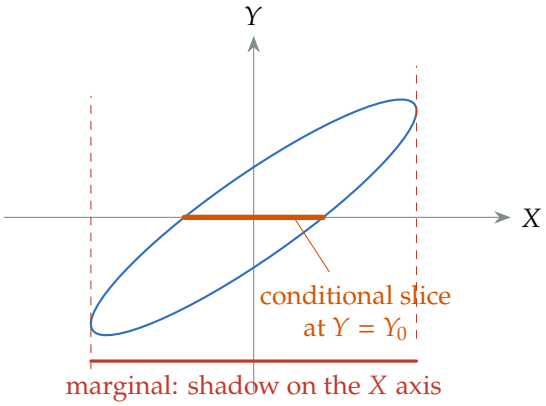

Figure 5.29: Conditional against marginal error for two correlated parameters. The ellipse is a contour of the Gaussian posterior. Holding Y at its best value and asking how far X may move gives the short orange slice, of half-width $(-A)^{-1/2}$. Letting Y take any value gives the full shadow of the ellipse on the X axis, between the red dashed tangents, of half-width proportional to $\sqrt{B/(C^2-AB)}$.

Key idea: error bars from the curvature

Near its peak, the log-posterior is a quadratic form with Hessian $\mathbf{H}$. The posterior is then approximately Gaussian with covariance $\mathbf{C} = -\mathbf{H}^{-1}$. The honest (marginal) error bar on θ_i is $\sqrt{\mathbf{C}_{ii}} = \sqrt{[(-\mathbf{H})^{-1}]_{ii}}$, the square root of a diagonal element of the *inverse*. The inverse of a

diagonal element, $1/\sqrt{-H_{ii}}$, is the conditional error with all other parameters frozen, and is always smaller or equal.

The link to the Fisher matrix. The Laplace approximation and the Fisher forecast of Chapter 10 are the same object, seen after and before the data are taken. Here is why. With a flat prior, $-\mathbf{H}$ is the curvature of the log-likelihood at its maximum, called the *observed information*. Average it over all the data sets the model could have produced, and we get the **Fisher matrix** $\mathbf{F}$, with $F_{ij} = -\mathbb{E}[\partial_i \partial_j \ln \mathcal{L}]$. So $\mathbf{F}^{-1}$ is the expected posterior covariance. Then $\sqrt{(\mathbf{F}^{-1})_{ii}}$ is the expected marginal error, and $1/\sqrt{F_{ii}}$ the expected conditional one [Padilla §3.8].

For a Gaussian likelihood with a model linear in the parameters, L is exactly quadratic. The Hessian then does not depend on the parameters, and the approximation is exact [Sivia §3.4, (3.52)]. For nonlinear models the peak itself is usually found step by step, by Newton–Raphson steps $\boldsymbol{\theta}_{k+1} = \boldsymbol{\theta}_k - \mathbf{H}^{-1}\nabla L$ [Sivia (3.55)], as in Chapter 3.

Example: contours for two parameters. Which contour of a two-parameter posterior holds 68% of the probability? Measure the distance from the peak by $Q = (\boldsymbol{\theta}-\boldsymbol{\theta}_0)^\mathsf{T}\mathbf{C}^{-1}(\boldsymbol{\theta}-\boldsymbol{\theta}_0)$. Within the Gaussian approximation, $Q = 2[L(\boldsymbol{\theta}_0) - L(\boldsymbol{\theta})]$, the "$\Delta\chi^2$" from the peak. The contours are the curves $Q = k$, so we need the distribution of Q. Change variables to $\boldsymbol{u} = \mathbf{C}^{-1/2}(\boldsymbol{\theta} - \boldsymbol{\theta}_0)$. This turns the Gaussian into M independent standard normals, so $Q = \sum_i u_i^2$ has a χ^2 distribution with M degrees of freedom (Chapter 2). For $M = 2$ that distribution is an exponential, $p(Q) = \frac{1}{2}e^{-Q/2}$, so

$$\mathrm{P}(Q \le k) \overset{(1)}{=} \int_0^k \tfrac{1}{2}e^{-Q/2}\mathrm{d}Q \overset{(2)}{=} 1 - e^{-k/2}$$

$$\Rightarrow \quad k_{68.3\%} = -2\ln(1-0.683) = 2.30, \qquad k_{95.4\%} = 6.17.$$

(1) The χ^2_2 density is $\frac{1}{2}e^{-Q/2}$.
(2) Elementary integral, then solve for k.

These are the contour levels "$\Delta\chi^2 = 2.30$ and 6.17" used in every two-parameter plot in cosmology [Padilla Table III]. In one dimension the same argument gives $\Delta\chi^2 = 1$ and 4 for $\pm1\sigma$ and $\pm2\sigma$: a one-parameter interval and a two-parameter contour at the same confidence need different thresholds.

5.10.3 When the approximation fails, and when it comes back: the lighthouse

A lighthouse stands at unknown position α along a straight coast, a known distance β out to sea [Sivia §2.4]. It emits short flashes in random directions, uniformly in the azimuth $\vartheta \in (-\pi/2, \pi/2)$. Detectors along the shore record *where* each flash arrives, $x = \alpha + \beta\tan\vartheta$, but not its direction (Figure 5.30). Where is the lighthouse?

The likelihood of one arrival point follows from the change of variables for densities (Chapter 1):

$$p(x \mid \alpha, \beta) \overset{(1)}{=} p(\vartheta)\left|\frac{\mathrm{d}\vartheta}{\mathrm{d}x}\right| \overset{(2)}{=} \frac{1}{\pi}\cdot\frac{1}{\beta\,(1+\tan^2\vartheta)} \overset{(3)}{=} \frac{\beta}{\pi\,[\beta^2 + (x-\alpha)^2]}.$$

(1) The probability in a small range $\mathrm{d}\vartheta$ equals that in the matching $\mathrm{d}x$.
(2) $p(\vartheta) = 1/\pi$ on $(-\pi/2, \pi/2)$, and $\mathrm{d}x/\mathrm{d}\vartheta = \beta/\cos^2\vartheta = \beta(1+\tan^2\vartheta)$.
(3) $\tan\vartheta = (x-\alpha)/\beta$.

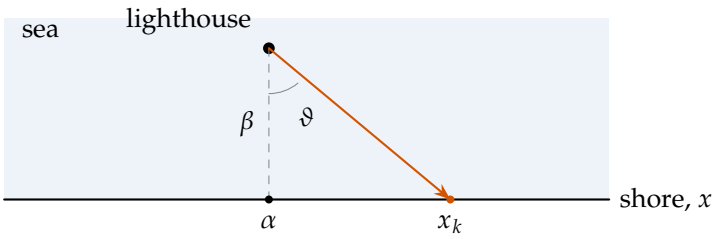

Figure 5.30: The lighthouse problem. A flash leaves at azimuth ϑ, uniformly distributed, and reaches the shore at $x_k = \alpha + \beta \tan \vartheta$. Only the arrival point is recorded.

This is a Cauchy (Lorentzian) density [Sivia (2.34)], with a peak at α and tails so heavy that its variance is infinite (Chapter 2). Take a flat prior on α and independent flashes at $x_1, \ldots, x_N$. The log-posterior is $L(\alpha) = \text{const} - \sum_k \ln[\beta^2 + (x_k - \alpha)^2]$ [Sivia (2.38)]. The condition $L' = 0$ for its peak cannot be solved in closed form, but on a grid the whole posterior is easy to compute.

Figure 5.31 shows the posterior as flashes accumulate, for a lighthouse at $\alpha = 1$ km with $\beta = 1$ km. After one or two flashes the posterior is broad with heavy tails. When two flashes land far apart, the posterior has two humps, one near each. In this run, by eight flashes it is a single bump. After 64 its standard deviation, 0.2039, agrees with the Laplace width 0.2026 from the curvature at the peak. After 512 flashes the posterior is $\alpha = 1.096 \pm 0.06506$ km, and the width matches the large-N prediction $\beta\sqrt{2/N} = 0.0625$ km that follows from the Fisher information of a Cauchy density.

The sample mean of the arrival points would be the answer for Gaussian data. Here it does not converge at all: after 64 flashes it is 3.578, and on average it is no closer to the truth than a single flash. Why? For Cauchy data the average of N points has the same Cauchy distribution as a single point, because the central limit theorem needs a finite variance (Chapter 2). One wild flash, sent almost parallel to the shore, can drag the mean anywhere. The posterior never uses the mean. It weighs every flash through the likelihood. A wild flash far from α has a likelihood that is nearly flat in α, so it barely moves the posterior [Sivia p. 36].

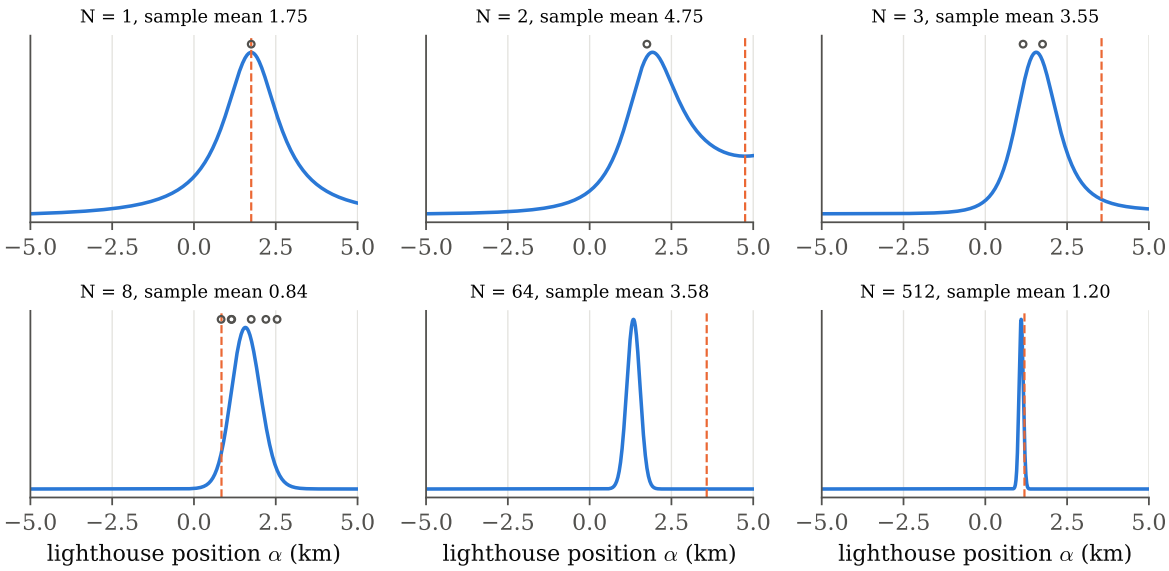

Figure 5.31: The posterior for the lighthouse position as flashes accumulate (N in each title). Circles at the top of the first four panels mark where the flashes landed, and the dashed vertical line is the sample mean of the arrival points. The posterior starts broad and sometimes two-peaked, becomes a narrow Gaussian-like peak near the true $\alpha = 1$ km, while the sample mean keeps jumping around.

The lighthouse shows both sides of the Gaussian approximation. With few data the posterior can be lopsided or have several peaks, and no "$\theta_0 \pm \sigma$" describes it. With many data from a well-behaved likelihood the posterior becomes a Gaussian of width $1/\sqrt{N\,I}$, where I is the Fisher information of one datum, whatever the shape of the single-datum likelihood. That second half is a theorem, the Bernstein–von Mises theorem of Section 5.13.

5.11 Nuisance parameters: integrating out what we do not care about

A spectrum shows a peak sitting on a smooth background: a Bragg peak on diffuse scattering, an emission line on a quasar's continuum, a resonance on the falling background of a collider mass spectrum. We want the amplitude A of the peak. The background level B is of no interest in itself, but it cannot be ignored, because the counts we measure are the sum of both, and a higher background leaves room for a smaller peak [Sivia §3.1]. Such a parameter, needed by the model and irrelevant to the question, is a **nuisance parameter**. How do we get a posterior for A alone that honestly includes our ignorance of B?

5.11.1 Marginalising: the sum rule applied to parameters

Bayes' theorem gives the joint posterior $p(A, B \mid \boldsymbol{d})$, a density over pairs of values. Our question is about A alone: what is the probability that A lies in some small range, whatever B is? That can happen in many ways, one for each value of B, and the sum rule says to add up their probabilities. This is marginalisation (Chapter 1). A marginal distribution isolates the probability of a single variable, here A, by averaging out the "nuisance" variables, here B, from the joint distribution:

$$p(A \mid \boldsymbol{d}) = \int p(A, B \mid \boldsymbol{d})\, \mathrm{d}B \tag{5.36}$$

[Sivia (3.9)], [Wasserman p. 183, (11.9)], [Padilla (38)]. In the tree picture it is the sum over all branches of B that lead to the same A. With more nuisance parameters the integral runs over all of them. This is why the standard output of a cosmological analysis is a set of marginal posteriors, of one or two parameters out of dozens [HobsonBMC (2.6)].

Working definition 5.5 (marginal posterior)

For parameters of interest $\boldsymbol{\theta}$ and nuisance parameters $\boldsymbol{\nu}$, the **marginal posterior** is $p(\boldsymbol{\theta} \mid \boldsymbol{d}) = \int p(\boldsymbol{\theta}, \boldsymbol{\nu} \mid \boldsymbol{d})\, \mathrm{d}\boldsymbol{\nu}$ [the joint posterior summed over every value of the nuisance parameters, each weighted by how credible it is]. *Operationally:* on a grid, sum the joint posterior along the nuisance axes. From samples of the joint posterior, simply ignore the nuisance coordinates (Section 5.14).

How does not knowing B change what we learn about A? To see it, split the integrand with the product rule, $p(A, B \mid \boldsymbol{d}) = p(A \mid B, \boldsymbol{d})\, p(B \mid \boldsymbol{d})$:

$$p(A \mid \boldsymbol{d}) = \int p(A \mid B, \boldsymbol{d})\; p(B \mid \boldsymbol{d})\, \mathrm{d}B. \tag{5.37}$$

The marginal is an average of the conditional posteriors $p(A \mid B, \boldsymbol{d})$, one for each assumed background, weighted by how credible that background is. Now suppose an independent calibration fixed the background exactly at b. Then $p(B \mid \boldsymbol{d}) = \delta(B - b)$ and

$$p(A \mid \boldsymbol{d}) \overset{(1)}{=} \int p(A \mid B, \boldsymbol{d})\, \delta(B - b)\, \mathrm{d}B \overset{(2)}{=} p(A \mid b, \boldsymbol{d}),$$

(1) The calibration puts all the probability for B at b.
(2) The delta function picks out the integrand at $B = b$.

So the conditional posterior is the special case in which the nuisance parameter is known perfectly [Sivia p. 44]. An analysis that "fixes" a parameter at a fiducial value is doing exactly this, without saying so: it gives that parameter a delta-function prior [HobsonBMC p. 42]. Any spread in $p(B \mid \boldsymbol{d})$ mixes conditionals centred at different places, so the marginal is broader.

Example: a peak on a background. Following Sivia, the expected count in channel k is $D_k = n_0[A\, e^{-x_k^2/2w^2} + B]$, a Gaussian peak of known width and position on a flat background, and the observed count N_k is Poisson with mean D_k [Sivia (3.1)–(3.4)]. With independent channels and a flat prior on $A, B \geq 0$,

$$\ln p(A, B \mid \{N_k\}) = \text{const} + \sum_k \big[N_k \ln D_k - D_k\big]$$

[Sivia (3.8)], the log of a product of Poisson probabilities with the factorials dropped. Here n_0 sets the overall count level, x_k is the position of channel k measured from the peak, and w is the peak width.

How much does not knowing B cost? It depends on whether the data can tell the peak from the background. Figure 5.32 shows two simulated set-ups, both with $A = 1$, $B = 2$.

- *Wide set-up* (top row): 15 channels spread well beyond the peak. The outer channels measure the background alone, so A and B are only moderately correlated, $\rho = -0.6688$. The marginal error on A is 0.2075, against 0.1538 if B were known to be 2.
- *Narrow set-up* (bottom row): 7 channels over a narrow range around the peak. No channel sees the background alone, so a little more background and a little less peak fit almost equally well. The correlation is $\rho = -0.9331$, and the marginal error on A grows to 0.4197, almost three times the conditional error 0.1517.

Both ratios agree with the factor $1/\sqrt{1-\rho^2}$ of Section 5.10. So when the data cannot separate signal from background, a calibration of the background is worth a lot. When they can, it adds little [Sivia p. 42].

Example: an unknown noise level. Readings x_k are Gaussian with mean μ and an error σ that nobody told us. Then σ is a nuisance parameter, and Chapter 3 showed that integrating it out with the prior $p(\sigma) \propto 1/\sigma$ gives $p(\mu \mid \boldsymbol{d}) \propto \big[\sum_k (x_k - \mu)^2\big]^{-N/2}$ [Sivia (3.38)], [HobsonBMC (2.26)]. Its shape in μ follows from splitting the sum about the sample mean $\bar{x}$:

$$\sum_k (x_k - \mu)^2 \overset{(1)}{=} \sum_k \big[(x_k - \bar{x}) + (\bar{x} - \mu)\big]^2$$
$$\overset{(2)}{=} \sum_k (x_k - \bar{x})^2 + 2(\bar{x} - \mu) \sum_k (x_k - \bar{x}) + N(\bar{x} - \mu)^2 \overset{(3)}{=} V + N(\bar{x} - \mu)^2,$$

(1) Add and subtract $\bar{x}$ inside each square.
(2) Expand the square. The middle factor $(\bar{x} - \mu)$ does not depend on k.
(3) $\sum_k (x_k - \bar{x}) = 0$ by the definition of $\bar{x}$, and $V \equiv \sum_k (x_k - \bar{x})^2$.

So $p(\mu \mid \boldsymbol{d}) \propto [N(\bar{x} - \mu)^2 + V]^{-N/2}$, a Student-$t$ curve centred on $\bar{x}$ [Sivia (3.41)–(3.44)]. For large N it approaches a Gaussian of width $\sqrt{V/N^2}$, the familiar $s/\sqrt{N}$ with $s^2 = V/N$. For small N its tails are much heavier than a Gaussian's. Not knowing the size of the noise costs precision, and marginalisation builds that cost in automatically. (Sivia's flat prior on σ gives the exponent $-(N-1)/2$ instead, a slightly wider curve. The choice matters only for very few data.)

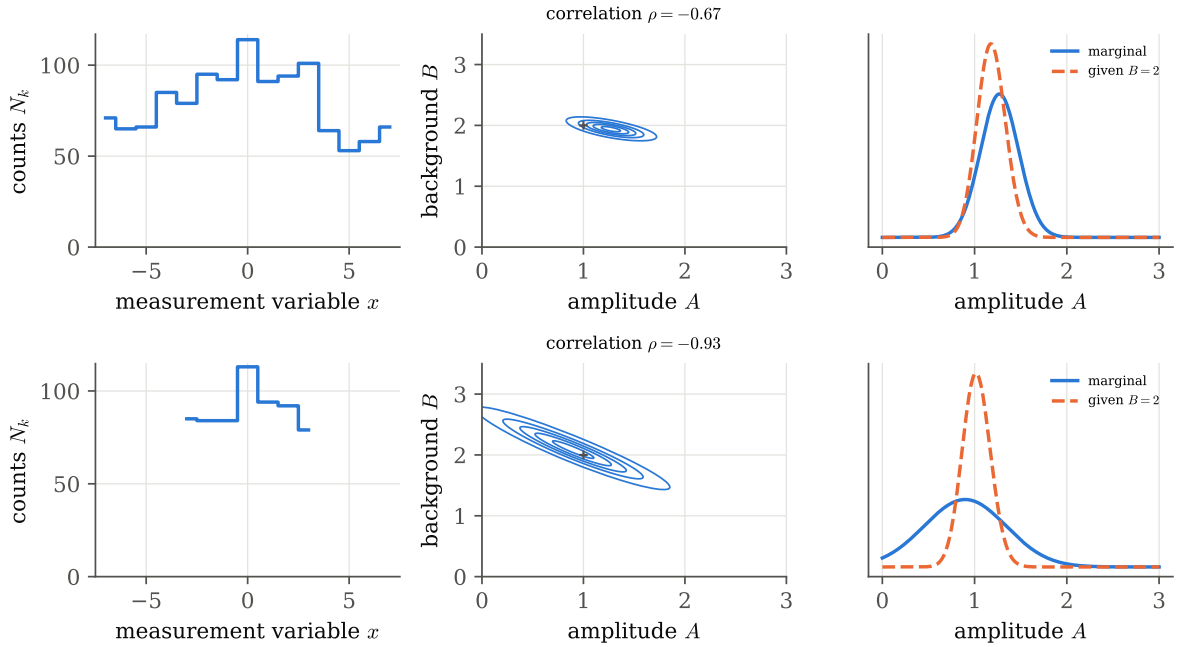

Figure 5.32: A peak of amplitude A on a flat background B, from Poisson counts. Top: 15 channels spanning the peak and the background around it. Bottom: 7 channels concentrated on the peak. Left: the simulated counts. Middle: contours of the joint posterior at 10, 30, 50, 70 and 90% of its maximum, with the true values marked by a cross. Right: the marginal posterior of A (solid) and the conditional posterior with B fixed at its true value (dashed). The narrow set-up correlates A and B strongly, and marginalising over B then widens the posterior of A a lot.

5.11.2 Marginalising against profiling

The frequentist way to remove a nuisance parameter is to *maximise* over it: the profile likelihood $\mathcal{L}_p(A) = \max_B \mathcal{L}(A, B)$ (Chapter 3). Do integration and maximisation agree?

For a Gaussian posterior they do. Write the log-posterior about its peak as $L = \frac{1}{2}(ax^2 + 2cxy + by^2)$ in the deviations $x = A - A_0$, $y = B - B_0$, with $a, b < 0$ and $ab > c^2$. Maximising over y at fixed x gives $by + cx = 0$, so $y^* = -cx/b$, and

$$L(x, y^*) \overset{(1)}{=} \tfrac{1}{2}\Big(ax^2 - \frac{2c^2x^2}{b} + \frac{c^2x^2}{b}\Big) \overset{(2)}{=} \tfrac{1}{2}\,\frac{ab - c^2}{b}\,x^2, \qquad \int e^{L}\,\mathrm{d}y \overset{(3)}{=} e^{\frac{1}{2}\frac{ab-c^2}{b}x^2}\sqrt{\frac{2\pi}{-b}}.$$

(1) Substitute $y^* = -cx/b$.
(2) Collect the terms over the common denominator b.
(3) Complete the square in y, $by^2 + 2cxy = b(y + cx/b)^2 - c^2x^2/b$, and do the Gaussian integral over y. Its value $\sqrt{2\pi/(-b)}$ does not depend on x.

Profile and marginal have the same x-dependence, so after normalisation they are the same curve, with variance $b/(c^2 - ab)$ as in (5.35). The equality rests on step (3): the width of the posterior in the nuisance direction, $(-b)^{-1/2}$, is the same for every x.

When that width changes with the parameter of interest, the two disagree. To see by how much, call the parameter of interest θ and the nuisance parameter ν. At each fixed θ, expand L about the best nuisance value $\hat{\nu}(\theta)$ and integrate the Gaussian in ν, exactly as in step (3). This gives

$$p(\theta \mid \boldsymbol{d}) = \int e^{L(\theta,\nu)}\,\mathrm{d}\nu \;\approx\; \underbrace{e^{L(\theta,\hat{\nu}(\theta))}}_{\text{profile}}\;\underbrace{\sqrt{2\pi}\,\sigma_\nu(\theta)}_{\text{volume}}, \qquad \sigma_\nu(\theta) = \big(-\partial_\nu^2 L\big)^{-1/2}\big|_{\hat{\nu}(\theta)}. \tag{5.38}$$

The first factor is the profile, the best fit at this θ. The second measures how many values of ν fit almost as well. So the marginal rewards values of θ for which many values of the nuisance parameter fit the data, a large "volume" of good fits. The profile only asks how good the best fit is.

Example: a weak bump of unknown position. Readings y_i at 60 positions $x_i \in [0, 10]$ follow $y_i = A\, e^{-(x_i-\mu)^2/2w^2} + \epsilon_i$ with unit Gaussian noise and known narrow width $w = 0.4$. A bump of true amplitude $A = 1.2$ sits at $\mu = 5$, and we take flat priors on $A \in [0, 4]$ and on the position $\mu \in [0, 10]$ (Figure 5.33). Here the amplitude A is the parameter of interest and the position μ the nuisance parameter.

How wide is the range of good positions? It depends on A. When A is large, only positions near the true bump fit, so the posterior in μ is narrow. When A is near zero, every position fits equally well, because a bump of zero height is invisible wherever it is. Then the whole prior range of μ contributes. That large volume pulls the marginal posterior of A towards zero. For the data of Figure 5.33 its mode is at $A = 0$, and it puts probability 0.5375 on $A < 0.5$. The profile ignores volume. It peaks at $A = 0.83$ and gives 0.2077 to $A < 0.5$. One data set could be a fluke, so we repeat the analysis on 500 fresh data sets with the same true bump. On average the marginal gives $A < 0.5$ a probability of 0.20 and the profile 0.07 (each to within about 0.01), and the marginal peaks at $A = 0$ in 50 of them.

Neither is wrong; they answer different questions. The profile says "the best bump anywhere has amplitude about 0.83". The marginal says "averaged over where a bump could be, small amplitudes are more credible than the best fit alone suggests". This is the Bayesian face of the look-elsewhere effect (Chapter 4). It is also a first view of how the evidence penalises a model for its prior volume, the Occam factor of model comparison.

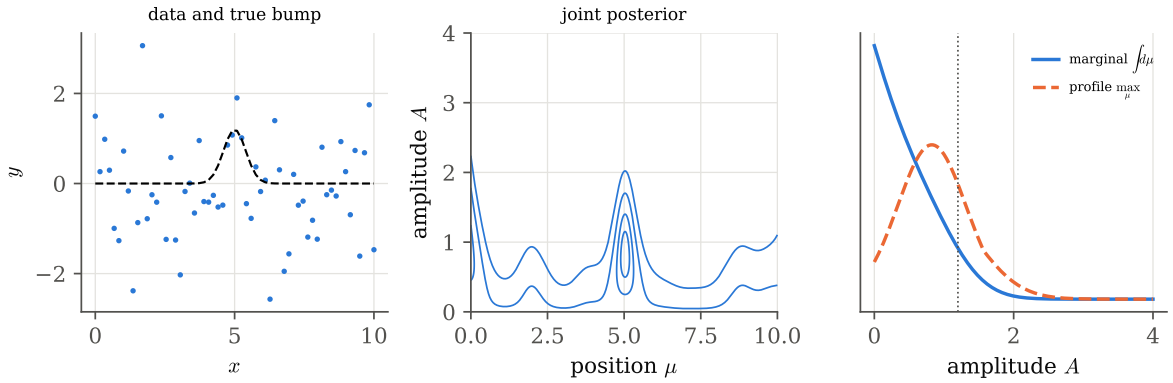

Figure 5.33: Marginal against profile for a weak bump whose position is unknown. Left: the data and the true bump (dashed). Middle: the joint posterior of amplitude and position. At small amplitude every position fits about equally well, so whatever probability the posterior keeps there is spread over the whole range of positions. Right: the marginal posterior of the amplitude (solid) integrates over position, so it gives small amplitudes more weight than the profile (dashed), which maximises over position and peaks near the best-fitting bump. The dotted line is the true amplitude.

Watch out: The peak of the joint is not the peak of the marginal

The best-fit point of a joint posterior, projected onto one parameter, is the peak of the profile, not of the marginal. For skewed or banana-shaped posteriors, and whenever the nuisance width changes across the parameter of interest, the two differ, and quoting "the best fit" next to a marginal interval can put the best fit outside the interval. In cosmology these "projection" or "prior-volume" effects are routine in analyses with many nuisance

parameters. Report which summary is quoted, and when they differ, report both [Sivia p. 54].

Marginals also hide structure. Two strongly correlated parameters may each have a broad marginal while their difference is sharply determined. And two pairs of parameters with the same marginals can have very different joint posteriors [Kruschke Fig. 12.1]. Whenever the question concerns a combination of parameters, compute the posterior of that combination from the joint, not from the marginals. With samples this is a one-line operation (Section 5.14).

5.12 Choosing a prior: subjective, flat and Jeffreys

Every posterior so far has needed a prior density $p(\theta)$ for the parameter θ we want, the weight each branch of the probability tree gets before the data arrive. Sometimes the choice is easy: an earlier experiment measured the same quantity, and its result is our prior. Often it is not. Suppose we are the first to measure the fraction θ of cosmic-ray muons that fire a new trigger. We believe it lies between 0 and 1 and not much more. What density should we write down, and how much does the answer depend on that choice?

Two schools answer differently [Wasserman pp. 181–182]. The first, called **subjectivism**, says that the prior should reflect our opinion about θ before the data are collected. The second looks for a prior that expresses no opinion at all, a "noninformative" prior. The obvious candidate is a flat prior, $p(\theta) \propto$ constant. Both are useful and both have traps. The trap of the flat prior is the more surprising one. A prior cannot be flat in every way of describing the same parameter, so "flat" always hides a choice of variable.

The questions, in words, are these.

1. How do we turn real but vague knowledge into a density?
2. What does a flat prior actually say, and when is a flat prior over an infinite range allowed?
3. Is there a rule that gives the same answer whichever variable we use to describe the parameter?

5.12.1 Priors that encode knowledge

A prior is a probability like any other. No probability, prior or likelihood, is ever simply "known". Each one is an assignment that reflects the information I we have. We call $p(X \mid I)$ a likelihood when X is data, and a prior when X is a parameter and no new measurement is involved. The difference is one of name, not of objectivity [Sivia §5.5]. What makes an assignment objective is consistency: two people with the same information should assign the same density. In practice there are three routes from knowledge to a density, which we take in turn.

Informal assessment. Think of ten points, each carrying 10% of the prior probability, and decide where they plausibly go [HobsonBMC §1.3.2]. That gives a rough centre, a rough width and a rough shape, which we then match to a standard density. For a *location* parameter [one that shifts the prediction, like a peak position or a mass] with centre c and width w, a Cauchy density

$$p(\theta) = \frac{w/\pi}{(\theta - c)^2 + w^2}$$

is a good choice. Its heavy tails still give real weight to values far from the guess, so the data can move the answer there if they demand it. For a positive *intensity* [a rate or an amplitude that

cannot be negative] of plausible size a, an exponential $p(\theta) = a^{-1}e^{-\theta/a}$, or a Gamma density if we also know a width, does the same job [HobsonBMC (1.28)–(1.30)]. The prior does not have to be "right" in some undefinable sense. It has to be reasonable.

Moment matching. If earlier data exist, choose a standard density with the same mean and standard deviation as those data [Lambert §5.6.2]. For example, five earlier determinations of a detector gain, with mean 1.02 and scatter 0.05, give the prior $\mathcal{N}(1.02, 0.05^2)$. Which moments to match is an arbitrary choice, so this is a practical recipe rather than a principle.

Example: a prior elicited from quantiles. Experts find quantiles easier to state than standard deviations. Suppose a colleague says: "I would give even odds that the Hubble constant lies between 67 and 73 $\mathrm{km\,s^{-1}Mpc^{-1}}$, and I think it is equally likely to be below 67 as above 73." That is a statement of the 25% and 75% quantiles, $q_{25} = 67$ and $q_{75} = 73$. For a Gaussian prior $\mathcal{N}(\mu, s^2)$ each quantile is $q = \mu + z\,s$, where z is the matching quantile of the standard normal, $z_{75} = -z_{25} = 0.6745$ [Lambert §5.6.3]. Then

$$q_{75} - q_{25} \overset{(1)}{=} (\mu + z_{75}s) - (\mu + z_{25}s) \overset{(2)}{=} 2 \times 0.6745\, s \qquad \Rightarrow \quad s = \frac{73 - 67}{1.349} = 4.45,$$

$$q_{75} + q_{25} \overset{(3)}{=} 2\mu \qquad \Rightarrow \quad \mu = 70.$$

(1) Each quantile of $\mathcal{N}(\mu, s^2)$ is μ plus the standard-normal quantile times s.
(2) $z_{25} = -z_{75}$ because the standard normal is symmetric.
(3) Adding instead of subtracting, the z terms cancel for the same reason.

So the elicited prior is $\mathcal{N}(70, 4.45^2)$. With a panel of experts, the pairs (z, q) from all of them lie roughly on one straight line $q = \mu + zs$, and a linear regression through them gives a pooled μ (the intercept) and s (the slope).

5.12.2 Flat priors, and flat priors over an infinite range

A flat prior $p(\theta) =$ constant lets the likelihood alone set the shape of the posterior, since $p(\theta \mid \boldsymbol{d}) \propto \mathcal{L}(\theta) \times$ constant. For a bounded parameter such as our trigger fraction, the constant is 1 on $[0, 1]$, and after z firings in N muons the posterior is Beta$(z + 1, N - z + 1)$ (Section 5.8), which seems very reasonable [Wasserman p. 182].

For a parameter with no natural bound, such as the mean θ of Gaussian readings, a constant over the whole real line has infinite area. So it is not a probability density at all. Such a prior is called **improper**. Can we use it anyway? We can still multiply it by the likelihood, and then check whether the product can be normalised.

Example: the mean of Gaussian readings with a flat improper prior. Take n readings $x_1, \ldots, x_n$, each $\mathcal{N}(\theta, \sigma^2)$ with known σ, and $p(\theta) = c$ on the whole real line. Write $\bar{x} = \frac{1}{n}\sum_i x_i$. Then

$$p(\theta \mid x_1, \ldots, x_n) \overset{(1)}{\propto} c \prod_{i=1}^{n} e^{-(x_i-\theta)^2/2\sigma^2} \overset{(2)}{\propto} \exp\Big[-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i - \theta)^2\Big]$$

$$\overset{(3)}{=} \exp\Big[-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i - \bar{x})^2\Big]\exp\Big[-\frac{n(\theta - \bar{x})^2}{2\sigma^2}\Big] \overset{(4)}{\propto} \exp\Big[-\frac{(\theta - \bar{x})^2}{2\sigma^2/n}\Big].$$

(1) Posterior $\propto$ likelihood $\times$ prior, dropping the factors $1/\sqrt{2\pi\sigma^2}$ that do not contain θ.

(2) The constant c drops out, and a product of exponentials is the exponential of the sum.
(3) Write $x_i - \theta = (x_i - \bar{x}) + (\bar{x} - \theta)$ and square. The cross term is $2(\bar{x} - \theta)\sum_i (x_i - \bar{x}) = 0$, because the deviations from the mean sum to zero.
(4) The first factor does not contain θ.

The posterior is $\mathcal{N}(\bar{x}, \sigma^2/n)$, a perfectly proper density, and its 95% interval $\bar{x} \pm 1.96\,\sigma/\sqrt{n}$ coincides exactly with the frequentist confidence interval of Chapter 3 [Wasserman p. 182]. An improper prior is harmless as long as the posterior it produces is a well-defined probability distribution.

The safe way to think about an improper prior is as the limit of proper ones [Sivia §5.5]. Use a prior that is flat between bounds A and B, compute the posterior, and watch what happens as $A \to -\infty$ and $B \to \infty$. Usually the posterior settles down and the bounds drop out, as they did above. If instead the conclusions depend strongly on A and B, the data carry very little information, and the prior range, which is prior knowledge, is doing the work. Every maximum-likelihood or least-squares fit uses this limit without saying so.

Improper priors are not harmless everywhere. Take the evidence $p(\boldsymbol{d}) = \int \mathcal{L}\, p\, \mathrm{d}\theta$ of a model whose prior is flat over a width W, so $p = 1/W$. The evidence carries this factor $1/W$, so as $W \to \infty$ it goes to zero. The model then loses any comparison with a model that knows even roughly what range to expect [HobsonBMC §1.3.2]. A flat prior over an enormous range is also not ignorance. It says we are almost certain that $|\theta|$ is enormous, since almost all of its area lies there. Are you really almost certain that $|\theta| > 10^{100}$?

5.12.3 Flat in which variable?

A flat prior is supposed to say "we know nothing". But knowing nothing about a parameter should also mean knowing nothing about any other way of describing it. Can one prior be flat in both? Return to the trigger fraction p with the flat prior $p \sim U(0,1)$, meant to represent our lack of information about p. A physicist might equally describe the trigger by its log-odds

$$\psi = \ln \frac{p}{1-p}, \qquad p = \frac{e^\psi}{1+e^\psi},$$

which runs over the whole real line. If we are ignorant about p, we are also ignorant about ψ, so we should use a flat prior for ψ too. But we have no freedom left: the flat prior on p already fixes the density of ψ. The rule is the change of variables for densities (Chapter 1): corresponding intervals must carry equal probability, $p_\Psi(\psi)\,|\mathrm{d}\psi| = p_P(p)\,|\mathrm{d}p|$. So

$$p_\Psi(\psi) \overset{(1)}{=} p_P\big(p(\psi)\big)\left|\frac{\mathrm{d}p}{\mathrm{d}\psi}\right| \overset{(2)}{=} 1 \times \frac{\mathrm{d}}{\mathrm{d}\psi}\frac{e^\psi}{1+e^\psi} \overset{(3)}{=} \frac{e^\psi(1+e^\psi) - e^\psi e^\psi}{(1+e^\psi)^2} \overset{(4)}{=} \frac{e^\psi}{(1+e^\psi)^2}. \tag{5.39}$$

(1) Change of variables for a density: equal probability in matching intervals.
(2) The flat density on $[0,1]$ is 1, and $p(\psi)$ increases, so the absolute value is not needed.
(3) Quotient rule.
(4) The $e^{2\psi}$ terms cancel.

This is a bump centred at $\psi = 0$, not a flat line [Wasserman p. 182]. How much of the probability does the bump hold in $|\psi| < 2$? That range corresponds to $p \in (1/(1+e^2), e^2/(1+e^2)) = (0.119, 0.881)$, which the flat prior gives probability 0.762. So a flat prior on p is a confident statement about ψ: the trigger is probably neither extremely efficient nor extremely inefficient.

Figure 5.34 shows why. Equal steps in p map onto steps in ψ that are narrow in the middle and wide at the ends. Each step carries the same probability, so probability gets squeezed into the middle of the ψ axis. The conclusion is unavoidable: "flat" has no meaning until we say flat

in which variable, because a flat prior on a parameter is not flat on a nonlinear function of it. Flat priors are not **transformation invariant**.

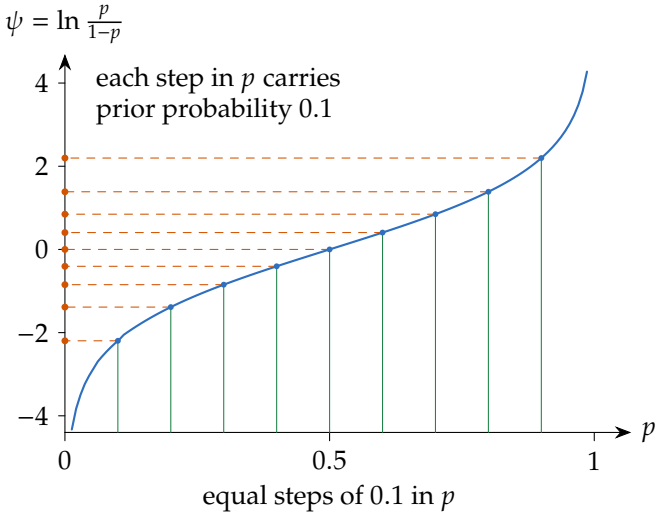

Figure 5.34: Why a flat prior in p is not flat in the log-odds ψ. The curve is $\psi = \ln[p/(1-p)]$. Nine equally spaced values of p (green lines) are carried up to the curve and across to the ψ axis (orange points). The orange points crowd together near $\psi = 0$ and spread apart towards the ends, so the same probability, 0.1 per step, is packed densely in the middle of the ψ axis and thinly at its ends: the bump of (5.39).

The same happens for any nonlinear function. Lambert's example is the probability $u = \theta^2$ that two randomly chosen individuals both carry a disease of prevalence θ [Lambert §5.6.1]. A flat prior on $\theta \in [0,1]$ gives u the density $p(u) = p(\theta)\,|\mathrm{d}\theta/\mathrm{d}u| = 1/(2\sqrt{u})$, which piles up at $u = 0$. For ten individuals, $v = \theta^{10}$, the pile-up is sharper still, $p(v) = \frac{1}{10}v^{-9/10}$. So a prior that looks uninformative about one quantity is quite informative about others. This is why "vague" or "diffuse" are better words than "uninformative".

Example: a scale parameter over four decades. The effect is largest for a positive *scale* parameter [one that sets a size, like a width, a lifetime or a noise level] whose order of magnitude is unknown. Let λ lie anywhere between 0.01 and 100, four decades. A prior flat in λ gives the decade $[10, 100]$ the probability $(100-10)/(100-0.01) = 0.9001$, and the decade $[0.01, 0.1]$ only 9.001×10^{-4}. So "complete ignorance" has become a 90% bet that λ is in the top decade. A prior flat in $\ln\lambda$ instead gives each of the four decades probability 0.25 (Figure 5.35, middle). For a quantity whose order of magnitude is unknown, the second is clearly what we mean.

Why flat in $\ln\lambda$ is special. A consistency argument makes this precise [Sivia §5.1]. The question is: what density says only "this is a location" or only "this is a scale"? Start with a location parameter X. If that is all we know, then moving the origin by x_0 cannot change our density: $p(X)\,\mathrm{d}X = p(X+x_0)\,\mathrm{d}(X+x_0)$ for every x_0. Since $\mathrm{d}(X+x_0) = \mathrm{d}X$, this says $p(X) = p(X+x_0)$, so p is constant: complete ignorance about a location is a uniform density. If all we know about a length L is that it is a scale, then changing the units by a factor β (nanometres to ångströms) cannot change our density:

$$p(L)\,\mathrm{d}L = p(\beta L)\,\mathrm{d}(\beta L) \overset{(1)}{\Rightarrow} p(L) = \beta\, p(\beta L) \quad \text{for all } \beta > 0$$
$$\overset{(2)}{\Rightarrow} p(\beta) = \frac{p(1)}{\beta} \overset{(3)}{\Rightarrow} p(L) \propto \frac{1}{L}.$$

(1) $\mathrm{d}(\beta L) = \beta\,\mathrm{d}L$ for a constant β. Divide by $\mathrm{d}L$.
(2) Set $L = 1$ and solve for $p(\beta)$.
(3) Rename β as L: the relation holds for every positive value.

This is **Jeffreys' prior** for a scale parameter [Sivia (5.17)–(5.18)]. In terms of $s = \ln L$ it is $p(s) = p(L)\,\mathrm{d}L/\mathrm{d}s = (1/L) \times L =$ constant: flat in the logarithm, which is why problems involving magnitudes are best done on logarithmic graph paper. It is improper on $(0, \infty)$, so we use it between bounds or check that the posterior is normalisable. It is also the prior $p(C_\ell) \propto 1/C_\ell$ used for a power-spectrum amplitude in Section 5.8.

5.12.4 Jeffreys' rule: a prior that does not depend on the coordinates

Is there a recipe that gives the same prior whichever variable we choose, so that "Jeffreys in θ" transformed to ψ equals "Jeffreys computed in ψ"? Jeffreys found one [Wasserman pp. 182–183].

Working definition 5.6 (Jeffreys' prior)

For a model with density $f(x \mid \theta)$ for one datum, **Jeffreys' prior** is $p(\theta) \propto \sqrt{I(\theta)}$, where $I(\theta) = -\mathbb{E}_\theta\big[\partial_\theta^2 \ln f(X \mid \theta)\big]$ is the Fisher information [how sharply one datum pins down θ on average, Chapter 3]. For several parameters, $p(\boldsymbol{\theta}) \propto \sqrt{\det I(\boldsymbol{\theta})}$ with the Fisher information matrix. *Operationally:* compute the expected curvature of $\ln f$, take its square root, and normalise if the result has finite area.

Why is it invariant? Let $\psi = h(\theta)$ be any smooth, one-to-one reparametrisation. Use the equivalent form $I(\theta) = \mathbb{E}_\theta[(\partial_\theta \ln f)^2]$ of the Fisher information from Chapter 3. Then

$$I_\psi(\psi) \overset{(1)}{=} \mathbb{E}\Big[\Big(\frac{\partial \ln f}{\partial \psi}\Big)^2\Big] \overset{(2)}{=} \mathbb{E}\Big[\Big(\frac{\partial \ln f}{\partial \theta}\Big)^2\Big]\Big(\frac{\mathrm{d}\theta}{\mathrm{d}\psi}\Big)^2 \overset{(3)}{=} I_\theta(\theta)\Big(\frac{\mathrm{d}\theta}{\mathrm{d}\psi}\Big)^2,$$
$$\sqrt{I_\psi(\psi)} \overset{(4)}{=} \sqrt{I_\theta(\theta)}\,\Big|\frac{\mathrm{d}\theta}{\mathrm{d}\psi}\Big|.$$

(1) Fisher information in the new variable, as the mean square of the score.
(2) Chain rule, $\partial_\psi = (\mathrm{d}\theta/\mathrm{d}\psi)\,\partial_\theta$. The factor is not random and comes out of the expectation.
(3) The definition of I_θ.
(4) Square root of both sides.

The last line is exactly the change-of-variables law for a density, $p_\psi(\psi) = p_\theta(\theta)\,|\mathrm{d}\theta/\mathrm{d}\psi|$. So the square root of the Fisher information transforms as a density must. Computing Jeffreys' prior in θ and transforming it to ψ gives the same density as computing it in ψ directly. Geometrically, I is a metric on parameter space [it measures how distinguishable nearby parameter values are by their data], and $\sqrt{\det I}$ is its volume element. Jeffreys' prior spreads prior mass uniformly over distinguishable models, not over coordinate intervals [HobsonBMC (1.47)–(1.54)].

Example: the Bernoulli trigger. One muon fires the trigger, $x = 1$, with probability p, or not, $x = 0$. Then $\ln f = x \ln p + (1 - x)\ln(1 - p)$ and

$$I(p) \overset{(1)}{=} -\mathbb{E}\Big[-\frac{X}{p^2} - \frac{1 - X}{(1 - p)^2}\Big] \overset{(2)}{=} \frac{p}{p^2} + \frac{1 - p}{(1 - p)^2} \overset{(3)}{=} \frac{1}{p} + \frac{1}{1 - p} = \frac{1}{p(1 - p)}.$$

(1) Differentiate $\ln f$ twice in p.
(2) $\mathbb{E}[X] = p$ and $\mathbb{E}[1 - X] = 1 - p$.
(3) Cancel. Adding the fractions gives $1/[p(1 - p)]$.

Jeffreys' prior is $\sqrt{I(p)} = p^{-1/2}(1-p)^{-1/2}$, the Beta$(\frac{1}{2}, \frac{1}{2})$ density [Wasserman p. 183, Ex. 11.6]. It is not flat; it rises at both ends. Compare it with the two other popular choices. The flat prior in p is $p^0(1-p)^0$. The prior flat in ψ is the improper Haldane prior Beta$(0,0) \propto p^{-1}(1-p)^{-1}$. It is flat in ψ because its density in ψ is $p^{-1}(1-p)^{-1} \times \mathrm{d}p/\mathrm{d}\psi = p^{-1}(1-p)^{-1} \times p(1-p) = 1$, using $\mathrm{d}p/\mathrm{d}\psi = p(1-p)$ from (5.39). Jeffreys' exponents, $-\frac{1}{2}$, lie halfway between the flat prior's 0 and Haldane's -1.

Example: a Poisson rate and a Gaussian width. Take a count n with mean λT, where λ is the rate and T the exposure. Then $\ln f = n \ln \lambda - \lambda T + \text{const}$, so $\partial^2_\lambda \ln f = -n/\lambda^2$ and $I = \mathbb{E}[n]/\lambda^2 = T/\lambda$. Jeffreys' prior is therefore $\lambda^{-1/2}$. With zero observed events the posterior is $\propto \lambda^{-1/2} e^{-\lambda T}$, a Gamma$(\frac{1}{2}, T)$ density. For this density $2T\lambda$ has the χ^2 distribution with one degree of freedom, whose 95% point is 3.84. So the 95% upper limit is $\lambda < 3.84/(2T) = 1.92/T$, against $3.00/T$ from the flat prior (Section 5.8). Now take the width σ of Gaussian noise. Then $\ln f = -\ln \sigma - (x-\mu)^2/2\sigma^2$, so $\partial^2_\sigma \ln f = 1/\sigma^2 - 3(x-\mu)^2/\sigma^4$, whose expectation is $1/\sigma^2 - 3/\sigma^2 = -2/\sigma^2$. So $I = 2/\sigma^2$ and Jeffreys' prior is $1/\sigma$, the scale prior found above from units alone.

Does it matter? The three priors on real numbers. Figure 5.35 and Listing 5.7 compare the flat Beta$(1,1)$, Jeffreys Beta$(\frac{1}{2}, \frac{1}{2})$ and Haldane Beta$(0,0)$ priors for the trigger. With 1 firing in 10 muons the posterior means are 0.1667, 0.1364 and 0.1, and the 95% upper limits are 0.3644, 0.3306 and 0.2831. With so little data, the choice among "noninformative" priors changes the answer by a third. With 100 firings in 1000 muons the means are 0.1008, 0.1004 and 0.1 and the upper limits 0.1169, 0.1165 and 0.116: the choice has become irrelevant. A large sample makes the prior irrelevant for a reason, and the same reason tells us when it fails (Section 5.13).

Listing 5.7: Flat in which variable: a flat prior seen in the log-odds, mass per decade for a scale parameter, and three "noninformative" priors on the same data (`code/ch05/14_priors.py`)

Lines 31–32 draw 10^5 values of p from the flat prior and transform each to its log-odds. This is the change of variables done by sampling, and line 35 overlays the exact density (5.39). Line 38 counts the fraction with $|\psi| < 2$, 0.763, against the exact 0.762. Lines 41–44 compute the prior mass per decade on $[0.01, 100]$ for the two priors: for the flat prior it is the width of the decade over the width of the range, and for the log-flat prior the log-width over the log-width of the range. Lines 55–58 update each of the three Beta priors with the conjugate rule Beta$(a + z, b + N - z)$ of Section 5.8 and read off the posterior mean and the 95% quantile.

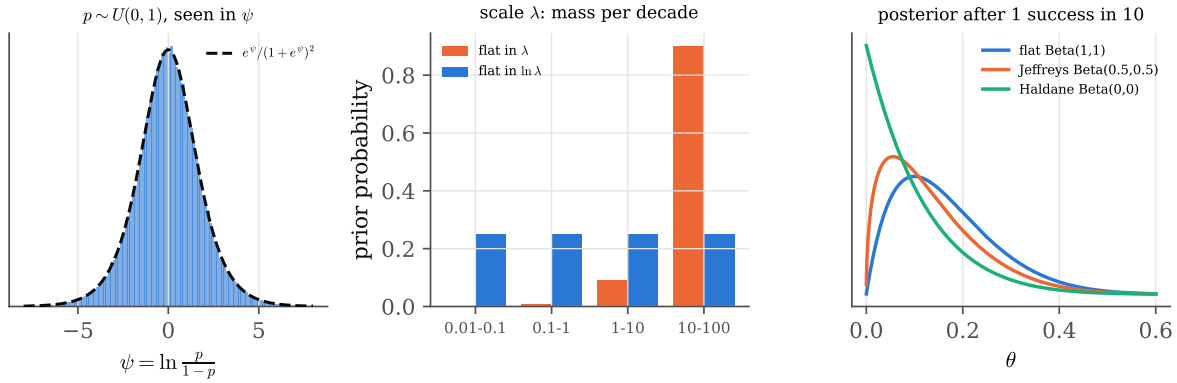

Figure 5.35: Flat depends on the variable. Left: 10^5 draws from a flat prior on p, histogrammed in the log-odds ψ, follow the bump $e^\psi/(1+e^\psi)^2$ (dashed). Middle: the prior probability of each decade of a scale parameter between 0.01 and 100. Flat in λ puts 90% in the top decade. Flat in $\ln\lambda$ gives each decade a quarter. Right: posteriors for a trigger efficiency after 1 firing in 10 muons, from the flat, Jeffreys and Haldane priors. With so few data they differ visibly.

Watch out: There is no prior that says nothing

Every prior says something about some function of the parameter. Jeffreys' rule is consistent across coordinates, but it depends on the likelihood, so it changes when the experiment changes, and in several dimensions $\sqrt{\det I}$ can behave badly or fail to normalise [HobsonBMC §1.3.2]. The general need for informal assessment means that the search for a universal "objective" prior is doomed. Choose a reasonable prior, say why, and check how much the answer depends on it [Lambert §5.7].

In practice most analyses use what Gelman calls **weakly informative** priors [Lambert §5.6.1]: smooth, proper densities that give zero weight only to impossible values (a negative rate, a lifetime longer than the age of the universe) and spread the rest broadly over physically sensible values. They avoid the arbitrary hard edges of a flat box, which produce kinked posteriors and can trap the answer on the wrong side of the edge (Section 5.13).

5.13 Forgetting the prior: when the data win and when they cannot

Two physicists measure the same trigger efficiency θ, the fraction of muons that fire a new trigger, with true value 0.3. The first has no opinion and uses the flat prior Beta$(1, 1)$. The second remembers a similar trigger with efficiency near 0.8 and is confident: Beta$(80, 20)$, a

prior worth $\kappa = a + b = 100$ muons (Section 5.8). Their priors barely overlap. They then record the same muons. After ten muons they still disagree. After a hundred thousand they agree to a fraction of an error bar (Figure 5.36). Is this agreement guaranteed? How fast does it come? And when does it never come, however much data we take?

A second kind of forgetting is easy to confuse with this one. A Markov chain Monte Carlo sampler (Chapter 9) started at a silly point forgets where it started. That is a different mechanism with a different cure. Keeping the two apart matters every time someone says "the prior washes out".

5.13.1 Why the prior is forgotten

Write the log-posterior for N independent data $x_1, \dots, x_N$ as

$$\ln p(\theta \mid x_1, \dots, x_N) = \underbrace{\ln p(\theta)}_{\text{one term}} + \underbrace{\sum_{i=1}^{N} \ln f(x_i \mid \theta)}_{N \text{ terms}} + \text{const.} \tag{5.40}$$

Here $f(x \mid \theta)$ is the density of one datum. The prior is a single term that does not grow with N. The log-likelihood $\ell_N(\theta) = \sum_i \ln f(x_i \mid \theta)$ is a sum of N terms, so it grows in proportion to N. As data accumulate, the likelihood therefore becomes a tall, narrow spike. The prior varies slowly across that spike, so it can only nudge it. How much? Expand both terms about the maximum-likelihood estimate $\hat\theta$, the peak of ℓ_N. The curvature of ℓ_N there is $N\hat I$, where $\hat I = -\ell_N''(\hat\theta)/N$ is the observed information per datum, close to the Fisher information $I(\theta)$ for large N (Chapter 3). Write $g = \frac{\mathrm{d}}{\mathrm{d}\theta} \ln p(\theta)\big|_{\hat\theta}$ for the slope of the log-prior there. Then

$$\begin{aligned} \ln p(\theta \mid x_1, \dots, x_N) &\overset{(1)}{\approx} \text{const} + g\,(\theta - \hat\theta) - \frac{N\hat I}{2}(\theta - \hat\theta)^2 \\ &\overset{(2)}{=} \text{const}' - \frac{N\hat I}{2}\Big(\theta - \hat\theta - \frac{g}{N\hat I}\Big)^2 . \end{aligned} \tag{5.41}$$

(1) Taylor expansion about $\hat\theta$: the log-likelihood to second order (its first derivative vanishes at its peak), the log-prior to first order (it changes little across the narrow likelihood peak).

(2) Complete the square: $-\frac{c}{2}u^2 + gu = -\frac{c}{2}(u - g/c)^2 + g^2/2c$ with $u = \theta - \hat\theta$ and $c = N\hat I$. The $g^2/2c$ goes into the constant.

The posterior is approximately Gaussian with

$$\text{mean } \hat\theta + \frac{g}{N\hat I}, \qquad \text{width } \frac{1}{\sqrt{N\hat I}}, \qquad \frac{\text{shift caused by the prior}}{\text{width}} = \frac{g}{\sqrt{N\hat I}}. \tag{5.42}$$

The prior moves the posterior by an amount that falls as $1/N$. The posterior width falls only as $1/\sqrt{N}$. So, measured in error bars, the influence of any smooth prior dies away as $N^{-1/2}$. Two analysts with log-prior slopes g_1 and g_2 at $\hat\theta$ disagree by $|g_1 - g_2|/\sqrt{N\hat I}$ posterior standard deviations.

Key idea: Bernstein–von Mises

If the model is regular, the parameter is identifiable and of fixed dimension, and the prior is smooth and nonzero at the true value, then for large N the posterior is approximately $\mathcal{N}\big(\hat\theta,\, 1/[NI(\hat\theta)]\big)$, whatever the prior. The posterior mean approaches the maximum-likelihood estimate, and a 95% credible interval approaches the 95% confidence interval

$\hat{\theta} \pm 1.96/\sqrt{NI(\hat{\theta})}$ [Wasserman p. 181, Thm. 11.5].

This is the Gaussian approximation of Section 5.10 with a promise attached: for large N the curvature comes from the likelihood alone, so every reasonable prior gives the same answer. This is why frequentist and Bayesian error bars on well-measured quantities agree.

Example: two observers with Gaussian priors. Observers A and B have priors $\mathcal{N}(\mu_A, \Sigma_A^2)$ and $\mathcal{N}(\mu_B, \Sigma_B^2)$ for a quantity θ and share N readings with Gaussian noise σ and mean $\bar{m}$ [Padilla §3.4]. The rule "precisions add" of Section 5.8 gives each observer $i \in \{A, B\}$ a Gaussian posterior with

$$\hat{\mu}_i \overset{(1)}{=} \frac{N\bar{m}/\sigma^2 + \mu_i/\Sigma_i^2}{N/\sigma^2 + 1/\Sigma_i^2} \overset{(2)}{=} \frac{\bar{m} + r_i\,\mu_i}{1 + r_i}, \qquad r_i \equiv \frac{\sigma^2/N}{\Sigma_i^2},$$
$$\tau_i^2 \overset{(3)}{=} \frac{1}{N/\sigma^2 + 1/\Sigma_i^2} \overset{(4)}{=} \frac{\sigma^2/N}{1 + r_i}.$$

(1) Precision-weighted mean (5.32): the N readings count as one measurement $\bar{m}$ with variance σ^2/N.
(2) Divide numerator and denominator by N/σ^2.
(3) The posterior precision is the sum of the two precisions.
(4) Same division.

The ratio r_i compares the error of the data, $\sigma/\sqrt{N}$, with the width of the prior, Σ_i. When $r_i \ll 1$, the data dominate and $\hat{\mu}_i \to \bar{m}$ for both observers. How fast do they converge? Since $r_i \propto 1/N$, the difference $\hat{\mu}_A - \hat{\mu}_B \approx r_A\mu_A - r_B\mu_B - (r_A - r_B)\bar{m}$ falls as $1/N$. The common width $\tau \approx \sigma/\sqrt{N}$ falls only as $1/\sqrt{N}$. Their ratio falls as $N^{-1/2}$, the law of (5.42) again. With one reading the two posteriors can be far apart. After a hundred they are practically indistinguishable [Padilla Fig. 3].

Example: the confident and the open-minded physicist. Return to the two physicists of the opening: true efficiency 0.3, a flat prior, and a confident prior Beta(80, 20). For the trigger the conjugate update is exact, so we can follow the whole approach to agreement, not only its end. With z firings in N muons and prior Beta(a, b) of mean $m_0 = a/\kappa$, the posterior mean is

$$\frac{a + z}{\kappa + N} = \frac{N\hat{\theta} + \kappa m_0}{N + \kappa} \quad \Rightarrow \quad \text{mean} - \hat{\theta} = \frac{\kappa\,(m_0 - \hat{\theta})}{N + \kappa},$$

with $\hat{\theta} = z/N$. For the confident prior, $\kappa(m_0 - \hat{\theta}) \approx 100 \times (0.8 - 0.3) = 50$. The flat prior's own pull, $2(0.5 - \hat{\theta})/(N + 2)$, is tiny by comparison. Dividing by the posterior width $\sqrt{\hat{\theta}(1 - \hat{\theta})/N} \approx 0.458/\sqrt{N}$ gives the gap between the two analysts in units of the posterior width,

$$\frac{\text{gap}}{\text{width}} \approx \frac{50}{N + 100} \cdot \frac{\sqrt{N}}{0.458} = \frac{109\sqrt{N}}{N + 100}.$$

Surprisingly, this *grows* at first, because the posteriors narrow faster than they approach each other. It peaks at $N = \kappa = 100$, at about 5.5 widths. That is the moment of greatest embarrassment: both analysts are confident, and they disagree. Then the gap falls as $109/\sqrt{N}$, the $N^{-1/2}$ law, and drops below one width only when $N \gtrsim 1.2 \times 10^4$. The simulation in Figure 5.36 follows this curve: its gap peaks at 5.885 widths near $N = 122$ and stays below one width from $N = 12999$ on.

The lesson: a prior worth κ observations needs many times κ observations to be forgotten. For a prior centred far from the truth, how many times is set by how many widths away its centre lies. This matches Sivia's finding that a fair-minded coin prior needs about a thousand flips before the data overrule it [Sivia §2.1], and Lambert's that a strong model is less sensitive to the prior [Lambert §5.7].

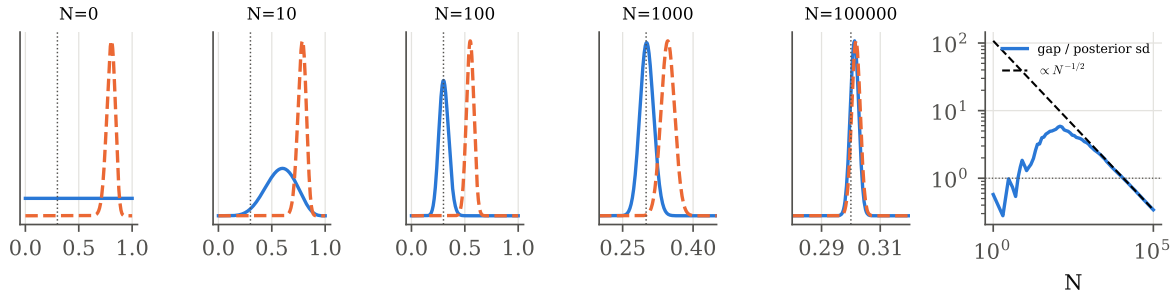

Figure 5.36: Two analysts forget their priors. First five panels: posteriors from the flat prior (solid) and from the confident prior Beta(80, 20) (dashed) after $N = 0$ to 10^5 tosses of a trigger with true efficiency 0.3 (dotted). The horizontal axis zooms in as the posteriors narrow. Last panel: the distance between the two posterior means in units of the posterior width. It rises until N is about the prior's weight of 100, then falls as $N^{-1/2}$ (dashed line) and crosses one width (dotted line) near $N = 10^4$.

5.13.2 When the prior is never forgotten

The derivation of (5.41) used every condition in the key idea: enough data, a prior nonzero at the truth, an identifiable parameter, a fixed number of parameters, and a truth away from the edge. Each one can fail, and each failure shows up in physics. We take them in turn.

Weak data. The theorem is about large N. For N comparable to the weight κ of an informative prior, or for a handful of events of any kind, the posterior is a genuine compromise and the prior matters. After one trigger firing in ten muons the three "noninformative" priors of Section 5.12 gave upper limits differing by a third, and in the $N = 10$ panel of Figure 5.36 the two analysts are 1.452 widths apart, with the gap still growing. With weak data the only honest course is to report the prior and show how the answer moves when it changes: a **prior sensitivity analysis** [Lambert §5.7].

A prior that is zero at the truth. A health minister is "morally certain" that the prevalence of a disease is below 25%, so the analysis uses a prior that is zero above 0.25 [Lambert §5.7.1]. The true value is 0.3. The posterior is prior times likelihood, so it is zero above 0.25 whatever the data say. As data accumulate the likelihood climbs steadily towards 0.3, and all the posterior can do is pile up against the wall at 0.25 (Figure 5.37, right). More data make the posterior *narrower at the wrong value*. The expansion (5.41) failed because $\ln p(\theta) = -\infty$ at the truth, so g does not exist. A prior should be zero only where a value is physically impossible.

A parameter the data cannot see. A detector records the total count n from two channels with rates λ_1 and λ_2 but cannot tell them apart, so $n \sim \text{Poisson}\big((\lambda_1 + \lambda_2)T\big)$ in exposure T. What can the count say about how the total is split between the channels? Reparametrise by the total rate $\Lambda = \lambda_1 + \lambda_2$ and the fraction $f = \lambda_1/\Lambda$ of the first channel, and take independent priors

$p(\Lambda)\,p(f)$. Then

$$p(f \mid n) \overset{(1)}{=} \int p(\Lambda, f \mid n)\,\mathrm{d}\Lambda \overset{(2)}{=} \frac{\int \mathrm{P}(n \mid \Lambda)\,p(\Lambda)\,p(f)\,\mathrm{d}\Lambda}{\iint \mathrm{P}(n \mid \Lambda')\,p(\Lambda')\,p(f')\,\mathrm{d}\Lambda'\,\mathrm{d}f'}$$
$$\overset{(3)}{=} p(f)\,\frac{\int \mathrm{P}(n \mid \Lambda)\,p(\Lambda)\,\mathrm{d}\Lambda}{\int \mathrm{P}(n \mid \Lambda')\,p(\Lambda')\,\mathrm{d}\Lambda'} = p(f).$$

(1) Marginalise over the total rate (Section 5.11).
(2) Bayes' theorem. The likelihood depends on Λ only, because the detector sees only the total.
(3) $p(f)$ comes out of the Λ integral, and $\int p(f')\,\mathrm{d}f' = 1$.

So the posterior of f is its prior, exactly, for any number of counts. The data pin down Λ ever more precisely, but the prior alone decides the split. In the simulation, 5068 counts fix Λ to 1.4%, yet two different priors on f give two completely different posteriors for λ_1 (Figure 5.37, left). Such a parameter is **not identifiable** [different values of it predict exactly the same distribution of data]. Real cases are common: a cosmological amplitude and a galaxy bias that enter only as a product, two backgrounds with the same shape, a mass and a coupling that enter a rate only in combination.

More parameters than data. The theorem assumes the number of parameters stays fixed while N grows. Wasserman gives a simplified version of the Robins–Ritov example, a missing-data problem with $B \gg N$ unknown probabilities $\theta_1, \ldots, \theta_B$ [Wasserman pp. 186–188, Ex. 11.9]. With far fewer data than parameters, most θ_j never appear in the likelihood, so their posterior equals their prior. The posterior of their average $\psi = \frac{1}{B}\sum_j \theta_j$ therefore barely moves from its prior. Yet a simple frequentist weighted average, the Horvitz–Thompson estimator, does learn ψ: its error falls as $1/\sqrt{N}$ however large B is. It succeeds because it uses the known probability that each datum is observed. Those probabilities drop out of the likelihood, so no method built on the likelihood can use them. Bayesian methods are tied to the likelihood function, and in high-dimensional problems the likelihood may not give accurate inferences.

A truth on the edge. If the true value sits on the boundary of the allowed range, such as a signal strength of exactly zero with the prior restricted to nonnegative values, the posterior is a half-Gaussian piled against the edge, not a Gaussian, and the credible and confidence intervals need not agree (Chapter 4).

5.13.3 Forgetting the prior is not forgetting the start of a chain

When a posterior cannot be computed on a grid, we explore it with a Markov chain: a random walk in parameter space, biased so that it spends time in each region in proportion to the posterior there (Chapter 9). A chain started far from the bulk of the posterior wanders for a while before it settles. That early part, the **burn-in**, is thrown away, and after it the chain has forgotten where it started. It is tempting to say the chain has also "washed out" the prior. It has not, because the two forgettings work by different mechanisms.

- *A chain forgets its starting point* because every step is drawn from a rule that leaves one target distribution unchanged, and repeated steps pull any starting distribution towards that target (Chapter 9 proves the contraction). Running the chain longer is the cure for a bad start.

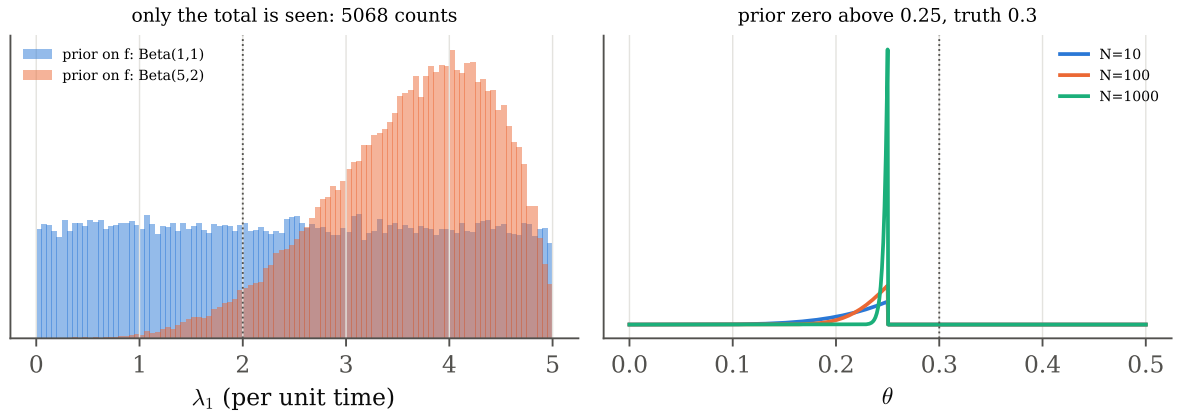

Figure 5.37: Two ways the prior is never forgotten. Left: a detector that sees only the total of two channels. With 5068 counts the total rate is known precisely, but the posterior of the first channel's rate λ_1 is set by the prior on its fraction: a flat prior gives the broad blue histogram, a Beta(5, 2) prior the orange one. The dotted line is the true $\lambda_1 = 2$. Right: a prior that is zero above 0.25 when the truth is 0.3 (dotted). With 10, 100 and 1000 data the posterior only piles up more sharply against the wall.

- *A posterior forgets its prior* only through the likelihood, (5.42): more *data*. The target of the chain is prior×likelihood, prior included, so a chain run forever reproduces the prior's influence perfectly.

Example: four chains. Take 6 firings in 20 muons and the two priors of the trigger example. We run a Metropolis chain [a random walk whose proposed steps are accepted or rejected by comparing posterior values] from $\theta = 0.02$ and from $\theta = 0.98$ for each prior, 2×10^4 steps each, and discard the first 5000.

Listing 5.8: A Metropolis chain on the trigger posterior: only a ratio of posteriors enters (`code/ch05/15_bvm.py`)

```
94 def log_post(t, pa, pb):
95     if t <= 0 or t >= 1:
96         return -np.inf
97     return (Z + pa - 1) * np.log(t) + (NN - Z + pb - 1) * np.log(1 - t)
98
99
100 def metropolis(t0, pa, pb, n=20000, step=0.08):
101     chain = np.empty(n); t, lp = t0, log_post(t0, pa, pb)
102     for i in range(n):
103         tp = t + step * rng.standard_normal()
104         lpp = log_post(tp, pa, pb)
105         if np.log(rng.uniform()) < lpp - lp:          # only a ratio of posteriors enters
106             t, lp = tp, lpp
107         chain[i] = t
108     return chain
```

Lines 94–97 are the log-posterior, $\ln[\theta^{z+a-1}(1-\theta)^{N-z+b-1}]$ up to a constant, and $-\infty$ outside $(0, 1)$. Line 103 proposes a Gaussian step. Line 105 accepts it with probability $\min(1, p_{\text{new}}/p_{\text{old}})$. This is computed from the difference of log-posteriors, so the unknown evidence cancels and never appears.

The results separate the two forgettings (Figure 5.38). With the flat prior the two chains give means 0.3147 and 0.3182 from their two starts, against the exact posterior mean 0.3182. With the confident prior they give 0.7172 and 0.716, against the exact 0.7167. Within a few dozen

steps each chain has forgotten whether it started at 0.02 or 0.98. But no number of steps brings the two priors together: they sample two different posteriors, both correctly. Only more muons would.

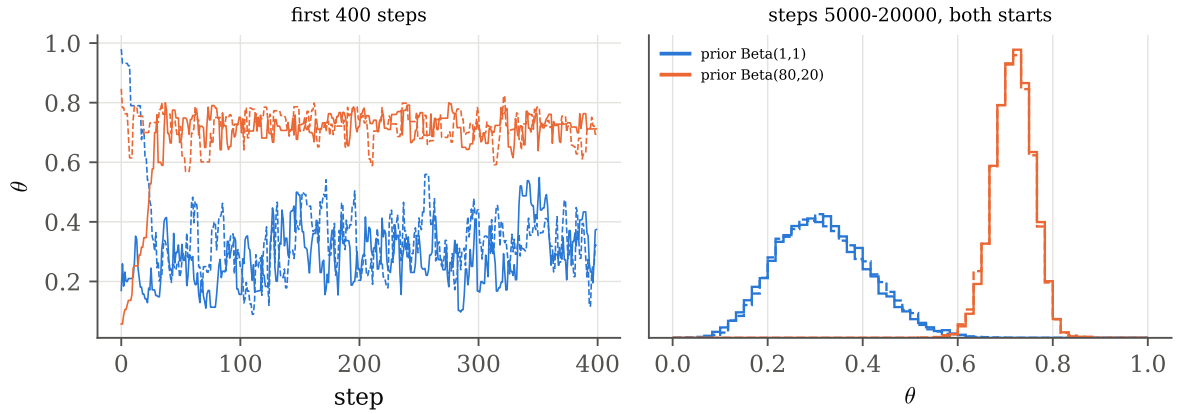

Figure 5.38: Two kinds of forgetting. Left: the first 400 steps of four Metropolis chains on the trigger posterior after 6 firings in 20 muons, started at 0.02 (solid) and 0.98 (dashed), with the flat prior (blue) and the confident prior (orange). Each pair forgets its start within a few dozen steps. Right: histograms of steps 5000 to 20000. Chains with the same prior agree whatever the start. Chains with different priors disagree however long they run.

Watch out: Burn-in does not remove a prior

Discarding burn-in removes the memory of the chain's starting point. It does nothing to the prior, which is part of the distribution the chain is built to sample. If two analyses with different priors disagree, running the chains longer will only make the disagreement more precise. The cure is more informative data, or a prior sensitivity analysis that reports how the result depends on the prior.

5.14 Sampling the posterior: a histogram instead of an integral

A mass on a spring oscillates as $x(t) = A\cos\omega t$. Where are we most likely to find it if we look at a random moment? "A random moment" already contains an assumption: the moment of looking is uniform in time, so the phase ωt is uniform over a cycle. With that assumption there are two ways to answer. One is a calculation: change variables from the uniform phase to the position and obtain the arcsine density $1/(\pi\sqrt{A^2 - x^2})$ (Chapter 1). The other needs no calculus at all. Pick a large set of random times, compute x at each, and histogram the values. The histogram piles up at the turning points, where the mass moves slowly, and it traces out the arcsine curve (Figure 5.40, bottom right). This idea can be used to find the probability distribution of position: we plot the histogram for x for a large set of random values of t.

The same idea works for a posterior. Suppose that instead of a formula for $p(\theta \mid \boldsymbol{d})$ we had a machine that produces random values $\theta_1, \ldots, \theta_B$ distributed according to it. Then a histogram of $\theta_1, \ldots, \theta_B$ approximates the posterior density $p(\theta \mid \boldsymbol{d})$ [Wasserman p. 180]. Every integral we have needed so far becomes a count or an average over the draws: a mean, a marginal, the probability of an interval. This is the bridge from Bayesian inference to Monte Carlo, and it is how almost all modern posteriors are handled.

The question, in words: if we can draw from the posterior, what can we compute from the draws, and how accurately?

Working definition 5.7 (posterior sample)

A **posterior sample** is a set of values $\theta_1, \dots, \theta_B$, each drawn from $p(\theta \mid \boldsymbol{d})$ [so that the fraction of draws in any interval approaches the posterior probability of that interval as B grows]. *Operationally:* the posterior probability of a set S is estimated by the fraction of draws in S, the posterior mean of any function $g(\theta)$ by $\frac{1}{B}\sum_i g(\theta_i)$, and a quantile by the corresponding order statistic of the sorted draws.

5.14.1 Why a histogram of draws is the density

Take a bin of width Δ around θ_j. Each draw lands in it independently with probability $P_j = \int_{\text{bin}} p(\theta \mid \boldsymbol{d})\,\mathrm{d}\theta \approx p(\theta_j \mid \boldsymbol{d})\,\Delta$, so the count n_j in the bin is binomial, $n_j \sim \text{Bin}(B, P_j)$ (Chapter 2). The histogram height, count divided by $B\Delta$, then has

$$\mathbb{E}\left[\frac{n_j}{B\Delta}\right] \overset{(1)}{=} \frac{BP_j}{B\Delta} \overset{(2)}{\approx} p(\theta_j \mid \boldsymbol{d}),$$
$$\frac{\text{sd}(n_j)}{\mathbb{E}[n_j]} \overset{(3)}{=} \frac{\sqrt{BP_j(1-P_j)}}{BP_j} \overset{(4)}{\approx} \frac{1}{\sqrt{BP_j}}.$$

(1) The mean of a binomial count is BP_j.
(2) $P_j \approx p(\theta_j \mid \boldsymbol{d})\Delta$ for a narrow bin.
(3) The standard deviation of a binomial count is $\sqrt{BP_j(1-P_j)}$.
(4) A single bin holds a small fraction of the probability, $P_j \ll 1$.

So the histogram is centred on the density. Its relative error in a bin is one over the square root of the expected count there. For example, with $B = 200000$ draws and a bin holding 1% of the probability, the expected count is 2000 and the height is good to about $1/\sqrt{2000} \approx 2\%$. The same counting argument says that averages over draws converge: the average of $g(\theta_i)$ has mean $\mathbb{E}[g(\theta) \mid \boldsymbol{d}]$ and standard deviation $\text{sd}(g)/\sqrt{B}$ for independent draws [Wasserman p. 181].

Watch out: Monte Carlo error is not the error bar

Two different widths appear. The *posterior width* $\text{sd}(\theta \mid \boldsymbol{d})$ is the physical uncertainty on the parameter. It is set by the data and does not shrink when we draw more samples. The *Monte Carlo error* $\text{sd}(\theta \mid \boldsymbol{d})/\sqrt{B}$ is how well the draws reproduce the exact posterior mean. It shrinks with B and says nothing about the physics. Quote the first as the error bar. Make sure the second is much smaller.

5.14.2 What the draws give for free

Figure 5.39 collects the operations. Each of them replaces an integral by a one-line manipulation of an array of draws.

Means and intervals. The posterior mean is estimated by $\frac{1}{B}\sum_i \theta_i$. The ends of the 95% equal-tailed interval are the 2.5% and 97.5% sample quantiles, and the HDI is the shortest window that contains 95% of the sorted draws (Section 5.9) [Wasserman p. 181].

Functions of the parameter. If $\tau = g(\theta)$, then $\tau_i = g(\theta_i)$ is a sample from the posterior of τ. No change of variables is needed [Wasserman pp. 180–181]. To see how much work this saves, take a coin's heads probability p after $s = 10$ heads in $n = 14$ tosses, with a flat prior. Write

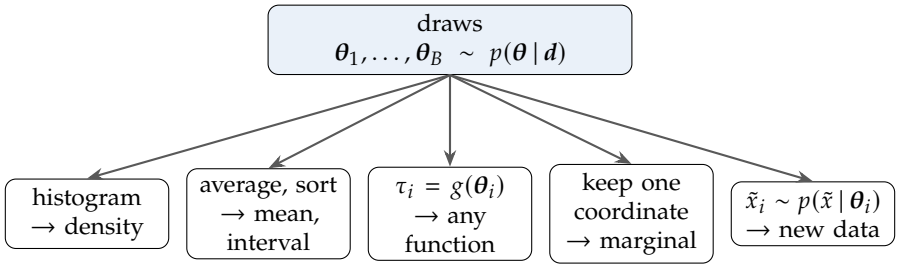

Figure 5.39: One array of posterior draws, five products. Histogramming it approximates the density. Averaging and sorting give the mean and the interval ends. Applying a function to each draw gives draws of that function. Ignoring all but one coordinate gives draws of that parameter's marginal. Simulating a new data set from each draw gives the distribution of future data.

$x^n = (x_1, \ldots, x_n)$ for the tosses. The posterior is $p \mid x^n \sim \text{Beta}(s+1, n-s+1)$ (Section 5.8). What is the posterior density of the log-odds $\psi = \ln[p/(1-p)]$? The exact route goes through the cumulative distribution H of ψ, and then its derivative h:

$$H(\psi \mid x^n) \overset{(1)}{=} \mathrm{P}\left(\ln \frac{P}{1-P} \le \psi \;\middle|\; x^n\right) \overset{(2)}{=} \mathrm{P}\left(P \le \frac{e^\psi}{1+e^\psi} \;\middle|\; x^n\right) \overset{(3)}{=} \int_0^{e^\psi/(1+e^\psi)} f(p \mid x^n)\, \mathrm{d}p,$$

$$h(\psi \mid x^n) \overset{(4)}{=} f\left(\frac{e^\psi}{1+e^\psi} \;\middle|\; x^n\right) \frac{e^\psi}{(1+e^\psi)^2} \overset{(5)}{=} \frac{\Gamma(n+2)}{\Gamma(s+1)\Gamma(n-s+1)} \left(\frac{e^\psi}{1+e^\psi}\right)^{s+1} \left(\frac{1}{1+e^\psi}\right)^{n-s+1}.$$

(1) Definition of the cumulative distribution of $\Psi = \ln[P/(1-P)]$, with P the random heads probability.
(2) The log-odds is increasing in P, so the inequality can be inverted.
(3) The probability of an interval is the integral of the posterior density over it.
(4) Differentiate with respect to ψ: fundamental theorem of calculus and chain rule, with $\mathrm{d}p/\mathrm{d}\psi$ from (5.39).
(5) Insert the Beta density $f(p \mid x^n) = \frac{\Gamma(n+2)}{\Gamma(s+1)\Gamma(n-s+1)} p^s (1-p)^{n-s}$ at $p = e^\psi/(1+e^\psi)$, and note that $\frac{e^\psi}{(1+e^\psi)^2} = p(1-p)$ raises each power by one.

This is Wasserman's Example 11.3 [Wasserman p. 180]. The sampling route takes two lines: draw $P_i \sim \text{Beta}(11, 5)$, set $\psi_i = \ln[P_i/(1-P_i)]$, and histogram [Wasserman p. 181, Ex. 11.4]. The two agree (Figure 5.40, top left). For a function of several parameters, or one with no inverse in closed form, the sampling route is the only practical one.

Marginals and combinations. Take several parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_p)$ and B draws $\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(B)}$. Their first coordinates $\theta_1^{(1)}, \ldots, \theta_1^{(B)}$ are a sample from the marginal posterior of θ_1. Keeping one coordinate and ignoring the rest replaces the $(p-1)$-dimensional integral of Section 5.11 [Wasserman p. 183, (11.9)].

A combination of parameters is just as easy. After a detector upgrade we want to know: did the efficiency improve? Before the upgrade $x_1 = 18$ of $n_1 = 40$ test pulses were detected, and after it $x_2 = 28$ of $n_2 = 40$. Call the two efficiencies p_1 and p_2. With a flat prior on the square $(p_1, p_2) \in [0,1]^2$,

$$p(p_1, p_2 \mid x_1, x_2) \propto p_1^{x_1}(1-p_1)^{n_1-x_1}\; p_2^{x_2}(1-p_2)^{n_2-x_2},$$

which factorises into $\text{Beta}(x_1+1, n_1-x_1+1)$ for p_1 times $\text{Beta}(x_2+1, n_2-x_2+1)$ for p_2: under the posterior the two efficiencies are independent [Wasserman pp. 183–184, Ex. 11.7]. The improvement is $\tau = p_2 - p_1$. Draw B values of each efficiency and subtract, $\tau_i = p_{2,i} - p_{1,i}$. The fraction of positive differences estimates $\mathrm{P}(p_2 > p_1 \mid \boldsymbol{d}) = 0.9877$, and the 95% interval for the improvement is $(0.03117, 0.4355)$ (Figure 5.40, bottom left). If the parameters were correlated, the same

subtraction of draws would use the correlation automatically, because each draw is a pair taken together. The separate marginals would have thrown that correlation away.

Predicting new data. The **posterior predictive distribution** of a future data set $\tilde{x}$ averages the forward model over our uncertainty about θ:

$$p(\tilde{x} \mid \boldsymbol{d}) \overset{(1)}{=} \int p(\tilde{x}, \theta \mid \boldsymbol{d})\, \mathrm{d}\theta \overset{(2)}{=} \int p(\tilde{x} \mid \theta, \boldsymbol{d})\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta \overset{(3)}{=} \int p(\tilde{x} \mid \theta)\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta.$$

(1) Sum rule: marginalise the joint distribution of new data and parameter.
(2) Product rule.
(3) Given θ, the new data are independent of the old data: the old data influence the prediction only through what they tell us about θ.

The sampling recipe mirrors the formula: for each draw θ_i, simulate one new data set $\tilde{x}_i$ from $p(\tilde{x} \mid \theta_i)$. The collection $\tilde{x}_1, \ldots, \tilde{x}_B$ is a sample from the predictive distribution [Lambert §7.8].

Example: two more heads. After 10 heads in 14 tosses, what is the probability that the next two tosses are both heads? The exact answer, found in Section 5.8, is $B(13,5)/B(11,5) = 0.4853$, not the plug-in $(10/14)^2 = 0.51$ [Padilla §2.3]. By sampling: for each draw p_i, toss two simulated coins with heads probability p_i and record whether both came up heads. The fraction is 0.4839, within the Monte Carlo error $\sqrt{0.485 \times 0.515/B} \approx 0.001$ of the exact value.

Example: failures in the next batch. One detector module in a batch of ten fails its burn-in test. How many failures should we expect in the next batch of ten?

- *Plug-in.* Take the failure rate to be exactly 0.1 and use $\mathrm{Bin}(10, 0.1)$. Its central 80% range is 0 to 2 failures.
- *Posterior predictive.* With a flat prior the posterior of the rate is $\mathrm{Beta}(1+1, 1+9) = \mathrm{Beta}(2, 10)$. Draw a rate, then a batch of ten with that rate, and repeat. The central 80% range is 0 to 4 (Figure 5.40, top right) [Lambert §7.8].

The predictive range is wider because it includes two sources of spread: our uncertainty about the rate, and the binomial scatter of a batch. It also gives zero failures probability 0.2612, against the plug-in 0.3487, because the rate could well be larger than 0.1. Plugging in a best value always makes predictions look more certain than they are.

5.14.3 The same code for every posterior

Listing 5.9: Posterior draws put to work: a function of the parameter, two predictive calculations and a difference of two efficiencies (`code/ch05/16_sampling.py`)

```
# ------------------------------------------------------------------ function of a parameter
s, n = 10, 14

```

Lines 35–36 draw B values of the heads probability from Beta(11, 5) and turn each into a log-odds, and line 39 is the exact density from the chain above, used only as a check. Line 47 is the two-heads prediction: two uniform numbers per draw, each below p_i with probability p_i. Lines 49–50 draw a failure rate and then a whole new batch for each draw, and lines 54–55 read the 80% predictive range off the cumulative histogram. Lines 66–68 draw the two efficiencies independently and subtract them, and lines 74–75 turn the differences into a probability and an interval. The last panel of the figure is the oscillator: uniform phases, $x = A\cos\omega t$, histogram. It is the same three lines as the log-odds, with a random phase in the place of a random heads probability.

Here every draw came from a standard generator, because every posterior was a Beta density. That is the luxury of conjugacy (Section 5.8). For a realistic posterior in six or twenty dimensions we have neither a grid nor a generator. We can only evaluate $\mathcal{L}(\boldsymbol{\theta})\,p(\boldsymbol{\theta})$ at any point we choose. Monte Carlo methods turn uniform random numbers into draws from simple distributions (Chapter 6), and Markov chain Monte Carlo builds a random walk whose visited points are draws from a posterior known only up to its normalising constant (Chapter 9). Everything downstream of the draws, the histograms, averages, quantiles, functions, marginals and predictions of this section, stays exactly the same.

Recap

- For a continuous parameter, the observed data are the event, the parameter values are the hypotheses, and $p(\lambda \mid \boldsymbol{d}) = \mathcal{L}(\lambda)p(\lambda)/p(\boldsymbol{d})$ is a density. On a grid, sum

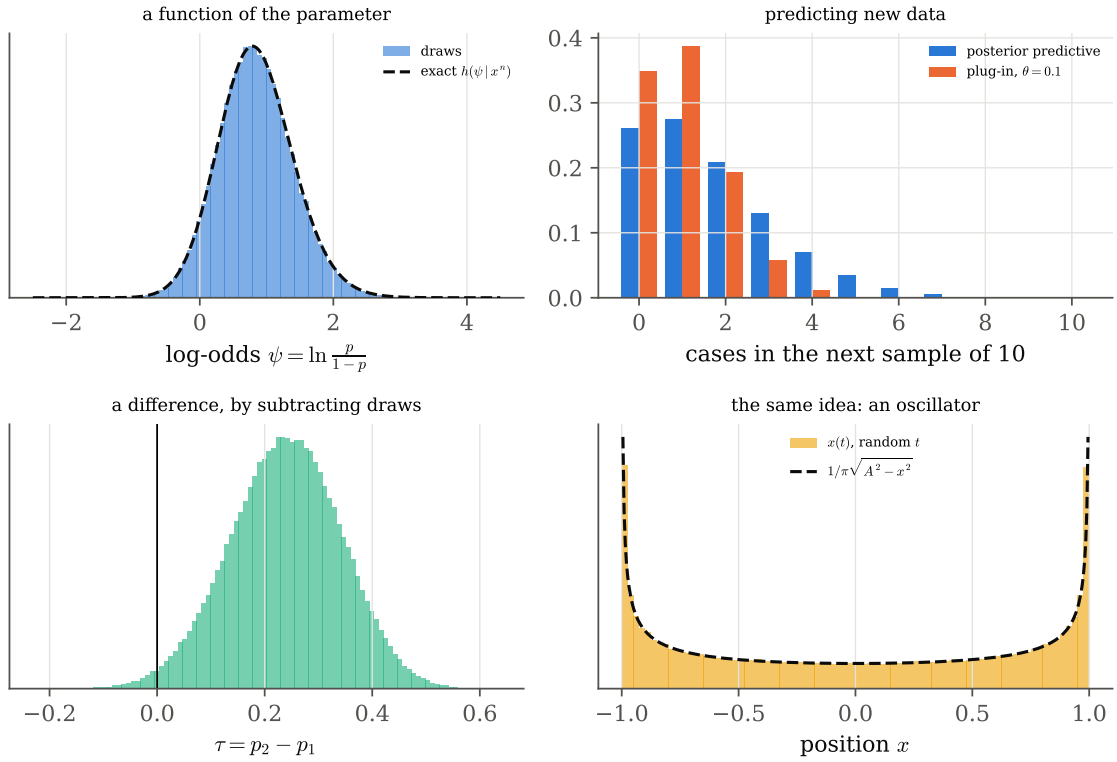

Figure 5.40: Posterior draws at work. Top left: draws of the heads probability after 10 heads in 14, turned into log-odds and histogrammed, against the exact density (dashed). Top right: the predicted number of failures in the next batch of ten modules after one failure in ten, from posterior draws (blue) and from plugging in the rate 0.1 (orange). Bottom left: the improvement in efficiency, from differences of draws. Bottom right: the same idea for an oscillator. Positions at uniformly random times follow the arcsine density (dashed).

log-likelihoods and subtract the maximum before exponentiating.

- Conjugate pairs (Beta–Binomial, Gamma–Poisson, Gaussian–Gaussian) give exact posteriors. In the Gaussian case precisions add and means are precision-weighted.
- Summaries: the posterior mean, median and mode minimise squared, absolute and all-or-nothing loss. Equal-tailed intervals are invariant under reparametrisation. HDIs are the shortest.
- Near a single peak the posterior is Gaussian with covariance minus the inverse Hessian of $\ln p$. Marginal errors come from the diagonal of the inverse.
- Nuisance parameters are integrated out. Profiling maximises over them instead, and the two differ by a volume factor.
- No prior is flat in every parametrisation. Jeffreys' prior $\sqrt{I(\theta)}$ is coordinate independent: $1/\sigma$ for a scale, Beta$(\frac{1}{2}, \frac{1}{2})$ for a Bernoulli probability.
- With many data a smooth prior's influence dies as $N^{-1/2}$ posterior widths (Bernstein–von Mises). It is never forgotten if it is zero at the truth, if the parameter is not identifiable, or if parameters outnumber data. A Markov chain forgets its start, not its prior.

- A histogram of posterior draws is the posterior. Functions, marginals and predictions of new data are one line each on the draws.

5.15 Which model produced the data?

Is the spectrum of primordial fluctuations exactly scale invariant, with spectral index $n_s = 1$, or is it tilted, with n_s a free number to be measured? Does a smooth falling background describe a diphoton mass spectrum, or does a resonance sit on top of it? Is a gravitational-wave event the merger of two black holes, or of two neutron stars whose tides leave a mark on the waveform? None of these asks for the value of a parameter inside a model we have agreed on. Each asks *which model* is right: which of several descriptions of nature, each with its own parameters, produced the data we have.

Until now the hypotheses were the possible values of a parameter θ inside one model. We observed data and asked which value of θ could have produced them. Now the hypotheses are whole models. The reasoning does not change. The four questions of Section 5.1 (what did we see, what could have produced it, how probable was it under each candidate, how do the prior probabilities change) get these answers: (1) we saw the whole data set $\boldsymbol{d}$; (2) the candidates are the models $M_1, M_2, \ldots$; (3) under each model the data have the probability $p(\boldsymbol{d} \mid M_i)$, the evidence derived below; (4) multiplying by the prior probabilities $\mathrm{P}(M_i)$ and normalising gives the posterior probability of each model.

Only step 3 is new, and it raises a question: how probable are the data under a model whose parameter we do not know? A model with a free parameter does not make one prediction for the data. It makes a different prediction for every value of its parameter, and before the data arrive we do not know which value nature chose. So the probability of the data under the model must be an average: over the parameter values the model allows, each weighted by how probable the model thought it was. Once this average is written down, Bayes' theorem chooses between models exactly as it chose between parameter values.

5.15.1 The probability of the data under a model

A model M, for our purposes, is two things [HobsonBMC §4.1], [Kruschke §10.1], [32, §4.1]:

1. a likelihood $p(\boldsymbol{d} \mid \boldsymbol{\theta}, M)$ [for each parameter value, the probability of the data this model would produce], and
2. a prior $p(\boldsymbol{\theta} \mid M)$ [how probable the model considered each parameter value before the data].

The two together are a complete recipe for generating data: draw $\boldsymbol{\theta}$ from the prior, then draw $\boldsymbol{d}$ from the likelihood at that $\boldsymbol{\theta}$. A tree shows the recipe (Figure 5.41). The first split chooses the model. The second chooses a parameter value inside the model. The leaves are the data. The observed data set $\boldsymbol{d}$ can be reached along many paths inside each model, one for every parameter value.

The probability of reaching the observed data inside model M is the sum over its paths. Each path contributes (probability of choosing $\boldsymbol{\theta}$)×(probability of producing $\boldsymbol{d}$ from $\boldsymbol{\theta}$). In symbols,

$$p(\boldsymbol{d} \mid M) \overset{(1)}{=} \int p(\boldsymbol{d}, \boldsymbol{\theta} \mid M)\, \mathrm{d}\boldsymbol{\theta}$$

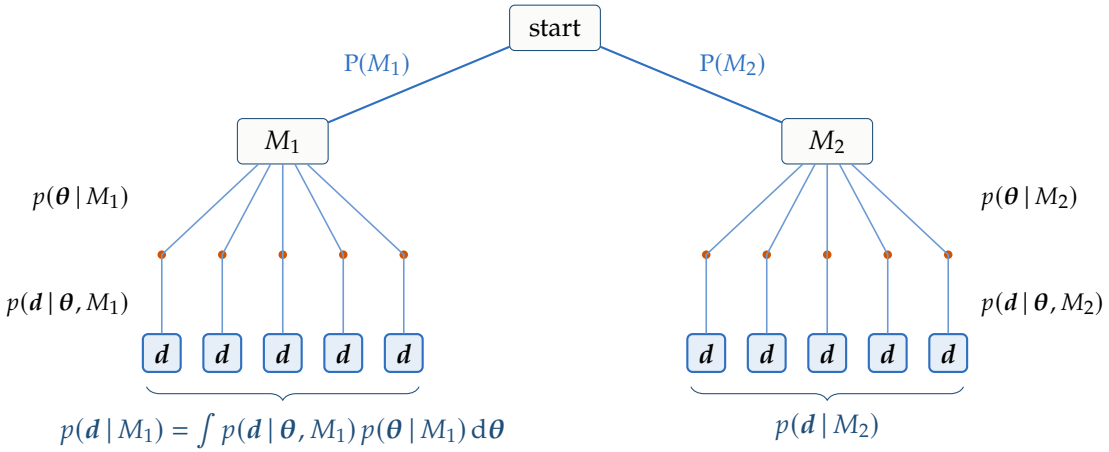

Figure 5.41: Two models as a probability tree. The first split picks the model, the second picks a parameter value inside it (orange dots stand for the continuum of values), and every path ends at the same observed data set $\boldsymbol{d}$. The probability of reaching $\boldsymbol{d}$ inside a model is the sum over all of that model's paths: the evidence.

$$\overset{(2)}{=} \int p(\boldsymbol{d} \mid \boldsymbol{\theta}, M)\, p(\boldsymbol{\theta} \mid M)\, \mathrm{d}\boldsymbol{\theta}. \tag{5.43}$$

(1) Marginalisation (the sum rule for densities): the probability of $\boldsymbol{d}$ is the joint probability of $\boldsymbol{d}$ and $\boldsymbol{\theta}$ integrated over every $\boldsymbol{\theta}$, because the parameter must have *some* value.
(2) The product rule inside the model: the joint probability of a path is the probability of choosing $\boldsymbol{\theta}$ times the probability of producing $\boldsymbol{d}$ from it.

We have met this number before. It is the denominator of Bayes' theorem for the parameters of M, $p(\boldsymbol{\theta} \mid \boldsymbol{d}, M) = p(\boldsymbol{d} \mid \boldsymbol{\theta}, M)\, p(\boldsymbol{\theta} \mid M)/p(\boldsymbol{d} \mid M)$. It is also called the prior predictive probability of the data: the model's forecast of the data before they are taken [Sivia p. 82, (4.3)], [HobsonBMC p. 83, (4.5)], [Kruschke p. 268, (10.4)], [Padilla (12)], [32, eq. (17)]. In parameter estimation it did not depend on $\boldsymbol{\theta}$, so it only normalised the posterior and we could drop it. In model comparison it is the quantity we need.

The words that go with (5.43) are worth remembering: "For the distribution of parameter values you thought reasonable before the data came along, what was the average value of the likelihood?" [HobsonBMC p. 83]. The evidence is the likelihood averaged over the prior.

Working definition 5.8 (evidence of a model)

The **evidence** (or **marginal likelihood**) of a model M is

$$Z_M \equiv p(\boldsymbol{d} \mid M) = \int p(\boldsymbol{d} \mid \boldsymbol{\theta}, M)\, p(\boldsymbol{\theta} \mid M)\, \mathrm{d}\boldsymbol{\theta},$$

the probability, before the data were seen, that M would produce the data set actually observed [the likelihood averaged over the prior of that model]. *Operationally:* draw many parameter values from the prior and average the likelihood, or integrate likelihood × prior on a grid. It is a probability (or density) of the data, not of the parameters, so it carries the units and the normalisation of $\boldsymbol{d}$.

The prior is part of the model, because the evidence averages over it. Two models with the same likelihood and different priors are different models, and they have different evidences. Everything else about model comparison follows from this point [Kruschke p. 268].

5.15.2 Posterior model probabilities and the Bayes factor

With the evidence of each model in hand, steps 3 and 4 of the reasoning are Bayes' theorem with the models as the hypotheses. If we believed model M_i with probability $\mathrm{P}(M_i)$ before the data, then

$$\mathrm{P}(M_i \mid \boldsymbol{d}) = \frac{p(\boldsymbol{d} \mid M_i)\ \mathrm{P}(M_i)}{\sum_j p(\boldsymbol{d} \mid M_j)\ \mathrm{P}(M_j)}. \tag{5.44}$$

The logic is unchanged: nature produced one observed data set, several models could have produced it, and the posterior shares the probability among them according to how readily each would have produced what we saw. For two models the denominator cancels in the ratio:

$$\begin{aligned} \frac{\mathrm{P}(M_1 \mid \boldsymbol{d})}{\mathrm{P}(M_2 \mid \boldsymbol{d})} &\overset{(1)}{=} \frac{p(\boldsymbol{d} \mid M_1)\ \mathrm{P}(M_1)/p(\boldsymbol{d})}{p(\boldsymbol{d} \mid M_2)\ \mathrm{P}(M_2)/p(\boldsymbol{d})} \\ &\overset{(2)}{=} \underbrace{\frac{p(\boldsymbol{d} \mid M_1)}{p(\boldsymbol{d} \mid M_2)}}_{B_{12}} \times \frac{\mathrm{P}(M_1)}{\mathrm{P}(M_2)}. \end{aligned} \tag{5.45}$$

(1) (5.44) for $i = 1$ and $i = 2$, with the common denominator written as $p(\boldsymbol{d}) = \sum_j p(\boldsymbol{d} \mid M_j)\,\mathrm{P}(M_j)$.
(2) $p(\boldsymbol{d})$ cancels, and we group the evidences and the priors.

Posterior odds equal the **Bayes factor** B_{12} times the prior odds [Kruschke p. 268, (10.5)], [Sivia p. 82, (4.2)], [32, eqs. (19)–(20)]. It is the odds form of Bayes' theorem (posterior odds = likelihood ratio × prior odds), with each hypothesis now a whole model. The Bayes factor is the factor by which the data change the odds, whatever the odds were before.

Working definition 5.9 (Bayes factor)

The **Bayes factor** of model M_1 against model M_2 is the ratio of their evidences,

$$B_{12} = \frac{Z_1}{Z_2} = \frac{p(\boldsymbol{d} \mid M_1)}{p(\boldsymbol{d} \mid M_2)},$$

[how many times more probable the observed data were under M_1 than under M_2]. $B_{12} > 1$ means the data moved the odds towards M_1. It is usually quoted as $\ln B_{12} = \ln Z_1 - \ln Z_2$.

Model comparison is parameter estimation for one more parameter: the label of the model. Give the model a label m that takes the values $1, 2, \ldots$. The complete unknown is then the pair (m, the parameters of model m). Bayes' theorem on this joint space shares out the probability at both levels at once: between the models, and between parameter values inside each model [Kruschke pp. 266–267, (10.1)–(10.3)]. Summing the joint posterior over the parameters of each model leaves the posterior of m alone, which is (5.44). Cosmologists speak of three levels of inference [HobsonBMC §4.2]: parameter estimation inside a model, model comparison between models, and model averaging, which combines the parameter posteriors of all models weighted by the model probabilities (Section 5.18).

Example: which factory minted this coin? The example is Kruschke's [Kruschke §10.2]. A novelty company has two coin factories. One makes tail-biased coins: the bias θ [the probability of heads] of its coins is spread as $\mathrm{Beta}(\theta \mid 3.5, 8.5)$, with mode 0.25. The other makes head-biased coins, $\mathrm{Beta}(\theta \mid 8.5, 3.5)$, mode 0.75. We are given one coin from one of the factories, we do not know which, and we toss it nine times.

The event. The coin shows a particular sequence with $z = 6$ heads in $N = 9$ tosses.

What could have produced it? Two models: M_1, the coin came from the tail-biased factory; M_2, from the head-biased factory. Inside each model the coin's own bias θ is unknown.

How probable was this sequence under each model? Under M_i with prior $\mathrm{Beta}(\theta \mid a, b)$, a coin of bias θ produces this sequence with probability $\theta^z(1-\theta)^{N-z}$. Averaging over the factory's biases,

$$p(\boldsymbol{d} \mid M_i) \overset{(1)}{=} \int_0^1 \theta^z(1-\theta)^{N-z}\,\frac{\theta^{a-1}(1-\theta)^{b-1}}{B(a,b)}\,\mathrm{d}\theta$$
$$\overset{(2)}{=} \frac{1}{B(a,b)}\int_0^1 \theta^{z+a-1}(1-\theta)^{N-z+b-1}\,\mathrm{d}\theta \overset{(3)}{=} \frac{B(z+a,\,N-z+b)}{B(a,b)}. \tag{5.46}$$

(1) The evidence (5.43): likelihood of the sequence times the Beta prior density, whose normalisation is the Beta function $B(a,b) = \int_0^1 \theta^{a-1}(1-\theta)^{b-1}\mathrm{d}\theta$.
(2) Collect the powers of θ and of $1-\theta$.
(3) The remaining integral is, by definition, the Beta function at the shifted arguments.

This is Kruschke's (10.6). For the tail-biased factory ($a = 3.5$, $b = 8.5$) it gives $p(\boldsymbol{d} \mid M_1) = 4.993 \times 10^{-4}$, and for the head-biased factory ($a = 8.5$, $b = 3.5$) it gives $p(\boldsymbol{d} \mid M_2) = 0.002339$. A 1001-point grid over θ reproduces both to the digits shown. The Bayes factor is $B_{12} = 0.2135$: six heads in nine were 4.683 times more probable from the head-biased factory.

Only then the priors, and the normalisation. If either factory was equally likely to have made our coin, the prior odds are one, and

$$\mathrm{P}(M_1 \mid \boldsymbol{d}) \overset{(1)}{=} \frac{B_{12}}{1+B_{12}} = \frac{0.2135}{1+0.2135} = 17.6\%, \qquad \mathrm{P}(M_2 \mid \boldsymbol{d}) = 82.4\%.$$

(1) From (5.45) with prior odds 1: $\mathrm{P}(M_1 \mid \boldsymbol{d})/\mathrm{P}(M_2 \mid \boldsymbol{d}) = B_{12}$ and the two posteriors add to one.

Figure 5.42 shows where the numbers come from. The evidence is the area under likelihood×prior. The head-biased factory puts its prior where the likelihood is large, so its area is almost five times bigger.

Notice what the comparison did *not* give us: any statement about the bias of this coin. For that we go back to parameter estimation inside each model. Inside the tail-biased factory the posterior is $\mathrm{Beta}(z+a, N-z+b)$ with mean $(z+a)/(N+a+b) = 0.4524$; inside the head-biased factory the mean is 0.6905. If we must give one answer for the bias without deciding on a factory, we average the two posteriors with the model probabilities as weights, 17.6% and 82.4%, which gives the mean 0.6486 [Kruschke §10.4]. We return to this averaging in Section 5.18.

Example: background only, or background plus signal? A counter records events from a source that may or may not exist. The background is well measured: in the time of the run we expect $b = 2$ background counts.

The event. The run records $n = 5$ counts.

What could have produced it? Model M_0: background only, counts $\sim \mathrm{Poisson}(b)$. Model M_1: background plus a signal of unknown strength s, counts $\sim \mathrm{Poisson}(b+s)$. Before the run, the physics of the source allows any s between 0 and $s_{\max} = 10$ counts, and we take s uniform in that range.

How probable were five counts under each model? Under M_0 there is nothing to average: $p(n \mid M_0) = e^{-b}b^n/n! = 0.03609$. Under M_1 we average the Poisson probability over the prior of

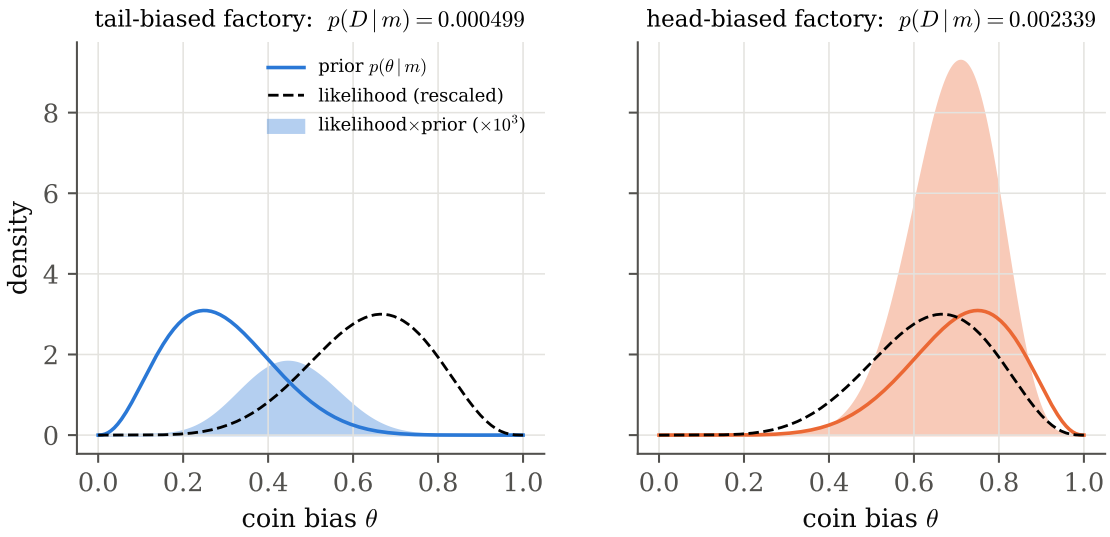

Figure 5.42: The evidence as an area. In each panel the solid curve is the factory's spread of coin biases (its prior), the dashed curve the likelihood of six heads in nine tosses (rescaled to fit), and the shaded region their product, whose area is the evidence printed above the panel. The likelihood is the same in both panels; only the prior differs, and with it the overlap.

s:

$$p(n \mid M_1) \overset{(1)}{=} \frac{1}{s_{\max}} \int_0^{s_{\max}} \frac{e^{-(b+s)}(b+s)^n}{n!}\,\mathrm{d}s \overset{(2)}{=} \frac{1}{s_{\max}} \int_b^{b+s_{\max}} \frac{e^{-u}u^n}{n!}\,\mathrm{d}u$$
$$\overset{(3)}{=} \frac{1}{s_{\max}}\Big[F_n(b) - F_n(b+s_{\max})\Big], \qquad F_n(a) \equiv \sum_{j=0}^{n} \frac{e^{-a}a^j}{j!}. \tag{5.47}$$

(1) The evidence (5.43) with the uniform prior density $1/s_{\max}$.
(2) Substitute $u = b + s$.
(3) The identity $\int_a^\infty e^{-u}u^n/n!\,\mathrm{d}u = F_n(a)$, the probability that a Poisson variable of mean a is at most n. It follows by integrating by parts n times; each step peels off one term $e^{-a}a^j/j!$. It says that the waiting time to the $(n+1)$-th event of a unit-rate Poisson process exceeds a exactly when at most n events happened before a.

With $F_5(2) = 0.9834$ and $F_5(12) = 0.02034$ this gives $p(n \mid M_1) = 0.09631$ (quadrature agrees). The Bayes factor is $B_{10} = 2.669$ in favour of a signal, and with even prior odds the probability that the source is there is 0.7274.

The Bayes factor is smaller than the best fit would suggest, and the gap is the price of not knowing s. The best signal value is $\hat{s} = n - b = 3$. At that value five counts are 4.862 times more probable than under background only. The Bayes factor is only 2.669. Why? The signal model does not commit to $s = 3$. It also spreads its probability over values like $s = 9$, which would have produced far more than five counts, and those values pull the average down. The ratio of the two numbers, 0.5489, is the price the signal model pays for not knowing s in advance; Section 5.16 derives this price in general. The price depends on how wide the prior range is. If the physics had allowed anything up to $s_{\max} = 100$, the same five counts would have given $B_{10} = 0.2725$, and the data would then favour background only. The prior range of a parameter is part of what the model claims.

Key idea: The evidence judges a model with its prior

A model is a likelihood *and* a prior. Its evidence is the likelihood averaged over its prior, and the Bayes factor, the ratio of two evidences, multiplies the prior odds of the models. A model that spreads its prior over parameter values the data do not favour gets a smaller average, even if its best fit is excellent.

Two cautions about reading a quoted Bayes factor. First, conventions differ. $B_{01} = Z_0/Z_1$ and $B_{10} = Z_1/Z_0 = 1/B_{01}$ are both in use, and some authors call $\ln(Z_0/Z_1)$ itself "the Bayes factor" [Padilla (13)–(14)]. Always check which model is in the numerator and whether a logarithm has been taken. Second, a Bayes factor is not the posterior odds. It multiplies the prior odds, so a model with prior probability zero stays at zero whatever its Bayes factor [Kruschke §10.5.1].

5.15.3 No model is rejected on its own

Can we ask how probable one model is, without naming any competitor? No. Look at the denominator of (5.44): it is a sum over the competitors, each with its evidence. Suppose we try to make do with "M is false" as the only alternative. The denominator then needs $p(\boldsymbol{d} \mid \text{not } M)$, the probability of the data given that M is false. That number cannot be computed, because "M is false" makes no prediction for the data [Sivia pp. 87–88]. We need well-defined alternatives, each making its own prediction. Once we have a list of them, the question has become model comparison.

A bad fit, on its own, does not make a model improbable. A large χ^2 means a small likelihood $p(\boldsymbol{d} \mid \boldsymbol{\theta}, M)$ at the best parameters. The posterior probability of M also needs the prior and the evidence of the alternatives, and a bad fit says nothing about those. What a bad fit does do is tell us to go and look for an alternative [Sivia p. 88]. The history of Neptune shows that support for a theory is always support against something [32, §4.1]. Finding Neptune near the predicted position strengthened Newtonian gravity against a theory that predicted no planet there. It did nothing to Newton's standing against Einstein's gravity, which predicts the same orbit. How much an observation supports a theory depends on what it is compared with.

5.16 Occam's razor from the evidence

A better fit alone cannot choose between models. Here is why. Forty measurements y_i are taken at equally spaced points x_i between 0 and 10, each with Gaussian noise of standard deviation $\sigma = 1$. One physicist says the points scatter about a straight line, $y = a + bx$. A second says there is also a Gaussian bump on top of the line, the signature of a resonance, with known width $W = 0.5$, height A and unknown position μ. Whatever the data, the second physicist's best fit is at least as good as the first's, because setting $A = 0$ turns the bump model into the line. So the best-fit χ^2 never prefers the simpler model, and a rule that picks the model with the smallest χ^2 would find a bump in every data set. For the same reason a tenth-order polynomial always beats a straight line, and nobody believes it [Sivia p. 81].

The evidence settles this without any extra rule. The more flexible model spread its prior over many parameter values, and the data rule most of them out. So its *average* likelihood, which is the evidence, can be low even when its *best* likelihood is high.

5.16.1 Mr A and Mr B

The simplest version is a story due to Jeffreys, as told by Gull and Sivia [Sivia §4.1]. Mr A has a theory with no adjustable parameter. Mr B has a theory with one adjustable parameter λ.

Whose theory should we prefer, given data $\boldsymbol{d}$?

The event is the data $\boldsymbol{d}$. *The hypotheses* are A and B. *How probable was* $\boldsymbol{d}$ *under each?* For Mr A this is a straightforward likelihood, $p(\boldsymbol{d} \mid A)$, since his theory predicts the data with nothing left to choose. Mr B cannot predict the data without a value of λ, so his probability of the data is the evidence (5.43), an average over his prior for λ. To make it concrete, Sivia makes two simple assumptions (Figure 5.43):

1. Before seeing the data, Mr B will only say that λ lies between $\lambda_{\min}$ and $\lambda_{\max}$, so his prior is uniform: $p(\lambda \mid B) = 1/(\lambda_{\max} - \lambda_{\min})$ in that range, zero outside [Sivia (4.4)].
2. His likelihood has a single peak at the best value λ_0, of height $p(\boldsymbol{d} \mid \lambda_0, B)$, and near the peak it is Gaussian with width $\delta\lambda$ [Sivia (4.5)]:

$$p(\boldsymbol{d} \mid \lambda, B) \approx p(\boldsymbol{d} \mid \lambda_0, B)\, \exp\!\left[-\frac{(\lambda - \lambda_0)^2}{2\,\delta\lambda^2}\right].$$

The likelihood is a function of λ but not a density in λ: its area is not one. Its height at the peak is the probability of the data at the best value.

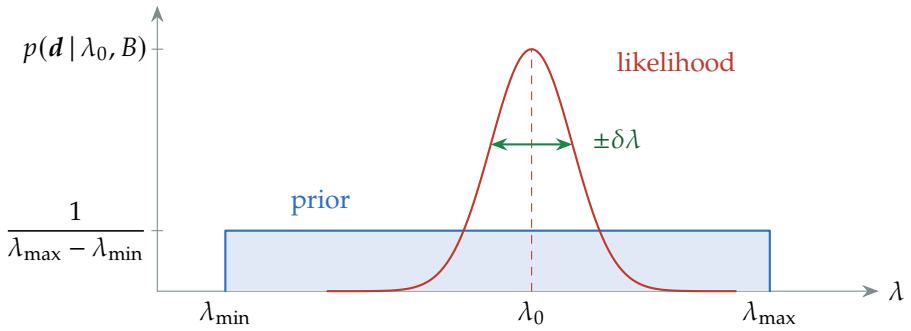

Figure 5.43: Mr B's prior and likelihood for his parameter. The prior (blue box) spreads unit probability evenly over the range $\lambda_{\min}$ to $\lambda_{\max}$; its height is drawn exaggerated. The likelihood (red) is large only within about $\delta\lambda$ of its peak. The evidence is the likelihood averaged over the box, so it is roughly the peak height times the fraction of the box the peak occupies.

With these two assumptions the average over Mr B's prior can be done by hand:

$$\begin{aligned} p(\boldsymbol{d} \mid B) &\overset{(1)}{=} \int p(\boldsymbol{d} \mid \lambda, B)\, p(\lambda \mid B)\, \mathrm{d}\lambda \overset{(2)}{=} \frac{1}{\lambda_{\max} - \lambda_{\min}} \int_{\lambda_{\min}}^{\lambda_{\max}} p(\boldsymbol{d} \mid \lambda, B)\, \mathrm{d}\lambda \\ &\overset{(3)}{=} \frac{p(\boldsymbol{d} \mid \lambda_0, B)}{\lambda_{\max} - \lambda_{\min}} \int_{-\infty}^{\infty} e^{-(\lambda-\lambda_0)^2/2\delta\lambda^2}\, \mathrm{d}\lambda \overset{(4)}{=} \frac{p(\boldsymbol{d} \mid \lambda_0, B)\; \delta\lambda\sqrt{2\pi}}{\lambda_{\max} - \lambda_{\min}}. \end{aligned} \tag{5.48}$$

(1) The evidence (5.43) for Mr B.
(2) The uniform prior is a constant inside the range and zero outside, so it comes out of the integral and restricts the limits [Sivia (4.6)].
(3) The Gaussian form of the likelihood. We also assumed the peak lies well inside the range, so extending the limits to $\pm\infty$ loses almost nothing.
(4) The Gaussian integral $\int e^{-u^2/2s^2}\mathrm{d}u = s\sqrt{2\pi}$ [Sivia (4.7)].

Put this into the odds (5.45) with $M_1 = A$ and $M_2 = B$:

$$\frac{\mathrm{P}(A \mid \boldsymbol{d})}{\mathrm{P}(B \mid \boldsymbol{d})} = \underbrace{\frac{\mathrm{P}(A)}{\mathrm{P}(B)}}_{\text{prior odds}} \times \underbrace{\frac{p(\boldsymbol{d} \mid A)}{p(\boldsymbol{d} \mid \lambda_0, B)}}_{\text{best-fit ratio}} \times \underbrace{\frac{\lambda_{\max} - \lambda_{\min}}{\delta\lambda\sqrt{2\pi}}}_{\text{Occam factor}}. \tag{5.49}$$

This is Sivia's (4.8). Each of the three factors answers its own question. The first says what we thought before the data. The second says how well each theory does at its best; since Mr B can always tune λ, this ratio can only favour him. The third is new. It compares the range of λ that Mr B's theory allowed before the data, $\lambda_{\max} - \lambda_{\min}$, with the range the data allow, about $\delta\lambda$. The first is usually much wider, so this factor is large and favours Mr A. It is called the **Occam factor** (Sivia writes Ockham), because it puts a number on William of Ockham's rule that "it is vain to do with more what can be done with fewer" [Sivia p. 84].

Working definition 5.10 (Occam factor)

For a model with parameters, the **Occam factor** is the ratio of its evidence to its best-fit likelihood,

$$\frac{Z}{\mathcal{L}_{\max}} \approx \frac{\text{volume of parameter space allowed by the posterior}}{\text{volume allowed by the prior}} \leq 1,$$

[the fraction of the prior's parameter range that the data leave standing]. The evidence is the best fit times the Occam factor.

Reading (5.49) in a few limits tells us how the razor behaves [Sivia pp. 84–86]:

- *Good data, genuine effect.* If Mr B's extra parameter is really needed, the best-fit ratio is tiny (his fit is much better) and it overwhelms the Occam factor. Most of the time the goodness of fit decides.
- *Good data, no effect.* If Mr B's fit is not much better, the best-fit ratio stays near one, while more data make $\delta\lambda$ smaller and the Occam factor larger. Mr A is favoured ever more strongly as the data improve.
- *Poor data.* If the data barely constrain λ, then $\delta\lambda$ approaches the prior range and the likelihood is flat, so both the best-fit ratio and the Occam factor approach one. The posterior odds return to the prior odds: poor data have taught us nothing.
- *Unbounded prior.* If $\lambda_{\max} - \lambda_{\min} \to \infty$, the Occam factor is infinite and Mr B always loses. Jeffreys worried about this. In practice the range is always bounded by what we know. A new fifth force with a huge coupling would have been noticed long ago, so its strength has an upper bound before any new experiment.

Two variations make the razor sharper.

- *Both theories have one parameter.* Give Mr A a parameter μ, with a uniform prior and a Gaussian likelihood of width $\delta\mu$, just like Mr B's. Each evidence now carries its own Occam factor. With equal prior ranges the ranges cancel, and the posterior odds are the best-fit ratio times $\delta\mu/\delta\lambda$ [Sivia (4.9)]. So for equally good fits the theory with the *larger* error bar wins. That sounds backwards, but a larger error bar means that more of the theory's parameter values agree with the data.
- *The same theory, two prior ranges.* Let Mr A and Mr B hold the same theory, but let Mr A claim a narrower prior range, still wide enough to contain the fit. Everything cancels except the ranges, and the odds are the ratio of the ranges in Mr A's favour. He predicted the parameter more precisely, and the evidence rewards him for it.

None of this touches parameter estimation. Inside Mr B's theory the posterior for λ is likelihood times prior divided by the evidence [Sivia (4.10)]. The prior is the constant $1/(\lambda_{\max} - \lambda_{\min})$, and it appears in both the numerator and the evidence (5.48), so it cancels; so does the peak height. What is left is the Gaussian $\lambda = \lambda_0 \pm \delta\lambda$, whatever the range, as long

as the range contains the peak. The range matters only when we compare models. The same equation serves both purposes; we are asking it different questions.

Example: the counting experiment again. In Section 5.15.2 five counts on an expected background of $b = 2$ gave a best-fit likelihood ratio of 4.862 for a signal, but a Bayes factor of only 2.669. The Occam factor explains the difference. We need the width δs of the likelihood. The log-likelihood is $\ln p(n \mid s) = -(b+s) + n \ln(b+s) - \ln n!$. Its second derivative is $-n/(b+s)^2$, and at the peak $\hat{s} = n - b$, where $b + s = n$, this is $-1/n$. A Gaussian of width δs has second derivative of its logarithm $-1/\delta s^2$, so $\delta s = \sqrt{n} = \sqrt{5}$. The prior range is $s_{\max} = 10$, and (5.48) gives the Occam factor

$$\frac{\delta s \sqrt{2\pi}}{s_{\max}} = \frac{\sqrt{10\pi}}{10} \approx 0.56,$$

close to the exact ratio 0.5489 of evidence to best fit. The Gaussian approximation is rough for a Poisson likelihood with five counts, but the size of the penalty is right: a signal prior of width 10 against a data width of about 2.2.

Example: must be fair, or anything goes? Kruschke's version compares two coin factories that differ only in how widely they spread their coin biases [Kruschke §10.5]. The "must-be-fair" factory makes coins with $\theta \sim \text{Beta}(500, 500)$, all very close to 0.5. The "anything-goes" factory makes $\theta \sim \text{Beta}(1, 1)$, uniform on $[0, 1]$. The second model is the more flexible: it contains a coin matching any observed fraction of heads. The evidence of each is (5.46). For $z = 15$ heads in $N = 20$ tosses the Bayes factor of fair against anything is 0.3229: the fair model has no bias near 0.75, and loses. For $z = 11$ heads it is 3.337: now the fair model wins, although the anything model contains the bias 0.55 that matches the data exactly. The anything model pays for spreading its prior over biases like 0.1 and 0.9 that these data rule out. Figure 5.44 shows the pattern for every possible z: the simpler model wins whenever the data are consistent with it, here for $7 \le z \le 13$.

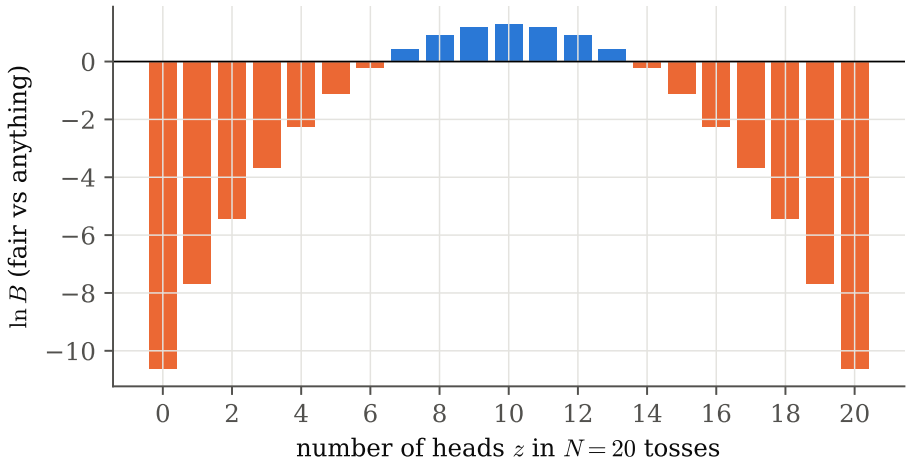

Figure 5.44: Natural Occam's razor for coins. For each possible number of heads in twenty tosses, the bar is the log Bayes factor of the must-be-fair factory against the anything-goes factory. Near ten heads the simple model wins by a modest factor (blue); far from ten it loses by a large one (orange), because it simply cannot produce such data.

The picture is asymmetric, and that is typical. A simple model that is wrong is punished hard, because it has no parameter value near the data. A flexible model that is unnecessary is punished gently, by a factor of a few, the size of its Occam factor.

5.16.2 Many parameters: the Laplace approximation

The same argument works in D dimensions. Near its peak $\hat{\boldsymbol{\theta}}$ the logarithm of the likelihood is approximately quadratic,

$$\ln \mathcal{L}(\boldsymbol{\theta}) \approx \ln \mathcal{L}_{\max} - \tfrac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^{\mathsf{T}} \mathbf{F} \, (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}),$$

where $\mathbf{F}$ is the matrix of second derivatives of $-\ln \mathcal{L}$ at the peak [the curvature of the log-likelihood, the Fisher matrix of Chapter 10 evaluated on these data]. Its inverse is the covariance of the Gaussian approximation to the posterior. If the prior $\pi(\boldsymbol{\theta})$ changes little across the peak,

$$\begin{aligned} Z &\overset{(1)}{=} \int \mathcal{L}(\boldsymbol{\theta})\, \pi(\boldsymbol{\theta}) \, \mathrm{d}^D\boldsymbol{\theta} \overset{(2)}{\approx} \mathcal{L}_{\max}\, \pi(\hat{\boldsymbol{\theta}}) \int e^{-\frac{1}{2}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})^{\mathsf{T}}\mathbf{F}(\boldsymbol{\theta}-\hat{\boldsymbol{\theta}})} \, \mathrm{d}^D\boldsymbol{\theta} \\ &\overset{(3)}{=} \mathcal{L}_{\max}\, \pi(\hat{\boldsymbol{\theta}}) \, \frac{(2\pi)^{D/2}}{\sqrt{\det \mathbf{F}}} \overset{(4)}{=} \mathcal{L}_{\max} \times \frac{(2\pi)^{D/2}\sqrt{\det \mathbf{C}}}{V_\pi}. \end{aligned} \tag{5.50}$$

(1) The evidence, with $\mathcal{L}(\boldsymbol{\theta}) = p(\boldsymbol{d} \mid \boldsymbol{\theta}, M)$ and $\pi(\boldsymbol{\theta}) = p(\boldsymbol{\theta} \mid M)$.

(2) The quadratic expansion of $\ln \mathcal{L}$, and the prior taken out at the peak.

(3) The D-dimensional Gaussian integral. Rotate to the eigenvectors of the symmetric positive matrix $\mathbf{F}$; the integral factorises into D one-dimensional integrals $\sqrt{2\pi/f_k}$, one per eigenvalue f_k, and the product of the eigenvalues is $\det \mathbf{F}$.

(4) For a uniform prior on a region of volume V_π, $\pi(\hat{\boldsymbol{\theta}}) = 1/V_\pi$; and $\mathbf{C} = \mathbf{F}^{-1}$, so $1/\sqrt{\det \mathbf{F}} = \sqrt{\det \mathbf{C}}$.

This is the **Laplace approximation** to the evidence [Sivia (4.20)], [32, eqs. (24)–(25)]. The factor $(2\pi)^{D/2}\sqrt{\det \mathbf{C}}$ is the volume of the posterior's "error ellipsoid", so the Occam factor of (5.49) generalises to the ratio of the posterior volume to the prior volume. In one dimension it is $\sqrt{2\pi}\,\delta\lambda$ over $\lambda_{\max} - \lambda_{\min}$ again.

Key idea: Evidence ≈ best fit × Occam factor

$$Z \;\approx\; \mathcal{L}_{\max} \times \frac{V_{\text{posterior}}}{V_{\text{prior}}}.$$

A model is rewarded for fitting the data well and penalised by the fraction of its prior parameter space that the data rule out. Every parameter the data constrain adds a factor $\sqrt{2\pi}\,\sigma_k/(\text{prior range}_k)$ (for uncorrelated parameters); a model is favoured only if its better fit pays for all of them.

Two remarks keep the formula honest. First, a parameter the data do not constrain at all has a posterior as wide as its prior, contributes a factor one, and costs nothing. Adding the price of fish at Billingsgate market to a cosmological model changes no prediction, so the likelihood is flat in it and the evidence is unchanged however wide its prior [HobsonBMC p. 85], [32, p. 16]. What the evidence penalises is not the number of parameters but wasted predictive range: parameter values the model allowed and the data rule out. Hobson and collaborators put it as "the Bayesian evidence rewards model predictiveness" [HobsonBMC p. 83]. Second, if the likelihood has several separate peaks, each contributes its own term. With M identical bumps whose labels can be permuted, the likelihood has $M!$ equivalent peaks and the Laplace sum must count all of them [Sivia (4.20)]. An exact integral over the whole prior box counts them automatically.

5.16.3 A line, or a line plus a bump?

Back to the forty points. The two models are

$$M_0 \text{ (line)}: \quad y_i = a + b x_i + \epsilon_i,$$
$$M_1 \text{ (line + bump)}: \quad y_i = a + b x_i + A\, e^{-(x_i-\mu)^2/2W^2} + \epsilon_i, \qquad \epsilon_i \overset{\text{iid}}{\sim} \mathcal{N}(0,1),$$

with the bump width $W = 0.5$ known. The priors are part of the models and are fixed before looking at the data: a uniform on $[0, 20]$ and b uniform on $[-2, 2]$ in both models; in M_1 also A uniform on $[0, A_{\max}]$ with $A_{\max} = 10$ (a generous ceiling, ten times the noise) and μ uniform on $[0, 10]$ (the range we measured). We simulate two data sets, one with a real bump of height 2.5 at $\mu = 6.2$ and one with no bump, both on the line $y = 5 + 0.3x$ (Figure 5.45).

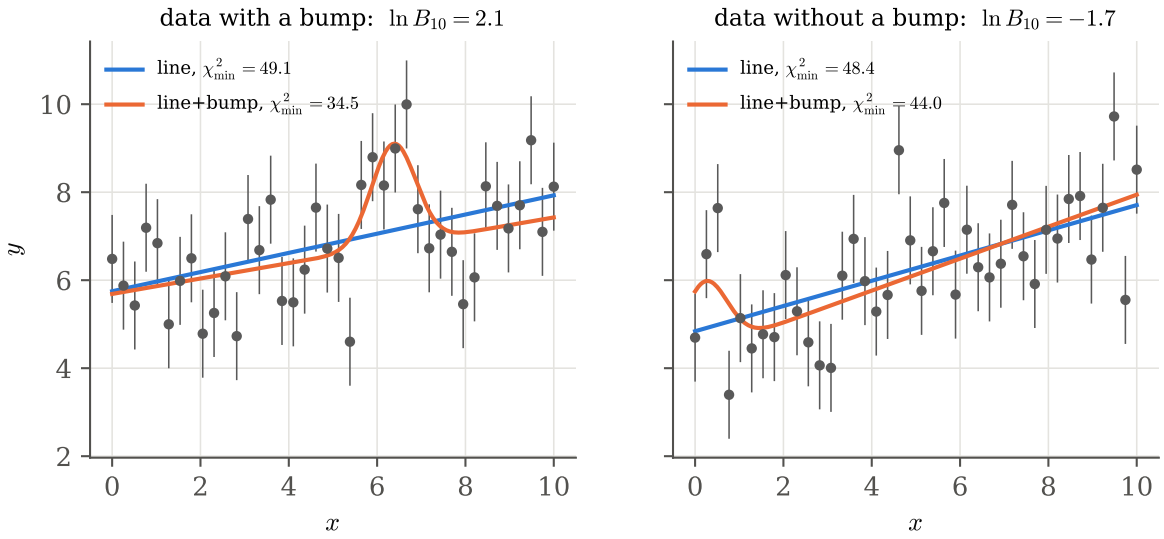

Figure 5.45: Two simulated data sets of forty points with unit error bars, and the best fits of both models. Left: a bump of height 2.5 is present near $x = 6.2$; the bump model finds it and its χ^2 drops by 14.53. Right: there is no bump; the bump model still finds a small improvement by fitting a noise fluctuation. The log Bayes factor of bump against line is printed above each panel.

Integrating out the line exactly. The evidence of M_1 is a four-dimensional integral over (a, b, A, μ). The line parameters a, b enter the model linearly, so the likelihood is Gaussian in them and their integral can be done exactly. That leaves a two-dimensional integral over (A, μ) for the grid. The question for each bump is: once the bump (A, μ) is subtracted, how well can the best line fit what remains? Write the data as the vector $\boldsymbol{y}$ (here $N = 40$), the two line shapes as the columns of the $N \times 2$ matrix $X = (\mathbf{1}, \boldsymbol{x})$, and the bump shape at position μ as the vector $\boldsymbol{g}_\mu$. For fixed (A, μ) the line fits $\boldsymbol{y} - A\boldsymbol{g}_\mu$. What it cannot fit is the part of $\boldsymbol{y} - A\boldsymbol{g}_\mu$ that points in directions no line can reach, $P_\perp(\boldsymbol{y} - A\boldsymbol{g}_\mu)$, where $P_\perp = \mathbb{1} - X(X^\mathsf{T}X)^{-1}X^\mathsf{T}$ is the projector onto those directions. Writing $\boldsymbol{r} = P_\perp \boldsymbol{y}$ and $\boldsymbol{u}_\mu = P_\perp \boldsymbol{g}_\mu$,

$$\chi^2_{\min}(A,\mu) - \chi^2_{\min,\text{line}} \overset{(1)}{=} \|\boldsymbol{r} - A\boldsymbol{u}_\mu\|^2 - \|\boldsymbol{r}\|^2 \overset{(2)}{=} -2A\,\boldsymbol{r}\cdot\boldsymbol{u}_\mu + A^2\,\boldsymbol{u}_\mu\cdot\boldsymbol{u}_\mu. \tag{5.51}$$

(1) With $\sigma = 1$, the minimum of χ^2 over the line is the squared length of the residual the line cannot absorb; for the line model alone that residual is $\boldsymbol{r}$.

(2) Expand the square: $\|\boldsymbol{r} - A\boldsymbol{u}\|^2 = \|\boldsymbol{r}\|^2 - 2A\,\boldsymbol{r}\cdot\boldsymbol{u} + A^2\|\boldsymbol{u}\|^2$.

The integral over (a, b) at fixed (A, μ) is the same Gaussian integral in both models, because both use the same line shapes and the same prior box for the line. It cancels in the Bayes factor, which is therefore

$$B_{10} = \frac{1}{A_{\max} \cdot 10} \int_0^{A_{\max}} \int_0^{10} \exp\Big[-\tfrac{1}{2}\big(\chi^2_{\min}(A,\mu) - \chi^2_{\min,\text{line}}\big)\Big]\, \mathrm{d}\mu\, \mathrm{d}A. \tag{5.52}$$

In words: the likelihood ratio of each bump to the best line, averaged over the prior box of bumps. (We assumed that the line's prior box is wide enough to contain its likelihood; with the boxes above it is, by many standard deviations.)

Listing 5.10: The Bayes factor of bump against line on a grid (`code/ch05/lib_bump.py`)

```
72 def dchi2_grid(y, A, mu):
73     """chi2_min over (a, b) at each (A, mu), minus the line's chi2_min.  Shape (len(A),
       len(mu))."""
74     ry = PPERP @ y
75     U = PPERP @ bump(X[:, None], mu[None, :])                    # projected bump shapes,
       (N, n_mu)
76     uy = ry @ U / SIGMA**2                                       # (n_mu,)
77     uu = np.sum(U * U, axis=0) / SIGMA**2
78     return -2 * A[:, None] * uy[None, :] + A[:, None] ** 2 * uu[None, :]
79
80
81 def ln_bayes_factor(y, a_max=A_MAX, mu_fixed=None, nA=2001, nmu=2001, return_grid=False):

       fixed)."""
83     A = np.linspace(0.0, a_max, nA)
84     mu = np.array([mu_fixed]) if mu_fixed is not None else np.linspace(*MU_RANGE, nmu)
85     dc = dchi2_grid(y, A, mu)
86     f = np.exp(-0.5 * dc)                                        # likelihood ratio to the
       best line
87     inner = f[:, 0] if mu_fixed is not None else np.trapezoid(f, mu, axis=1) / L_MU
88     lnB = np.log(np.trapezoid(inner, A) / a_max)
89     if return_grid:
90         return lnB, A, mu, dc
91     return lnB
```

Lines 74–78 build (5.51) for every (A, μ) on the grid at once: the projected data $\boldsymbol{r}$, the projected bump shapes $\boldsymbol{u}_\mu$ (one column per position), their dot products, and the quadratic in A. Line 86 exponentiates to get the likelihood ratio to the best line; lines 87–88 average it over μ and then over A with the trapezoid rule, which is (5.52). Working with the ratio to the best line keeps the numbers of order one; the raw likelihoods are about e^{-60}.

The data with a bump. The line has $\chi^2_{\min} = 49.07$ for 38 degrees of freedom, the bump model 34.54 at $\hat{A} = 2.307$, $\hat{\mu} = 6.373$. The best bump improves the fit by $\Delta\chi^2 = 14.53$, a best-fit likelihood ratio of $e^{7.265}$. The Bayes factor is $\ln B_{10} = 2.096$ ($B_{10} = 8.133$; a grid of half the resolution changes $\ln B_{10}$ by 1.236×10^{-8}). The difference, $\ln B_{10} - \frac{1}{2}\Delta\chi^2 = -5.169$, is the logarithm of the Occam factor. Here the bump is favoured, but by odds of 8.133 to 1, not by the $e^{7.265}$ that the fit improvement alone suggests.

The Laplace approximation (5.50) lets us read the Occam factor off the map of Figure 5.46. At the best fit the posterior standard deviations are $\sigma_A = 0.6053$ and $\sigma_\mu = 0.1415$, so the posterior area in the (A, μ) plane is $2\pi\sqrt{\det \mathbf{C}_{A\mu}} = 0.5381$, against a prior area of $A_{\max} \times 10 = 100$. Their ratio, 0.005381, is the Occam factor, and the Laplace estimate of the Bayes factor is $\ln B_{10} = 2.04$, close to the exact 2.096. The bump model allowed 100 square units of bumps and the data kept only 0.5381 of them.

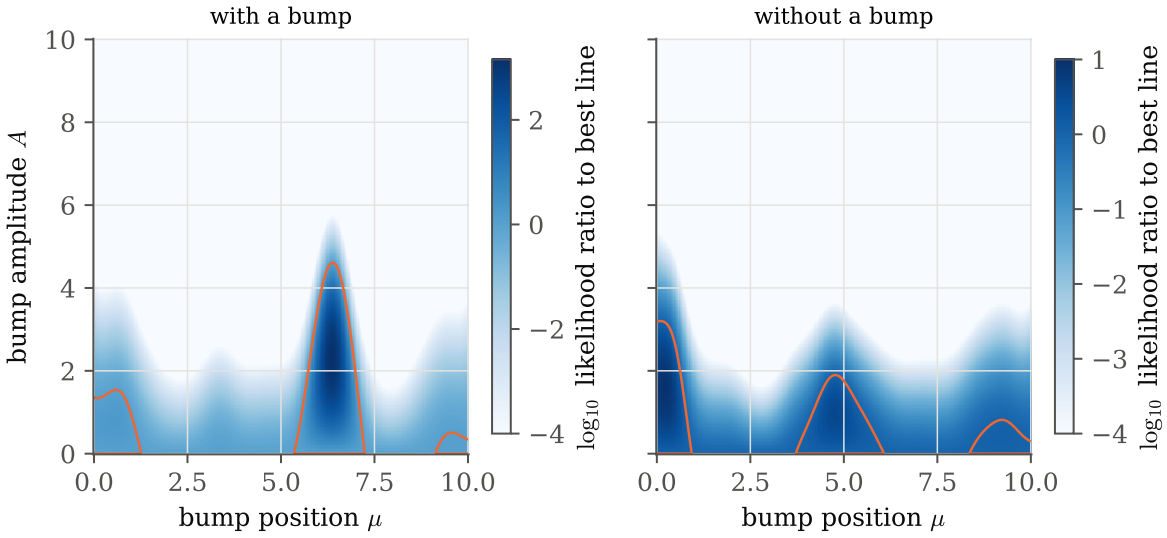

Figure 5.46: The likelihood of every bump in the prior box, relative to the best line, in powers of ten. With a bump in the data (left) a small island near $\mu = 6.373$, $A = 2.307$ is far better than the line; almost all the rest of the box is worse. Without a bump (right) nothing is much better than the line. The orange contour marks a likelihood ratio of one. The Bayes factor is the average of this map over the box.

The data without a bump. Here the bump model still finds something: a noise fluctuation at $\hat{\mu} = 0.2214$ improves χ^2 from 48.37 to 43.98. A χ^2 drop of a few units for two extra parameters is what noise does. The evidence agrees: $\ln B_{10} = -1.675$, so the line is favoured by a factor $1/0.1873$. The Occam factor, $e^{-3.868}$, outweighs the modest improvement of the fit. For both data sets the razor cuts in the right direction, and it needed no rule beyond the sum and product rules.

If we had known where to look. Not knowing where the bump sits has a price, and the evidence charges it automatically. Suppose theory had predicted the resonance at $\mu = 6.2$, so that M_1 has only the amplitude free. Then the prior no longer wastes probability on positions the data rule out. For the data with a bump, $\ln B_{10} = 4.668$ ($B_{10} = 106.5$), which is 13.09 times larger than with the position free. At the predicted position the amplitude is 2.18 ± 0.6018, a local significance of 3.622σ. So not knowing the position costs a factor of 13.09. This is the look-elsewhere effect of Chapter 4. There it needed a separate trials factor; here it appears by itself, as the Occam factor of the parameter μ.

5.17 Reading a Bayes factor

With three years of WMAP data and the large-scale-structure surveys of the time, a cosmological model with a free spectral index n_s was found to have a log evidence 1.99 ± 0.26 higher than the Harrison–Zel'dovich model with $n_s = 1$ [HobsonBMC Table 4.4]. The same data gave $n_s = 0.958 \pm 0.016$, nearly three standard deviations from one. How impressed should we be by $\ln B = 2$? Is it the same statement as "three sigma", the significance of Chapter 4? And would another reasonable choice of prior have given a different number?

5.17.1 The Jeffreys scale

A Bayes factor multiplies the prior odds. With even prior odds and only two models, the posterior probability of the favoured model is

$$\mathrm{P}(M_1 \mid \boldsymbol{d}) = \frac{B_{10}}{1 + B_{10}}, \qquad \text{e.g.} \quad B_{10} = e^1 \approx 2.7 \;\to\; 0.73, \quad e^{2.5} \approx 12 \;\to\; 0.92, \quad e^5 \approx 150 \;\to\; 0.993, \tag{5.53}$$

from (5.45) with $\mathrm{P}(M_1) = \mathrm{P}(M_0)$ and $\mathrm{P}(M_1 \mid \boldsymbol{d}) + \mathrm{P}(M_0 \mid \boldsymbol{d}) = 1$. Jeffreys proposed words for these levels, and a version of his scale is quoted in almost every cosmology paper that computes an evidence [HobsonBMC §4.5], [Padilla Table II], [32, Table 1], [33]:

$\lvert\ln B\rvert$	odds	probability	Jeffreys	Hobson et al.	Trotta
< 1	$< 3:1$	< 0.75	not worth more than a bare mention	—	inconclusive
1–2.5	3 : 1 to 12 : 1	0.75–0.92	significant	weak	weak
2.5–5	12 : 1 to 150 : 1	0.92–0.993	strong to very strong	significant	moderate
> 5	$> 150:1$	> 0.993	decisive	strong	strong

The probability column assumes even prior odds and two models, and the table rounds $e^1 \approx 2.7$ up to 3 : 1. The thresholds are a convention, calibrated on experience, not a theorem. Three cautions come with them.

- *The scale is logarithmic.* Moving up one level needs roughly ten times more support. Evidence accumulates slowly [32, p. 14].
- *It applies to posterior odds.* The words are meant for the ratio of posterior model probabilities; they coincide with the Bayes factor only when the prior odds are even [HobsonBMC p. 90]. A Bayes factor of 20 for an exotic model that we believed at 1 : 1000 beforehand still leaves it at 1 : 50.
- *The priors are uncertain too.* Because a Bayes factor depends on the prior widths (Section 5.17.2), Hobson and collaborators soften Jeffreys' words: $\ln B$ between 1 and 2.5 is only "weak", between 2.5 and 5 "significant", above 5 "strong" (third column of the table) [HobsonBMC p. 90]. Trotta's column is similar. Kruschke's rule of thumb, "substantial" above $B = 3$, is the same first threshold [Kruschke p. 268].

An evidence computed numerically also has an error, like ±0.26 above, and a difference in $\ln B$ smaller than its error means nothing.

Example: is the primordial spectrum tilted? The two models are the tilted one (n_s free) and Harrison–Zel'dovich ($n_s = 1$). In the WMAP analysis [HobsonBMC pp. 91–93] the log Bayes factor of tilted against Harrison–Zel'dovich grew as the data improved:

- first-year WMAP with other data: $\ln B = -0.58 \pm 0.12$, inconclusive, with a slight preference for the simpler model;
- three-year WMAP alone: 0.34 ± 0.26, still inconclusive;
- three-year WMAP with other data: 1.99 ± 0.26, odds of about 7 : 1, "significant" in Jeffreys' words and "weak" in the softer scale.

Then inflation was taken seriously. Slow roll predicts a tilt *and* a tensor-to-scalar ratio r, so this model has two new parameters. Its verdict depended on the prior for r. With r uniform between 0 and 1, the n_s–r model came out at $\ln B = -1.45 \pm 0.45$, disfavoured against Harrison–Zel'dovich. With $\ln r$ uniform from -80 to 0 it came out at 1.90 ± 0.24, about as good as the n_s-only model. The data were identical. Why did the prior on r matter so much? The data allow only small r. A uniform prior on $[0, 1]$ puts most of its weight on larger values of r, which the data exclude, so it pays an Occam factor. The logarithmic prior puts most of its weight on tiny r, which the data cannot distinguish from zero. There the likelihood is flat, so this prior pays almost nothing: this is the Billingsgate effect of Section 5.16.2.

5.17.2 The prior width sets the price

The wider the prior range of an extra parameter, the less the data favour it. The reason is the Occam factor of (5.49): it is the data's range divided by the prior range. So once the prior range is much wider than the likelihood, the Bayes factor in favour of the extra parameter falls in proportion to the range: every factor of ten in the range subtracts $\ln 10 \approx 2.3$ from $\ln B_{10}$. Take the bump of Section 5.16.3 and vary only the prior range $A_{\max}$ of its amplitude (Figure 5.47). For the data with a bump, $\ln B_{10}$ first rises, because a prior that stops below the fitted amplitude $\hat{A} = 2.307$ cannot reach the bump; it peaks once the range just covers it; then it falls along a straight line of slope -1 in $\ln A_{\max}$. At $A_{\max} = 100$ it is -0.2067, against 2.096 at $A_{\max} = 10$: the same bump, with the same local significance of 3.622σ, is now worth ten times less evidence. For the data without a bump $\ln B_{10}$ starts at zero (for a tiny range the two models are the same model) and falls steadily, reaching -3.977 at $A_{\max} = 100$.

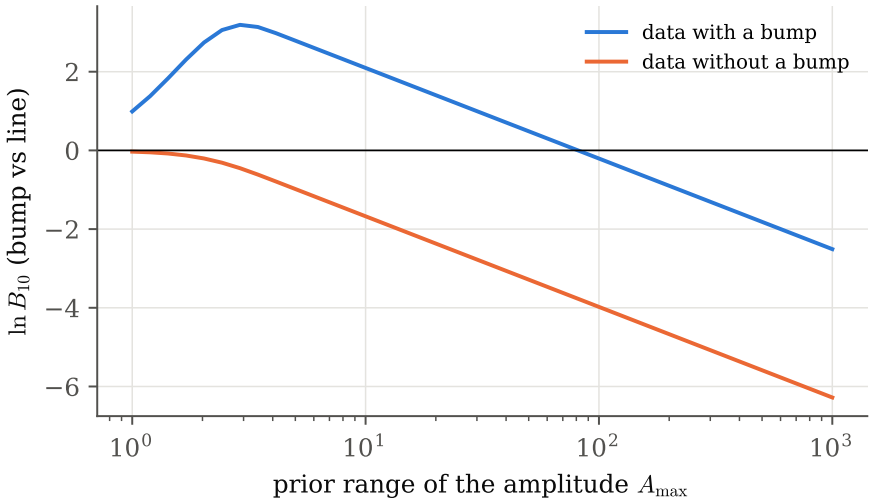

Figure 5.47: The Bayes factor of bump against line as the prior range of the bump amplitude is widened, for the two data sets of Figure 5.45. Past the fitted amplitude both curves fall by $\ln 10$ per decade of $A_{\max}$: each widening of the prior spreads the model's probability over more bumps the data rule out.

So which range is right? The answer has to come from physics, before the data: the largest resonance the experiment would already have noticed, the range of n_s that slow-roll inflation allows ($0.8 \lesssim n_s \lesssim 1.2$), the coupling a fifth force could have without being seen [Sivia p. 85], [32, §4.5]. If several plausible ranges give the same qualitative verdict, the verdict is robust. If not, the honest report is the Bayes factor as a function of the range, which is what Figure 5.47 is. In the (information, significance) plane of Section 5.17.3 a change of prior width is a horizontal shift [32, §4.4].

Example: two vague priors, one posterior, two verdicts. Two priors that both claim to know nothing can give opposite verdicts [Kruschke §10.6]. A coin gives $z = 65$ heads in $N = 100$ tosses. Model one is must-be-fair, $\theta \sim \text{Beta}(500, 500)$, where θ is the probability of heads. Model two is anything-goes, and we must choose a vague prior for it.

- With Beta$(1, 1)$, uniform, the Bayes factor of fair against anything is 0.1253: anything-goes wins by 8 : 1.
- With the Haldane prior Beta$(0.01, 0.01)$, recommended by some statisticians as maximally uninformative, the Bayes factor is 5.728: must-be-fair wins by nearly 6 : 1.

The verdict reversed. Yet the posteriors of θ under the two vague priors are practically the same: their 95% HDIs are $[0.5543, 0.7382]$ and $[0.5564, 0.7418]$, and both exclude 0.5. How can the posterior stay put while the evidence flips? The evidence (5.43) is the likelihood averaged over the prior. The Haldane prior puts almost all its probability extremely close to $\theta = 0$ and $\theta = 1$. So its density near $\theta = 0.65$, where the likelihood lives, is tiny, and the average of the likelihood over the prior is tiny with it. The posterior, by contrast, is renormalised: it does not care about the overall level of the prior near 0.65, only about its shape there, and there both priors are nearly flat.

Lambert shows the same thing for a binomial sample [Lambert §10.6, Fig. 10.12]: fifteen counts, each out of ten trials, with a Beta(a, a) prior on the success probability (Figure 5.48). As a goes from 0.01 to 1 to 10 the posterior hardly moves (mean 0.5, standard deviation 0.04069 against 0.04043), while $\ln p(\boldsymbol{d})$ goes from -32.78 to -28.86 to -27.66: a factor 50.36 in the evidence between the first two "vague" choices.

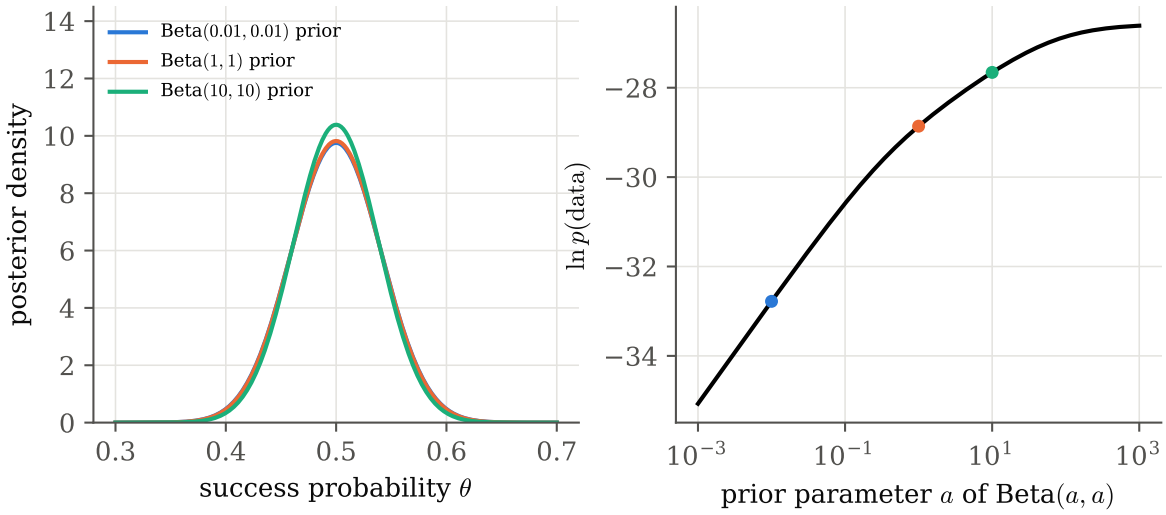

Figure 5.48: Left: the posterior of a success probability under three symmetric Beta priors, for fifteen binomial counts out of ten trials each; the three curves nearly coincide. Right: the log evidence of the same data as a function of the prior parameter a; the three dots are the three priors on the left. The posterior barely notices the prior, the evidence notices it a lot.

Kruschke's remedy is to put the competing models on an equal footing: inform the priors of *both* models with the same small, representative part of the data, and compute the Bayes factor from the rest [Kruschke §10.6.1]. Why does this help? Even a few data points overwhelm a vague prior and bring each model's parameters "into the ballpark", so the arbitrary choice of vague prior no longer matters. For the coin, use 6 heads in the first 10 tosses to update both priors, then compare on the remaining 90. The Bayes factor of fair against anything becomes 0.05571 starting from the uniform prior and 0.05748 starting from the Haldane prior. The two vague

priors now agree, and both say the coin is not fair, as the HDIs did. Intrinsic and fractional Bayes factors are more systematic versions of the same idea.

Watch out: Vague priors are harmless for estimation, not for comparison

A wide or "uninformative" prior is usually safe when estimating a parameter, because the likelihood dominates the posterior. In model comparison the overall height of the prior where the likelihood lives enters directly, and changing from one vague prior to another can change the Bayes factor by orders of magnitude. An improper prior, one that cannot be normalised (flat on the whole real line), gives an evidence with an arbitrary constant in it, so Bayes factors with improper priors on the extra parameters are undefined [Wasserman p. 185], [HobsonBMC §1.3].

5.17.3 Lindley's paradox

The simplest nested comparison can be done exactly, and it holds a surprise. We have a measurement $\hat{\theta}$ of a quantity θ with Gaussian error σ. Model M_0 says the effect is absent, $\theta = 0$. Model M_1 says it is present, with a size we can only bound: $\theta \sim \mathcal{N}(0, \Sigma^2)$ with Σ the scale of effects the theory allows. Call $\lambda = |\hat{\theta}|/\sigma$ the significance of the measurement, the "number of sigma".

The event: the value $\hat{\theta}$. *The hypotheses:* M_0 and M_1. *How probable was $\hat{\theta}$ under each?* Under M_0 it is the Gaussian density $\mathcal{N}(\hat{\theta}; 0, \sigma^2)$. Under M_1 we average over θ:

$$p(\hat{\theta} \mid M_1) \overset{(1)}{=} \int \mathcal{N}(\hat{\theta}; \theta, \sigma^2)\, \mathcal{N}(\theta; 0, \Sigma^2)\, \mathrm{d}\theta \overset{(2)}{=} \mathcal{N}(\hat{\theta}; 0, \sigma^2 + \Sigma^2),$$

$$B_{01} = \frac{p(\hat{\theta} \mid M_0)}{p(\hat{\theta} \mid M_1)} \overset{(3)}{=} \sqrt{\frac{\sigma^2 + \Sigma^2}{\sigma^2}}\, \exp\!\left[-\frac{\hat{\theta}^2}{2\sigma^2} + \frac{\hat{\theta}^2}{2(\sigma^2 + \Sigma^2)}\right] \overset{(4)}{=} \sqrt{1 + \frac{\Sigma^2}{\sigma^2}}\, \exp\!\left[-\frac{\lambda^2}{2}\, \frac{\Sigma^2}{\sigma^2 + \Sigma^2}\right]. \quad (5.54)$$

(1) The evidence of M_1: the likelihood of the measurement averaged over the prior of the effect.

(2) The measurement is the true effect plus independent Gaussian noise, so it is a sum of two independent Gaussians of variances Σ^2 and σ^2, and its density is the Gaussian of the summed variance (the convolution of two Gaussians; complete the square in θ to check).

(3) Ratio of the two Gaussian densities: the prefactors give the square root, the exponents subtract.

(4) Combine the exponents over the common denominator and write $\hat{\theta}^2/\sigma^2 = \lambda^2$.

This is Trotta's (21) [32, p. 13]. When the data are much more precise than the prior, $\sigma \ll \Sigma$, the last factor becomes $e^{-\lambda^2/2}$ and

$$\ln B_{01} \approx \ln \frac{\Sigma}{\sigma} - \frac{\lambda^2}{2} \quad (5.55)$$

[32, eq. (26)]: the Occam term $\ln(\Sigma/\sigma)$, the logarithm of the ratio of prior to posterior width, against the goodness-of-fit term $\lambda^2/2$. The more the data have taught us (Σ/σ large), the more significance is needed to prefer the extra parameter. Figure 5.49 maps (5.54) over the plane of information $I_{10} = \log_{10}(\Sigma/\sigma)$ and significance λ. For moderately informative data, I_{10} between 1 and 2, the measurement must lie about 4σ from zero before the extra parameter is favoured robustly; results at 2–3σ are inconclusive or even favour the simpler model [32, §4.4].

What happens if the significance stays fixed while the data grow? With n measurements of unit noise, $\sigma = 1/\sqrt{n}$; take $\Sigma = 1$ and a result exactly at $\lambda = 1.96$, the two-sided $p = 0.05$ of Chapter 4. The Bayes factor (5.54) is $\sqrt{1+n}\, \exp[-\tfrac{1}{2}(1.96)^2\, n/(1+n)]$, which grows like $\sqrt{n}$. With even prior odds the posterior probability of the null (Figure 5.50) is 0.3512 at $n = 1$,

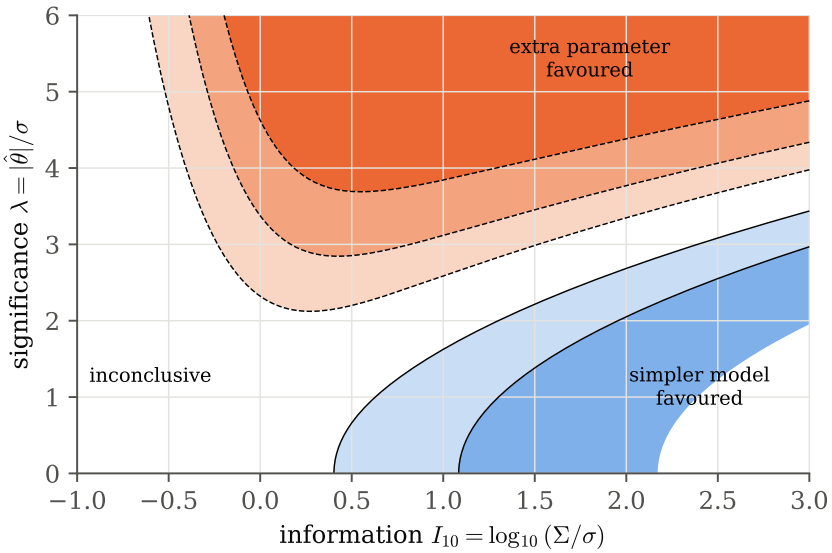

Figure 5.49: The Bayes factor for one extra parameter with Gaussian prior and likelihood, over the plane of information (how much narrower the likelihood is than the prior, in powers of ten) and significance (how many standard deviations the measurement lies from zero). Contours are at $|\ln B| = 1, 2.5, 5$. Blue: the simpler model is favoured; orange: the extra parameter is favoured; white: inconclusive. A wider prior moves a result to the right.

0.8228 at $n = 10^3$ and 0.9932 at $n = 10^6$. At a fixed "1.96σ" the data favour the null once n exceeds about 41.25, and overwhelmingly so for large samples. Even at $p = 0.01$ ($\lambda = 2.58$) the probability of the null at $n = 10^6$ is 0.9731. This is **Lindley's paradox** [34]: the same p-value means evidence *against* the null in a small experiment and evidence *for* it in a large one.

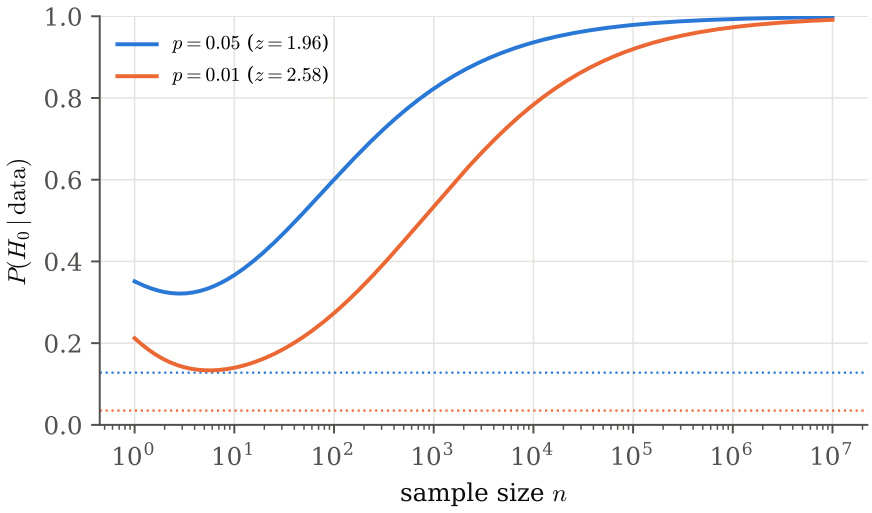

Figure 5.50: Lindley's paradox. The posterior probability of "no effect" for a result held at fixed significance (1.96σ, blue; 2.58σ, orange) as the sample size grows, with a unit-width prior on the effect and even prior odds. The dotted lines are the lowest value any prior could give (the bound of Section 5.17.4).

There is nothing paradoxical in the mechanism. At fixed significance the measured effect $\hat{\theta} = 1.96/\sqrt{n}$ shrinks as n grows. The alternative spread its prior over effects of size $\Sigma = 1$, and the data increasingly say that the effect, if there is one, is far smaller than anything M_1 expected. The measurement becomes a successful prediction of M_0. The p-value, which only asks how

surprising the data are under M_0, cannot see this. Large modern data sets (Planck maps, LHC luminosities, years of detector time) are exactly where the two answers part company, which is why "how many sigma" is not by itself a good measure of the evidence for a new effect [32, §5.4].

5.17.4 What a p-value can and cannot say

Wasserman's version of the Bayesian test makes the link to Chapter 4 explicit [Wasserman pp. 184–185]. Take the data $x^n = (x_1, \dots, x_n)$ with likelihood $\mathcal{L}(\theta)$, and test $H_0 : \theta = \theta_0$ against $H_1 : \theta \neq \theta_0$. Give each hypothesis prior probability $\frac{1}{2}$, and give θ a prior density $f(\theta)$ under H_1. Then

$$\mathrm{P}(H_0 \mid x^n) = \frac{\mathcal{L}(\theta_0)}{\mathcal{L}(\theta_0) + \int \mathcal{L}(\theta) f(\theta)\, \mathrm{d}\theta}, \tag{5.56}$$

which is (5.44) with $Z_0 = \mathcal{L}(\theta_0)$ and Z_1 the average of the likelihood over f. The prior f matters here in a way it did not in estimation, and it must be proper. Is there anything we can say whatever f is? Yes: a bound. An average cannot exceed the maximum, so $\int \mathcal{L} f \, \mathrm{d}\theta \le \mathcal{L}(\hat\theta)$, where $\hat\theta$ is the maximum-likelihood value. Putting this into the denominator,

$$\mathrm{P}(H_0 \mid x^n) \;\ge\; \frac{\mathcal{L}(\theta_0)}{\mathcal{L}(\theta_0) + \mathcal{L}(\hat\theta)}. \tag{5.57}$$

For a Gaussian measurement at significance z, $\mathcal{L}(\hat\theta)/\mathcal{L}(\theta_0) = e^{z^2/2}$, which at $z = 1.96$ is 6.826. So a result at "$p = 0.05$" leaves the null with posterior probability at least 0.1278, whatever prior the alternative is given. The most favourable prior for H_1 is a spike at $\hat\theta$, chosen after seeing the data, which is cheating; any honest prior does worse.

A less extreme and more useful bound restricts the alternative to priors that are symmetric about θ_0 and do not increase away from it. Sellke, Bayarri and Berger showed that over this class [35]

$$B_{10} \;\le\; \bar B_{10} = -\frac{1}{e\, p \ln p} \qquad (p \le e^{-1}) \tag{5.58}$$

for a p-value p [32, §4.5, eq. (27)]. It turns a significance into the best odds it could possibly support:

p-value	0.05	0.01	0.003	0.001	3×10^{-4}	5.7×10^{-7}
significance z	1.96	2.576	2.968	3.291	3.615	5.001
best odds $\bar B_{10}$	2.456	7.988	21.11	53.26	151.2	44889
$\ln \bar B_{10}$	0.8985	2.078	3.05	3.975	5.018	10.71

A "99%" result supports odds of 8 : 1 at best, short of the moderate level. Strong evidence at best needs about 3.6σ. A useful rule of thumb is to read an s-sigma result as roughly an $(s-1)$-sigma one [32, p. 18]. The 5σ discovery convention of particle physics corresponds to best odds of about $4.5 \times 10^4 : 1$.

Key idea: Significance is not evidence

A p-value is the probability, computed as if H_0 were true, of the observed result *together with every result lying further out in the same direction* (Section 4.1.3). A Bayes factor compares how probable the result actually observed was under H_0 and under a specified alternative. Even with the alternative's prior chosen as favourably as honesty allows, a 2σ result supports odds of at most about 2.5 : 1, and at fixed significance larger samples favour the null

(Lindley).

The difference lies in those further-out results. The p-value collects the probability of outcomes that were not observed, and it never asks what the alternative predicted. The Bayes factor uses only the observed outcome, under both hypotheses. When a paper reports "3σ evidence", the Bayes factor is the number that says how much the data should move us, and the prior on the new effect is what the claim is really about.

5.18 Nested models, shortcuts and model averaging

Almost every model comparison in cosmology has the shape of our bump hunt. The base model is ΛCDM with its six parameters. The candidate extension adds a parameter that is zero, or some other fixed value, in the base model: the spatial curvature Ω_k, the running $\mathrm{d}n_s/\mathrm{d}\ln k$, the tensor ratio r, the non-Gaussianity f_{NL}, the dark-energy equation of state through $w+1$, an extra number of neutrino species $N_\nu - 3.04$, and upwards of twenty more [HobsonBMC Table 4.2]. In the bump hunt the base model is the line and the extension adds a bump that disappears at $A = 0$. The simpler model sits inside the bigger one as a special value of the new parameter. Such models are called **nested**. Nesting makes the Bayes factor easier to compute, makes it natural to combine the models, and leads to some useful approximations.

5.18.1 The Savage–Dickey density ratio

Write the parameters of the bigger model M_1 as $(\boldsymbol{\phi}, \psi)$: the common parameters $\boldsymbol{\phi}$ (the line, a and b) and the new parameter ψ (the amplitude A). The simpler model M_0 is M_1 with ψ fixed at ψ_* ($A = 0$). Two conditions make the models genuinely nested [HobsonBMC (4.12)], [32, eq. (22)]:

1. the likelihoods agree at the special value: $p(\boldsymbol{d} \mid \boldsymbol{\phi}, \psi_*, M_1) = p(\boldsymbol{d} \mid \boldsymbol{\phi}, M_0)$;
2. the prior of M_1 factorises into the prior of M_0 for the common parameters times a prior for the new one: $p(\boldsymbol{\phi}, \psi \mid M_1) = p(\boldsymbol{\phi} \mid M_0)\, p(\psi \mid M_1)$.

Now ask a question about the bigger model alone: after the data, how probable is it that the new parameter sits at its special value? That is the posterior density of ψ at ψ_*, and it turns out to contain the Bayes factor:

$$
\begin{aligned}
p(\psi_* \mid \boldsymbol{d}, M_1) &\overset{(1)}{=} \int p(\boldsymbol{\phi}, \psi_* \mid \boldsymbol{d}, M_1)\, \mathrm{d}\boldsymbol{\phi} \overset{(2)}{=} \frac{1}{Z_1} \int p(\boldsymbol{d} \mid \boldsymbol{\phi}, \psi_*, M_1)\, p(\boldsymbol{\phi} \mid M_0)\, p(\psi_* \mid M_1)\, \mathrm{d}\boldsymbol{\phi} \\
&\overset{(3)}{=} \frac{p(\psi_* \mid M_1)}{Z_1} \int p(\boldsymbol{d} \mid \boldsymbol{\phi}, M_0)\, p(\boldsymbol{\phi} \mid M_0)\, \mathrm{d}\boldsymbol{\phi} \overset{(4)}{=} p(\psi_* \mid M_1)\, \frac{Z_0}{Z_1}.
\end{aligned}
\tag{5.59}
$$

(1) The marginal posterior of ψ: integrate the joint posterior over the common parameters.
(2) Bayes' theorem in M_1: likelihood times prior over the evidence Z_1, with the factorised prior of condition 2.
(3) Condition 1 replaces the likelihood by that of M_0; the prior density of ψ at ψ_* is a constant and comes out.
(4) The remaining integral is the evidence Z_0 of the simpler model, (5.43).

Rearranged, this is the **Savage–Dickey density ratio** [HobsonBMC (4.13)], [32, eq. (23)].

Working definition 5.11 (Savage–Dickey density ratio)

For nested models with a factorised prior,

$$B_{01} = \frac{Z_0}{Z_1} = \frac{p(\psi_* \mid \boldsymbol{d}, M_1)}{p(\psi_* \mid M_1)},$$

[how much the data raised (or lowered) the probability density of the new parameter at its "absent" value]. *Operationally:* run the bigger model only, histogram the samples of ψ near ψ_*, and divide the height of the normalised histogram there by the prior density.

The ratio has a direct reading. If the data pile up the posterior of the new parameter at its null value, higher than the prior put it, the simpler model gains; if they push the posterior away from it, the simpler model loses. Only a one-dimensional marginal density is needed, and its normalisation is a one-dimensional integral, so there is no high-dimensional evidence integral left to do.

Example: the bump amplitude at zero. Take the data without a bump. The new parameter is $\psi = A$ with $\psi_* = 0$ and prior density $p(A = 0 \mid M_1) = 1/A_{\max} = 0.1$. The bump position μ exists only in M_1, but at $A = 0$ the likelihood does not depend on it and its prior integrates to one, so the derivation goes through with μ integrated along with $\boldsymbol{\phi}$. On the grid, the posterior density of A at $A = 0$ times $A_{\max}$ is 5.338, which is the exact $B_{01} = 1/B_{10} = 5.338$ of Section 5.16.3. From a Markov chain (Section 5.19.3) we estimate the density by the fraction of samples with $A < 0.1$, divided by 0.1; this gives $B_{01} \approx 5.571 \pm 0.5489$, where the error comes from splitting the chain into twenty batches. How close this comes to the exact value varies from run to run, for two reasons. The estimate is an average over the first bin, and the posterior density changes across it (the grid average over the bin is 5.049); a finer bin needs more samples. And the chain moves into and out of the first bin slowly, so twenty batches can understate its random error.

For the data *with* a bump the same estimate is much harder. There $B_{01} = 1/8.133$, so the posterior density at $A = 0$ is small and few samples land there. A histogram is accurate only where samples land, so the estimate is noisy. This is the known weakness of the method: it is noisy exactly when the simpler model is disfavoured [HobsonBMC p. 89]. The factorisation condition can also fail quietly, for instance when a prior boundary of the common parameters depends on the new one.

5.18.2 Model averaging

Sometimes no model wins clearly, and we still want the best statement about a quantity θ that all the models share. Probability theory gives it directly: we do not know which model is true, so we sum the joint posterior over the models,

$$p(\theta \mid \boldsymbol{d}) = \sum_i p(\theta \mid \boldsymbol{d}, M_i)\ \mathrm{P}(M_i \mid \boldsymbol{d}), \tag{5.60}$$

the posterior of θ inside each model, weighted by the probability of that model [Kruschke §10.4], [HobsonBMC §4.2]. This is **Bayesian model averaging**. For the two coin factories of Section 5.15.2 it gave the averaged mean bias 0.6486, between the two factories' 0.4524 and 0.6905, with the tail-biased factory showing up as a long left tail of the averaged posterior.

A model in which θ is fixed still takes part. The line model fixes the amplitude A at 0, so it contributes a spike $\mathrm{P}(M_0 \mid \boldsymbol{d})\,\delta(\theta)$ to the average. Hobson and collaborators compare the averaged posterior to a quantum superposition that later data may collapse onto fewer models

[HobsonBMC p. 82]. Predictions of future data are averaged the same way. Basing them on the winning model alone ignores the probability that it is wrong.

Example: which dark-energy model? Five models of the dark-energy equation of state w were compared with the same supernova, CMB and large-scale-structure data [HobsonBMC Table 4.5]. Model I is ΛCDM, $w = -1$ exactly. Models II and III let w take a constant value with priors $-1 \le w \le -0.33$ and $-2 \le w \le -0.33$. Model IV gives w two parameters, $w(a) = w_0 + w_a(1-a)$ with $-2 \le w_0 \le -0.33$ and $-1.33 \le w_a \le 1.33$, and model V lets $w(a)$ vary with redshift, between -1 and 1 for $0 \le z \le 2$. The log Bayes factors against ΛCDM are 0, -1.3, -1.8, -2.0 and -4.1. With equal prior probability for each model, the posterior probabilities are $e^{\ln B_{iI}}$ divided by their sum:

$$\mathrm{P}(M_\mathrm{I} \mid \boldsymbol{d}) \overset{(1)}{=} \frac{1}{1 + e^{-1.3} + e^{-1.8} + e^{-2.0} + e^{-4.1}} = \frac{1}{1 + 0.273 + 0.165 + 0.135 + 0.017} = 0.63,$$

(1) Equation (5.44) with equal priors: each model's share is its evidence over the total, and dividing every evidence by that of ΛCDM turns the evidences into $e^{\ln B}$.

and the other four models get 0.17, 0.10, 0.09 and 0.01 in the same way. Every extension fits at least as well as ΛCDM at its best, since each contains $w = -1$. The evidence prefers ΛCDM because the extensions spread their priors over values of w the data exclude, and the more parameters or the wider the range, the larger the penalty. None of the extensions is decisively ruled out (no $|\ln B|$ exceeds 5), and the probabilities depend on the prior ranges chosen for w, which is the lesson of Section 5.17.2.

Does the answer you need depend on the model? Averaging is the formal remedy for model uncertainty. The informal remedy is a **sensitivity analysis**: fit several reasonable models and check whether the quantity you actually care about changes [Lambert §10.8]. Lambert's example is a rainfall model for sizing a dam. A two-state model (dry, wet) and a three-state model (dry, wet, persistently wet) fit 100 days of rain equally well on every standard test. But let each generate long rain series, and the three-state model gives far more probability to long runs of wet days. Long wet runs are the very quantity the dam depends on. So fit quality cannot choose between the models, and the conclusion that matters differs between them. The cautious report gives the answer of the pessimistic model and says why. The same habit applies to a forecast of a background tail under different fit functions, or of a cosmological parameter under different sets of nuisance parameters. A sensitivity analysis matters most when data are few or the decision is sensitive to the modelling choice.

5.18.3 How many bumps?

Sivia's "how many lines are there?" is the multi-model version of the bump hunt [Sivia §4.2]. A spectrum is a sum of M peaks of known shape on a background, M is unknown, and each value of M is a model with $2M$ peak parameters (amplitudes and positions). With a uniform prior on M over a few values, $\mathrm{P}(M \mid \boldsymbol{d})$ is proportional to the evidence Z_M [Sivia (4.15)], a $2M$-dimensional integral over a uniform box of amplitudes and positions [Sivia (4.16)–(4.19)].

We do it for $M = 0, 1, 2$ bumps on our line, with the line integrated out exactly as in (5.51) and the priors of Section 5.16.3 for each bump. For two bumps, $\chi^2_{\min}$ minus the line's $\chi^2_{\min}$ is a quadratic form in (A_1, A_2) with coefficients $\boldsymbol{r} \cdot \boldsymbol{u}_{\mu_j}$ and $\boldsymbol{u}_{\mu_j} \cdot \boldsymbol{u}_{\mu_k}$, so the four-dimensional grid (81 amplitudes and 161 positions per bump) costs only multiplications; refining it changes $\ln Z$ by 7.188×10^{-7}. The box includes both orderings of the two positions, so the $M!$ equivalent peaks of Sivia's (4.20) are counted automatically. Besides the one-bump data we simulate a data set with two bumps of height 2.5 at $\mu = 4$ and 5.4 (Figure 5.51).

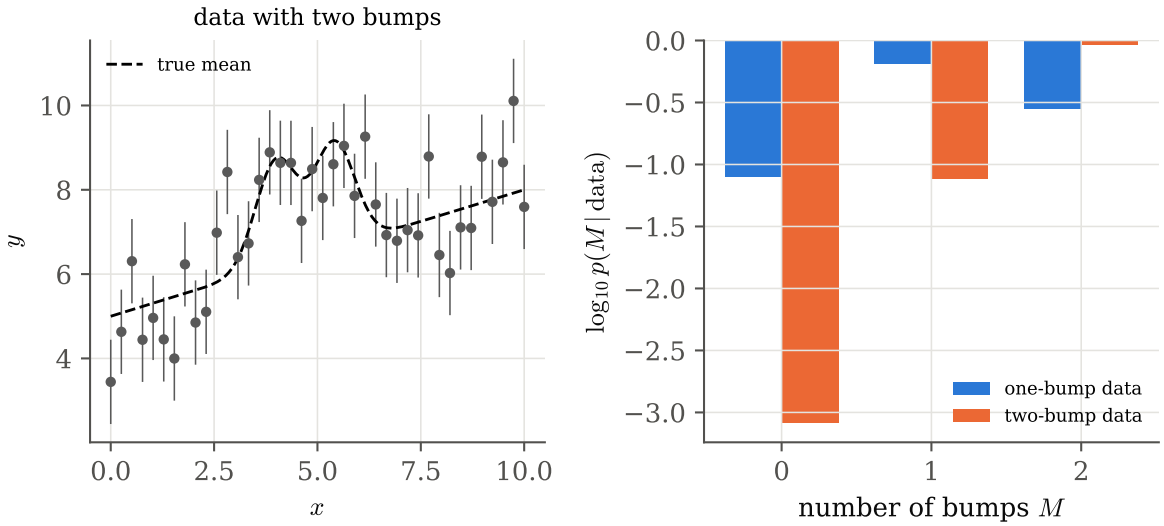

Figure 5.51: How many bumps? Left: forty points containing two overlapping bumps, with the true mean curve. Right: the posterior probability of each number of bumps, in powers of ten, for the one-bump data of Figure 5.45 and for the two-bump data.

	one-bump data					two-bump data				
M	$\chi^2_{\min}$	AIC	BIC	$\ln Z_M$	$P(M \mid \boldsymbol{d})$	$\chi^2_{\min}$	AIC	BIC	$\ln Z_M$	$P(M \mid \boldsymbol{d})$
0	49.07	53.07	56.44	−68.61	0.07901	63.32	67.32	70.7	−75.73	8.192×10^{-4}
1	34.54	42.54	49.29	−66.51	0.6425	44.62	52.62	59.38	−71.2	0.07661
2	30.1	42.1	52.24	−67.35	0.2784	30.98	42.98	53.11	−68.71	0.9226

For the one-bump data the evidence gives one bump the probability $P(M = 1 \mid \boldsymbol{d}) = 0.6425$, although the two-bump model fits better ($\chi^2_{\min} = 30.1$ against 34.54). For the two-bump data it gives two bumps 0.9226. The χ^2 column alone would always choose the most bumps. Two data sets could be lucky, so we repeat the count on 100 fresh data sets of each kind. The evidence picks one bump in 80 of the one-bump sets and two bumps in 80 of the two-bump sets.

5.18.4 Information criteria

The table also shows two quantities that are popular because they need no integral. Both are built from $-2 \ln \mathcal{L}_{\max}$, which for Gaussian noise is $\chi^2_{\min}$ plus a constant, plus a penalty for the number of parameters k [Lambert §10.5], [32, §4.7], [HobsonBMC (4.14)]:

$$\text{AIC} = -2 \ln \mathcal{L}_{\max} + 2k, \qquad \text{BIC} = -2 \ln \mathcal{L}_{\max} + k \ln N,$$

with N the number of data points; smaller is better. (The table uses $\chi^2_{\min}$ for $-2 \ln \mathcal{L}_{\max}$ and counts the line's two parameters, $k = 2, 4, 6$.)

The **Bayesian information criterion** is a crude evidence. Start from the Laplace approximation (5.50) with a general prior density [32, eqs. (39)–(41)]:

$$\begin{aligned} \ln Z &\overset{(1)}{\approx} \ln \mathcal{L}_{\max} + \ln \pi(\hat{\boldsymbol{\theta}}) + \frac{k}{2} \ln 2\pi - \frac{1}{2} \ln \det \mathbf{F} \\ &\overset{(2)}{\approx} \ln \mathcal{L}_{\max} + \ln \pi(\hat{\boldsymbol{\theta}}) + \frac{k}{2} \ln 2\pi - \frac{k}{2} \ln N - \frac{1}{2} \ln \det \mathbf{F}_1 \\ &\overset{(3)}{\approx} \ln \mathcal{L}_{\max} - \frac{k}{2} \ln N = -\tfrac{1}{2} \,\text{BIC}. \end{aligned} \tag{5.61}$$

(1) The logarithm of (5.50), with k parameters.
(2) For N independent data points the curvature of the log-likelihood grows in proportion to N: $\mathbf{F} = N\mathbf{F}_1$, with $\mathbf{F}_1$ the curvature per data point, and $\det(N\mathbf{F}_1) = N^k \det \mathbf{F}_1$.
(3) Keep only the terms that grow with N: $\ln \mathcal{L}_{\max}$ grows like N, $\ln N$ grows slowly, and the prior, 2π and $\mathbf{F}_1$ terms stay constant. They are dropped.

So $-\frac{1}{2}\Delta\text{BIC}$ approximates $\ln B$ for large N. The dropped constant terms are exactly the ones that carry the prior. That is why BIC is attractive (no prior to choose) and also why it is limited. It charges every parameter the same price $\frac{1}{2}\ln N$, as if every prior range were one data point's worth of information wide, whether the parameter is constrained or not. In our table $-\frac{1}{2}\Delta\text{BIC}$ gives 3.576 for one bump against none on the one-bump data, where the exact $\ln B$ is 2.096. Our prior ranges for the bump are wider than BIC assumes, so BIC under-charges.

The **Akaike information criterion** comes from a different question: which model will predict new data best, measured by a Kullback–Leibler divergence [Lambert §10.5.5]. Its penalty, 2 per parameter, is weaker still. In the 100 fresh one-bump data sets, where the truth has one bump, AIC chooses two bumps over one in 33, BIC in 8, and the evidence in 6.

Lambert describes the Bayesian descendants of AIC: DIC, which uses the posterior mean and the posterior variance of the log-likelihood as the penalty; WAIC, which averages the likelihood of each data point over the posterior; and leave-one-out cross-validation (LOO-CV), which predicts each point from a fit to all the others [Lambert §§10.5.6–10.5.8]. Trotta relates DIC to the Bayesian complexity, the effective number of parameters the data actually constrain [32, §4.6], [HobsonBMC (4.9)–(4.11)]. All of these answer "which model predicts best?", not "which model produced the data?". Lambert prefers them to Bayes factors because of the prior sensitivity of Section 5.17.2 [Lambert §10.6]; cosmologists mostly compute evidences, because their models come with physically motivated prior ranges.

Taxonomy: Which number answers which question

tool	what it computes	when to trust it
evidence Z, Bayes factor	probability of the data under each model, prior included	always the target; needs the prior and an integral
Laplace	$\mathcal{L}_{\max}\times$ posterior volume / prior volume	one Gaussian-like peak well inside the prior
Savage–Dickey	posterior over prior density of the new parameter at its null value	nested models, factorised prior, enough samples near the null
BIC	$\ln Z$ keeping only terms that grow with N	many independent data, all parameters constrained, priors about one datum wide
AIC, DIC, WAIC, LOO-CV	expected accuracy of predictions for new data	when prediction, not the generating model, is the question
$\Delta\chi^2$, p-value	improvement of the best fit; surprise under the null	never on its own for comparing models

5.18.5 Estimating a difference, or comparing models?

A trigger is upgraded. Before the upgrade $x_1 = 28$ of $n_1 = 40$ test pulses fired it; after, $x_2 = 35$ of $n_2 = 40$. Did the efficiency change? There are two different questions hidden in these words.

Estimation: by how much did it change? Give the two efficiencies p_1, p_2 independent flat priors. Their posteriors are independent, $p_j \mid x_j \sim \text{Beta}(x_j + 1, n_j - x_j + 1)$, and the posterior of the change $\tau = p_2 - p_1$ is obtained by drawing pairs and subtracting, exactly as in Wasserman's example of two binomials [Wasserman pp. 183–184]. With 200000 draws (Figure 5.52), $\text{P}(\tau > 0 \mid \boldsymbol{d}) = 0.9694$, the posterior mean of τ is 0.1666, and the central 95% interval is $[-0.007736, 0.3402]$.

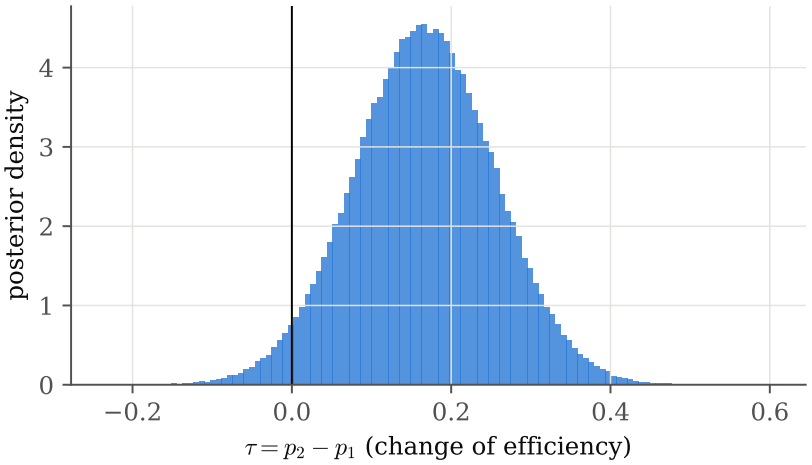

Figure 5.52: The posterior of the change of trigger efficiency, from 2×10^5 pairs of draws of the two Beta posteriors. About 97% of the area lies to the right of zero. The picture answers "by how much did it change?" and says nothing about whether the change is exactly zero, which has zero probability under this continuous posterior.

Comparison: did it change at all? Now let the hypotheses be two models. M_{same}: one efficiency p for both periods, flat prior. M_{diff}: independent p_1, p_2, flat priors. The evidence of each is a Beta integral like (5.46); the binomial coefficients are the same in both and cancel in the ratio:

$$B_{\text{same,diff}} \overset{(1)}{=} \frac{\int_0^1 p^{x_1+x_2}(1-p)^{n_1+n_2-x_1-x_2}\,\mathrm{d}p}{\int_0^1 p_1^{x_1}(1-p_1)^{n_1-x_1}\mathrm{d}p_1 \int_0^1 p_2^{x_2}(1-p_2)^{n_2-x_2}\mathrm{d}p_2} \overset{(2)}{=} \frac{B(x_1+x_2+1,\, n_1+n_2-x_1-x_2+1)}{B(x_1+1, n_1-x_1+1)\,B(x_2+1, n_2-x_2+1)}. \tag{5.62}$$

(1) The evidences (5.43) with flat priors (density one on $[0,1]$ and on $[0,1]^2$); the likelihood of the two samples is a product of two binomials.

(2) Each integral is a Beta function, as in (5.46).

Numerically $B_{\text{same,diff}} = 0.7517$, so with even prior odds $\text{P}(M_{\text{same}} \mid \boldsymbol{d}) = 0.4291$.

The two answers look contradictory: probability 0.9694 that the efficiency went up, and probability 0.4291 that it did not change. They are not, because they answer different questions with different priors.

- The estimation put zero prior probability on "exactly no change", since a continuous prior gives any single value probability zero.
- The comparison put half of all prior probability on exactly that value, and spread the other half over all pairs (p_1, p_2), most of which the data exclude.

Which is right depends on the physics. If the upgrade could plausibly have done nothing at all (a firmware change that might not have been loaded), the point hypothesis deserves its prior mass and the comparison is the right question. If the upgrade certainly changed something, and we want to know how much, estimation is the right question. Kruschke makes the same point about restricted models with negligible prior plausibility: testing every possible equality among nine baseball positions gives 21147 restricted models, most of which nobody believes, and estimation of the full model is more informative [Kruschke §10.5.1]. Lambert's advice is similar: when one model extends another, estimate within the bigger model and check its predictions [Lambert §10.7].

Watch out: A point null is a strong claim

Comparing "the effect is exactly zero" with "the effect is something" gives the point null a finite share of prior probability on a single value. That is appropriate when theory singles the value out ($n_s = 1$, $\Omega_k = 0$, $w = -1$, a symmetry that forbids a coupling). It is not appropriate for effects that are surely nonzero but possibly small; there the question is the size of the effect, and a credible interval answers it.

5.19 Why we need sampling

The denominator of Bayes' theorem, the integral over all parameter values, is the part of Bayesian inference that does not scale to many parameters. Every evidence so far was computed exactly or on a small grid. The coin factories had a Beta-function formula. The bump model had four parameters, but two of them, the line, entered linearly and could be integrated by hand, which left a two-dimensional grid. Real problems are not so kind. The base cosmological model has six parameters. Each evaluation of its CMB likelihood runs a Boltzmann code and takes of order a second. Its extensions add more parameters, none of them linear [HobsonBMC p. 87]. There are two ways out. For parameters, never compute the denominator. For models, compute it with an algorithm that spends its effort where the likelihood is.

5.19.1 The cost of a grid

A grid needs about w/Δ points along each axis to cover a width w with resolution Δ, so $(w/\Delta)^D$ points in D dimensions [HobsonBMC p. 58], [Sivia §3.4], [Kruschke §5.4]. The exponent is the whole problem. We can watch it happen by computing the bump evidence of Section 5.16.3 the brute-force way, on a grid over all four parameters (a, b, A, μ) with n points per axis and no analytic help (Figure 5.53). The wall time grows as n^4. With $n = 12$ the answer is $\ln B_{10} = 4.558$, wrong by more than a unit because the grid is too coarse to resolve the peak; with $n = 24$ it is 2.379; with $n = 64$ it is 2.1, against the exact 2.096, after 9.43 seconds.

At the measured cost of 5.621×10^{-7} seconds per grid point, a six-parameter problem with a thousand points per axis, 10^{18} points, would take $1.784e+04$ years. With a CMB likelihood at one second per call it would take 3.175×10^{10} years, more than twice the age of the Universe. And almost all of that work is wasted, because almost every grid point sits where the likelihood is negligible. How small is the region that matters? The bulk of the posterior occupies a fraction of about e^{-H} of the prior volume. Here H is the information gained from the data (the

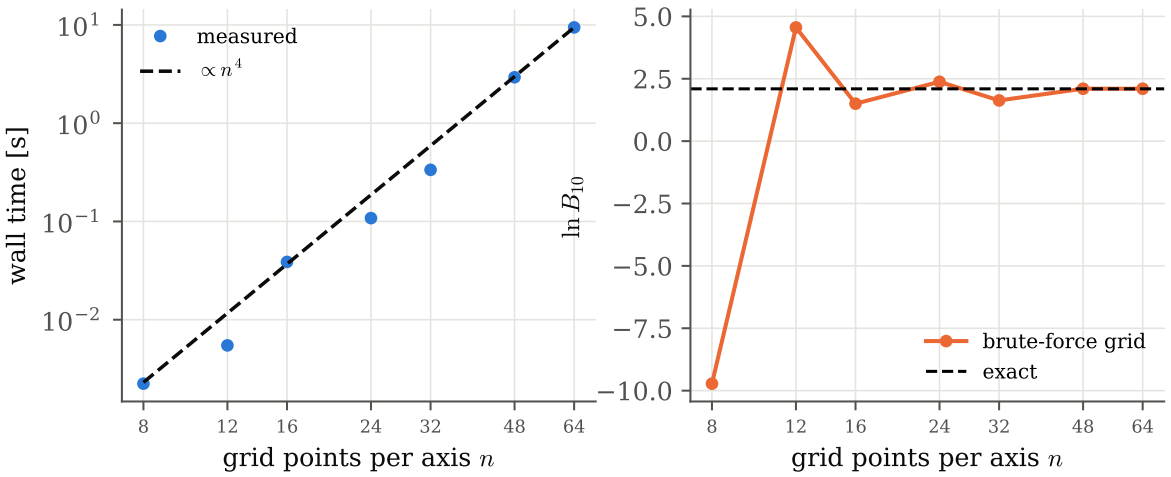

Figure 5.53: The bump evidence by brute force over the four-dimensional prior box. Left: the wall time grows as the fourth power of the number of points per axis (dashed line). Right: the log Bayes factor from the grid settles on the exact value only once the grid is fine enough to resolve the likelihood peak, which occupies a tiny corner of the box.

Kullback–Leibler divergence from prior to posterior), and it grows in proportion to the number of well-measured parameters [HobsonBMC p. 20].

5.19.2 Sampling the prior does not rescue us

A grid is one way to do an integral; random points are another. The evidence is an average of the likelihood over the prior, so draw $\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_K$ from the prior and average: $\hat{Z} = \frac{1}{K}\sum_k \mathcal{L}(\boldsymbol{\theta}_k)$ [Kruschke (10.7)]. The estimate is unbiased, and its error falls like $1/\sqrt{K}$ whatever the dimension. The catch is the constant in front of $1/\sqrt{K}$. For the simplest test case, a Gaussian likelihood of width s centred in the unit cube $[0,1]^D$ with a uniform prior, the relative variance of one term is

$$\frac{\mathrm{Var}_\pi[\mathcal{L}]}{Z^2} \overset{(1)}{=} \frac{\mathbb{E}_\pi[\mathcal{L}^2]}{Z^2} - 1 \overset{(2)}{=} \frac{\int e^{-|\boldsymbol{\theta}-\boldsymbol{\theta}_0|^2/s^2}\,\mathrm{d}^D\boldsymbol{\theta}}{\left(\int e^{-|\boldsymbol{\theta}-\boldsymbol{\theta}_0|^2/2s^2}\,\mathrm{d}^D\boldsymbol{\theta}\right)^2} - 1 \overset{(3)}{=} \frac{(s\sqrt{\pi})^D}{(s\sqrt{2\pi})^{2D}} - 1 = \left(\frac{1}{2\sqrt{\pi}\,s}\right)^D - 1. \quad (5.63)$$

(1) The variance is the mean square minus the square of the mean, and the mean of $\mathcal{L}$ over the prior is Z.

(2) The prior density is one on the cube, so averages over the prior are integrals; squaring the Gaussian halves its width parameter. We neglect the parts of the Gaussians outside the cube, which is exact enough for $s \ll 1$.

(3) Gaussian integrals: $\int e^{-u^2/s^2}\mathrm{d}u = s\sqrt{\pi}$ and $\int e^{-u^2/2s^2}\mathrm{d}u = s\sqrt{2\pi}$, once per dimension.

The relative error of $\hat{Z}$ is the square root of (5.63) divided by $\sqrt{K}$. For $s = 0.05$ the base is $1/(2\sqrt{\pi}\,s) \approx 5.6$: every extra dimension multiplies the required number of draws by more than five. With $K = 100000$ draws the simulation (Figure 5.54) finds a relative error of 0.01888 for $D = 2$ and 0.2925 for $D = 5$, roughly as (5.63) predicts. For $D = 8$ the estimate is so lopsided that our 20 repeated runs cannot pin down its error: most runs fall short, and the typical run gives only 0.1252 of the true value. By $D = 10$ the typical estimate is 8.293×10^{-4} of the true value: almost no draw lands where the likelihood is, and the rare draw that does dominates the sum. The fraction of prior draws inside the bulk of the posterior tells the same story: 0.04682 at $D = 2$, 7.315×10^{-4} at $D = 5$, 9.500×10^{-6} at $D = 8$. Kruschke's verdict on prior sampling is that it may need "a ginormous number of samples" [Kruschke p. 275].

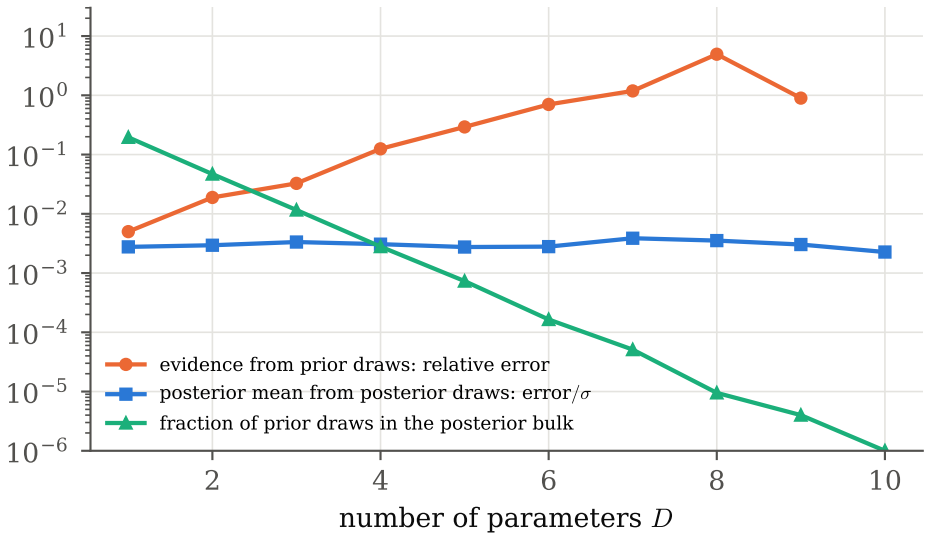

Figure 5.54: The curse of dimension for a Gaussian likelihood of width 0.05 in the unit cube, with 10^5 draws each time. Orange: relative error of the evidence estimated from draws of the prior, shown only while some runs still reach the likelihood peak. Green: fraction of prior draws that land in the bulk of the posterior. Blue: error of the posterior mean of one parameter estimated from draws of the posterior, in units of the posterior width; it does not grow with the dimension.

The blue curve of Figure 5.54 is the hopeful one. If instead we had draws from the *posterior*, the posterior mean of a parameter would have error $\sigma/\sqrt{K}$, independent of D: $0.002947\,\sigma$ at $D = 2$ and $0.002263\,\sigma$ at $D = 10$, both of the order of $1/\sqrt{10^5} \approx 0.003$. This is the central limit theorem at work on the samples [HobsonBMC §3.1], and it is why cosmologists sample: a few thousand posterior draws summarise a posterior in any number of dimensions [HobsonBMC p. 58]. What we need is a way to draw from the posterior without knowing its normalisation.

5.19.3 Ratios are all we need for parameters

The normalisation of the posterior is the evidence, and it cancels from every ratio of posterior densities:

$$\frac{p(\boldsymbol{\theta}' \mid \boldsymbol{d})}{p(\boldsymbol{\theta} \mid \boldsymbol{d})} \overset{(1)}{=} \frac{p(\boldsymbol{d} \mid \boldsymbol{\theta}')\,p(\boldsymbol{\theta}')/p(\boldsymbol{d})}{p(\boldsymbol{d} \mid \boldsymbol{\theta})\,p(\boldsymbol{\theta})/p(\boldsymbol{d})} \overset{(2)}{=} \frac{\mathcal{L}(\boldsymbol{\theta}')\,\pi(\boldsymbol{\theta}')}{\mathcal{L}(\boldsymbol{\theta})\,\pi(\boldsymbol{\theta})}. \tag{5.64}$$

(1) Bayes' theorem at the two points $\boldsymbol{\theta}'$ and $\boldsymbol{\theta}$.
(2) The evidence $p(\boldsymbol{d})$ is the same number at both points and cancels.

A method that only ever asks "how much more probable is this point than that one?" can therefore move through parameter space using likelihood times prior alone. The Metropolis algorithm does exactly this [36]. From the current point $\boldsymbol{\theta}$, propose a random step to $\boldsymbol{\theta}'$; accept it with probability min(1, ratio (5.64)); otherwise stay where you are and count the current point again. We don't want the unbiased random walker, but instead a biased random walker which spends more time in the region where probability is higher: the accept–reject step, which uses only the ratio, is the bias. That the fraction of time the walker spends in each region converges to the posterior probability of that region is proved in Chapter 9; here we only watch it work.

Listing 5.11: A Metropolis walk on the bump posterior that uses only ratios (`code/ch05/28_sampling_evidence.py`)

```
37 def metropolis(y, rng, n_steps=1_000_000, step=(0.25, 0.04, 0.35, 0.12)):
38     ab = np.linalg.lstsq(lb.DESIGN, y, rcond=None)[0]
39     theta = np.array([ab[0], ab[1], 1.0, 5.0])                    # start: best line, small
       bump mid-range
40     lp = lb.ln_post_unnorm(theta, y)
41     chain = np.empty((n_steps, 4)); acc = 0
42     for k in range(n_steps):
43         prop = theta + np.array(step) * rng.standard_normal(4)
44         lp_new = lb.ln_post_unnorm(prop, y)
45         if np.log(rng.random()) < lp_new - lp:                     # only the RATIO of
       posteriors enters
46             theta, lp = prop, lp_new; acc += 1
47         chain[k] = theta
48     return chain, acc / n_steps
```

Line 39 starts the walker at the best line with a small bump in the middle of the box. Line 43 proposes a Gaussian step in all four parameters. Line 44 evaluates the logarithm of likelihood times prior, which is $-\infty$ outside the prior box, so steps out of the box are always rejected. Line 45 is the whole algorithm: accept if a uniform random number is below the ratio, in logarithms. Nothing in the loop knows the evidence.

Example: the bump posterior from a chain. For the data with a bump, 1000000 steps take 43.73 seconds, with acceptance rate 0.3533; we discard the first 50000 as the walker finds the peak. The histograms of the chain (Figure 5.55) lie on the grid posteriors. The posterior mean position is 6.37 from the chain, 6.371 from the standard ensemble sampler `emcee` run as a cross-check (640000 samples), and 6.349 on the grid; the mean amplitude is 2.215 (chain), 2.212 (`emcee`) and 2.199 (grid).

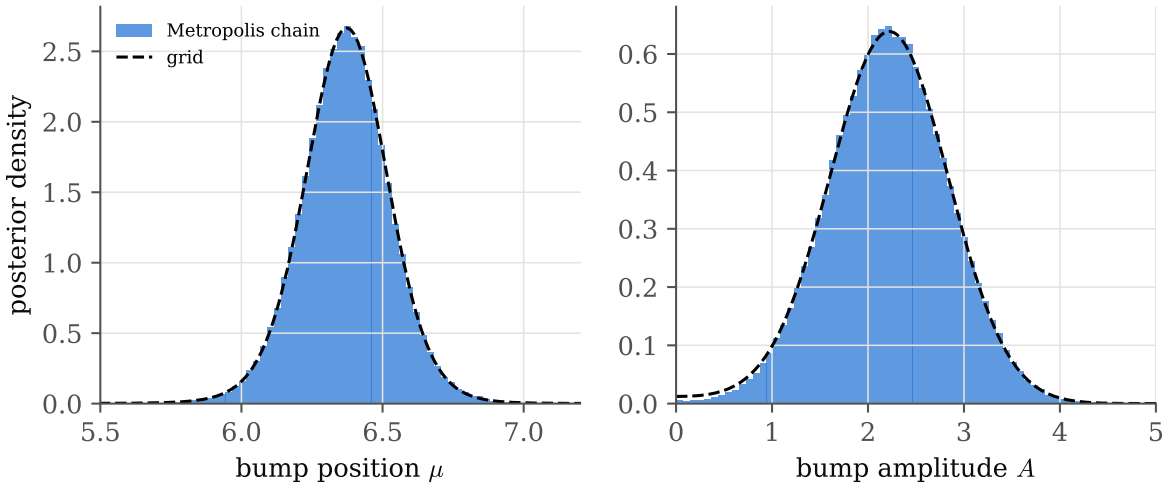

Figure 5.55: The posterior of the bump position and amplitude from a Metropolis chain of 10^6 steps that only ever evaluated ratios of likelihood times prior (histograms), against the grid posterior (dashed). The chain never computed the evidence, yet reproduces the normalised shape.

A chain can miss part of a posterior, and the reason matters. Besides the peak, a bump posterior can have a faint "pedestal": bumps of small amplitude anywhere in $0 < \mu < 10$, which fit about as well as the line. How much probability the pedestal holds depends on how clearly the data show the bump. For our data the grid gives it 0.007269 (for $A < 0.5$). The chain spends 0.003826 of its time there and `emcee` 0.005811; 6 chains with different seeds give between 0.003826 and 0.007526. When the pedestal holds a noticeable share, a chain reaches it only in rare excursions, so its share is mostly luck, set by how many times it happened to wander off

the peak. Because the pedestal is spread over the whole range of μ, those rare visits matter most for the posterior standard deviation of μ: 0.4253 on the grid against 0.1609 to 0.2646 from the chains. Why are the visits rare? A walker that takes small local steps crosses from the peak to a distant low-amplitude region only rarely, so a finite chain can under-represent that region. How long a chain must run, and how to tell whether it has, is the subject of Chapter 9.

How this is used in real research: Verification here, the instrument elsewhere

For the bump posterior the chain can be checked against a grid, so the chain only *verifies* what we already know. In a cosmological analysis there is no grid: the posterior of ΛCDM and its extensions from Planck, BAO and supernova data exists only as a chain from codes such as CosmoMC [37], Cobaya or MontePython, and the chain *is* the result. Convergence is then judged from the chains themselves, for instance by comparing several chains started far apart [38], and the samples are turned into marginal densities and triangle plots with `getdist`. The two-step habit of this book carries over: write the sampler from scratch once to see the mechanism, then use and cross-check the research code.

5.19.4 The evidence needs more than a chain

A chain never computes the evidence, so it cannot simply report it. Wasserman gives a sharp form of the difficulty [Wasserman Example 11.10]. Suppose a density is known up to its constant, $f(x) = c\,g(x)$ with g known, and we can draw n samples $x_1, \dots, x_n$ from f. Can the samples tell us c? Treat c as a parameter. The likelihood of the samples is $\prod_i c\,g(x_i) \propto c^n$, the same function of c whatever the samples are, so a Bayesian analysis learns nothing about c from them. Yet c can be estimated another way. Estimate the density $\hat{f}$ from the samples at any point x; then $\hat{c} = \hat{f}(x)/g(x)$.

The same trick works for the evidence. Bayes' theorem, rearranged, gives an identity for the evidence at *any* parameter value $\boldsymbol{\theta}$:

$$p(\boldsymbol{\theta} \mid \boldsymbol{d}) = \frac{\mathcal{L}(\boldsymbol{\theta})\,\pi(\boldsymbol{\theta})}{Z} \quad \Longrightarrow \quad Z = \frac{\mathcal{L}(\boldsymbol{\theta})\,\pi(\boldsymbol{\theta})}{p(\boldsymbol{\theta} \mid \boldsymbol{d})}. \tag{5.65}$$

The numerator, likelihood times prior, we can compute. The denominator is the normalised posterior density, which the samples estimate. Here $\mathcal{L}(\boldsymbol{\theta})\pi(\boldsymbol{\theta})$ plays the role of the known g, and Z the role of $1/c$. The Savage–Dickey ratio of Section 5.18.1 is this idea for nested models at the point $\psi = \psi_*$. The `MCEvidence` code estimates the posterior density from the nearest-neighbour distances of chain samples [Padilla §7]. Kruschke describes a version that averages over the chain instead of using one point [Kruschke (10.8)]: for any normalised density $h(\boldsymbol{\theta})$, $1/Z = \mathbb{E}_{\text{post}}[h(\boldsymbol{\theta})/(\mathcal{L}(\boldsymbol{\theta})\pi(\boldsymbol{\theta}))]$, which works well when h resembles the posterior and badly when it does not (with h equal to the prior it becomes the harmonic-mean estimator, whose variance can be infinite). All these need a good density estimate in the region that matters, which is again hard in many dimensions. The reliable general-purpose methods are built for the evidence from the start.

A chain can also be made to carry the model index. Give the model label m a prior and let the sampler move in the joint space of m and the parameters of each model, so that the fraction of steps spent at m estimates $\mathrm{P}(m \mid \boldsymbol{d})$, and the ratio of the fractions estimates the posterior odds [Kruschke §10.3.2]. The difficulty is that, when the chain sits at $m = 1$, the parameters that belong only to model 2 have no likelihood to pull them anywhere, so they wander over their whole prior. When the chain proposes a jump to $m = 2$, those parameters are almost certainly somewhere the data exclude, and the jump is rejected. The chain rarely changes model. The remedy is a **pseudo-prior**: while the chain sits in another model, the idle parameters are drawn

from a stand-in density placed where their own model's posterior lives, so that a jump to that model lands somewhere sensible. A pseudo-prior costs a preliminary run in each model, and, because it does not enter the final answer, it only affects efficiency, not the result.

5.19.5 Nested sampling

Skilling's nested sampling turns the D-dimensional evidence integral into a one-dimensional one [39], [HobsonBMC §1.4.1]. How can that be? The evidence only asks how much prior mass has how much likelihood; it does not care where in parameter space that mass sits. So sort all the prior mass by likelihood. For each likelihood level ℓ let

$$X(\ell) = \int_{\mathcal{L}(\boldsymbol{\theta})>\ell} \pi(\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{\theta}$$

be the prior mass enclosed by the contour $\mathcal{L} = \ell$ [HobsonBMC (1.57)]. It falls from $X = 1$ at $\ell = 0$ to $X = 0$ at the maximum likelihood, and its inverse $\mathcal{L}(X)$ is the likelihood of the contour that encloses prior mass X (Figure 5.56). Then

$$\begin{aligned} Z &\overset{(1)}{=} \int \pi(\boldsymbol{\theta}) \Big[\int_0^\infty \mathbb{1}\big(\mathcal{L}(\boldsymbol{\theta}) > \ell\big)\,\mathrm{d}\ell \Big] \mathrm{d}\boldsymbol{\theta} \overset{(2)}{=} \int_0^\infty \Big[\int_{\mathcal{L}(\boldsymbol{\theta})>\ell} \pi(\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{\theta} \Big] \mathrm{d}\ell \\ &\overset{(3)}{=} \int_0^\infty X(\ell)\,\mathrm{d}\ell \overset{(4)}{=} \int_0^1 \mathcal{L}(X)\,\mathrm{d}X. \end{aligned} \tag{5.66}$$

(1) Write the positive number $\mathcal{L}(\boldsymbol{\theta})$ as the length of the interval $0 < \ell < \mathcal{L}(\boldsymbol{\theta})$, an integral of the indicator $\mathbb{1}(\cdot)$, which is one when its condition holds and zero otherwise.
(2) Exchange the order of integration: for fixed ℓ the indicator restricts $\boldsymbol{\theta}$ to the region inside the contour $\mathcal{L} = \ell$.
(3) The inner integral is the enclosed prior mass $X(\ell)$.
(4) The area under the decreasing curve $X(\ell)$, plotted against ℓ, is the same region of the plane as the area under its inverse $\mathcal{L}(X)$, plotted against X [HobsonBMC (1.58)].

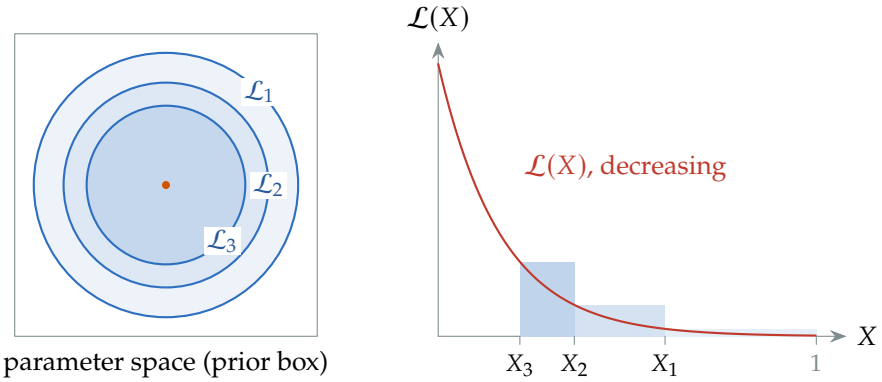

Figure 5.56: Nested sampling in pictures. Left: nested likelihood contours in parameter space; the contour $\mathcal{L}_i$ encloses prior mass X_i, and each step moves inward. Right: the same contours as a decreasing curve $\mathcal{L}(X)$ over the unit interval of prior mass. The evidence is the area under the curve, accumulated strip by strip (shaded), each strip of height $\mathcal{L}_i$ and width $X_{i-1} - X_i$. Here each step shrinks X by the factor 0.6.

A one-dimensional integral of a decreasing function is easy, if we know $\mathcal{L}$ at a sequence of known X values. Nested sampling produces such a sequence with the X values known statistically. Keep N "live" points drawn from the prior. At each step:

1. find the live point with the lowest likelihood, $\mathcal{L}_i$; record it and its estimated enclosed mass X_i;
2. replace it by a new point drawn from the prior subject to $\mathcal{L} > \mathcal{L}_i$ [HobsonBMC (1.61)];
3. add the strip $\mathcal{L}_i\,(X_{i-1} - X_i)$ to the running sum; stop when the live points could not add a significant amount any more.

Why do we know X_i? Before step i the N live points are independent draws from the prior inside the contour $\mathcal{L}_{i-1}$, so their enclosed masses are uniform on $[0, X_{i-1}]$. The discarded point is the one with the largest enclosed mass (the lowest likelihood). The ratio $t = X_i/X_{i-1}$ is therefore the largest of N uniform numbers on $[0,1]$, whose density is Nt^{N-1} [HobsonBMC (1.62)]: the probability that all N lie below t is t^N, and its derivative is Nt^{N-1}. On average

$$\mathbb{E}[\ln t] \overset{(1)}{=} \int_0^1 Nt^{N-1} \ln t \, \mathrm{d}t \overset{(2)}{=} \Big[t^N \ln t\Big]_0^1 - \int_0^1 t^N \, \frac{\mathrm{d}t}{t} \overset{(3)}{=} -\frac{1}{N}, \tag{5.67}$$

(1) The expectation of $\ln t$ over the density Nt^{N-1}.
(2) Integration by parts, with $Nt^{N-1}\mathrm{d}t = \mathrm{d}(t^N)$.
(3) The boundary term vanishes at both ends ($t^N \ln t \to 0$ as $t \to 0$), and $\int_0^1 t^{N-1}\mathrm{d}t = 1/N$.

so $\ln X_i \approx -i/N$: each step shrinks the enclosed prior mass by about $e^{-1/N}$ [HobsonBMC (1.63)]. The prior mass shrinks geometrically, so the algorithm reaches the tiny region $X \sim e^{-H}$ where the posterior lives after about NH steps, a number linear rather than exponential in the information. The uncertainty of the X_i gives an uncertainty of $\ln Z$ of about $\sqrt{H/N}$; it can also be found by redrawing the shrinkage factors t many times from Nt^{N-1} and recomputing the sum [HobsonBMC p. 24].

Example: the bump evidence by nested sampling. We run nested sampling from scratch on the (A, μ) problem of Section 5.16.3, with the line integrated out, so that the result is the Bayes factor B_{10} itself. With $N = 100$ live points the run takes 1211 steps and ends at $\ln X = -12.11$. It returns $\ln B_{10} = 2.066 \pm 0.1805$, the error from redrawing the shrinkage factors, against the exact 2.096 (Figure 5.57). The information is $H = 3.982$, so Skilling's estimate of the error is $\sqrt{H/N} = 0.1996$, and 8 independent runs scatter with standard deviation 0.2064 about a mean of 2.083. The algorithm knows its own error.

Our version is honest but naive in one place. Step 2 draws new points from the whole prior until one beats the current lowest likelihood; late in the run almost every draw fails, and the run spends 90.45 million likelihood evaluations. Research codes draw the replacement point from a short constrained Markov chain or from ellipsoids fitted around the live points, and need of order 10^5 likelihood evaluations for a cosmological evidence [32, §4.3]. With a likelihood that takes a second, that is the difference between a day and several years. Thermodynamic integration, which heats a Markov chain from the prior to the posterior, is the older alternative and typically costs about a hundred times more [32, §4.3], [HobsonBMC §4.4.1]. Two further options are VEGAS, an adaptive multidimensional integrator that refines a sampling density on the fly and is popular in particle physics, and parallel tempering, in which Markov chains at different "temperatures" (likelihood raised to a power below one, so that the landscape is flatter) run side by side and swap states, which helps chains cross between separated peaks [HobsonBMC §4.4.1].

5.19.6 The same question for lists, parameters and models

Bayes' theorem has now been used on three kinds of hypotheses, and the questions never changed. For a short list (Monty's doors, a disease, two urns) the posterior was a set of numbers.

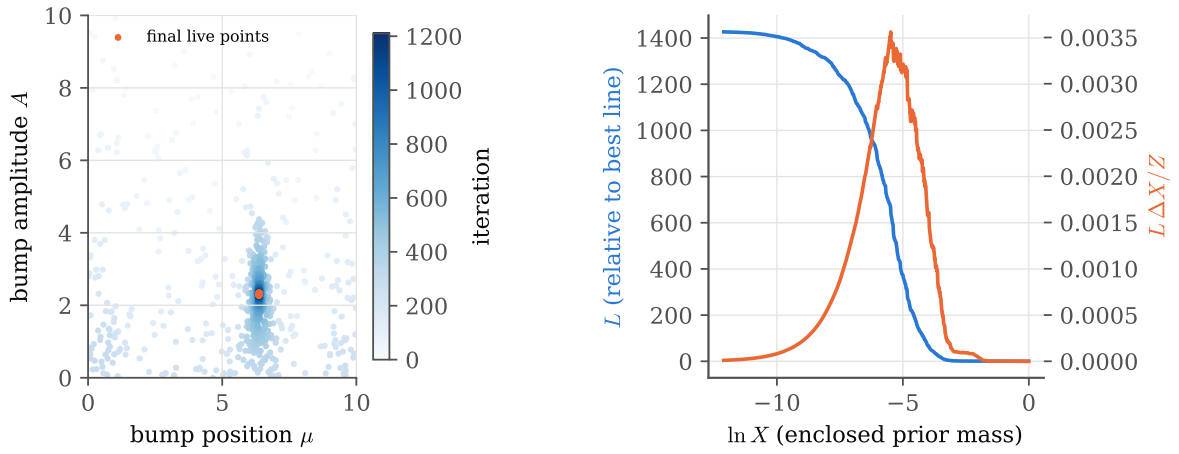

Figure 5.57: Nested sampling of the bump evidence. Left: the discarded points in the plane of bump position and amplitude, shaded by the step at which they were discarded; the early ones are spread over the whole prior box, the late ones close in on the peak, where the final live points sit. Right: the likelihood of the discarded points against the logarithm of the enclosed prior mass (blue), and each point's share of the evidence (orange). The evidence comes from a band around $\ln X \approx -5$, that is, from about e^{-5} of the prior.

For the values of a continuous parameter it was a density. For whole models it was again a set of numbers, and the probability of the data under each model was itself an average over that model's parameters. Each time we asked the two questions of Section 5.6: which hypotheses could have produced what we observed, and how probable the observation was under each. For model comparison the first question lists the models, each with its prior; the second is answered by the evidence.

The difference between the two uses lies in the evidence. For parameter estimation inside a model the evidence cancels, and a sampler that uses only ratios delivers the posterior. For model comparison it does not cancel, so it must be computed: exactly, by a Laplace or Savage–Dickey approximation, or by nested sampling. The Markov chains of Chapter 9 and the Fisher forecasts of Chapter 10 are the two tools the rest of the book uses to answer the second question in many dimensions.

Recap

- A model is a likelihood and a prior. Its evidence $Z = \int \mathcal{L}\,\pi\,\mathrm{d}\boldsymbol{\theta}$ is the probability it gave to the observed data: the likelihood averaged over its prior.
- $\mathrm{P}(M_i \mid \boldsymbol{d}) \propto Z_i\,\mathrm{P}(M_i)$; posterior odds = Bayes factor × prior odds. The comparison says nothing about parameters; model averaging combines the parameter posteriors with the model probabilities as weights.
- No model is rejected on its own: $p(\boldsymbol{d} \mid \text{not } M)$ is undefined without specific alternatives.
- Occam's razor is derived, not assumed: $Z \approx \mathcal{L}_{\max} \times V_{\text{post}}/V_{\text{prior}}$. Better fits are rewarded, wasted prior range is penalised, unconstrained parameters cost nothing. For the bump: a best-fit gain of $e^{7.265}$ became odds of $8.133 : 1$.
- Read Bayes factors on the logarithmic Jeffreys scale ($|\ln B| = 1, 2.5, 5$), as posterior odds, and with their numerical and prior uncertainty.
- The evidence depends on prior widths ($-\ln 10$ per decade of range) and can reverse between two vague priors that give the same posterior; improper priors are forbidden.

Equally informed priors, physically motivated ranges and sensitivity plots are the remedies.

- Lindley: at fixed significance, large samples favour the null. A p-value bounds the odds: at most $1/(e\,p\ln p)$ against the null, 2.5 : 1 at 2σ, 150 : 1 at 3.6σ.
- Nested models: Savage–Dickey $B_{01} = p(\psi_* \mid \boldsymbol{d})/\pi(\psi_*)$ from the bigger model alone; BIC is the Laplace evidence without its prior terms; AIC, WAIC and LOO rank predictions, a different question.
- Estimating a difference and testing whether it is exactly zero are different questions with different priors, and can give opposite-looking answers.
- Grids cost n^D and prior sampling fails exponentially in D; posterior samples give errors independent of D. Ratios of posteriors do not need the evidence (Metropolis, Chapter 9); the evidence needs its own algorithm, such as nested sampling, $Z = \int_0^1 \mathcal{L}(X)\,\mathrm{d}X$ with $\ln X_i \approx -i/N$.

Reading the literature

- **The main line.** Wasserman, *All of Statistics*, Chapter 11: the Bayesian method, conjugate examples, simulation from the posterior, flat and Jeffreys priors, Bayesian testing and its prior-free bound, and the strengths and weaknesses of Bayesian inference [Wasserman pp. 175–189].
- **The gentlest route.** Kruschke, *Doing Bayesian Data Analysis*, Chapters 2 and 5 (credibility, Bayes' rule), 6 (the Beta–Bernoulli model), 10 (model comparison, Occam's razor, prior sensitivity) and 12 (HDIs, estimation against testing).
- **The physicist's tutorial.** Sivia, *Data Analysis: A Bayesian Tutorial*, Chapters 1–3 (plausible reasoning, parameter estimation, the Gaussian approximation, marginalisation), 4 (Mr A and Mr B, how many lines) and 5 (assigning priors).
- **Priors, prediction and checks.** Lambert, *A Student's Guide to Bayesian Statistics*, Chapters 3–7 and 9 (Bayes' rule, likelihood, priors, the denominator, conjugacy) and 10 (predictive checks, AIC to LOO-CV, Bayes factors, sensitivity analysis).
- **Cosmology.** Hobson, Jaffe, Liddle, Mukherjee and Parkinson (eds.), *Bayesian Methods in Cosmology*, Chapter 1 (foundations, priors, nested sampling), Chapter 3 (Monte Carlo parameter estimation) and Chapter 4 (model selection, Savage–Dickey, the Jeffreys scale, the spectral index). Trotta's review "Bayes in the sky" [32] covers evidence, Occam's razor, the Lindley paradox and the p-value calibration in cosmological language. Padilla et al. [40] is a hands-on introduction with code.
- **Original papers.** Kass and Raftery on Bayes factors [33]; Lindley's paradox [34]; Sellke, Bayarri and Berger on calibrating p-values [35]; Skilling on nested sampling [39]; Metropolis et al. on the algorithm of Chapter 9 [36].
- **Pictures.** *Seeing Theory*, chapter "Bayesian Inference", for interactive versions of the updating examples.

Chapter summary

Bayesian inference turns the direction of probability around. Instead of asking what a hypothesis predicts, we start from an outcome already observed and ask which hypotheses might lie behind it, and how probable each is after the fact. Bayes' theorem answered this question first for a short list of hypotheses, then for a continuous parameter, and then for whole models, where the denominator we had been ignoring became the quantity of interest. In the pipeline of the book,

$$\text{model} \to \text{data} \to \text{summary } S \to P(S \mid \theta) \to \boxed{\text{infer physics}},$$

Bayesian inference is the last arrow: the sampling distribution $P(S \mid \theta)$ becomes the likelihood, and the posterior over parameters and models is the inference. Chapter 4 gave the frequentist form of the same arrow.

Bayes' theorem with a list of hypotheses

concept	operational meaning	used later in
prediction vs inference	$\mathrm{P}(E \mid H)$ reads the tree forward; $\mathrm{P}(H \mid E)$ asks which path produced the observed leaf	every chapter
joint table, logical not causal	one table of (hypothesis, outcome) probabilities: columns predict, rows infer; a posterior links hypothesis and evidence logically, it does not say the evidence caused anything	every chapter
Bayes' theorem	product rule in both orders: $\mathrm{P}(H \mid E) = \mathrm{P}(E \mid H)\,\mathrm{P}(H)/\mathrm{P}(E)$	Chapters 8 and 9
information shrinks the sample space	conditioning on E keeps only the region where E holds and re-measures everything inside it	Chapter 8
unit-square picture	priors are widths, likelihoods heights, posterior = surviving rectangle over total surviving area	Chapter 8
reasoning in words	the event; what could have produced it; its probability under each hypothesis; then priors and normalise. Monty Hall: "Monty opened C"; what made him open that door?; $\frac{1}{2}, 1, 0$ for car behind A, B, C; posterior $\frac{1}{3}, \frac{2}{3}, 0$	every chapter
base rates	a tall bar in a thin strip can lose to a short bar in a wide one (rare signals, trigger purity)	Chapters 8 and 12
reallocation of credibility	zero likelihood eliminates, zero prior can never be revived, noisy data only nudge	Chapter 9
odds, likelihood ratio	posterior odds = likelihood ratio × prior odds; independent evidence adds in logarithms	Chapters 8 and 10
sequential updating	yesterday's posterior is today's prior, if the data are independent given the hypothesis	Chapter 9
denominator, prior predictive	$\mathrm{P}(E) = \sum_i \mathrm{P}(E \mid H_i)\,\mathrm{P}(H_i)$: normaliser and forecast; needs every hypothesis	Chapters 6 and 9

Parameter estimation

concept	operational meaning	used later in
posterior density	likelihood × prior on a grid, normalised; the parameter value is the hypothesis, the data the event	Chapters 8 and 9
conjugate priors	Beta–Binomial, Gamma–Poisson, Normal–Normal: posterior in closed form, pseudo-counts and inverse-variance weights	Chapters 7 and 8
posterior summaries	mean, median, mode from three losses; equal-tailed interval; HDI, the shortest set	Chapters 9 and 10
credible vs confidence	probability of θ in a set given the data, against coverage over repetitions	Chapters 8 and 10
Gaussian (Laplace) approximation	peak and curvature: $\sigma^2 = (-\partial^2 \ln p)^{-1}$, covariance $= -H^{-1}$, $\Delta\chi^2$ regions	Chapter 10
marginalising, profiling	integrate nuisance parameters out (volume included) or maximise over them	Chapters 8 to 10
choosing a prior	knowledge, flat (in which variable?), Jeffreys $\propto \sqrt{I}$; improper priors as limits	Chapter 9
forgetting the prior	the likelihood dominates for many data (Bernstein–von Mises); not the same as a chain forgetting its start	Chapter 9
posterior sampling	a histogram of draws is the density; functions of parameters for free	Chapters 6, 9 and 12

Model comparison and the need for sampling

concept	operational meaning	used later in
evidence Z	likelihood averaged over the model's prior; the probability the model gave to the data	Chapters 9 and 12
Bayes factor, posterior odds	$B_{12} = Z_1/Z_2$ multiplies the prior odds; quote $\ln B$ and which model is on top	Chapters 9 and 12
Occam factor	$Z \approx \mathcal{L}_{\max} V_{\text{post}}/V_{\text{prior}}$; wasted prior range is penalised, unconstrained parameters are free	Chapter 10
Jeffreys scale	$\lvert\ln B\rvert = 1, 2.5, 5$: odds 3, 12, 150; apply to posterior odds, with the prior uncertainty	Chapter 12
prior sensitivity	$\ln B$ falls by $\ln 10$ per decade of prior range; vague priors can reverse it; improper priors forbidden	Chapter 12
Lindley, p-value bounds	fixed significance favours the null at large n; $B_{10} \leq -1/(e\, p \ln p)$	Chapters 8 and 12
Savage–Dickey	$B_{01} = p(\psi_* \mid \boldsymbol{d})/\pi(\psi_*)$ from the bigger model's samples	Chapter 9
model averaging	parameter posteriors weighted by model probabilities	Chapter 14
BIC, AIC, WAIC, LOO	crude evidence without prior terms; predictive accuracy, a different question	Chapter 12
estimation vs comparison	"how large is the effect?" against "is it exactly zero?": different priors, different answers	Chapters 8 and 12
curse of dimension	grids cost n^D; prior draws miss the posterior; posterior draws do not care about D	Chapters 6 and 9
ratios, Metropolis	the evidence cancels in posterior ratios; a biased random walk samples the posterior	Chapter 9

Physics Toolkits

Chapter T1

Cosmology for the Data Analyst

Where this chapter is going

A cosmological model is a machine. We feed it six numbers, and it returns the *statistics* of the sky: the angular power spectrum C_ℓ of the microwave background (how much the temperature varies on each angular scale), the matter power spectrum $P(k)$ (the same for the matter density, scale by scale), and the distance to every redshift. CAMB [8] is that machine in code. The machine never returns the sky itself. Our sky, with its particular hot and cold spots and its particular galaxies, is one noisy draw from the statistics the machine predicts. Every later chapter works across that gap. The model predicts a distribution. The data are one draw from it. Statistics is how we read the six numbers back from that one draw.

The book follows one pipeline (Chapter 0): a theory, its data, a compressed statistic, that statistic's scatter, and back to the theory. Cosmology is the first step. It fixes what each summary *should* be on average. The physics behind each object is worked out in the cosmology notes. The data analyst needs less: which objects the statistics uses, what each one means in one line, the equation that defines it, where CAMB and the cosmology notes write it differently, and how the predicted statistics move when the six numbers move. Figure T1.1 is the map.

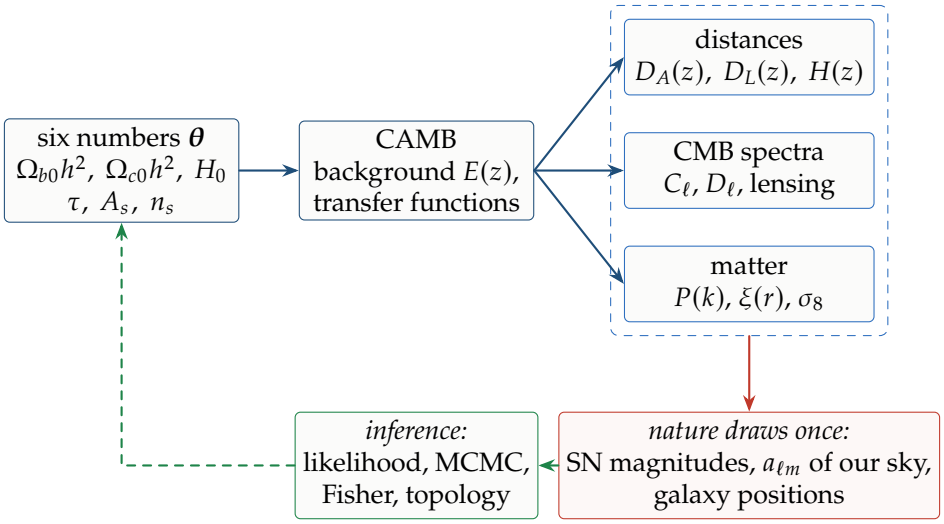

Figure T1.1: The machine and its one output we can see. Six numbers go into CAMB, which returns three families of predicted statistics (blue). Nature does not hand us those statistics: it hands us a single noisy draw from them (red), and the statistics of the later chapters (green) turn that draw back into constraints on the six numbers.

The link between the cosmology and the statistics is how the outputs move when the inputs move. Nudge one parameter and watch C_ℓ respond. That response is a derivative, and the

Fisher matrix of Chapter 10 is built from such derivatives. If two parameters produce responses that look alike, the data cannot tell those parameters apart. This is a degeneracy, and the MCMC chains of Chapter 9 show it as a long ridge. On the matter side, the linear $P(k)$ is the input of the Gaussian random fields of Chapter 7. On small scales gravity makes the real spectrum (computed by the halofit recipe) depart from the linear one. There the field is no longer Gaussian, and the topological summaries of Chapter 12 have something to find that the power spectrum misses.

The microwave light is also polarized, and a field of polarization sticks splits into a part that looks the same in a mirror and a part that does not. Ordinary physics leaves no correlation between the two, so a measured one is a test of whether the laws of physics, or our own detectors, prefer one hand (Sections T1.9 and T1.12).

T1.1 Six numbers in, statistics out

Think of the flat ΛCDM model as a function with six inputs. Two inputs are physical densities: the baryon density $\Omega_{b0}h^2$ and the cold dark matter density $\Omega_{c0}h^2$ [today's density of each component divided by the critical density, times h^2; the product is a physical density that does not depend on H_0]. One input fixes the distances: either the Hubble constant $H_0 = 100\,h$ km s^{-1} Mpc^{-1}, or equivalently the angle $\theta_{\rm MC}$ that the sound horizon at decoupling subtends on the sky. One is the optical depth to reionisation, τ [the expected number of Thomson scatterings a CMB photon undergoes after the Universe is re-ionised; a fraction $e^{-\tau}$ of the photons arrive unscattered]. The last two describe the primordial fluctuations: their amplitude A_s and their spectral tilt n_s. Everything else is held fixed: the radiation density (from the measured CMB temperature), flatness $\Omega_{K0} = 0$, and a single massive neutrino of 0.06 eV.

These numbers appear in three places, and Table T1.1 translates between them: the symbol used in the cosmology notes, the keyword that CAMB's Python interface takes, and the Planck 2018 value with its 68% error [25, Table 1]. The book's fiducial model (`code/camb_fiducial.py`) is this best fit. The $\pm1\sigma$ errors are the step sizes of the first experiment (Section T1.3).

symbol (cosmology notes)	one-line meaning	CAMB keyword	Planck 2018 (68%)
$\Omega_{b0}h^2$	physical baryon density; sets the baryon loading of the acoustic oscillations	`ombh2`	0.02237 ± 0.00015
$\Omega_{c0}h^2$	physical cold dark matter density; sets matter–radiation equality	`omch2`	0.1200 ± 0.0012
$100\,\theta_{\rm MC}$ *or* H_0	angular size of the sound horizon at decoupling, or the expansion rate today	`cosmomc_theta` or `H0`	1.04092 ± 0.00031; $H_0 = 67.36 \pm 0.54$ (derived)
τ	optical depth to reionisation	`tau`	0.0544 ± 0.0073
A_s	amplitude of the primordial curvature spectrum at $k_* = 0.05\,\mathrm{Mpc}^{-1}$	`As`	$\ln(10^{10}A_s) = 3.044 \pm 0.014$
n_s	tilt of that spectrum, $n_s = 1$ being scale invariant	`ns`	0.9649 ± 0.0042

Table T1.1: The six ΛCDM numbers in three notations. Planck samples $\theta_{\rm MC}$ because the data measure that angle almost directly; CAMB is usually called with H_0 instead, and the book's scripts do so (CAMB's `cosmomc_theta` takes $\theta_{\rm MC}$ itself, not $100\,\theta_{\rm MC}$). The error on $\ln(10^{10}A_s)$ is the fractional error on A_s, 1.4%.

The machine's output is a set of averages, not a sky. This is the one idea from cosmology that the statistics cannot do without. Take the CMB. Write the temperature pattern of the sky as a sum of spherical harmonics $Y_{\ell m}$; the coefficient of each one is a number $a_{\ell m}$, and large ℓ means small angular scales. What does the model predict about these numbers? It predicts a definite value for C_ℓ, the average of $|a_{\ell m}|^2$, computed from the primordial power spectrum and the radiation transfer function. It never predicts any single $a_{\ell m}$. Each $a_{\ell m}$ of our sky is one random draw from a distribution of variance C_ℓ. The matter field works the same way: the model predicts $P(k)$, the variance of each Fourier mode of the matter density, and not the modes themselves. So comparing theory with data always means comparing a predicted *distribution* with one *draw*. A single draw scatters about its mean, and nothing can remove that scatter, because we have only one sky. That scatter is cosmic variance.

Key idea: What the model predicts

A cosmological model predicts the statistics of the fields (their power spectra, correlation functions and distances), never the fields themselves. The observed sky is one realisation. Every estimator in the later chapters is a function of that realisation, and its sampling distribution around the predicted statistic is what the likelihood describes.

T1.2 The objects the statistics uses

A revision of the cosmology a data analyst needs follows the order in which the machine of Section T1.1 works. First comes the smooth background, the expansion of the Universe and the distances that follow from it. Then the primordial seed and how the radiation and matter eras process it. Last come the statistics of the two fields that result, the temperature of the sky and the density of matter. For every object the question comes first, then the equation it starts from and the working equation the book uses, then the size of the thing, then the chapters that use it. The physics between the two equations is worked out in the cosmology notes. Here it is a sentence.

How fast the Universe expands: $H(z)$ and $E(z)$. The question is how the expansion rate H changed over cosmic history, because every distance below is built from it. A homogeneous, isotropic universe has the Friedmann–Lemaître–Robertson–Walker metric, with one function of time in it, the scale factor $a(t)$. Einstein's equations then reduce to the first Friedmann equation

$$H^2 \equiv \left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}\rho - \frac{K}{a^2} + \frac{\Lambda}{3},$$

where ρ is the total density of radiation and matter, K the spatial curvature and Λ the cosmological constant. Each component dilutes in its own way as space expands: radiation as a^{-4} (the photons also lose energy), matter as a^{-3}, curvature as a^{-2}, and Λ not at all. Write the redshift as $1 + z = a_0/a$ and divide by today's rate H_0. The result is the working equation, in terms of the dimensionless expansion rate $E(z) \equiv H(z)/H_0$:

$$E^2(z) = \Omega_{r0}(1+z)^4 + \Omega_{m0}(1+z)^3 + \Omega_{K0}(1+z)^2 + \Omega_{\Lambda 0}, \qquad \Omega_{K0} = 1 - \Omega_{m0} - \Omega_{r0} - \Omega_{\Lambda 0}.$$

The Ω_{X0} are today's densities as fractions of the critical density $3H_0^2/8\pi G$, with $X = r$ for radiation, m for matter, K for curvature and Λ for the cosmological constant, and the second relation says that the fractions add up to one. For the Planck fit, $\Omega_{m0} \approx 0.315$, $\Omega_{\Lambda 0} \approx 0.685$, $\Omega_{r0} \approx 9 \times 10^{-5}$ and $\Omega_{K0} \approx 0$. The matter term wins over the others at $z \gtrsim 0.3$, and radiation beats matter only for $z \gtrsim 3000$. Today's numbers are $E(1) \approx 1.79$, so the Universe expanded 1.8 times faster at $z = 1$. Of the six parameters of Table T1.1, the data fix not Ω_{m0} itself but

the physical density $\Omega_{m0}h^2 = \Omega_{b0}h^2 + \Omega_{c0}h^2\,(+\Omega_{\nu0}h^2) \approx 0.143$, which is what the expansion history before the epoch of dark energy depends on. This is the model mean of the supernova and BAO data of Chapters 3 and 5, and the matter density is what the fits of Chapters 9 and 10 constrain.

How far away is a source: D_C, D_M, D_A and D_L. The question is what "distance" means for an object at redshift z, because the same source has a different distance depending on whether we measure it with a ruler or a candle. A light ray travels along a null path, $c\,\mathrm{d}t = a\,\mathrm{d}\chi$ in terms of the comoving radial coordinate χ, and $\mathrm{d}z = -(1+z)H\,\mathrm{d}t$. Integrating along the ray from the source to us gives the comoving distance, with the Hubble distance $D_{H0} \equiv c/H_0$ as the unit:

$$a_0\chi(z) = D_{H0}\int_0^z \frac{\mathrm{d}z'}{E(z')}.$$

Curvature bends the ray's transverse separation, so the comoving transverse distance is $a_0 f_K[\chi(z)]$, where $f_K(\chi) = \chi$ in a flat universe and is a sin or sinh of χ in a closed or open one. A source of physical size s at redshift z subtends the angle $\vartheta = s/D_A$ with the angular-diameter distance, and a source of luminosity L gives the flux $F = L/4\pi D_L^2$ with the luminosity distance:

$$D_A(z) = \frac{a_0 f_K[\chi(z)]}{1+z}, \qquad D_L(z) = (1+z)^2 D_A(z).$$

The first divides by $1+z$ because the source was closer to us when the light left it, and the second multiplies by $(1+z)^2$ because redshift costs each photon energy and stretches the arrival rate. The Hubble distance is $D_{H0} = c/H_0 \approx 4450\,\mathrm{Mpc}$. For the Planck model, a source at $z = 1$ has comoving distance 3.4 Gpc, $D_A = 1.7\,\mathrm{Gpc}$ and $D_L = 6.8\,\mathrm{Gpc}$, and the last-scattering surface at $z \approx 1090$ is 13.9 Gpc away. Note that D_A does not grow forever: it peaks near 1.8 Gpc at $z \approx 1.6$ and then falls, so a rod at high redshift looks larger on the sky. Supernova magnitudes depend on $D_L(z)$, and the BAO ruler of the next paragraph on $D_A(z)$ and $H(z)$ (Chapters 3 and 5).

The acoustic ruler: the sound horizon r_s. The question is how far a sound wave could travel in the early plasma, because that length is a ruler that the CMB calibrates. Before recombination photons and baryons were locked into one fluid. A pressure wave in it moves at the sound speed $c_s = c/\sqrt{3(1+R)}$, which is the radiation value $c/\sqrt{3}$ slowed down by the baryons' inertia. Here $R \equiv 3\rho_b/(4\rho_\gamma)$ is the baryon-to-photon momentum ratio, a number of order 0.6 at the drag epoch. The distance such a wave covers up to conformal time η is

$$r_s(\eta) \equiv \int_0^\eta c_s\,\mathrm{d}\eta' = \int_0^\eta \frac{c\,\mathrm{d}\eta'}{\sqrt{3(1+R)}}.$$

Two epochs matter. At the last scattering of photons ($z_* \approx 1090$) the CMB records the waves. Its angular scale is $\theta_{\mathrm{MC}} = r_s(z_*)/a_0 f_K[\chi_*] \approx 0.0104$ rad, and the acoustic peaks are spaced in ℓ by about $\pi/\theta_{\mathrm{MC}} \approx 300$. At the later drag epoch ($z_{\mathrm{drag}} \approx 1060$) the baryons are released from the photons, the wave stops, and $r_s(z_{\mathrm{drag}}) \approx 147.10\,\mathrm{Mpc}$ is the radius of the shell that galaxies inherit as the BAO scale. The first is the angle in the third row of Table T1.1; the second is the standard ruler of Section T1.4. Both appear in Chapters 5, 7 and 12.

The primordial seed: $\mathcal{P}_\zeta$, A_s and n_s. The question is what the fluctuations looked like before any physics of the radiation or matter eras acted on them. Inflation, in the cosmology notes, stretches quantum fluctuations into a nearly Gaussian random field of comoving curvature

perturbation $\zeta(\boldsymbol{x})$. Its Fourier modes are independent, with variance $P_\zeta(k)$. For any spectrum P_X, the dimensionless version

$$\mathcal{P}_X(k) \equiv \frac{k^3 P_X(k)}{2\pi^2}$$

is the variance of the field per logarithmic interval of k, since $\int \mathrm{d}^3k/(2\pi)^3\, P_X = \int \mathrm{d}\ln k\, \mathcal{P}_X$. Inflation predicts a nearly scale-invariant power law. The cosmology notes write it with an amplitude A_S and a tilt n_S (capital S), and CAMB with A_s and n_s:

$$A_S^2 \equiv \tfrac{4}{25}\,\mathcal{P}_\zeta, \quad A_S^2(k) \propto k^{n_S-1}; \qquad \mathcal{P}_\zeta(k) = A_s\Big(\frac{k}{k_*}\Big)^{n_s-1}, \quad k_* = 0.05\,\mathrm{Mpc}^{-1}.$$

Section T1.2.1 (item 3) converts between them: $A_s = \frac{25}{4}A_S^2(k_*)$. The size is $A_s \approx 2.1\times10^{-9}$, so ζ has an rms of 5×10^{-5} per $\ln k$, and $n_s = 0.965$, slightly less than one, so there is a little more power on large scales than on small. The primordial spectrum is the input of the Gaussian random fields of Chapter 7 and the quantity the parameter fits of Chapter 9 constrain.

From seed to sky: the CMB transfer function and C_ℓ. The question is how the primordial ζ becomes the temperature pattern we see. The photon, baryon, dark matter and neutrino fluids obey the Boltzmann hierarchy, and as the photons stream to us they carry the acoustic oscillations, the gravitational redshifts, and the effect of reionisation. All of this is linear in ζ. So each Fourier mode $\zeta_{\boldsymbol{k}}$ produces a temperature anisotropy at multipole ℓ with a fixed coefficient $g_{T\ell}^{(s)}(k)$, the radiation transfer function [how much anisotropy at multipole ℓ one unit of ζ at wavenumber k produces], and the sum over k of the independent contributions gives

$$C_\ell = \frac{2}{\pi}\int k^2\,\mathrm{d}k\, P_\zeta(k)\, g_{T\ell}^{(s)}(k)^2.$$

This integral is what CAMB evaluates. C_ℓ is the variance of the sky at multipole ℓ, that is at angular scale $\vartheta \approx \pi/\ell$, and the cosmology notes define it through the expansion of the temperature contrast $\Theta = \delta T/T = \sum_{\ell m} a_{\ell m} Y_{\ell m}$:

$$\langle a_{\ell m} a^*_{\ell' m'}\rangle = \delta_{\ell\ell'}\delta_{mm'}\, C_\ell, \qquad C(\vartheta) = \frac{1}{4\pi}\sum_\ell (2\ell+1)\, C_\ell\, P_\ell(\cos\vartheta).$$

The second relation is the correlation of two directions an angle ϑ apart, with P_ℓ the Legendre polynomial. Because the sky is one draw, the estimator is $\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_m |a_{\ell m}|^2$, and it obeys $(2\ell+1)\widehat{C}_\ell/C_\ell \sim \chi^2_{2\ell+1}$, the cosmic-variance law of Chapter 7. The plotted combination is $D_\ell \equiv \ell(\ell+1)C_\ell/2\pi$. For the fiducial model D_ℓ^{TT} peaks at $5732\,\mu\mathrm{K}^2$ at $\ell = 220$, and the fractional cosmic variance at one ℓ is $\sqrt{2/(2\ell+1)}$, about 9% at $\ell = 100$. The spectrum is the input of Chapters 7 to 10.

From seed to structure: the matter transfer function and growth. The question is how the same seed becomes the density field of galaxies. Two things happen, one depending on scale and one not. The first is growth. A small overdensity in pressureless matter grows according to the equation

$$\ddot{D} + 2H\dot{D} - \tfrac{3}{2}H^2\Omega_m(t)\, D = 0, \qquad D_+(a) = \frac{5}{2}\frac{H(a)}{H_0}\,\Omega_{m0}\int_0^a \frac{\mathrm{d}a'}{[a'E(a')]^3},$$

where the damping term $2H\dot{D}$ is Hubble friction and the last term is gravity. The growing solution is the integral on the right, and in a matter-dominated universe it is simply $D_+ \propto a$. The

second is the scale dependence. A mode that enters the horizon during radiation domination is held back, because radiation pressure prevents it from clumping, while a mode that enters later grows undisturbed. The **transfer function** packages this,

$$T(k,a) = \frac{\delta(k,a)\,D_+(a_\mathrm{i})}{\delta(k,a_\mathrm{i})\,D_+(a)}, \qquad P_\delta(k,a_0) = P_\delta(k,a_\mathrm{i})\,T^2(k,a_0)\left[\frac{D_+(a_0)}{D_+(a_\mathrm{i})}\right]^2,$$

where a_i is an early time before any scale of interest has entered the horizon, and the second relation is the first one squared. The transfer function goes to one for $k \ll k_\mathrm{eq}$ and falls as $(k_\mathrm{eq}/k)^2$ for $k \gg k_\mathrm{eq}$ (up to a logarithm), where $k_\mathrm{eq} \approx 0.017\,h\,\mathrm{Mpc}^{-1}$ is the wavenumber of the horizon at matter–radiation equality. Growth is a size we can read off: the matter fluctuations at $z = 1$ are 0.61 of those today (0.4928 against 0.8111 in the σ_8 below). Used in Chapter 7.

The statistics of the matter field: $P(k)$, $\xi(r)$ and σ_8. The question is how to describe a random field of matter density with statistics we can predict. Write $\delta = (\rho - \bar\rho)/\bar\rho$ for the density contrast, with Fourier modes $\delta_{\boldsymbol{k}}$. Homogeneity makes distinct modes uncorrelated, and the variance of one mode is the matter power spectrum $P_\delta(k)$ (also written P_m). Its real-space partner is the correlation function $\xi(r)$, the excess probability of finding two points at separation r:

$$\langle \delta_{\boldsymbol{k}}\delta_{\boldsymbol{k}'}\rangle = \delta^{(3)}(\boldsymbol{k}+\boldsymbol{k}')\,P_\delta(k), \qquad \xi(r) = \int_0^\infty \frac{\mathrm{d}k}{2\pi^2}\,k^2 P_\delta(k)\,\frac{\sin kr}{kr}.$$

The second equation is the Fourier transform of the first, after the angle average of $e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$ is done, which gives $\sin kr/kr$. P_δ peaks near k_eq at a few $10^4\,(h^{-1}\mathrm{Mpc})^3$, and the two spectra of linear theory and halofit separate at $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ at $z = 0$. The single-number summary of the amplitude is the rms fluctuation in a sphere of radius $8\,h^{-1}$Mpc:

$$\sigma_8^2 \equiv \int \frac{\mathrm{d}^3\boldsymbol{k}}{(2\pi)^3}\,\left|W_{8h^{-1}\mathrm{Mpc}}(k)\right|^2 P_m(k), \qquad W_R(k) = \frac{3j_1(kR)}{kR}.$$

Here W_R is the Fourier transform of a spherical top-hat of radius R and j_1 the spherical Bessel function, so the integral weights P by how much of each mode a sphere of that size sees. The value is $\sigma_8 = 0.8111$: fluctuations in $8\,h^{-1}$Mpc spheres are about 80% of the mean density, just short of non-linear. Section T1.4 computes both $\xi(r)$ and σ_8 from the CAMB $P(k)$. They feed the Gaussian-field simulations of Chapter 7, the Fisher forecasts of Chapter 10 and the topological summaries of Chapter 12.

Lensing of the CMB. The question is what happens to the pattern on the way to us. Matter between us and the last-scattering surface deflects the photons by a small angle, so the temperature we see in direction $\boldsymbol{n}$ was emitted from a slightly different direction:

$$\hat T[\boldsymbol{n}] = T[\boldsymbol{n} + \boldsymbol{\xi}(\boldsymbol{n})], \qquad \boldsymbol{\xi} = \boldsymbol{\nabla}\psi.$$

The deflection $\boldsymbol{\xi}$ (not the correlation function $\xi(r)$) is the gradient on the sky of a single scalar, the projected lensing potential ψ, which is the matter potential integrated along the line of sight with a geometric weight. The size is a few arcminutes, which is why the effect is a smoothing of the acoustic peaks and a coupling between modes, not a visible distortion. The same ψ builds the shear of galaxy images in Section T1.6, with a source plane at last scattering. Used in Chapters 8 and 12.

The primordial three-point function: $f_{\rm NL}$. The question is whether the seed is exactly Gaussian. A Gaussian ζ is fully described by P_ζ and has zero three-point function. Any departure shows up in the bispectrum B_ζ, the Fourier transform of $\langle\zeta\zeta\zeta\rangle$, and the amplitude $f_{\rm NL}$ is defined by comparing it with the products of two power spectra:

$$\tfrac{6}{5} f_{\rm NL} \equiv \frac{B_\zeta(k_1,k_2,k_3)}{P_\zeta(k_1)P_\zeta(k_2)+P_\zeta(k_1)P_\zeta(k_3)+P_\zeta(k_2)P_\zeta(k_3)}.$$

Planck finds $f_{\rm NL}^{\rm local} = -0.9 \pm 5.1$, consistent with a Gaussian field. A non-zero $f_{\rm NL}$ is invisible to C_ℓ and $P(k)$ and is searched for with the tools of Chapter 12.

object	working equation	typical size	used in
$E(z)$	$E^2 = \Omega_{r0}(1+z)^4+\Omega_{m0}(1+z)^3+\Omega_{K0}(1+z)^2+\Omega_{\Lambda 0}$	$\Omega_{m0}\approx 0.315$, $E(1)\approx 1.79$	Chapters 3 and 5

$f_{\rm NL}$	$\frac{6}{5}f_{\rm NL} = B_\zeta/(PP+\text{perms})$	-0.9 ± 5.1	Chapter 12

Table T1.2: The objects of the section at a glance: the working equation of each, a typical size, and where it is used.

T1.2.1 Conventions to carry forward

The same object is often written differently in the cosmology notes, in CAMB and in this book. There are only a few such differences. Each one, if missed, changes a number by a large factor without any warning.

1. **C_ℓ versus D_ℓ.** The book writes $D_\ell \equiv \ell(\ell+1)C_\ell/2\pi$, the combination that is usually plotted, because it makes the acoustic peaks comparable in height. CAMB's `get_cmb_power_spectra` returns D_ℓ by default and returns the raw C_ℓ only with `raw_cl=True`. The fiducial spectra in `data/camb_fiducial.npz` are raw C_ℓ. Every statistic of the later chapters ($\widehat{C}_\ell$, cosmic variance $2C_\ell^2/(2\ell+1)$, the $\chi^2_{2\ell+1}$ law) is written for the raw C_ℓ.
2. **Units of C_ℓ.** In the cosmology notes $\Theta = \delta T/T$ is dimensionless, so C_ℓ is too. With `CMB_unit="muK"`, CAMB returns $T_0^2\,C_\ell$ in μK^2, with $T_0 = 2.7255\,$K $= 2.7255\times10^6\,\mu$K. Noise spectra must be in the same units as the signal before they are added.

3. **The primordial amplitude.** The cosmology notes normalise the scalar amplitude as $A_S^2 \equiv \frac{4}{25}\mathcal{P}_\zeta$. CAMB and Planck use $\mathcal{P}_\zeta(k) = A_s(k/k_*)^{n_s-1}$ with pivot $k_* = 0.05\,\mathrm{Mpc}^{-1}$, so that $A_s = \mathcal{P}_\zeta(k_*) = \frac{25}{4}A_S^2(k_*)$. The Planck number $\ln(10^{10}A_s) = 3.044$ refers to CAMB's A_s.

4. **Fourier conventions and $P(k)$.** Two Fourier conventions appear, and both lead to the same numerical $P(k)$, the one CAMB returns; only the non-linear mapping needs care. The matter spectrum in the cosmology notes uses the symmetric transform (a factor $(2\pi)^{-3/2}$ on each side), with $\langle\delta_{\boldsymbol{k}}\delta_{\boldsymbol{k}'}\rangle = \delta^{(3)}(\boldsymbol{k}+\boldsymbol{k}')P_\delta$. The non-Gaussianity material puts $(2\pi)^3\delta^{(3)}$ there instead. Both give the same $\xi(r)$ relation in the table above, and so the same $P(k)$. The non-linear mapping in the cosmology notes writes the dimensionless variance as $4\pi k^3P(k)$. That form assumes a P carrying an extra factor $(2\pi)^{-3}$. With CAMB's $P(k)$ the same quantity is $k^3P(k)/2\pi^2$.

5. **Factors of h.** CAMB's `get_matter_power_spectrum` takes k in $h\,\mathrm{Mpc}^{-1}$ and returns P in $(h^{-1}\mathrm{Mpc})^3$; σ_8 is defined in h^{-1}Mpc. Derived lengths, such as the drag-epoch sound horizon, come back in plain Mpc. To compare one with $\xi(r)$ plotted against r in h^{-1}Mpc, multiply it by $h = H_0/100$.

6. **Lensing potential.** The cosmology notes call the projected potential ψ; CAMB and Planck call the same object ϕ. CAMB's `lens_potential` output is $[\ell(\ell+1)]^2C_\ell^{\phi\phi}/2\pi$, not $C_\ell^{\phi\phi}$. The fiducial CMB spectra of the book are lensed.

7. **Real and complex $a_{\ell m}$.** The cosmology notes write the one-point density of $a_{\ell m}$ for a real Gaussian variable of variance C_ℓ. In fact, for $m \neq 0$ the $a_{\ell m}$ are complex, with $a_{\ell,-m} = (-1)^m a_{\ell m}^*$, and their real and imaginary parts each have variance $C_\ell/2$. The count does not change: there are still $2\ell+1$ independent real numbers per ℓ, so the $\chi^2_{2\ell+1}$ law still holds. Chapter 7 does the counting.

Watch out: A factor that looks like a physics result

Mixing A_S^2 with CAMB's A_s moves the amplitude by 25/4; mixing C_ℓ with D_ℓ moves it by $\ell(\ell+1)/2\pi$, about 10^5 at $\ell = 1000$. Neither error crashes a script. Both give a spectrum with a sensible shape and a wrong height. Checking that D_ℓ^{TT} of the fiducial model peaks at $5732\,\mu\mathrm{K}^2$ at $\ell = 220$ catches both.

T1.3 Experiment 1: how each parameter moves the CMB spectra

The inference chapters need one thing from the machine above all. If we turn one input knob a little, how does the output move? For the CMB the output is the whole curve C_ℓ, so the answer is a curve for each parameter. We find it the most direct way. Write θ_i for the i-th of the six parameters of Table T1.1 ($i = 1, \ldots, 6$; this θ_i is any parameter, not the angle θ_{MC}), and δ_i for its Planck 1σ error.

1. Start at the Planck best fit.
2. Run CAMB at $\theta_i + \delta_i$ and at $\theta_i - \delta_i$, with the other five parameters held at the best fit.
3. Form the symmetric fractional response

$$R_i(\ell) \equiv \frac{C_\ell(\theta_i+\delta_i) - C_\ell(\theta_i-\delta_i)}{2\,C_\ell(\text{fiducial})}, \qquad \frac{\partial C_\ell}{\partial\theta_i} \approx \frac{C_\ell\,R_i(\ell)}{\delta_i}. \tag{T1.1}$$

The second relation follows from the first. A derivative is approximately the change in C_ℓ divided by the change in θ_i, here $[C_\ell(\theta_i+\delta_i) - C_\ell(\theta_i-\delta_i)]/2\delta_i$; by the definition of R_i, the

numerator equals $2\,C_\ell\,R_i(\ell)$, and the 2 cancels. This second relation is why the experiment matters. The derivatives $\partial C_\ell/\partial\theta_i$ are exactly what enters the CMB Fisher matrix of Chapter 10, and `code/chT1/01_cl_derivatives.py` computes them by this central difference. The step $\delta_i = 1\sigma$ also gives the size of R_i a plain meaning: a response of 1% is what a change of one standard deviation in that parameter does to the spectrum.

Listing T1.1: Planck 1σ steps, one CAMB call, and the $\pm\delta$ loop (`code/chT1/01_cl_derivatives.py`)

```
30 STEP = dict(ombh2=0.00015, omch2=0.0012, H0=0.54, tau=0.0073,

50             par = dict(FIDUCIAL)
51             par[name] = FIDUCIAL[name] + sgn * d
52             out[f"tt_{name}_{tag}"], out[f"ee_{name}_{tag}"] = spectra(par)
```

The steps in lines 30–31 are the Planck errors of Table T1.1; A_s is stepped by 1.4% of itself because Planck quotes the error on $\ln(10^{10}A_s)$. The function `spectra` (lines 36–42) makes one CAMB call and keeps the lensed TT and EE spectra as raw C_ℓ in $\mu\mathrm{K}^2$ up to $\ell = 2500$. The loop in lines 48–52 moves one parameter up and down while the other five stay at the fiducial values. That makes thirteen CAMB runs in all: one at the fiducial model, plus two for each of the six parameters. The results are cached in `data/chT1/cl_derivs.npz`.

Figure T1.2 shows the six responses. Each can be read physically in one sentence:

- A_s: a flat +1.41% at every ℓ, because the primordial amplitude multiplies the whole spectrum.
- τ: a flat -1.46% for $\ell \gtrsim 30$, the $e^{-2\tau}$ screening of the anisotropies by the reionised electrons, with no effect on the largest scales of TT and a large rise (46%) in the low-ℓ EE reionisation bump, which those same electrons create (see the cosmology notes).
- n_s: a straight line in $\ln\ell$, rotating the spectrum about $\ell \approx 542$, since a tilt adds power on one side of the pivot and removes it on the other.
- $\Omega_{b0}h^2$ and $\Omega_{c0}h^2$: wiggles in phase with the acoustic peaks, largest 1.1% for $\Omega_{c0}h^2$, because the baryon loading and the epoch of matter–radiation equality set the relative heights of the peaks (see the cosmology notes).
- H_0, at fixed physical densities: a slow drift at low ℓ from the late-time decay of the potentials, and oscillations at high ℓ because a changed distance to last scattering slides every peak sideways in ℓ (see the cosmology notes).

Two of these curves are nearly the same curve with opposite sign. Above $\ell \approx 30$ the A_s response is flat and positive, and the τ response is flat and negative. How alike are they? Treat

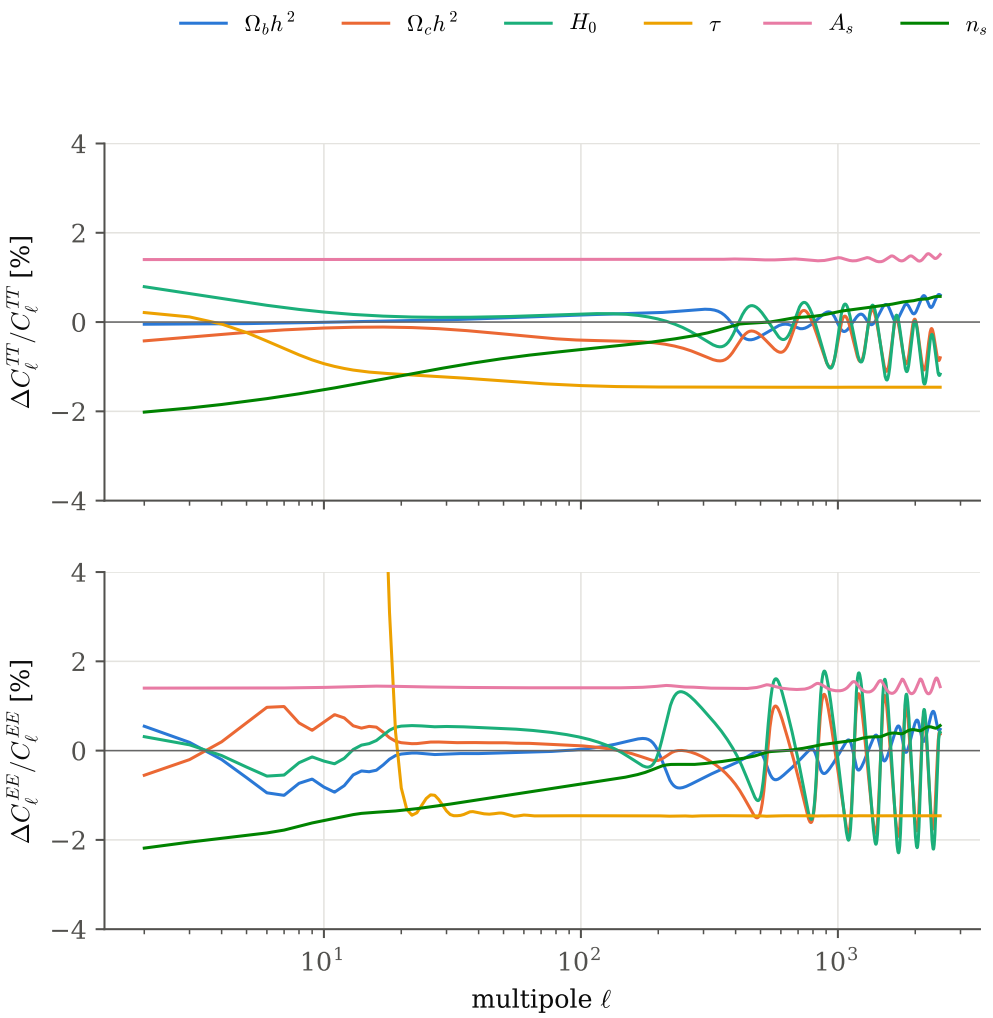

Figure T1.2: Fractional change of the lensed TT (top) and EE (bottom) spectra when each ΛCDM parameter moves by its Planck 1σ error, Eq. (T1.1). A flat line is a pure change of amplitude, a slanted line is a tilt, and a wiggle means the acoustic peaks change height or position. The τ curve in EE leaves the plot at low ℓ (it reaches 46%).

each response as a list of numbers, one per ℓ, and compute the cosine of the angle between the two lists, giving each ℓ the weight $2\ell + 1$ (the number of $a_{\ell m}$ at that ℓ). A cosine of +1 or −1 means the same shape up to a factor. Over $30 \le \ell \le 2500$ it is −0.999. The reason is visible in the list above: at high ℓ the spectrum is proportional to A_s times the screening factor $e^{-2\tau}$, so it depends on the two only through $A_s e^{-2\tau}$. Raise A_s and raise τ together so that $A_s e^{-2\tau}$ stays fixed, and the high-ℓ spectrum does not change. Figure T1.3 puts $+R_{A_s}$ on top of $-R_\tau$ to make this visible.

This is what a degeneracy looks like before any statistics is done: two columns of derivatives that are almost parallel. In Chapter 10 it makes the Fisher matrix nearly singular along one direction. As a result, the marginalised errors on A_s and τ (each parameter's error when the other is left free) are far larger than the conditional ones (its error when the other is held fixed). In Chapter 9 the same degeneracy appears as a long, thin ridge in the MCMC samples of $(\ln 10^{10} A_s, \tau)$. The right panel shows how it is broken in practice. Large-angle polarisation measures τ on its own, and A_s then follows from the high-ℓ amplitude.

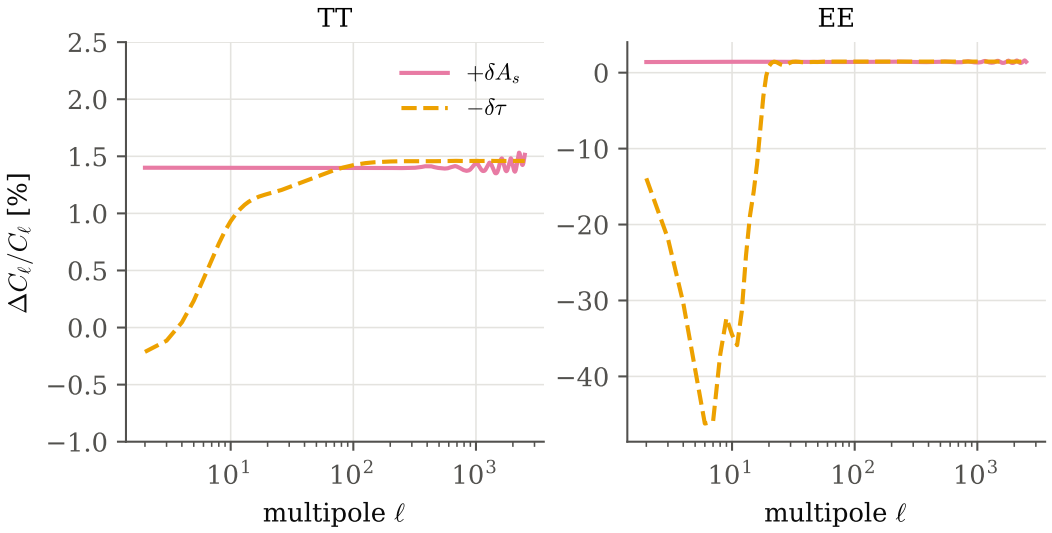

Figure T1.3: The A_s–τ degeneracy. The solid curve is the response to $+1\sigma$ in A_s, the dashed curve minus the response to $+1\sigma$ in τ. In TT (left) they coincide for $\ell \gtrsim 30$, so high-ℓ temperature data measure only the combination $A_s e^{-2\tau}$. In EE (right) they separate completely at $\ell \lesssim 20$, where the reionisation bump responds to τ alone.

How this is used in real research: Verification and research

Here the finite differences only *verify* what the physics already tells us (a flat A_s response, the $e^{-2\tau}$ screening, the tilt about a pivot). In a Fisher forecast the same derivatives are the research instrument, and their accuracy has to be tested: the step must be small enough that C_ℓ is linear in θ_i over $\pm\delta_i$, and large enough that CAMB's numerical noise does not dominate the difference. The standard check is to halve and double δ_i and confirm that the derivative does not move; Chapter 10 does this.

T1.4 Experiment 2: the matter power spectrum and the BAO bump

The second experiment turns to the matter field, the three-dimensional counterpart of the CMB sky. CAMB returns the matter power spectrum $P(k)$ at any redshift, either in linear theory or with the halofit correction [41] [a fit to N-body simulations that maps the linear $P(k)$ to the non-linear one]. From the linear $P(k)$ we compute two things ourselves. The first is the correlation function $\xi(r)$, from the Fourier integral in the $P(k)$ row of the last table in Section T1.2. The second is σ_8, from the top-hat integral in the σ_8 row. CAMB also reports σ_8, so the second is a check on our code.

Listing T1.2: $\xi(r)$ and σ_R from the linear $P(k)$ (`code/chT1/02_pk_xi.py`)

```
def xi_of_r(k, pk, r, s=1.0):
    """xi(r) as in the cosmology notes, on a dense log-k grid with Gaussian damping."""
    kk = np.logspace(-4, np.log10(50), 20000)
    pp = np.exp(np.interp(np.log(kk), np.log(k), np.log(pk))) * np.exp(-(kk * s) ** 2)
    kr = np.outer(r, kk)
    integrand = kk ** 3 * pp * np.sinc(kr / np.pi) / (2 * np.pi ** 2)  # d ln k form
    return np.trapezoid(integrand, np.log(kk), axis=1)

def tophat_sigma(k, pk, R):
    """sigma_R from the linear P(k) and a spherical top hat of radius R (Mpc/h)."""
    x = k * R
```

```
60      W = 3 * (np.sin(x) - x * np.cos(x)) / x ** 3
61      return np.sqrt(np.trapezoid(k ** 3 * pk * W ** 2 / (2 * np.pi ** 2), np.log(k)))
```

`xi_of_r` evaluates $\xi(r) = \int \frac{\mathrm{d}k}{2\pi^2} k^2 P(k) \frac{\sin kr}{kr}$ as an integral over $\ln k$. Since $\mathrm{d}k = k\,\mathrm{d}\ln k$, the factor $k^2\,\mathrm{d}k$ becomes $k^3\,\mathrm{d}\ln k$; that is the k^3 in line 53. (`np.sinc(x/np.pi)` is $\sin x/x$.) The factor $e^{-k^2 s^2}$ with $s = 1\,h^{-1}$Mpc in line 51 is there only so the integral converges: it damps the fast-oscillating tail of the integrand. It acts on scales a hundred times smaller than the BAO peak and does not move the peak. `tophat_sigma` is the σ_R integral with the window $W_R(k) = 3(\sin kR - kR\cos kR)/(kR)^3 = 3j_1(kR)/(kR)$. At $R = 8\,h^{-1}$Mpc it gives $\sigma_8 = 0.8112$, against CAMB's 0.8111, and 0.4928 at $z = 1$, where structure has had less time to grow.

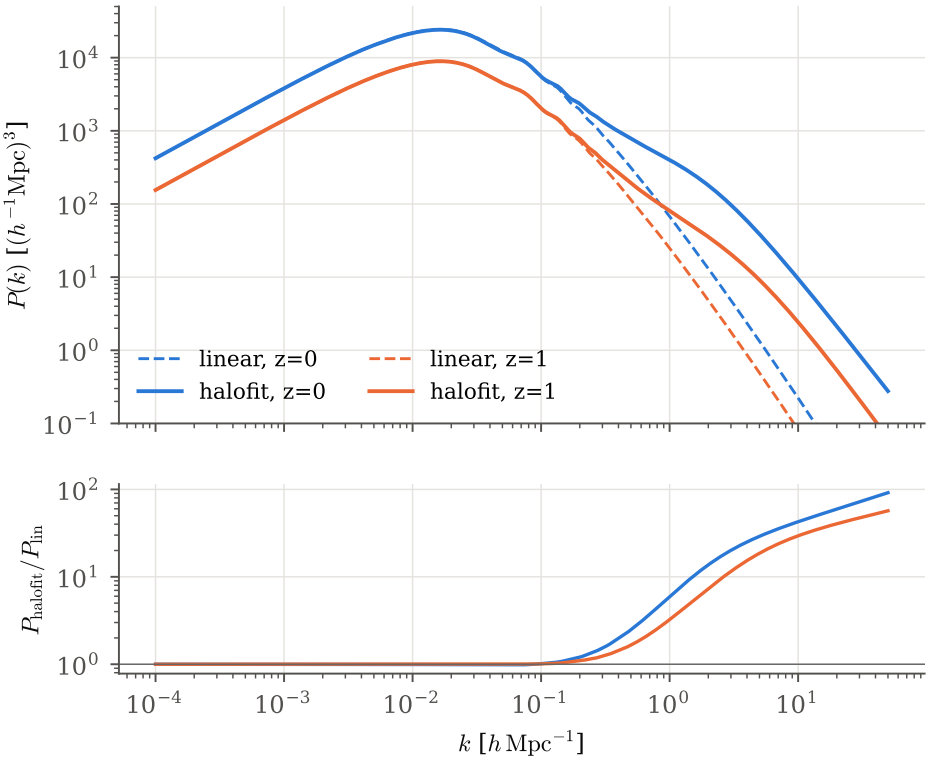

Figure T1.4: Matter power spectrum of the fiducial model at $z = 0$ (blue) and $z = 1$ (orange), linear theory dashed and halofit solid. The lower panel is the ratio halofit/linear: the two agree on large scales and differ by 10% at $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ at $z = 0$, and only at $k \approx 0.21\,h\,\mathrm{Mpc}^{-1}$ at $z = 1$.

Figure T1.4 shows two pieces of physics.

The first is the turnover at $k \approx 0.017\,h\,\mathrm{Mpc}^{-1}$. It marks the size of the horizon at matter–radiation equality. Modes with larger k (smaller scales) entered the horizon earlier, during radiation domination, and grew little there. So the transfer function falls roughly as $(k_{\mathrm{eq}}/k)^2$ (up to a logarithm), where k_{eq} is the turnover wavenumber. Since $P(k) \propto k^{n_s} T^2$ and $n_s \approx 1$, beyond the turnover $P(k)$ falls roughly as $k \cdot k^{-4} = k^{-3}$ (see the cosmology notes).

The second is where halofit leaves linear theory. At $z = 0$ the two differ by 10% at $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ and by a factor 5.9 at $k = 1\,h\,\mathrm{Mpc}^{-1}$. The reason is gravitational collapse into haloes, which piles up power on small scales. For the statistics this boundary matters more than any number on the plot. On large scales the matter field is close to Gaussian, and $P(k)$ carries all of its information; this is the regime of the Gaussian random fields of Chapter 7. On small scales the field is non-Gaussian, and $P(k)$ no longer tells the whole story. There, summaries that see the shape of the field, the topological summaries of Chapter 12, have something extra to find.

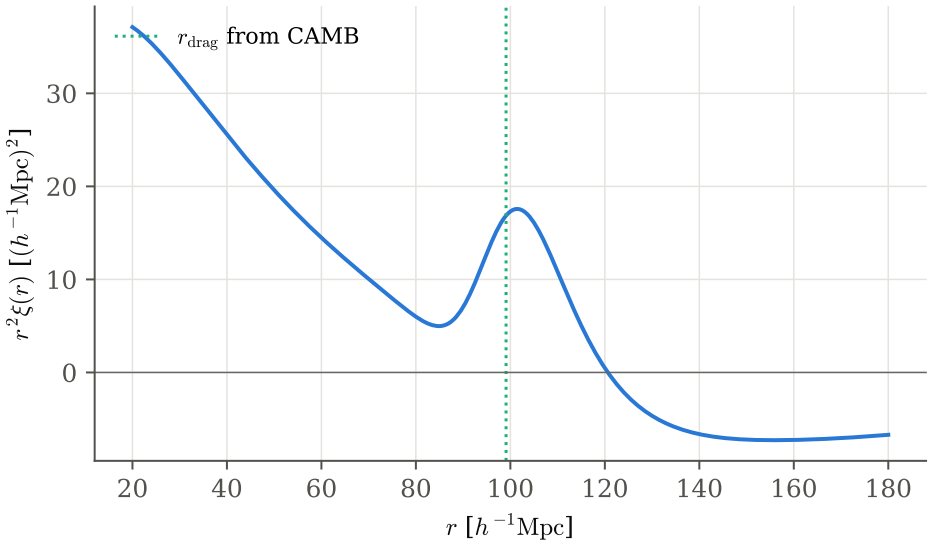

Figure T1.5: The linear correlation function at $z = 0$, multiplied by r^2 so that the bump is visible. The peak at $r \approx 101.5\,h^{-1}$Mpc sits close to the drag-epoch sound horizon computed by CAMB (dotted line, 99.1 h^{-1}Mpc).

Figure T1.5 shows the same information in real space, and there the baryon acoustic oscillations are much easier to see. In $P(k)$ they are small wiggles on a steep curve. In $\xi(r)$ they collapse into a single bump near $r \approx 101.5\,h^{-1}$Mpc. Where does the bump come from? Each initial overdensity launched a spherical sound wave into the photon–baryon plasma. The wave travelled until the baryons were released from the photons at the drag epoch, and then stopped. Its radius at that moment is the sound horizon $r_s(z_{\mathrm{drag}})$ of the BAO row, and it leaves an excess of pairs of points at that separation (see the cosmology notes). CAMB gives $r_s(z_{\mathrm{drag}}) = 147.10\,\mathrm{Mpc}$, that is 99.1 h^{-1}Mpc. The peak of $r^2\xi$ sits a couple of percent higher because it rides on the sloping broad-band part of ξ.

Why does this matter? The CMB fixes r_s precisely, so the bump is a ruler of known length. Its observed position in a galaxy survey at redshift z therefore measures $D_A(z)$ (from its angular size) and $H(z)$ (from its extent along the line of sight). This is how BAO data enter the parameter fits mentioned in Chapter 5. The bump was first detected in the galaxy correlation function by [42]. In Chapter 7 it is a feature to recover from a simulated field with noisy estimates of $\xi(r)$. In Chapter 12 it is one of the structures that a summary beyond the two-point function must respect.

Recap

- Six numbers ($\Omega_{b0}h^2, \Omega_{c0}h^2, H_0$ or $\theta_{\mathrm{MC}}, \tau, A_s, n_s$) go into CAMB; out come $E(z)$ and distances, C_ℓ, $P(k)$, $\xi(r)$, σ_8.
- The model predicts statistics, $C_\ell = \langle|a_{\ell m}|^2\rangle$ and $P(k)$, never the $a_{\ell m}$ or $\delta_{\boldsymbol{k}}$ themselves. Our sky is one draw.
- Conventions: raw C_ℓ (not D_ℓ) in all statistics; $\mu\mathrm{K}^2$ means a factor T_0^2; CAMB's $A_s = \frac{25}{4}A_S^2$ of the cosmology notes; $P(k)$ in $(h^{-1}\mathrm{Mpc})^3$; CAMB's ϕ is the notes' ψ.
- Nudging each parameter by 1σ gives $\partial C_\ell/\partial\theta_i$, the Fisher derivatives; A_s and τ respond identically above $\ell \approx 30$ (cosine -0.999), and low-ℓ EE breaks the tie.
- Linear and halofit $P(k)$ separate at $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ today; $\xi(r)$ has the BAO bump near

$r_s(z_{\rm drag}) \approx 99.1\,h^{-1}$Mpc; our σ_8 matches CAMB's to better than 0.1%.

T1.5 Weak lensing: the matter field written on galaxy shapes

Light from a distant galaxy crosses billions of light years of clumpy matter on its way to us. Every lump it passes bends it a little. What arrives is an image that is slightly displaced, slightly enlarged and slightly stretched in one direction, typically by about one per cent. Nothing in the image says which part of it is the stretch: a galaxy that looks elongated may simply be elongated. Yet the stretch is the cleanest probe of matter we have, because gravity bends light whatever the matter is made of, dark or luminous, and no assumption about how galaxies trace mass enters. This is **weak gravitational lensing**, and **cosmic shear** is its version with the large-scale structure as the lens [43, 44].

For the data analyst, weak lensing is the situation of Section T1.1 in a sharper form. There the model predicted the variance C_ℓ of the CMB sky and the sky was one draw. Here the model predicts the angular power spectrum $C_\ell^{\kappa\kappa}$ of a lensing field κ (defined below), the sky gives one draw of κ, and on top of that we do not see κ itself. We see the shapes of galaxies, and each shape is mostly the galaxy's own.

The question. What we observe is a catalogue: for every galaxy, a position on the sky and an **ellipticity** [a complex number $\varepsilon = \varepsilon_1 + i\varepsilon_2$ whose size is how elongated the image is and whose phase is twice the angle of its long axis]. What could have produced the ellipticity of one particular galaxy? There are two candidates, and we take them one at a time.

1. *The galaxy's own shape.* Galaxies are not round. Their intrinsic ellipticities $\varepsilon^{(0)}$ scatter with an rms $\sigma_e \approx 0.27$ per component [45], and their long axes point in random directions. So the intrinsic part has mean zero, but it is large.
2. *The shear of the matter in front of it.* The lensing stretch γ is about 0.01, thirty times smaller. But it is *coherent*: two galaxies that lie close together on the sky sent their light past the same lumps, so they are stretched in nearly the same way.

Only now do we compute anything. In the weak regime the two simply add,

$$\varepsilon \approx \varepsilon^{(0)} + \gamma. \tag{T1.2}$$

The reason is that ε is defined from the shape of the image, and a shear of one per cent changes that shape by one per cent: to first order in small quantities it moves the ellipticity by γ itself, whatever the galaxy's own shape was. Section T1.6.1 works this out for a round source; with the other common definition of ε the shift is 2γ instead (convention 3 of Section T1.6.2). A single galaxy tells us almost nothing, since the shear is buried under a noise thirty times larger. But the intrinsic parts of different galaxies are independent, and the shears of neighbours are correlated. Two moves turn this into a measurement.

Average galaxies that share one shear. Take N galaxies close enough together that they all feel the same γ, and average their ellipticities:

$$\bar\varepsilon \equiv \frac{1}{N}\sum_{a=1}^{N}\varepsilon_a \overset{(1)}{=} \gamma + \frac{1}{N}\sum_{a=1}^{N}\varepsilon_a^{(0)}, \qquad \mathbb{E}\,\bar\varepsilon \overset{(2)}{=} \gamma, \qquad \mathrm{Var}\,\bar\varepsilon_1 \overset{(3)}{=} \frac{\sigma_e^2}{N}. \tag{T1.3}$$

(1) Insert (T1.2) for each galaxy; the shear is the same in every term, so its average is itself.
(2) The intrinsic ellipticities point in random directions, so each has mean zero.

(3) The variance of a mean of N independent readings of variance σ_e^2, (3.20), applied to one real component; the same holds for $\bar{\varepsilon}_2$.

So the noise on the shear estimate is $0.27/\sqrt{N}$ per component. How large must N be? A signal-to-noise ratio of one on a single shear of 0.01 needs $0.27/\sqrt{N} = 0.01$, that is $N = (0.27/0.01)^2 \approx 730$ galaxies, all sharing that one shear. A map with many independent shear values, each measured several times better than that, needs millions of galaxies.

Correlate pairs. The shear changes across the sky, so averaging is limited to small patches. Correlation uses every pair instead. For two galaxies $a \neq b$, multiply the ellipticity of one by the complex conjugate of the other and expand:

$$\begin{aligned}\langle \varepsilon_a \varepsilon_b^* \rangle &\overset{(1)}{=} \langle (\varepsilon_a^{(0)} + \gamma_a)(\varepsilon_b^{(0)} + \gamma_b)^* \rangle \\ &\overset{(2)}{=} \langle \varepsilon_a^{(0)} \varepsilon_b^{(0)*} \rangle + \langle \varepsilon_a^{(0)} \gamma_b^* \rangle + \langle \gamma_a \varepsilon_b^{(0)*} \rangle + \langle \gamma_a \gamma_b^* \rangle \overset{(3)}{=} \langle \gamma_a \gamma_b^* \rangle . \end{aligned} \tag{T1.4}$$

(1) Equation (T1.2) for each galaxy.
(2) Multiply out the brackets; the average of a sum is the sum of the averages.
(3) The intrinsic shapes of two different galaxies are independent, each with mean zero, so the first term is the product of two zero means. In the two middle terms an intrinsic shape is independent of the shear in front of the other galaxy, and the same reasoning makes them vanish. Only the correlation of the shears survives.

Galaxy a paired with itself would add $\langle \left| \varepsilon_a^{(0)} \right|^2 \rangle$, which does not vanish; this is why the self-pairs are left out, and why shape noise reappears as an added term in the power spectrum (Section T1.6). The information is in the statistics of many shapes, never in one shape. This is why every weak-lensing number in the later chapters is a two-point function, a peak count or a topological summary of a field built from millions of galaxies, and why its noise term is set by how many galaxies there are.

Figure T1.6 shows what the two parts of the lensing distortion do, exaggerated twenty-five-fold. The **convergence** κ [the projected matter density along the line of sight, in units of a critical density] enlarges an image without changing its shape. The **shear** $\gamma = \gamma_1 + i\gamma_2$ [the tidal part of the lensing distortion, which stretches the image along one axis and squeezes it along the perpendicular one] turns a circle into an ellipse.

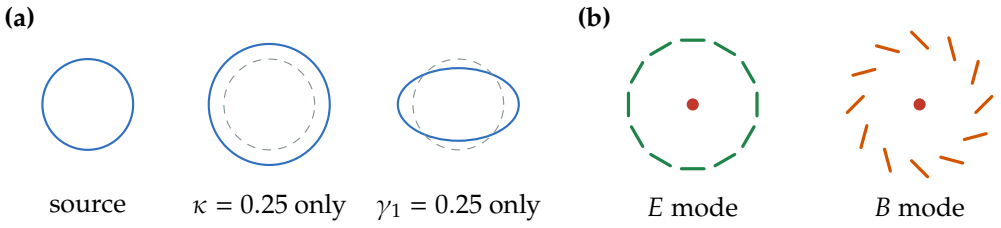

Figure T1.6: (a) A round source (left), the same source magnified by convergence alone (middle), and stretched by shear alone (right); the dashed circle is the source for comparison. Real values are near 0.01, not 0.25. (b) Each stick is the long axis of a sheared image. Around a mass concentration (red dot) lensing lines the images up tangentially, the E pattern. Rotating every stick by 45° gives the B pattern, a swirl, which lensing by a scalar potential cannot make.

The sticks in panel (b) have no arrowheads, and that is the key property of shear. An ellipse rotated by 180° is the same ellipse. What kind of number can describe such a stick?

A stick first. Let the long axis of an ellipse make an angle ϕ with the first reference axis. If we turn the reference axes by an angle α, the same stick is now seen at $\phi - \alpha$. A complex number that records the direction must be a function $f(\phi)$, and the simplest functions of an angle are

the pure tones $e^{im\phi}$ with a whole number m. Which m will do? The stick at $\phi + \pi$ is the same stick, so we need $e^{im(\phi+\pi)} = e^{im\phi}$, that is $e^{im\pi} = 1$, and m must be even. The choice $m = 1$ fails: $e^{i(\phi+\pi)} = -e^{i\phi}$, so the same stick would get two opposite values. That is the description of an arrow, a vector, which returns to itself only after a full turn of 2π. The choice $m = 0$ is allowed but records no direction at all. The smallest useful choice is $m = 2$, so a stretch of size $|\gamma|$ along the angle ϕ is written $\gamma = |\gamma|\, e^{2i\phi}$, the form in the table of Section T1.6. When the axes turn by α,

$$\gamma = |\gamma|\, e^{2i\phi} \;\longrightarrow\; |\gamma|\, e^{2i(\phi-\alpha)} = e^{-2i\alpha}\gamma. \tag{T1.5}$$

A quantity that picks up the phase $e^{-is\alpha}$ under a turn of the axes is said to have **spin** s. Shear has spin 2. The CMB polarization $Q + iU$ is also a headless stick and changes in exactly the same way (see the cosmology notes). Every tool built for CMB polarization (the split into E and B modes, spin-2 spherical harmonics, `healpy`'s polarization transforms) uses only the rule (T1.5), so it applies to shear without change.

Where the two angles live. Every lensing formula below is written in two angles, θ_1 and θ_2. They locate a point on the sky the way x and y locate a point on a sheet of graph paper held at arm's length. The patch we analyse is a few degrees across at most, so we may treat it as flat: a plane facing us, with its origin on one chosen line of sight (in Figure T1.7, the one through a lump of matter), and θ_1, θ_2 the two angles, measured from that line, to a point on it. Now follow the light of one galaxy. Without the lump, the galaxy would be seen in the direction $\boldsymbol{\theta}_S$ where it really is. The light that actually reaches us left the galaxy in a slightly different direction, was bent as it passed the lump, and arrives along a straight final leg. We place every object where its light appears to come from, so we extend that last leg backwards, and it meets the sky plane at a different point, $\boldsymbol{\theta}$. The catalogue records $\boldsymbol{\theta}$; the true $\boldsymbol{\theta}_S$ is never seen. The difference is the deflection, $\boldsymbol{\theta}_S = \boldsymbol{\theta} - \hat{\boldsymbol{\alpha}}(\boldsymbol{\theta})$, the second row of the table in Section T1.6.

The deflection by itself changes nothing we can measure. If every point of a galaxy moved by the same $\hat{\boldsymbol{\alpha}}$, the image would simply be the galaxy, displaced, and we never know where it would have been. What we can measure is how the deflection *changes* across one image: points on the side nearer the lump are pulled more than points on the far side, so the image is enlarged (κ) and stretched (γ). Panel (b) of Figure T1.7 shows the outcome for the lump of the figure: the image is pushed outward and stretched along the circle around the lump, the tangential pattern of Figure T1.6(b).

The pattern around a lump. Does the formula of the table, $\gamma_1 = \frac{1}{2}(\psi_{,11} - \psi_{,22})$, $\gamma_2 = \psi_{,12}$, really give the tangential sticks of panel (b)? Take the simplest lens, a point mass at the origin, whose potential on the sky is $\psi = A \ln\theta$ with $A > 0$ and $\theta = \sqrt{\theta_1^2 + \theta_2^2}$. On the first axis, at $(\theta_1, 0)$ with $\theta_1 > 0$,

$$\psi_{,11} \overset{(1)}{=} A\,\frac{\theta_2^2 - \theta_1^2}{\theta^4} = -\frac{A}{\theta_1^2}, \qquad \psi_{,22} \overset{(1)}{=} A\,\frac{\theta_1^2 - \theta_2^2}{\theta^4} = +\frac{A}{\theta_1^2}, \qquad \psi_{,12} \overset{(1)}{=} -\frac{2A\theta_1\theta_2}{\theta^4} = 0,$$
$$\gamma_1 \overset{(2)}{=} -\frac{A}{\theta_1^2} < 0, \qquad \gamma_2 \overset{(2)}{=} 0. \tag{T1.6}$$

(1) Differentiate $A \ln\theta = \frac{A}{2}\ln(\theta_1^2 + \theta_2^2)$ twice, then set $\theta_2 = 0$.
(2) The shear components of the table.

In panel (a) a positive γ_1 stretches the circle along the first axis, so a negative γ_1 stretches it along the second: on the first axis the stick stands vertical, at right angles to the line to the mass, which is tangential. Every other point follows from the rule (T1.5): turning the axes so that the first one points at the new position leaves the same calculation. In complex form the result is $\gamma = -(A/\theta^2)e^{2i\varphi} = (A/\theta^2)e^{2i(\varphi+\pi/2)}$ at polar angle φ, a stick at angle $\varphi + 90°$, always tangential.

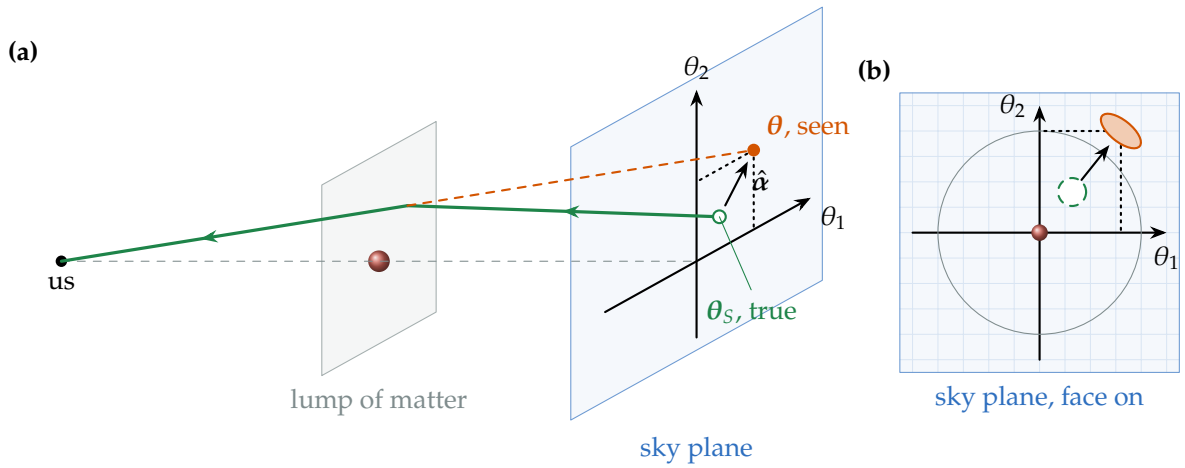

Figure T1.7: What the two angles θ_1, θ_2 are. (a) A patch of sky, treated as a flat plane facing us, with its origin on the line of sight through a lump of matter (dashed grey). A galaxy sits at the true position $\boldsymbol{\theta}_S$ (open green circle). Its light (solid green) is bent where it passes the lump, so it reaches us along a final leg that, extended backwards (dashed orange), meets the sky plane at $\boldsymbol{\theta}$ (orange dot): this is where the galaxy is seen and catalogued, and the dotted lines read off its two coordinates. The black arrow, from the true position to the seen one, is the deflection $\hat{\boldsymbol{\alpha}} = \boldsymbol{\theta} - \boldsymbol{\theta}_S$. (b) The same patch face on. The round galaxy (dashed green) is seen further from the lump and stretched along the grey circle around it, tangentially. The deflection is exaggerated enormously; the lens drawn halfway is for clarity, any lump between us and the galaxy acts the same way.

Why lensing makes no B. The E and B rows of the second table of Section T1.6 ($\Delta = \nabla^2$ is the angular Laplacian) split a shear field into the part whose sticks line up tangentially or radially about each point (rotation 0) and the part whose sticks sit at 45° (the swirl). Insert the lensing shear into the B row:

$$\Delta B \overset{(1)}{=} -2\partial_1\partial_2\,\tfrac{1}{2}(\psi_{,11} - \psi_{,22}) + (\partial_1^2 - \partial_2^2)\,\psi_{,12} \overset{(2)}{=} -\psi_{,1112} + \psi_{,1222} + \psi_{,1112} - \psi_{,1222} = 0,$$
$$\Delta E \overset{(3)}{=} \tfrac{1}{2}(\psi_{,1111} - 2\psi_{,1122} + \psi_{,2222}) + 2\psi_{,1122} = \tfrac{1}{2}\Delta(\psi_{,11} + \psi_{,22}) \overset{(4)}{=} \Delta\kappa. \qquad \text{(T1.7)}$$

(1) The B row of the table with $\gamma_1 = \frac{1}{2}(\psi_{,11} - \psi_{,22})$ and $\gamma_2 = \psi_{,12}$.
(2) Partial derivatives can be taken in any order, so the four fourth derivatives cancel in pairs.
(3) The E row with the same substitution, multiplied out.
(4) $\kappa = \frac{1}{2}\nabla^2\psi$, from the first table.

A B pattern needs a curl, and a shear built from the second derivatives of one scalar potential has none: lensing makes only E, and its E is κ. A B mode in the data therefore measures what went wrong, not what the cosmos did: residual errors in the correction for the telescope's point-spread function, intrinsic alignments, or approximations in the theory, and the astrophysical ones among these are at the per-cent level of the E signal [44, §3.6], so a larger B points to an error in the processing. Measuring B and finding it consistent with zero is the standard *null test* of a weak-lensing analysis, the lensing counterpart of the hypothesis tests of Chapter 4.

T1.6 The objects a weak-lensing analysis uses

A weak-lensing analysis is a chain of objects, each defined from the one before (Figure T1.8). Light from a distant galaxy crosses the matter between us and it, and the matter bends the ray. That bending is described first at one point of the sky, by a single scalar potential and its derivatives. Next the three-dimensional matter field is projected along the line of sight, which

gives the statistics of the sky that a model predicts. Last come the galaxy shapes, the noise they carry and the nuisances that stand between them and the model. For each object the question comes first, then the equation it starts from and the working equation of the book, then a size and the chapters that use it. The physics between the two equations is in the cosmology notes.

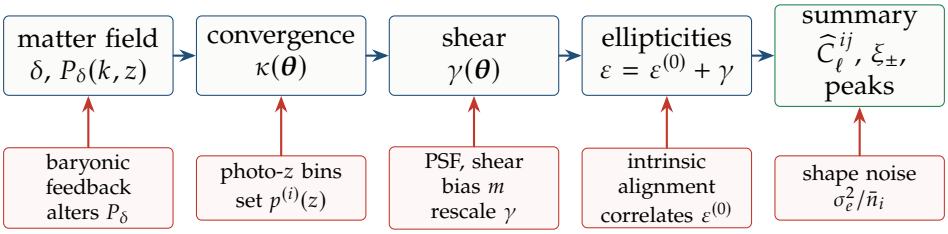

Figure T1.8: The weak-lensing chain. The matter field is projected into a convergence map, whose tidal part is the shear, which is added to the intrinsic shapes of the galaxies; the summary statistics are computed from those shapes. Each red box is a nuisance or noise source that enters at the object above it and has to be modelled and marginalised, or, for shape noise, added to the covariance.

The lens map at one point. The question is how the image of a source moves and deforms when matter lies in front of it. Work on a small patch of sky, treated as flat. The observed direction is $\boldsymbol{\theta} = (\theta_1, \theta_2)$, and $\boldsymbol{\theta}_S$ is the direction the source would have without lensing (Figure T1.7). A weak gravitational field perturbs the metric by the Newtonian potential Φ (equal to the second potential Ψ when anisotropic stress is negligible), and a light ray in it is bent at each point by the transverse gradient of Φ. Adding up the bends along the line of sight, each weighted by the geometry of the line of sight, gives one scalar, the **lensing potential**:

$$\psi(\boldsymbol{\theta}, \chi) = \frac{2}{c^2} \int_0^\chi \mathrm{d}\chi' \, \frac{f_K(\chi - \chi')}{f_K(\chi) f_K(\chi')} \, \Phi\big[f_K(\chi')\boldsymbol{\theta}, \chi'\big].$$

Here χ is comoving distance and $f_K(\chi)$ the curvature function ($f_K = \chi$ in a flat universe). Every lensing quantity is a derivative of ψ. The first derivative is the deflection, and it maps the observed position back to the true one:

$$\hat{\boldsymbol{\alpha}} = \boldsymbol{\nabla}\psi, \qquad \boldsymbol{\theta}_S = \boldsymbol{\theta} - \boldsymbol{\nabla}\psi(\boldsymbol{\theta}).$$

The second derivative says how a small image is deformed. A comma denotes an angular derivative, $\psi_{,ab} \equiv \partial^2\psi / \partial\theta_a \partial\theta_b$, and the Jacobian of the map from image to source is the distortion matrix, whose entries are named after what they do:

$$\mathcal{A}_{ab} \equiv \frac{\partial \theta_{S,a}}{\partial \theta_b} = \delta_{ab} - \psi_{,ab} = \begin{pmatrix} 1 - \kappa - \gamma_1 & -\gamma_2 \\ -\gamma_2 & 1 - \kappa + \gamma_1 \end{pmatrix},$$
$$\kappa = \tfrac{1}{2}\nabla^2\psi, \qquad \gamma_1 = \tfrac{1}{2}(\psi_{,11} - \psi_{,22}), \qquad \gamma_2 = \psi_{,12}.$$

Here ∇^2 is the angular Laplacian. The trace part is the **convergence** κ, the projected density (for a thin lens, $\kappa = \Sigma/\Sigma_{\mathrm{crit}}$), which magnifies the image isotropically. The traceless part is the **shear** $\gamma \equiv \gamma_1 + i\gamma_2 = |\gamma|\, e^{2i\phi}$, a tidal stretch with direction ϕ and a spin of two. A galaxy shape responds not to γ but to the reduced shear $\gamma/(1-\kappa) \approx \gamma$ for $\kappa \ll 1$, because κ rescales the image and leaves only the ratio visible. All of κ, γ are of order 10^{-2} for cosmic shear, which is why each galaxy is a weak and noisy measurement and a survey needs millions. The deflection itself is a few arcminutes. The potential and its derivatives are used in Chapters 7 and 12 and in Chapter T3.

object	physical meaning	key equation (cosmology notes)	used in
lensing potential ψ	the Newtonian potential projected along the line of sight with a geometric weight; every lensing quantity is a derivative of it	$\psi(\boldsymbol{\theta},\chi) = \frac{2}{c^2}\int_0^{\chi} \mathrm{d}\chi' \, \frac{f_K(\chi-\chi')}{f_K(\chi) f_K(\chi')}\, \Phi[f_K(\chi')\boldsymbol{\theta},\chi']$	Ch. 12, T3
deflection	how far the image is moved from where the source really is	$\hat{\boldsymbol{\alpha}} = \boldsymbol{\nabla}\psi, \quad \boldsymbol{\theta}_S = \boldsymbol{\theta} - \boldsymbol{\nabla}\psi(\boldsymbol{\theta})$	Ch. 12, T3
distortion matrix	how a small image is mapped back to its source	$\mathcal{A}_{ab} \equiv \frac{\partial\theta_{S,a}}{\partial\theta_b} = \delta_{ab} - \psi_{,ab} = \begin{pmatrix} 1-\kappa-\gamma_1 & -\gamma_2 \\ -\gamma_2 & 1-\kappa+\gamma_1 \end{pmatrix}$	Ch. 12
convergence κ	projected density; isotropic magnification of the image	$\kappa = \frac{1}{2}\nabla^2\psi$ (thin lens: $\kappa = \Sigma/\Sigma_{\mathrm{crit}}$)	Ch. 7, 12
shear γ	tidal stretch of the image; spin-2	$\gamma_1 = \frac{1}{2}(\psi_{,11} - \psi_{,22}), \quad \gamma_2 = \psi_{,12}, \quad \gamma \equiv \gamma_1 + i\gamma_2 = \lvert\gamma\rvert\, e^{2i\phi}$	Ch. 12
reduced shear	what a galaxy shape actually responds to, since κ rescales the image	$\frac{\gamma}{1-\kappa} \approx \gamma$ for $\kappa \ll 1$	Ch. 12

Three remarks on this table. The cosmology notes write the potential with angular derivatives as $\tilde{\psi}$, and the thin-lens and CMB versions as ψ; for the data analyst all are the same object, and we write ψ. The off-diagonal entries of $\mathcal{A}$ are $-\gamma_2$, because $\mathcal{A}_{12} = -\psi_{,12}$ and $\gamma_2 = \psi_{,12}$; a matrix printed with $+\gamma_2$ uses the opposite sign of γ_2. And the reduced shear has no letter in the table on purpose. The literature calls it g, but $g(\chi)$ is already the lensing efficiency in the next table; we use the letter only in Section T1.6.1, where the reduced shear is derived.

From the matter field to the statistics of the sky. The question is how the three-dimensional matter field becomes a map and a power spectrum on the sky. The sources have a redshift distribution $p_z(z)$, normalised to one, and $p_\chi(\chi)$ is the same distribution in comoving distance, $p_\chi\,\mathrm{d}\chi = p_z\,\mathrm{d}z$. The lensing potential above is for one source distance. Averaging over the source sample, with χ_H the comoving horizon, the weight of matter at distance χ is the **lensing efficiency**

$$g(\chi) \equiv \int_{\chi}^{\chi_H} p_\chi(\chi') \, \frac{f_K(\chi'-\chi)}{f_K(\chi')}\, \mathrm{d}\chi'.$$

It is zero at the observer, where there is no lever arm, and zero behind the sources, which cannot be lensed by matter behind them, so it peaks midway. Poisson's equation turns the potential into the matter density contrast δ, and the second derivative of ψ gives the convergence as a weighted projection of δ, with $a(\chi)$ the scale factor at distance χ:

$$\kappa(\boldsymbol{\theta}) = \frac{3}{2}\frac{H_0^2}{c^2}\Omega_{m0} \int_0^{\chi_H} g(\chi) f_K(\chi)\, \frac{\delta[f_K(\chi)\boldsymbol{\theta},\chi]}{a(\chi)}\, \mathrm{d}\chi.$$

The prediction the data are compared with is the variance of κ per angular mode, the convergence power spectrum, with $P_\delta(k,\chi)$ the matter power spectrum of Section T1.2 (non-linear in practice) and the index i labelling a redshift bin:

$$P_\kappa(\ell) = \frac{9H_0^4}{4c^4}\Omega_{m0}^2 \int_0^{\chi_H} \left[\frac{g(\chi)}{a(\chi)}\right]^2 P_\delta\!\left(\frac{\ell}{f_K(\chi)}, \chi\right) \mathrm{d}\chi, \qquad g^2 \to g_i g_j \text{ for bins.}$$

This is the Limber approximation, and it is built below from the independent-slices picture. Since Ω_{m0} and the amplitude of P_δ (σ_8) multiply it, cosmic shear measures them together. The shear has the same spectrum, $P_\gamma = P_\kappa$, and surveys often measure it in real space through the correlations $\xi_\pm(\vartheta) = \int_0^\infty \frac{\mathrm{d}\ell}{2\pi}\,\ell P_\kappa(\ell)\,J_{0,4}(\ell\vartheta)$ (J_0 for +, J_4 for −, with J_n the Bessel functions). To go from the shear map back to a mass map one uses the Kaiser–Squires inversion [46], in the two-dimensional Fourier transforms $\hat\gamma(\boldsymbol{\ell})$ and $\hat\kappa(\boldsymbol{\ell})$ with $\boldsymbol{\ell} = (\ell_1, \ell_2)$ the angular wavevector:

$$\hat\kappa(\boldsymbol{\ell}) = \tfrac{1}{\pi}\hat{\mathcal{D}}^*(\boldsymbol{\ell})\hat\gamma(\boldsymbol{\ell}), \qquad \hat{\mathcal{D}}(\boldsymbol{\ell}) = \pi\frac{\ell_1^2 - \ell_2^2 + 2i\ell_1\ell_2}{\ell^2}.$$

A spin-2 field splits into a curl-free part E and a curl part B by $\Delta E = (\partial_1^2 - \partial_2^2)\gamma_1 + 2\partial_1\partial_2\gamma_2$ and $\Delta B = -2\partial_1\partial_2\gamma_1 + (\partial_1^2 - \partial_2^2)\gamma_2$, where Δ is the angular Laplacian. Lensing gives $E = \kappa$ and $B = 0$, so B is a null test. The CMB is lensed in the same way, with a single source plane at last scattering, χ_*, so that $g(\chi) = f_K(\chi_* - \chi)/f_K(\chi_*)$ and the remapping is $\hat T[\boldsymbol{n}] = T[\boldsymbol{n} + \boldsymbol{\xi}(\boldsymbol{n})]$ with $\boldsymbol{\xi} = \boldsymbol{\nabla}\psi$ (Section T1.2). Typical sizes: $g \sim 1$ at its peak, a convergence rms of about 1%, and ℓ from tens to a few thousand. Used in Chapters T3, 7, 8, 10 and 12.

object	physical meaning	key equation (cosmology notes)	used in
lensing efficiency	how strongly matter at distance χ lenses the source sample: zero at the observer and behind the sources	$g(\chi) \equiv \int_\chi^{\chi_H} p_\chi(\chi')\,\frac{f_K(\chi'-\chi)}{f_K(\chi')}\,\mathrm{d}\chi'$	Ch. 10, 12
convergence field	the matter contrast projected with the lensing weight	$\kappa(\boldsymbol{\theta}) = \frac{3}{2}\frac{H_0^2}{c^2}\Omega_{m0}\int_0^{\chi_H} g(\chi) f_K(\chi)\,\frac{\delta[f_K(\chi)\boldsymbol{\theta},\chi]}{a(\chi)}\,\mathrm{d}\chi$	Ch. 7, 12
Limber $C_\ell^{\kappa\kappa}$	the variance of κ per angular mode, the prediction the data are compared with	$P_\kappa(\ell) = \frac{9H_0^4}{4c^4}\Omega_{m0}^2\int_0^{\chi_H}\left[\frac{g(\chi)}{a(\chi)}\right]^2 P_\delta\Big(\frac{\ell}{f_K(\chi)},\chi\Big)\mathrm{d}\chi$; bins i,j: $g^2 \to g_i g_j$; full sky: $C_\ell^{\kappa\kappa} = \frac{1}{4}\ell^2(\ell+1)^2 C_\ell^{\psi\psi} \to P_\kappa(\ell)$	Ch. 7, 10, 12
shear two-point	shear has the same spectrum as κ; its real-space correlations are what surveys often measure	$P_\gamma(\ell) = P_\kappa(\ell)$, $\xi_\pm(\vartheta) = \int_0^\infty \frac{\mathrm{d}\ell}{2\pi}\,\ell P_\kappa(\ell)\,J_{0,4}(\ell\vartheta)$ (J_0 for +, J_4 for −)	Ch. 12
Kaiser–Squires	a mass map from the shear field [46], up to a constant sheet	$\hat\kappa(\boldsymbol{\ell}) = \frac{1}{\pi}\hat{\mathcal{D}}^*(\boldsymbol{\ell})\hat\gamma(\boldsymbol{\ell})$, $\hat{\mathcal{D}}(\boldsymbol{\ell}) = \pi\frac{\ell_1^2 - \ell_2^2 + 2i\ell_1\ell_2}{\ell^2}$	Ch. 12
E and B modes	curl-free and curl parts of a spin-2 field; lensing gives $E = \kappa$, $B = 0$	$\Delta E = (\partial_1^2 - \partial_2^2)\gamma_1 + 2\partial_1\partial_2\gamma_2$, $\Delta B = -2\partial_1\partial_2\gamma_1 + (\partial_1^2 - \partial_2^2)\gamma_2$	Ch. 12, T3
CMB lensing	the CMB is lensed too, with a single source plane at last scattering, χ_*	$\hat T[\boldsymbol{n}] = T[\boldsymbol{n} + \boldsymbol{\xi}(\boldsymbol{n})]$, $\boldsymbol{\xi} = \boldsymbol{\nabla}\psi$, $g(\chi) = f_K(\chi_* - \chi)/f_K(\chi_*)$	Ch. 8, T3

The Limber row is the one the later chapters lean on, so it is worth reading in words. The convergence spectrum at multipole ℓ is a sum over distances χ of the matter power at the wavenumber $k = \ell/f_K(\chi)$ that projects onto that angle, weighted by g^2/a^2. Two pieces of it need a reason: why that wavenumber, and why the weight is squared. The full calculation is in the cosmology notes; the two ideas behind it are short.

One angle picks one wavenumber at each distance. A wave in the matter of wavelength $2\pi/k$, at comoving distance χ, spans an angle $2\pi/[k f_K(\chi)]$ on the sky, since a transverse comoving

length L at that distance subtends $L/f_K(\chi)$. A pattern on the sky with multipole ℓ repeats every $2\pi/\ell$ radians (the flat-sky form of (7.43)). The two match when $2\pi/\ell = 2\pi/[k f_K(\chi)]$, that is $k = \ell/f_K(\chi)$. The same ℓ therefore probes large wavenumbers in nearby matter and small wavenumbers in distant matter, and a single multipole mixes a whole range of k.

A sum of independent slices. Cut the line of sight into slices of thickness $\Delta\chi$, thick compared with the wavelengths of interest, and let δ_s be the density contrast averaged through slice s. The convergence row of the table is then a weighted sum, $\kappa = \sum_s w_s \delta_s \Delta\chi$ with $w_s = \frac{3}{2}(H_0/c)^2 \Omega_{m0}\, g f_K/a$ evaluated at slice s. Matter in two thick slices is nearly uncorrelated, because the waves that could connect them are averaged away inside each slice; assuming exactly zero correlation is the **Limber approximation**. For a sum of independent terms the variances add, each multiplied by the square of its weight, and the same holds mode by mode for the power:

$$P_\kappa(\ell) \overset{(1)}{=} \sum_s w_s^2\, \Delta\chi^2\, P_s(\ell) \overset{(2)}{=} \sum_s w_s^2\, \Delta\chi^2\, \frac{P_\delta\big(\ell/f_K, \chi_s\big)}{f_K^2\, \Delta\chi} \overset{(3)}{=} \frac{9H_0^4}{4c^4}\, \Omega_{m0}^2 \int \left[\frac{g}{a}\right]^2 P_\delta\Big(\frac{\ell}{f_K}, \chi\Big) \mathrm{d}\chi. \quad \text{(T1.8)}$$

(1) $\mathrm{Var}(\sum_s c_s X_s) = \sum_s c_s^2 \,\mathrm{Var}\, X_s$ for independent X_s; $P_s(\ell)$ is the angular power of slice s.
(2) The angular power of one thick slice: the three-dimensional power at the matching wavenumber, divided by $\Delta\chi$ because the averaging through the slice keeps only one wave in $\Delta\chi$ along the line of sight, and by f_K^2 to turn transverse comoving area into solid angle (see the cosmology notes).
(3) Insert w_s; the factor f_K^2 cancels, and the sum over thin slices becomes an integral.

This is the Limber row. The weight is squared because a power is the average of a squared amplitude, and the slices enter one at a time because they are independent.

Three things now follow. The prefactor carries Ω_{m0}^2, and in linear theory P_δ is proportional to σ_8^2, so for a fixed shape of P_δ

$$C_\ell^{\kappa\kappa} \propto \Omega_{m0}^2\, \sigma_8^2, \quad \text{(T1.9)}$$

and the two parameters enter together (Section T1.7 finds out how far this holds once the shape of P_δ is allowed to change). Each multipole mixes many wavenumbers, so a sharp feature in P_δ is smoothed away in $C_\ell^{\kappa\kappa}$. And the weight g is broad, so lensing measures a smeared, projected density and not a three-dimensional map. Splitting the sources into redshift bins (**tomography**) recovers some of the lost depth, through the cross spectra C_ℓ^{ij} with weights $g_i g_j$.

The last row is the CMB version. Lensing by the same structures remaps the CMB by deflections of a few arcminutes (see the cosmology notes). How can a map of the potential be recovered from a single lensed CMB sky, with no galaxy shapes at all? The question in words: *what does lensing do to the statistics of the CMB that the unlensed sky could never do?*

Unlensed modes are independent. Without lensing the CMB is statistically the same in every direction, and its Fourier modes on a flat patch are uncorrelated: $\langle T_\ell T_{\ell'}\rangle = 0$ unless $\boldsymbol{\ell}' = -\boldsymbol{\ell}$ (Section T1.1; the flat-sky version of the independence of the $a_{\ell m}$). *Lensing mixes them.* Hold one lensing potential fixed and expand the remapping of the table to first order in the small deflection:

$$\begin{aligned} \hat{T}(\boldsymbol{n}) &\overset{(1)}{=} T(\boldsymbol{n}) + \boldsymbol{\nabla}\psi \cdot \boldsymbol{\nabla} T, \\ \hat{T}_{\boldsymbol{\ell}} &\overset{(2)}{=} T_{\boldsymbol{\ell}} - \int \frac{\mathrm{d}^2\boldsymbol{\ell}_1}{(2\pi)^2} \left[(\boldsymbol{\ell} - \boldsymbol{\ell}_1)\cdot\boldsymbol{\ell}_1\right] \psi_{\boldsymbol{\ell}-\boldsymbol{\ell}_1} T_{\boldsymbol{\ell}_1}, \\ \big\langle \hat{T}_{\boldsymbol{\ell}} \hat{T}_{\boldsymbol{\ell}'} \big\rangle_{\mathrm{CMB}} &\overset{(3)}{=} \left[(\boldsymbol{L}\cdot\boldsymbol{\ell})\, C_\ell + (\boldsymbol{L}\cdot\boldsymbol{\ell}')\, C_{\ell'}\right] \psi_{\boldsymbol{L}}, \qquad \boldsymbol{L} \equiv \boldsymbol{\ell} + \boldsymbol{\ell}' \neq \boldsymbol{0}. \end{aligned} \quad \text{(T1.10)}$$

(1) Taylor expansion of $T(\boldsymbol{n} + \boldsymbol{\xi})$ with $\boldsymbol{\xi} = \boldsymbol{\nabla}\psi$, kept to first order.

(2) Fourier transform: each gradient becomes i times its wavevector, and the transform of a product is the convolution of the transforms, so the potential at wavevector $\boldsymbol{\ell} - \boldsymbol{\ell}_1$ moves CMB power from mode $\boldsymbol{\ell}_1$ into mode $\boldsymbol{\ell}$.
(3) Average over the unlensed CMB with ψ held fixed. The unlensed term alone gives zero for $\boldsymbol{L} \neq \boldsymbol{0}$; in each cross term only the pairing allowed by independence survives, giving the two terms with the unlensed spectrum C_ℓ; the term of second order in ψ is dropped.

So with lensing, two CMB modes whose wavevectors add up to $\boldsymbol{L}$ are correlated, by an amount proportional to $\psi_{\boldsymbol{L}}$ times a weight built from the known CMB spectrum. Multiplying pairs of observed modes, dividing by the weight and averaging over all pairs with the same $\boldsymbol{L}$ gives an estimate of $\psi_{\boldsymbol{L}}$: this is the **quadratic estimator** [47], which uses temperature and polarization in the same way. Its noise comes from the CMB itself, since each product $\hat{T}_{\boldsymbol{\ell}}\hat{T}_{\boldsymbol{\ell}'}$ also contains the chance product of two unlensed modes.

Planck reconstructed the lensing potential over the full sky in this way. Its total signal-to-noise ratio, summed over all L, is 40 (the "40σ" of the paper), the same kind of number as the signal-to-noise ratio of a galaxy survey computed in Section T1.8. From it alone Planck measured $\sigma_8\Omega_m^{0.25} = 0.589 \pm 0.020$ [48]. The kernel in the last row, $g(\chi)f_K(\chi) = f_K(\chi)f_K(\chi_* - \chi)/f_K(\chi_*)$, is largest midway to the last-scattering surface in distance; per unit redshift it peaks near $z \approx 2$ (Figure T1.11), far behind the galaxy samples. Section T1.7 finds that deeper samples hold a combination $\sigma_8\Omega_m^\alpha$ with a smaller α fixed, and the CMB, the deepest source of all, has $\alpha = 0.25$. A different combination of the same two parameters is what is used to break the degeneracy of the next section.

The data, their noise and the nuisances. The question is what the survey actually records and how it differs from the model's κ. The measured ellipticity of a galaxy, ε, is its own intrinsic shape $\varepsilon^{(0)}$ plus the shear. Since galaxies point in random directions, $\langle\varepsilon^{(0)}\rangle = 0$, and the average over many gives the reduced shear:

$$\varepsilon \approx \varepsilon^{(0)} + \gamma, \qquad \langle\varepsilon\rangle = \frac{\gamma}{1-\kappa} \quad \text{(Section T1.6.1)}.$$

The scatter of $\varepsilon^{(0)}$, with σ_e the rms of one component, acts as white noise added to the convergence spectrum, $\bar{n}_i$ being the number of galaxies per steradian in bin i:

$$N_i = \frac{\sigma_e^2}{\bar{n}_i}, \qquad \langle\widehat{C}_\ell^{ij}\rangle = C_\ell^{ij} + \delta_{ij}N_i.$$

This is the **shape noise**, with $\sigma_e \approx 0.27$. Redshifts of the sources are photometric ones $z_{\rm ph}$ [estimated from a few broad-band colours], with a scatter $p(z_{\rm ph}\,|\,z)$ about the true z, so the true distribution of each tomographic bin has tails: $p^{(i)}(z) \propto p_z(z)\int_{\text{bin }i} p(z_{\rm ph}\,|\,z)\,\mathrm{d}z_{\rm ph}$, and a shift Δz_i of each is a nuisance. The combination of the two parameters that cosmic shear measures best is $S_8 \equiv \sigma_8(\Omega_{m0}/0.3)^{0.5}$, about 0.8. Three more effects are modelled or marginalised. *Intrinsic alignment*: nearby galaxies are stretched by the same tidal field when they form, so $\varepsilon^{(0)}$ is not purely random, and an amplitude $A_{\rm IA}$ is added to C_ℓ^{ij}. *Baryonic feedback*: gas expelled from haloes by supernovae and active nuclei lowers P_δ at $k \gtrsim 1\,h\,\mathrm{Mpc}^{-1}$, which looks like a lower S_8 and is handled by scale cuts or a feedback parameter. *Shear bias*: an imperfect shape measurement rescales the shear, $\varepsilon \to (1+m)\gamma + \ldots$, with m calibrated on image simulations. Used in Chapters 9, 10 and 12.

object	physical meaning	key equation	used in
ellipticity	one galaxy's measured shape: its own shape plus the shear	$\varepsilon \approx \varepsilon^{(0)} + \gamma, \quad \langle\varepsilon^{(0)}\rangle = 0 \Rightarrow \langle\varepsilon\rangle = \dfrac{\gamma}{1-\kappa}$ (Section T1.6.1)	Ch. 12
shape noise	the intrinsic shapes act as white noise added to the convergence spectrum	$N_i = \dfrac{\sigma_e^2}{\bar{n}_i}, \quad \langle \widehat{C}_\ell^{ij} \rangle = C_\ell^{ij} + \delta_{ij} N_i$	Ch. 10, 12
photo-z bins	sources sorted by estimated redshift; each bin's true-z distribution has tails	$p^{(i)}(z) \propto p_z(z) \displaystyle\int_{\text{bin } i} p(z_{\text{ph}} \mid z)\, \mathrm{d}z_{\text{ph}}$; nuisance: a shift Δz_i of each	Ch. 10, 12
S_8	the amplitude combination cosmic shear measures best	$S_8 \equiv \sigma_8 \, (\Omega_{m0}/0.3)^{0.5}$	Ch. 9–12
intrinsic alignment	galaxies near each other are stretched by the same tidal field when they form, so $\varepsilon^{(0)}$ is not purely random	adds terms to C_ℓ^{ij} that mimic or cancel part of the lensing signal; an amplitude A_{IA} is marginalised	Ch. 10, 12
baryonic feedback	gas blown out of haloes by supernovae and active nuclei lowers P_δ at $k \gtrsim 1\, h\,\text{Mpc}^{-1}$	lowers $C_\ell^{\kappa\kappa}$ at high ℓ, like a lower S_8; handled by scale cuts or a feedback parameter	Ch. 10, 12
shear bias	imperfect shape measurement rescales the shear	$\varepsilon \to (1+m)\gamma + \ldots$, with m calibrated on image simulations	Ch. 12

Why is shape noise flat in ℓ, and why is it $\sigma_e^2/\bar{n}$? Here σ_e is the rms of one real component of $\varepsilon^{(0)}$, the first symbol of the data table and the 0.27 of Section T1.5, and $\bar{n}$ is the number of galaxies per steradian. Think of a pixel of solid angle A. It holds on average $\bar{n}A$ galaxies; the actual count scatters about that from pixel to pixel (Poisson scatter), but when $\bar{n}A$ is large this barely changes the average noise, and we ignore it. Then

$$\mathrm{Var}\big(\bar{\varepsilon}_1 \text{ in one pixel}\big) \overset{(1)}{=} \frac{\sigma_e^2}{\bar{n}A}, \qquad N \overset{(2)}{=} \mathrm{Var}\big(\bar{\varepsilon}_1 \text{ in one pixel}\big) \times A \overset{(3)}{=} \frac{\sigma_e^2}{\bar{n}}. \tag{T1.11}$$

(1) The variance of a mean, (3.20), for $\bar{n}A$ independent galaxies; the shear is the same for all of them and adds no scatter.

(2) Different pixels hold different galaxies, so the noise in one pixel is independent of the noise in every other one. A field of independent pixels has the same power at every ℓ, which is white noise, and its power is the pixel variance times the pixel area, (8.16): the discrete harmonic sum spreads the variance of each pixel evenly over all the modes the pixels can carry.

(3) The pixel area cancels, as it must: the noise power cannot depend on how we chose to pixelise the sky.

This is the same white-noise reasoning that gives the instrumental noise of a CMB map in Chapter 8. Is this the noise on κ or on γ? Both. The Kaiser–Squires row turns $\hat{\gamma}$ into $\hat{\kappa}$ with the factor $\hat{\mathcal{D}}^*/\pi$, and $\left|\hat{\mathcal{D}}\right|^2 = \pi^2$, since $\left|\ell_1^2 - \ell_2^2 + 2i\ell_1\ell_2\right| = \left|(\ell_1 + i\ell_2)^2\right| = \ell^2$. So the inversion keeps the size of every mode. The two shear components carry noise $\sigma_e^2/\bar{n}$ each, $2\sigma_e^2/\bar{n} = \sigma_\varepsilon^2/\bar{n}$ in all, and this splits equally into the E part, which is κ, and the B part; the κ noise power is $\sigma_e^2/\bar{n} = \sigma_\varepsilon^2/(2\bar{n})$, the relation of convention 2 of Section T1.6.2.

The size, for the survey of Section T1.8: 1.24 galaxies per arcmin^2 per bin (a fifth of 6.2), and

one steradian holds $(180 \times 60/\pi)^2 = (10800/\pi)^2 = 1.18 \times 10^7$ arcmin^2, so

$$\bar{n}_i = 1.24 \times 1.18 \times 10^7 \,\mathrm{sr}^{-1} = 1.47 \times 10^7 \,\mathrm{sr}^{-1}, \qquad N_i = \frac{0.27^2}{1.47 \times 10^7} = \frac{0.073}{1.47 \times 10^7} \approx 4.965 \times 10^{-9},$$

which the signal of the nearest bin exceeds only up to $\ell \approx 21$ (Figure T1.12).

T1.6.1 Reduced shear: what a galaxy shape responds to

The data table says that the mean ellipticity is $\gamma/(1-\kappa)$, while (T1.2) says γ. Which is it, and why should the convergence enter the shape at all, when panel (a) of Figure T1.6 shows it only enlarging the image? The answer is in the distortion matrix of the first table. Pull the factor $1-\kappa$ out of it:

$$\mathcal{A} \overset{(1)}{=} (1-\kappa)\begin{pmatrix} 1-\dfrac{\gamma_1}{1-\kappa} & -\dfrac{\gamma_2}{1-\kappa} \\ -\dfrac{\gamma_2}{1-\kappa} & 1+\dfrac{\gamma_1}{1-\kappa} \end{pmatrix} \overset{(2)}{=} (1-\kappa)\begin{pmatrix} 1-g_1 & -g_2 \\ -g_2 & 1+g_1 \end{pmatrix}, \qquad g \equiv g_1 + i g_2 \equiv \frac{\gamma}{1-\kappa}. \tag{T1.12}$$

(1) Divide every entry of $\mathcal{A}$ by $1-\kappa$ and multiply the whole matrix by it.
(2) Give the ratios a name. The literature's letter for the **reduced shear** is g; in this subsection only, g without an argument is the reduced shear, while $g(\chi)$ elsewhere remains the lensing efficiency.

The simplest source first. Take a round source of radius r, and turn the axes so that the stretch lies along the first one, $g = g_1 > 0$ (any other direction follows by the rule (T1.5)). $\mathcal{A}$ maps the image back to the source, so the image is the set of directions $\boldsymbol{\theta}$ with $|\mathcal{A}\boldsymbol{\theta}| = r$:

$$(1-\kappa)^2\left[(1-g)^2\theta_1^2 + (1+g)^2\theta_2^2\right] = r^2 \overset{(1)}{=} \text{an ellipse with } a = \frac{r}{(1-\kappa)(1-g)},\ b = \frac{r}{(1-\kappa)(1+g)},$$
$$\varepsilon = \frac{a-b}{a+b} \overset{(2)}{=} \frac{(1+g)-(1-g)}{(1+g)+(1-g)} = g. \tag{T1.13}$$

(1) $|\mathcal{A}\boldsymbol{\theta}|^2$ with the diagonal matrix of (T1.12); the semi-axes are read off where $\theta_2 = 0$ and where $\theta_1 = 0$.
(2) The ellipticity definition of convention 3 of Section T1.6.2; multiply the numerator and the denominator by $(1-\kappa)(1-g)(1+g)/r$, and κ cancels.

So κ only rescales the size, as in panel (a), and the shape responds to g, not to γ. For a source that is itself elliptical, the same calculation kept to first order in small quantities gives $\varepsilon \approx \varepsilon^{(0)} + g$, and averaging with $\langle\varepsilon^{(0)}\rangle = 0$ gives $\langle\varepsilon\rangle = g$, the table's entry. How different are g and γ? Expanding $1/(1-\kappa) = 1 + \kappa + \kappa^2 + \dots$ gives $g = \gamma(1 + \kappa + \dots)$. With $\kappa \approx 0.01$ the two differ by about one per cent of a one-per-cent effect, which is why the rest of the part writes γ; analyses at per-cent precision model g.

T1.6.2 Conventions to carry forward

As with the CMB conventions of Section T1.2.1, each of these changes a number by a fixed factor without any warning.

1. **CAMB outputs.** With a lensing source window (`SplinedSourceWindow` from `camb.sources`, called with `source_type="lensing"`) CAMB computes the Limber integral above for any $p_z(z)$, and `get_source_cls_dict(raw_cl=True)` returns $C_\ell^{\kappa\kappa}$ under the key `"W1xW1"` (and

C_ℓ^{ij} under `"WixWj"`). Without `raw_cl=True` it returns $\ell(\ell+1)C_\ell/2\pi$, which at $\ell = 1000$ is the raw C_ℓ times $1000 \times 1001/2\pi = 1.59 \times 10^5$. The key `"PxP"` is the CMB lensing potential, $C_\ell^{\phi\phi}$ in raw form, and CAMB's ϕ is the cosmology notes' ψ (Section T1.2.1, item 6). The factor between the two spectra comes from $\kappa = \frac{1}{2}\nabla^2\psi$ of the first table. On the sphere the Laplacian acting on a spherical harmonic gives $\nabla^2 Y_{\ell m} = -\ell(\ell+1)Y_{\ell m}$ (by (7.39), since $\boldsymbol{L}^2 = -\nabla^2$), so expanding both fields in harmonics gives $\kappa_{\ell m} = -\frac{1}{2}\ell(\ell+1)\psi_{\ell m}$. A power is the mean square of an amplitude, so the factor is squared: $C_\ell^{\kappa\kappa} = \frac{1}{4}[\ell(\ell+1)]^2 C_\ell^{\phi\phi}$.

2. **Shape-noise conventions.** Some papers quote the rms of one component, σ_e; others the rms of the whole complex ellipticity, $\sigma_\varepsilon^2 = \langle|\varepsilon^{(0)}|^2\rangle = 2\sigma_e^2$. The noise power is $\sigma_e^2/\bar{n} = \sigma_\varepsilon^2/(2\bar{n})$, as written in [44, eq. 52].

3. **Ellipticity definitions.** For $\varepsilon = \frac{a-b}{a+b}e^{2i\phi}$ (axes $a \geq b$, position angle ϕ) the response to shear is $\varepsilon \approx \varepsilon^{(0)} + \gamma$. Some codes use $\frac{a^2-b^2}{a^2+b^2}e^{2i\phi}$ instead, which responds as 2γ [44, §3.5].

4. **Flat versus full sky.** $P_\gamma = P_\kappa$ holds on a flat patch. On the sphere the E-mode shear spectrum is $\frac{(\ell+2)(\ell-1)}{\ell(\ell+1)}C_\ell^{\kappa\kappa}$. The reason: κ takes two derivatives of ψ in the combination of the Laplacian, which multiplies $\psi_{\ell m}$ by $\frac{1}{2}\ell(\ell+1)$ (item 1), while the shear takes two derivatives that each raise the spin by one, and on spin-weighted harmonics these multiply by $\sqrt{\ell(\ell+1)}$ and then $\sqrt{(\ell-1)(\ell+2)}$ (see the cosmology notes). The shear amplitude is therefore $\frac{1}{2}\sqrt{(\ell+2)(\ell+1)\ell(\ell-1)}\,\psi_{\ell m}$, and the ratio of the two powers is $(\ell+2)(\ell+1)\ell(\ell-1)/[\ell(\ell+1)]^2 = (\ell+2)(\ell-1)/[\ell(\ell+1)]$. It tends to one as ℓ grows: 0.982 at $\ell = 10$, 0.9998 at $\ell = 100$. Our Limber integral uses $k = (\ell+\frac{1}{2})/\chi$ rather than ℓ/χ. On the sphere the role of ℓ^2 in the flat-sky Laplacian is played by $\ell(\ell+1)$, so the effective flat wavenumber is $\sqrt{\ell(\ell+1)} = \ell + \frac{1}{2} - \frac{1}{8\ell} + \ldots$, and $\ell + \frac{1}{2}$ is the closer match; it is also where the spherical Bessel functions of the exact projection peak. The change in k is a fraction $1/(2\ell)$: 5% at $\ell = 10$, 0.5% at $\ell = 100$, and the spectrum moves by a fraction of the same order, so again only low ℓ is affected.

5. **The sign of γ_2.** It differs between survey catalogues and `healpy`'s polarization convention. The safe check is to build a shear map from a known κ map, invert it, and confirm that $+\kappa$ comes back in E and nothing in B.

Watch out: A factor of two that looks like a result

Mixing σ_e with σ_ε doubles or halves the noise power; mixing the two ellipticity definitions doubles or halves the shear, and so quadruples or quarters $C_\ell^{\kappa\kappa}$ inferred from shapes. Neither error breaks a script. Both shift S_8 by far more than its quoted error.

T1.7 Experiment 1: what cosmic shear measures, S_8

Suppose a survey measures a convergence spectrum that is somewhat higher than our fiducial prediction. What could have produced it? Before any calculation, there are two candidates, and the Limber row of Section T1.6 tells us how each one acts.

1. *More matter*, a larger Ω_{m0}. There are more lenses, and the prefactor Ω_{m0}^2 in the Limber integral grows. With h and the baryon density fixed, a larger Ω_{m0} also changes the shape of P_δ and how fast structure grows.

2. *The same matter, more clumped*, a larger σ_8. The prefactor is unchanged, but P_δ is larger at every k, by σ_8^2 in linear theory and by more on non-linear scales, where clumping feeds on itself.

Both raise $C_\ell^{\kappa\kappa}$. How probable is the observed spectrum under each candidate? If both predict nearly the same spectrum, the observation is about equally probable under both. The data then cannot prefer one over the other, and the posterior keeps both, exactly as in the inference of Section 1.7. So lensing data alone can only fix some combination of the two. The experiment finds that combination, and where the two candidates stop predicting the same thing.

T1.7.1 What we vary

Recall the two ingredients of the Limber row: $P_\delta(k, \chi)$ is the matter power spectrum at wavenumber k and distance χ, and $g(\chi)$ the lensing efficiency of the second table, a weighted count of how much source light lies behind χ. We change only Ω_m and σ_8, and choose five points of the (Ω_m, σ_8) plane, each with a job. Three lie on the line of constant $S_8 = 0.832$, the Planck value [25]. For a chosen Ω_m the definition of S_8 in the data table fixes σ_8:

$$\sigma_8 = S_8\left(\frac{0.3}{\Omega_m}\right)^{0.5}, \qquad \text{e.g.} \quad \Omega_m = 0.25: \quad \sigma_8 = 0.832 \times \sqrt{0.3/0.25} = 0.832 \times 1.095 = 0.911.$$

Two lie across the line, at the fiducial Ω_m with $S_8 = 0.76$ (close to what the lensing surveys find) and $S_8 = 0.90$.

point	Ω_m	σ_8	S_8	role
fiducial	0.3153	0.811	0.832	reference (Planck)
along, low Ω_m	0.25	0.911	0.832	same S_8, less matter, more clumped
along, high Ω_m	0.40	0.720	0.832	same S_8, more matter, less clumped
across, low	0.3153	0.741	0.76	S_8 lowered by 9%
across, high	0.3153	0.878	0.90	S_8 raised by 8%

What should we see? Across the line Ω_m is fixed, so in linear theory $C_\ell \propto \sigma_8^2$ by (T1.9), and a 9% change of S_8 should move the spectrum by about $(0.76/0.832)^2 - 1 = -17\%$ and $(0.90/0.832)^2 - 1 = +17\%$, a little more where non-linear growth adds to it. Along the line the answer is not obvious. If only the prefactor of (T1.9) mattered, a constant spectrum would need $\sigma_8\Omega_m$ fixed, and along the S_8 line, where $\sigma_8\Omega_m^{0.5}$ is fixed, the spectrum would still change by the factor $(0.40/0.25)$ in Ω_m between the two ends. But a larger Ω_m at fixed σ_8 also reshapes P_δ. If S_8 is the right combination, the three spectra on the line nearly coincide.

T1.7.2 What we hold fixed

Everything else stays at the fiducial values of Table T1.1, and all five models use one source sample:

held fixed	value
Hubble parameter h	0.6736
baryon density $\Omega_{b0}h^2$	0.02237
spectral index n_s	0.9649
neutrino mass $\sum m_\nu$	0.06 eV (one massive neutrino)
geometry	flat, $f_K(\chi) = \chi$
source distribution	$p_z \propto z^2 e^{-(z/0.5)^{1.5}}$, median redshift 0.71
non-linear P_δ	halofit [41]

The source distribution is a Stage-III-like sample. Its factor z^2 makes it start at zero, because nearby space holds little volume and so few galaxies; the factor $e^{-(z/0.5)^{1.5}}$ cuts it off where galaxies become too faint for the survey to measure their shapes.

T1.7.3 What we compute, and how

Listing T1.3: Setting (Ω_m, σ_8) and asking CAMB for $C_\ell^{\kappa\kappa}$ (`code/chT1/03_kappa_s8.py`)

```
48 def camb_params(om, s8, windows=True, as_ref=FIDUCIAL["As"]):
49     """CAMB parameters for flat LCDM at (Omega_m, sigma_8), other parameters fiducial.
50     Omega_m includes the massive neutrino; sigma_8 is set by rescaling A_s
51     (linear sigma_8 is proportional to sqrt(A_s))."""
52     import camb
53     from camb.sources import SplinedSourceWindow
54     par = dict(FIDUCIAL)
55     p0 = camb.set_params(**par)
56     par["omch2"] = om * H**2 - par["ombh2"] - p0.omnuh2
57     # first a cheap linear run to find sigma_8 at the reference A_s
58     plin = camb.set_params(**{**par, "As": as_ref}, WantTransfer=True)
59     plin.set_matter_power(redshifts=[0.0], kmax=2.0)
60     s8_ref = camb.get_results(plin).get_sigma8_0()
61     par["As"] = as_ref * (s8 / s8_ref) ** 2
62     p = camb.set_params(**par, lmax=LMAX + 200, lens_potential_accuracy=1,
63                         NonLinear=camb.model.NonLinear_both, halofit_version="takahashi")
64     if windows:
65         p.SourceWindows = [SplinedSourceWindow(z=ZGRID[1:], W=nz[1:], source_type="lensing")
66                            for nz in NZS]
67     return p, par
68
69
70 def kappa_spectra(om, s8):
71     """Raw C_ell^{kappa kappa} (ell = 0..LMAX) of the three source samples, as rows."""
72     import camb
73     p, _ = camb_params(om, s8)
74     cls = camb.get_results(p).get_source_cls_dict(raw_cl=True, lmax=LMAX)
75     return np.array([cls[f"W{i}xW{i}"] for i in (1, 2, 3)])
```

CAMB is not given Ω_m and σ_8 directly, so the function translates. Line 56 finds the cold-dark-matter density from the total matter density at fixed h, keeping the massive neutrino inside Ω_m:

$$\Omega_{c0}h^2 = \Omega_{m0}h^2 - \Omega_{b0}h^2 - \Omega_{\nu0}h^2, \qquad \Omega_{\nu0}h^2 = \frac{\sum m_\nu}{93.14\,\mathrm{eV}} = \frac{0.06}{93.14} = 6.4\times10^{-4},$$

so the fiducial $\Omega_m = 0.3153$ gives $0.3153\times0.6736^2 - 0.02237 - 0.00064 = 0.1200$, the fiducial $\Omega_{c0}h^2$. CAMB also takes A_s, not σ_8, as input. By its definition σ_8^2 is an integral of the linear power,

$$\sigma_8^2 = \int \frac{\mathrm{d}k}{k}\,\Delta^2(k)\,W^2(kR), \qquad R = 8\,h^{-1}\mathrm{Mpc},$$

with $\Delta^2 = k^3P_\delta/2\pi^2$ and W the top-hat window (7.32). The linear $\Delta^2(k)$ is A_s times factors (the tilt, the transfer function, the growth) that do not depend on A_s, so σ_8^2 is proportional to A_s, and the ratio of two values of σ_8^2 equals the ratio of their A_s. Lines 58–61 therefore do one cheap linear run at a reference A_s to find $\sigma_{8,\mathrm{ref}}$, and then set $A_s = A_{s,\mathrm{ref}}(\sigma_8/\sigma_{8,\mathrm{ref}})^2$; no iteration is needed, because the relation is exact. Lines 62–66 switch on the halofit non-linear spectrum and attach the source distributions as lensing windows. Line 74 asks for the raw spectra (convention 1 of Section T1.6.2).

A check by hand. Before trusting the library call we check it. The function `limber_by_hand` in the same script evaluates the Limber row of Section T1.6 directly, in four moves. It works in redshift rather than distance, using $\mathrm{d}\chi = (c/H)\,\mathrm{d}z$ with CAMB's $H(z)$. It builds the lensing efficiency on the redshift grid: since $p_\chi\,\mathrm{d}\chi' = p_z\,\mathrm{d}z'$ and $f_K = \chi$, the integral of the second table becomes $g(\chi_i) = \int_{z_i} p_z(z')\,[1 - \chi_i/\chi(z')]\,\mathrm{d}z'$, done as a trapezoid sum for every grid point. It

evaluates CAMB's non-linear P_δ at $k = (\ell + \frac{1}{2})/\chi$ (convention 4) through CAMB's interpolator. And it multiplies by the prefactor $\frac{9}{4}(H_0/c)^4\Omega_m^2$ and sums $[g/a]^2 P_\delta \, (\mathrm{d}\chi/\mathrm{d}z)$ over the grid with the trapezoid rule. Over $100 \le \ell \le 2000$ the two agree to a median of 0.1% (the dashed black curve in Figure T1.9).

Why should they differ at all? CAMB samples the redshifts and interpolates P_δ in its own way, and our sum uses a grid of 700 redshifts and drops wavenumbers above $60\,\mathrm{Mpc}^{-1}$ (at $\ell = 2000$ only the matter within 33 Mpc of us); both effects are far below one per cent. The choice of k matters more: had one code used ℓ/χ and the other $(\ell + \frac{1}{2})/\chi$, k would differ by a fraction $1/(2\ell)$, 0.5% at $\ell = 100$, and with P_δ falling roughly as $k^{-1.5}$ there the spectra would differ by close to 1%. The agreement is ten times better, so both use the same choice. And at low multipoles, where the Limber approximation itself is poorest, a library may compute the exact projection instead, which is why the comparison starts at $\ell = 100$. The lesson: a library result is trusted only after a short independent version reproduces it.

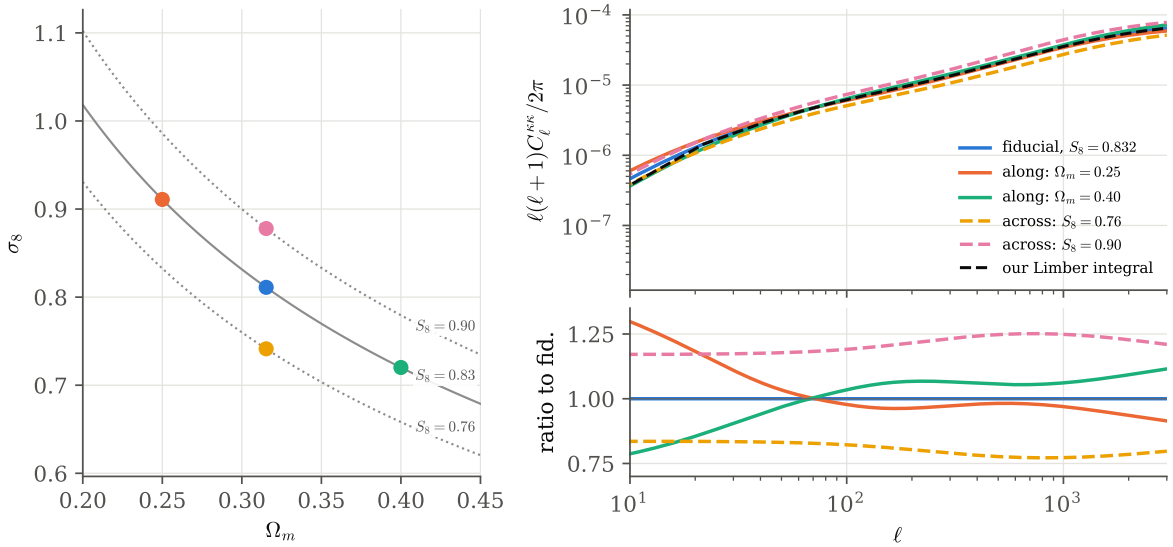

Figure T1.9: Left: the five models in the (Ω_m, σ_8) plane, with lines of constant S_8. Right: their convergence spectra (top) and the ratio to the fiducial one (bottom). The three solid curves, on the fiducial S_8 line, stay close together for $\ell \gtrsim 100$, even though Ω_m changes by a factor 1.6 along it. The two dashed curves, off the line by about 9% in S_8, are shifted by more than 20% at every ℓ. The dashed black curve is our own Limber integral for the fiducial model.

T1.7.4 The answer

Figure T1.9 is the answer. Along the line of constant S_8 the spectra differ by a median of −4% and +7% over $100 \le \ell \le 2000$ (at most 9%), although Ω_m runs from 0.25 to 0.40 and σ_8 from 0.911 to 0.720. Across the line, a change of about 9% in S_8 moves the spectrum by −22% and +24%. So the data pin down S_8 and leave the position along the line almost free: for $\ell \gtrsim 100$ the observation is about equally probable anywhere on the line, and the two candidates of the opening cannot be told apart there. Two things break that tie. A move across the line changes the spectrum by more than 20%, so the posterior is narrow in that direction. And at the low multipoles, $\ell \lesssim 50$, the three solid curves separate.

Why at low ℓ? The matter spectrum has a turnover, a peak at the wavenumber of the horizon size at matter–radiation equality, as described with the matter spectrum in Section T1.4. That wavenumber is $k_{\mathrm{eq}} \approx 0.073\,\Omega_{m0}h^2\,\mathrm{Mpc}^{-1}$, which is $0.073\,\Omega_{m0}h$ in the units $h\,\mathrm{Mpc}^{-1}$ in which σ_8 is defined (see the cosmology notes). At fixed h it moves in proportion to Ω_m, by the factor 1.6

between the ends of the line, and so the shape of P_δ around the turnover differs along the line even where its height does not. For the fiducial model $k_{\rm eq} \approx 0.073{\times}0.315{\times}0.674^2 \approx 0.010\,{\rm Mpc}^{-1}$; matter near the peak of the lensing weight, at $\chi \approx 1500$–$2000\,{\rm Mpc}$, projects it to $\ell = k\chi \approx 15$–20. Only the lowest multipoles see the turnover, and they carry few modes.

T1.7.5 Which exponent?

Is the exponent 0.5 in S_8 special? We can ask the spectrum which exponent it prefers. Change Ω_m by ±5% at fixed σ_8, then σ_8 by ±5% at fixed Ω_m, and form the logarithmic slopes. At $\ell = 500$ they are $\partial \ln C_\ell / \partial \ln \sigma_8 = 2.8$ and $\partial \ln C_\ell / \partial \ln \Omega_m = 1.6$.

The first slope can be checked against what we know. In linear theory $C_\ell \propto \sigma_8^2$ at fixed Ω_m, by (T1.9), so $\partial \ln C_\ell / \partial \ln \sigma_8 = 2$ exactly. Non-linear power grows faster than σ_8^2, because on small scales the extra clumping feeds on itself, and the measured 2.8 says how much faster: at $\ell = 500$ the spectrum responds about 40% more strongly than in linear theory. The same slope explains the across-line shifts of Figure T1.9: $(0.76/0.832)^{2.8} - 1 = -22\%$ and $(0.90/0.832)^{2.8} - 1 = +25\%$, close to the measured −22% and +24%, where the linear expectation of Section T1.7.1 was ±17%.

Which combination leaves the spectrum unchanged? Write $a \equiv \partial \ln C_\ell / \partial \ln \sigma_8$ and $b \equiv \partial \ln C_\ell / \partial \ln \Omega_m$, and ask for the small changes of the two parameters that keep C_ℓ fixed:

$$0 = {\rm d} \ln C_\ell \overset{(1)}{=} a\, {\rm d} \ln \sigma_8 + b\, {\rm d} \ln \Omega_m \quad \Longrightarrow \quad {\rm d} \ln \sigma_8 \overset{(2)}{=} -\frac{b}{a}\, {\rm d} \ln \Omega_m$$
$$\Longrightarrow \quad \ln \sigma_8 + \frac{b}{a} \ln \Omega_m \overset{(3)}{=} {\rm const} \quad \Longleftrightarrow \quad \sigma_8 \Omega_m^{b/a} = {\rm const}. \tag{T1.14}$$

(1) The change of a function of two variables is the sum of the changes along each (the chain rule), with $\ln \sigma_8$ and $\ln \Omega_m$ as the variables.
(2) Solve for ${\rm d} \ln \sigma_8$.
(3) Integrate, treating the ratio b/a as constant over the small region of interest; then take the exponential.

The exponent is the ratio of the two slopes,

$$\alpha(\ell) \equiv \frac{\partial \ln C_\ell^{\kappa\kappa} / \partial \ln \Omega_m}{\partial \ln C_\ell^{\kappa\kappa} / \partial \ln \sigma_8}. \tag{T1.15}$$

With the numbers above, $\alpha = 1.6/2.8 \approx 0.57$ at $\ell = 500$, which the unrounded slopes give as 0.55. For the fiducial sample $\alpha = 0.59$ at $\ell = 200$, 0.55 at $\ell = 500$ and 0.62 at $\ell = 2000$.

Figure T1.10 shows $\alpha(\ell)$ for three source samples, with median redshifts 0.49, 0.71 and 0.99. At $\ell = 500$ it is 0.58, 0.55 and 0.53. So the exponent 0.5 is a convention close to the truth, not a law: the best exponent depends on the scales and the redshifts a survey uses. This is why the surveys quote their own. HSC finds its tightest combination at $\alpha = 0.45$ and reports both $S_8(\alpha{=}0.45) = 0.800^{+0.029}_{-0.028}$ and the standard $S_8 = 0.780^{+0.030}_{-0.033}$ [49], and CMB lensing, with its deeper kernel, measures $\sigma_8 \Omega_m^{0.25}$ (Section T1.6).

T1.7.6 What the surveys find

The question the surveys asked is simple to state. The CMB shows the Universe at $z \approx 1100$, and the ΛCDM model extrapolates from it how clumpy matter should be today. Lensing measures today's clumpiness directly. *Do the two agree?* Each experiment measures something different:

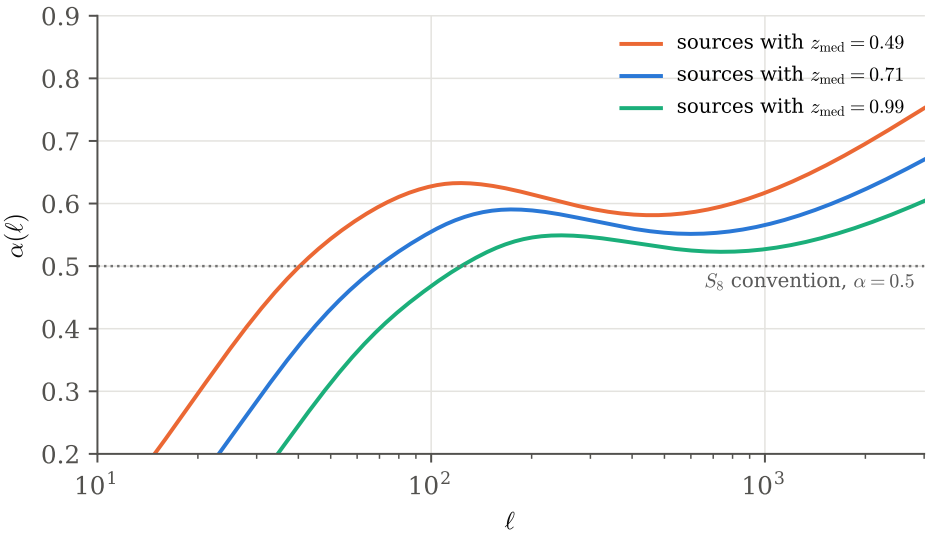

Figure T1.10: The exponent α of the combination $\sigma_8\Omega_m^\alpha$ that leaves $C_\ell^{\kappa\kappa}$ unchanged, multipole by multipole, Eq. (T1.15), for three source samples of increasing depth. Over the range where surveys have most of their signal, $100 \lesssim \ell \lesssim 1000$, it sits between 0.5 and 0.6, lower for deeper samples. It falls at low ℓ, where the shape of the matter spectrum near its turnover enters.

- *KiDS-1000* [45]: about 1000 deg^2 (777 deg^2 effective), about 21 million galaxies in five photometric bins out to $z \approx 1.2$; its headline number comes from a two-point statistic of the shear in all fifteen bin pairs.
- *DES Year 3* [50]: about 4100 deg^2, about 100 million galaxies in four bins, from the real-space correlations $\xi_\pm$.
- *HSC Year 1* [49]: only 137 deg^2 but the deepest images, four bins out to $z \approx 1.5$, from tomographic power spectra C_ℓ^{ij}.
- *Planck* [25]: the CMB temperature and polarization spectra over the full sky, with S_8 today computed from the fitted ΛCDM parameters.

experiment	published S_8	symmetrised error	distance from Planck
KiDS-1000	$0.759^{+0.024}_{-0.021}$	0.0225	2.8σ
DES Year 3	$0.759^{+0.025}_{-0.023}$	0.024	2.7σ
HSC Year 1	$0.780^{+0.030}_{-0.033}$	0.0315	1.5σ
Planck (CMB)	0.832 ± 0.013	0.013	—
this part	0.832; 0.76, 0.90	—	—

The distances in the last column are computed here, in one line of arithmetic. In the last row 0.832 is the solid model of Figure T1.9 and 0.76, 0.90 the dashed ones. If the two measurements are independent and their errors Gaussian, their difference has a variance equal to the sum of the two variances, the rule behind (3.20), so for KiDS-1000

$$\frac{0.832 - 0.759}{\sqrt{0.013^2 + 0.0225^2}} = \frac{0.073}{0.026} = 2.8.$$

The "about 3σ" that is often quoted is this number, rounded. It is only approximate: the errors are not symmetric (using the upper error, 0.024, which is the one facing Planck, gives 2.7σ), and the posteriors are not exactly Gaussian.

The sign of the shift is the one Figure T1.9 prepares. The lensing values sit near $S_8 = 0.76$, the lower dashed model, and the CMB value is the solid one: the surveys see a spectrum about 20% below what Planck's ΛCDM predicts. Whether this is new physics, a nuisance not fully modelled (the red boxes of Figure T1.8), or a fluctuation is one of the open questions of the field, and it is a question about statistics: about the sampling distribution of $\widehat{C}_\ell$, its covariance, and how much the nuisance parameters are allowed to move. The lesson of the comparison: a 9% difference in one number is a 20% difference in the spectrum, and whether it is significant depends entirely on errors that the later chapters learn to compute.

For the statistics chapters, the long valley of Figure T1.9 is a degeneracy of the kind met in Section T1.3: two parameters whose derivative curves are nearly proportional. In the Fisher matrix of Chapter 10 it makes the (Ω_m, σ_8) error ellipse long and thin, along $\sigma_8\Omega_m^\alpha = \text{const}$. In the MCMC of Chapter 9 it is a curved banana-shaped ridge. Chapter 12 forecasts the error on S_8 from simulated maps and asks whether summaries beyond $C_\ell^{\kappa\kappa}$ shorten the banana.

T1.8 Experiment 2: signal and shape noise in a Stage-III survey

The galaxy shapes carry a lensing signal of about 0.01 under an intrinsic scatter of 0.27. On which angular scales does the signal still win, and how many σ is the whole detection worth? In the language of Section T1.6: C_ℓ^{ij} is the convergence spectrum between redshift bin i and bin j, $N_i = \sigma_e^2/\bar{n}_i$ the shape-noise power of bin i from (T1.11), and the measured spectrum of bin i is $C_\ell^{ii} + N_i$. We want to know where C_ℓ^{ii} exceeds N_i.

T1.8.1 The survey

We take survey numbers close to KiDS-1000 [45]:

quantity	this experiment	KiDS-1000
area	$1000\,\text{deg}^2$	$\approx 1000\,\text{deg}^2$ ($777\,\text{deg}^2$ effective)
sky fraction f_{sky}	0.0242	—
galaxy density $\bar{n}$	6.2 arcmin^{-2}, all bins	6.2 arcmin^{-2}
shape scatter σ_e (per component)	0.27	0.25–0.27
photo-z scatter	Gaussian, $0.05(1+z)$	—
redshift bins	5, equal numbers	5

The sky fraction f_{sky} is the observed area divided by the area of the whole sky. The whole sky is 4π steradians, and one steradian is $(180/\pi)^2$ square degrees, so

$$f_{\text{sky}} = \frac{1000\,\text{deg}^2}{4\pi(180/\pi)^2\,\text{deg}^2} = \frac{1000}{41\,253} = 0.0242.$$

The source sample is the one of Section T1.7.2, with the fiducial cosmology.

T1.8.2 The binning

We cut the sample into five bins by photometric redshift, with equal numbers of galaxies in each. Equal numbers make every bin equally noisy, since N_i depends only on $\bar{n}_i$, so no bin is wasted on a handful of galaxies. A photometric redshift is estimated from a few broad colours, and its error grows with redshift because the spectral features it relies on are stretched by the factor $1 + z$; the simplest model of that is a Gaussian scatter of width $0.05(1 + z)$ about

the true redshift, without the outliers that real catalogues have. The bin edges come out at $z_{\rm ph} = 0.43, \ldots, 1.05$. Because of the scatter, a galaxy placed in one bin may truly belong to a neighbour, so the true-redshift distributions of the bins overlap.

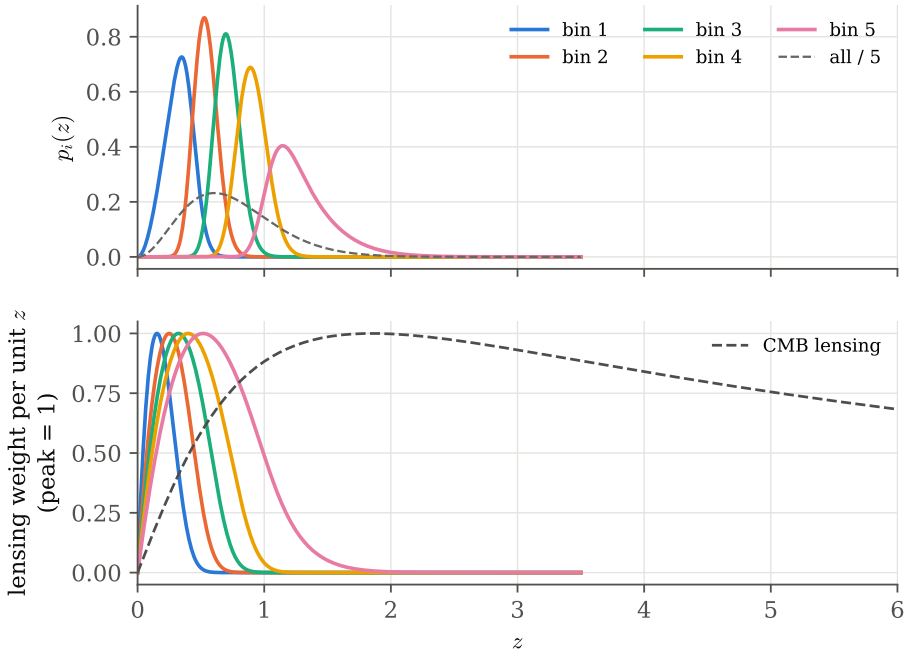

Figure T1.11: Top: the true-redshift distributions of the five photometric bins; photo-z scatter makes them overlap. Bottom: the lensing weight of each bin per unit redshift, $\propto g_i(\chi) f_K(\chi)/a$ times $\mathrm{d}\chi/\mathrm{d}z$, normalised to peak at one. Each weight is broad and peaks at about half the distance of its sources, so the five bins see heavily overlapping slices of matter. The CMB weight (dashed) peaks near $z \approx 2$.

Figure T1.11 shows the price of photometric redshifts and of projection together. The bins themselves overlap, and their lensing weights overlap even more, since every bin is lensed by all the matter in front of it. Tomography therefore does not give five independent maps. It gives five correlated maps whose full 5×5 matrix of spectra, auto and cross, carries the information, and the covariance of the analysis must include all fifteen of them.

T1.8.3 The noise and the error bars

Listing T1.4: The noise power of each bin (`code/chT1/04_kappa_noise.py`)

```
113     bins, chi, c0 = d["bins"], d["chi"], d["c0"]
114     frac = trapezoid(bins, Z, axis=1)                    # fraction of galaxies per
        bin
115     n_i = N_EFF * frac * ARCMIN2_PER_SR                  # per steradian
116     noise = SIGMA_E**2 / n_i
```

Line 114 counts the fraction of galaxies in each bin (a fifth, by construction). Line 115 converts the number density from arcmin^{-2} to sr^{-1}: one steradian holds $(10800/\pi)^2 = 1.18 \times 10^7$ arcmin^2, so 1.24 arcmin^{-2} becomes 1.47×10^7 sr^{-1}. Line 116 is the noise row of the table, $N_i = \sigma_e^2/\bar{n}_i \approx 4.965 \times 10^{-9}$, worked out in Section T1.6.

How large are the error bars on a measured band power? Start from the cosmic variance of

one multipole and make three changes:

$$\operatorname{Var}\widehat{C}_\ell \overset{(1)}{=} \frac{2C_\ell^2}{\nu} \overset{(2)}{=} \frac{2\,(C_\ell+N)^2}{(2\ell+1)\,f_{\rm sky}}, \qquad \operatorname{Var}\Big(\frac{1}{\Delta\ell}\sum_{\ell'\in\text{band}}\widehat{C}_{\ell'}\Big) \overset{(3)}{=} \frac{2\,(C_\ell+N)^2}{(2\ell+1)\,\Delta\ell\,f_{\rm sky}},$$

$$\Delta C_\ell \overset{(4)}{=} \sqrt{\frac{2}{(2\ell+1)\,\Delta\ell\,f_{\rm sky}}}\,(C_\ell+N). \tag{T1.16}$$

(1) The cosmic variance (7.77), written for ν independent modes; on the full sky $\nu = 2\ell+1$.
(2) Two changes. A survey that sees a fraction $f_{\rm sky}$ of the sky has only about $(2\ell+1)f_{\rm sky}$ independent modes per multipole. And what is measured is the spectrum of signal plus noise, whose variance per mode is $C_\ell + N$, so the scatter of the estimate is set by the sum, as in (7.81); the noise is part of what is measured.
(3) Averaging the $\Delta\ell$ independent multipoles of a band divides the variance by $\Delta\ell$, (7.79), the variance of a mean.
(4) The square root.

This is the Gaussian band-power error used in the literature [44, eq. 52].

What does this mean for inference? The observed band power is the model prediction plus one draw of noise with the variance of (T1.16). Read as a function of the parameters (Ω_m, σ_8), the probability of the data asks how plausible the noise draw is that turns the prediction $C_\ell(\Omega_m, \sigma_8)$ into what was observed: a Gaussian centred on the model, with the width of (T1.16). This is the likelihood from a noise model, (0.9), in its band-power form (Section 7.10.3). The S_8 degeneracy of Section T1.7 is a statement about this likelihood: moving along the line leaves the centre almost where it was, so the same noise draw is needed everywhere on the line, and the likelihood does not change.

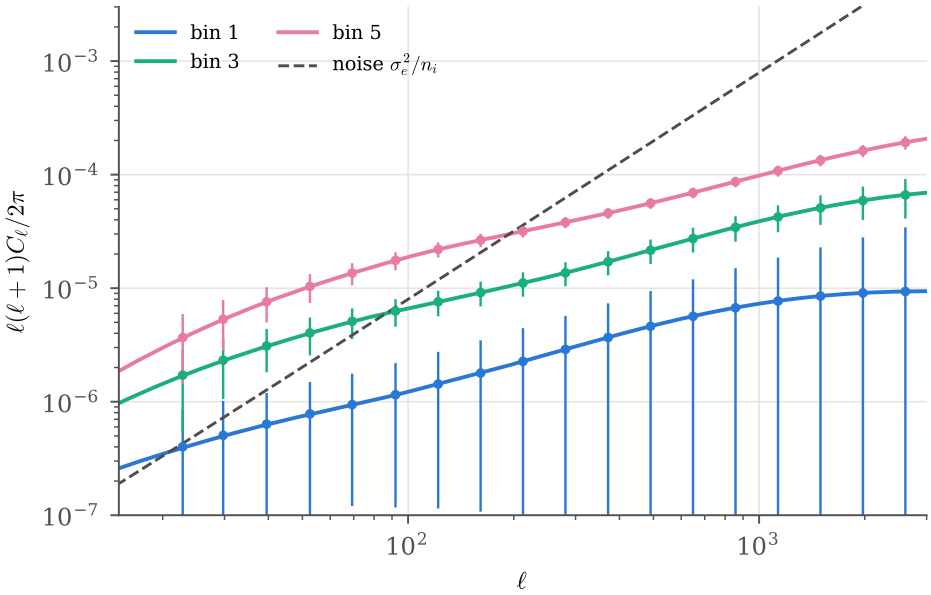

Figure T1.12: Convergence spectra of the nearest (1), middle (3) and farthest (5) bins, with Gaussian error bars on logarithmic bands of ℓ for a 1000 deg^2 survey, Eq. (T1.16). The dashed line is the shape noise, the same for every bin because the bins hold equal numbers of galaxies; it rises as ℓ^2 only because of the factor $\ell(\ell+1)$ on the axis. Beyond the crossing, the error bars are set mostly by the noise.

T1.8.4 Where the signal wins, and how many σ

Figure T1.12 gives the answer to the first question. The signal equals the noise at $\ell \approx 21$ in the nearest bin, $\ell \approx 87$ in the middle one and $\ell \approx 194$ in the farthest, which is lensed by the most matter. Beyond those multipoles each bin is noise-dominated. The measurement does not stop there, since there are many modes at high ℓ, but each additional mode adds little.

The signal-to-noise ratio of one bin. Ask how well the data fix the height of the signal. Multiply the predicted spectrum by an amplitude A, so that the measured spectrum has mean $AC_\ell + N$, and define the signal-to-noise ratio as $1/\sigma(A)$ at $A = 1$: the number of standard deviations by which the signal is distinguished from no signal. The Fisher information for A comes from (10.31), with $(2\ell+1)f_{\rm sky}$ modes per multipole:

$$\left(\frac{S}{N}\right)^2 \overset{(1)}{=} \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2} \frac{\left[\partial(AC_\ell+N)/\partial A\right]^2}{(C_\ell+N)^2} \overset{(2)}{=} \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2} \frac{C_\ell^2}{(C_\ell+N)^2}. \tag{T1.17}$$

(1) Equation (10.31) for one parameter, with the full-sky count $2\ell+1$ replaced by $(2\ell+1)f_{\rm sky}$, and the inverse error squared equal to the Fisher information.
(2) The derivative of $AC_\ell + N$ with respect to A is C_ℓ.

Each mode contributes the factor $\frac{1}{2}[C_\ell/(C_\ell+N)]^2$. Where the signal dominates, $C_\ell \gg N$, that factor is $\frac{1}{2}$, the most a mode can give; where the noise dominates it falls as $\frac{1}{2}(C_\ell/N)^2$, and since N is flat while C_ℓ falls, it drops quickly beyond the crossing. So the signal-to-noise ratio essentially counts the modes below the crossing multipole.

Five bins at once. With tomography the spectrum at each ℓ is a 5×5 matrix $\mathbf{C}_\ell$ with entries $C_\ell^{ij} + \delta_{ij}N_i$, and $\mathbf{S}_\ell$ is its signal part. The same calculation with the matrix form of the Fisher information gives

$$\left(\frac{S}{N}\right)^2 = \sum_\ell \frac{(2\ell+1)f_{\rm sky}}{2} \,\mathrm{Tr}\big[\mathbf{C}_\ell^{-1}\mathbf{S}_\ell\,\mathbf{C}_\ell^{-1}\mathbf{S}_\ell\big], \tag{T1.18}$$

which for one bin reduces to (T1.17). The fifteen distinct spectra are the entries of $\mathbf{S}_\ell$, and the inverse $\mathbf{C}_\ell^{-1}$ accounts for the correlations between bins that Figure T1.11 shows, so that shared information is not counted twice. Summing over $10 \le \ell \le 2000$, the total signal-to-noise ratio is 48. A single unbinned sample, with five times the galaxies and so a fifth of the noise, gives 42. The ratio is $48/42 \approx 1.14$: tomography adds about 14% to the detection. What it buys is the redshift dependence, which separates the growth of structure from the geometry and helps tell intrinsic alignments from lensing.

How well is the amplitude measured? If σ_8 were the only unknown, the Fisher information on $\ln\sigma_8$ is (T1.18) with each $\mathbf{S}_\ell$ replaced by the derivative $\partial\mathbf{C}_\ell/\partial\ln\sigma_8$ (the general form is (10.20)), and with a single parameter the error is $\sigma(\ln\sigma_8) = 1/\sqrt{F}$. The derivative comes from two more CAMB runs at $\sigma_8(1\pm\epsilon)$ with $\epsilon = 0.02$, as a central difference (Section 10.5):

$$\frac{\partial\mathbf{C}_\ell}{\partial\ln\sigma_8} \approx \frac{\mathbf{C}_\ell^+ - \mathbf{C}_\ell^-}{\ln(1+\epsilon) - \ln(1-\epsilon)} \approx \frac{\mathbf{C}_\ell^+ - \mathbf{C}_\ell^-}{2\epsilon}.$$

The result is $\sigma(\ln\sigma_8) = 0.8\%$. It can be checked against the signal-to-noise ratio. If the derivative were a fixed multiple s of the signal, $\partial\mathbf{C}_\ell/\partial\ln\sigma_8 = s\,\mathbf{S}_\ell$, then $F = s^2(S/N)^2$ and $\sigma(\ln\sigma_8) = 1/[s\,(S/N)]$. In linear theory $s = 2$, giving $1/(2\times48) = 1.0\%$. The computed 0.8% corresponds to $s \approx 1/(0.008\times48) \approx 2.6$, between the linear 2 and the 2.8 found at $\ell = 500$ in Section T1.7.5: the non-linear boost again.

At fixed Ω_m this is also the error on S_8. KiDS-1000 achieves about 3%. The gap between the two numbers is the content of the later chapters. The first cost can be sized here. Ω_m is free and

degenerate with σ_8 (Section T1.7). For two parameters with Fisher matrix entries $F_{\sigma\sigma}$, $F_{\Omega\Omega}$ and $F_{\sigma\Omega}$,

$$\sigma^2_{\mathrm{marg}}(\ln\sigma_8) \overset{(1)}{=} \left(F^{-1}\right)_{\sigma\sigma} \overset{(2)}{=} \frac{F_{\Omega\Omega}}{F_{\sigma\sigma}F_{\Omega\Omega} - F^2_{\sigma\Omega}} \overset{(3)}{=} \frac{1}{F_{\sigma\sigma}}\,\frac{1}{1-r^2}, \qquad r \equiv \frac{F_{\sigma\Omega}}{\sqrt{F_{\sigma\sigma}F_{\Omega\Omega}}}. \tag{T1.19}$$

(1) The marginal error is read from the inverse of the Fisher matrix (Section 10.4.3).
(2) The inverse of a 2×2 matrix.
(3) Divide the numerator and the denominator by $F_{\sigma\sigma}F_{\Omega\Omega}$; r is the cosine of the angle between the two derivative curves, weighted as in the Fisher sum.

So freeing Ω_m multiplies the error on $\ln\sigma_8$ by $1/\sqrt{1-r^2}$: by 2.3 for $r = 0.9$ and by 7 for $r = 0.99$, and the near-proportional derivative curves of Section T1.7 put r close to one. The combination S_8 is chosen to lie along the well-measured direction, so its error grows much less, which is why the surveys quote it. The rest of the gap comes from the other costs. Nuisance parameters for photo-z shifts, shear bias, intrinsic alignment and baryons are marginalised. The covariance has non-Gaussian and super-sample terms that Eq. (T1.16) ignores. And the smallest scales are cut because baryonic feedback is uncertain there. Chapter 10 computes each of these costs in the Fisher matrix, and Chapter 12 redoes the forecast with simulated maps.

How this is used in real research: What the full analysis does

Our numbers come from a Gaussian, nuisance-free forecast with all other parameters fixed. The published analyses measure tomographic $\xi_\pm(\vartheta)$, band powers or related statistics from tens of millions of shapes [45, 49, 50]. They take the covariance from analytic models checked against hundreds to thousands of ray-traced N-body simulations, such as the full-sky lensing maps of [51], and they sample the posterior of cosmological and nuisance parameters by MCMC. The same simulations are what make summaries beyond two-point statistics usable: peak counts [52, 53], Kaiser–Squires mass maps [54], lognormal fields as a fast model of the skewed κ distribution [55], and persistent homology of κ maps [56]. All of these return in Chapter 12.

The lesson of the two experiments for the rest of the book is in two parts. The signal is a projected, smoothed field whose two-point statistic is degenerate along S_8. The noise is white, large and known. So the statistical problem is to extract as much as possible from a noisy, non-Gaussian field with a small number of summaries. Chapter 12 takes up that problem with topological summaries.

Recap

- Lensing distorts galaxy images by about 1%: $\kappa = \frac{1}{2}\nabla^2\psi$ magnifies, the spin-2 shear $\gamma_1 = \frac{1}{2}(\psi_{,11} - \psi_{,22})$, $\gamma_2 = \psi_{,12}$ stretches; a galaxy measures $\varepsilon \approx \varepsilon^{(0)} + \gamma$, with the reduced shear $\gamma/(1-\kappa)$ as its mean.
- Lensing makes only E modes; a B mode is a null test for systematics.
- $C_\ell^{\kappa\kappa}$ is the Limber integral of $[g/a]^2 P_\delta$ over distance, with the broad lensing efficiency $g(\chi)$; CAMB computes it with lensing source windows, and our own integral agrees to 0.1%.
- Cosmic shear measures $\sigma_8\Omega_m^\alpha$ with $\alpha \approx 0.55$ for a Stage-III sample (S_8 takes $\alpha = 0.5$); along that line the spectrum changes by a few per cent, across it by $\sim 20\%$ for a 9% change in S_8.
- Shape noise $N_i = \sigma_e^2/\bar{n}_i$ is white; for a KiDS-like survey the signal beats it only up to

$\ell \approx 21$–194 per bin; total $S/N \approx 48$, $\sigma(\ln \sigma_8) = 0.8\%$ with everything else fixed, against $\approx 3\%$ achieved with nuisances marginalised.

- Nuisances: photo-z shifts, shear bias m, intrinsic alignments, baryonic feedback. CMB lensing (ψ reconstructed by a quadratic estimator) weights $z \approx 2$ and measures $\sigma_8 \Omega_m^{0.25}$.

T1.9 Polarization: sticks on the sky, and two kinds of pattern

So far the microwave sky has been a map of one number per direction, the temperature. Its statistics are the $a_{\ell m}$ and their variance C_ℓ (Section T1.2), and one sky is one draw from them. That description already handles everything in the temperature map: its acoustic peaks, its parameters, its scatter. Weak lensing then showed us a sky whose value at each point is not a number but a short stick without an arrowhead, the shear of a galaxy image, and it gave us the rule for how such a stick is written and how it changes when the axes turn (Section T1.5).

The microwave light carries a stick too. It is partly linearly polarized: at each point of the sky the electric field oscillates a little more along one direction than along the one at right angles. A temperature map cannot tell left from right. A field of sticks can.

Picture two wheels. The first is an old cart wheel, its spokes running straight out from the hub. The second is a toy pinwheel, its blades all leaning the same way, so that it swirls. Hold each in front of a mirror. The cart wheel in the mirror is the same cart wheel. The pinwheel in the mirror swirls the other way: a left-handed pinwheel has become a right-handed one. Now take the cart wheel and twist every spoke by the same small angle at the hub. It has become a faint pinwheel, and a pinwheel of one particular hand, set by the sense of the twist. A smudge on the glass that blurs the spokes in random directions would also spoil the clean radial pattern, but it would not prefer one hand: averaged over many wheels, it makes as many left swirls as right ones.

The polarization of the microwave sky behaves in the same way. Its sticks can be split into a spoke-like part, called E, and a pinwheel-like part, called B. The ordinary physics that made the sky at last scattering does not know left from right, so it cannot produce a net handedness. If something on the way to us twists every stick by the same angle β, part of E turns into B, and the new B has a definite hand, which appears as a correlation between E and B. Gravitational lensing, which plays the part of the smudge, also turns E into B, but without a hand. Everything that follows is a search for that hand.

The twist in symbols. Take one stick of length P at an angle ψ from a fixed reference axis, and recall from Eq. (T1.5) that a headless stick is described by the complex number $Pe^{2i\psi}$, the factor 2 because the stick at $\psi + \pi$ is the same stick. Let the stick be a spoke: it points from a hub at position angle φ, so $\psi = \varphi$. Twist it by β, so $\psi = \varphi + \beta$, and ask how much of it is still a spoke and how much now leans at 45° to the spoke direction, the pinwheel direction. Measured from the spoke direction, the twisted stick is $Pe^{2i\beta} = P\cos 2\beta + iP\sin 2\beta$: a spoke part $P\cos 2\beta$ and a pinwheel part $P\sin 2\beta$. There are two dials, the twist β and the hand, which is the sign of β. The naive way to detect the twist is to look for pinwheel power. That power is $P^2 \sin^2 2\beta$, which for a twist of a third of a degree is about 1.5×10^{-4} of the spoke power, and lensing makes pinwheel power of its own. The good choice is the product of the spoke part and the pinwheel part, $P^2 \cos 2\beta \sin 2\beta = \frac{1}{2} P^2 \sin 4\beta$. It is linear in β for small twists, it changes sign with the hand, and lensing gives zero for it on average. Its price is that we must know which way our own reference axis points to better than β: an instrument whose axis is off by an angle α adds α to every ψ, and that is a twist too. For the Planck satellite the uncertainty of α is 0.28° [57], as large as the twist that has been reported. Lesson: a twist shows up first in a cross product that changes sign in a mirror, not in power, and the instrument's own orientation is the

first thing it can be confused with.

A picture: gradient and curl. An ordinary vector field in a plane splits into a part that is the gradient of something, flowing straight out of hills and into valleys, and a part that is a curl, circulating around them. E and B are the same split for headless sticks. Around a hot or cold patch, E sticks line up along the radius or around the circle, the spokes and rims of a wheel; B sticks lean at 45° and swirl. A mirror leaves gradients alone and reverses circulation, so it leaves E alone and reverses B.

One idea, many names. A quantity that changes sign in a mirror is called a pseudoscalar, and a nonzero average of one means that the laws producing the data distinguish left from right. In particle physics this is a parity-violation test: in 1957 the electrons from polarized cobalt-60 nuclei were found to leave preferentially opposite to the nuclear spin, a correlation between a vector and an axial vector that a mirror reverses. In chemistry it is chirality, the handedness of a molecule, and in fluids it is helicity. In each case the statistic that detects the handedness is linear in a parity-odd quantity, and its expected value is zero when the laws are mirror symmetric. The mathematical language is that of how objects change under rotations and reflections, which is why spin weights and Fourier modes do all the work below.

We first write the stick in terms of the measured Stokes numbers and derive what a twist does to them, then split a field of sticks into E and B, show what a mirror does to each, and see why the ordinary sky has no EB and no TB. Section T1.10 then follows the twist and the smudge through to the power spectra.

T1.9.1 Stokes Q and U, and what a twist does to them

An instrument does not see sticks. It sees intensities. Fix two axes $\boldsymbol{e}_1, \boldsymbol{e}_2$ across the line of sight, and write the electric field of a wave as $a_1 e^{i\theta_1}$ along $\boldsymbol{e}_1$ and $a_2 e^{i\theta_2}$ along $\boldsymbol{e}_2$, with amplitudes a_1, a_2 and phases θ_1, θ_2. The cosmology notes define the four **Stokes parameters** as time averages,

$$I = \langle a_1^2 \rangle + \langle a_2^2 \rangle, \qquad Q = \langle a_1^2 \rangle - \langle a_2^2 \rangle, \qquad U = 2\langle a_1 a_2 \cos(\theta_1 - \theta_2) \rangle, \tag{T1.20}$$

plus a fourth, V, for circular polarization, which Thomson scattering does not produce and which we drop. I is the total intensity, which for the CMB we write as the temperature T. Q is the excess of intensity along $\boldsymbol{e}_1$ over $\boldsymbol{e}_2$, measured by a detector that compares the two. U is the same excess for a pair of axes turned by 45°.

Where is the stick? Take a wave linearly polarized along a direction at angle ψ from $\boldsymbol{e}_1$, with amplitude a. Its two components oscillate in step, $\theta_1 = \theta_2$, with $a_1 = a\cos\psi$ and $a_2 = a\sin\psi$. Then

$$\begin{aligned} Q &\overset{(1)}{=} a^2\cos^2\psi - a^2\sin^2\psi \overset{(2)}{=} a^2\cos 2\psi, \\ U &\overset{(3)}{=} 2a^2\cos\psi\sin\psi \overset{(4)}{=} a^2\sin 2\psi, \\ Q + iU &\overset{(5)}{=} P\, e^{2i\psi}, \qquad P \equiv \sqrt{Q^2+U^2} = a^2. \end{aligned} \tag{T1.21}$$

(1) Insert $a_1 = a\cos\psi$, $a_2 = a\sin\psi$ into the definition of Q; for a steady wave the time average does nothing.
(2) The double-angle identity $\cos^2\psi - \sin^2\psi = \cos 2\psi$.
(3) The definition of U with $\cos(\theta_1 - \theta_2) = \cos 0 = 1$.
(4) The double-angle identity $2\sin\psi\cos\psi = \sin 2\psi$.
(5) Euler's formula, $\cos 2\psi + i\sin 2\psi = e^{2i\psi}$. P is the polarized intensity, here all of I because the wave is fully polarized; an unpolarized part would add to I and nothing to Q or U.

So the measured pair (Q, U) is the stick of Section T1.5: its length is P, its angle is $\psi = \frac{1}{2}\arctan(U/Q)$ (taken in the right quadrant), and the factor two makes ψ and $\psi + 180°$ the same stick. Figure T1.13 is the dictionary: $Q > 0$ is a stick along $\boldsymbol{e}_1$, $Q < 0$ along $\boldsymbol{e}_2$, $U > 0$ and $U < 0$ the two diagonals.

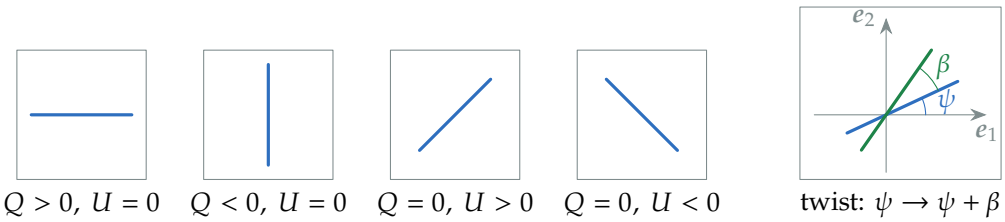

Figure T1.13: The Stokes dictionary. Each square shows one point of the sky with the polarization stick that the pair (Q, U) describes: along the first reference axis, along the second, and along the two diagonals. On the right, a stick at angle ψ (blue) is twisted by β (green); the twist adds β to ψ and so multiplies $Q + iU$ by $e^{2i\beta}$.

What a twist does. Suppose something turns the plane of polarization by an angle β, in the sense from $\boldsymbol{e}_1$ towards $\boldsymbol{e}_2$, without changing its strength. The stick at ψ becomes a stick at $\psi + \beta$ with the same P. Then

$$Q' + iU' \overset{(1)}{=} P\, e^{2i(\psi+\beta)} \overset{(2)}{=} e^{2i\beta}\,(Q + iU), \qquad Q' - iU' \overset{(3)}{=} e^{-2i\beta}\,(Q - iU),$$
$$\begin{pmatrix} Q' \\ U' \end{pmatrix} \overset{(4)}{=} \begin{pmatrix} \cos 2\beta & -\sin 2\beta \\ \sin 2\beta & \cos 2\beta \end{pmatrix} \begin{pmatrix} Q \\ U \end{pmatrix}. \tag{T1.22}$$

(1) (T1.21) for the twisted stick, whose angle is $\psi + \beta$ and whose length is unchanged.
(2) Split the exponential, $e^{2i(\psi+\beta)} = e^{2i\beta}e^{2i\psi}$, and use (T1.21) again for the untwisted stick.
(3) Q and U are real, so the complex conjugate of the first equation is the second.
(4) Write $e^{2i\beta} = \cos 2\beta + i \sin 2\beta$, multiply out $(\cos 2\beta + i \sin 2\beta)(Q + iU)$, and read off the real part Q' and the imaginary part U'.

The pair (Q, U) turns like a vector, but by twice the angle. A partly polarized wave obeys the same rule, because its unpolarized part sits in I and does not move, and every point of the sky obeys it with the same β if the cause of the twist is the same everywhere.

Example: three twists of one stick. Let a stick lie along $\boldsymbol{e}_1$, so $(Q, U) = (P, 0)$. A twist of $\beta = 45°$ gives $(Q', U') = (P\cos 90°, P \sin 90°) = (0, P)$: the stick is now on the diagonal and all of the signal has moved from Q to U. A twist of 90° gives $(-P, 0)$: the stick stands along $\boldsymbol{e}_2$, and Q has changed sign. A twist of $\beta = 0.35°$ gives $Q' = P\cos 0.70° = 0.99993\,P$ and $U' = P \sin 0.70° = 0.0122\,P$: a 1.2% leak of signal into U and a loss in Q of only 7×10^{-5}. Small twists move signal linearly in β and power quadratically.

A twist of the sticks or a turn of the axes? Equation (T1.5) said that turning the *axes* by α multiplies $Q + iU$ by $e^{-2i\alpha}$. That is the same stick described by a turned observer, so it changes the numbers and nothing physical. A twist turns the sticks themselves. The two are mirror images of each other in the formula, and that matters for an instrument: a detector whose reference axis is turned by $-\alpha$ from where we believe it to be reads every stick as if it had been twisted by $+\alpha$. In the data a miscalibrated axis and a physical twist look identical. We return to this in Sections T1.10.6 and T1.12.3.

Watch out: Two sign conventions for U

The angle ψ can be measured from north towards east, as astronomers do (the IAU convention), or towards west, which is the convention of HEALPix and of the Planck maps. Changing convention flips the sign of U, and therefore the sign of every twist angle, of B, and of the EB and TB spectra built below. A twist reported as positive in one convention is negative in the other. Always check which convention a map and a paper use before comparing signs.

T1.9.2 E and B on a small patch of sky

The numbers Q and U at a point depend on the axes we chose there, so they are not a good description of a pattern: turn the axes and they change. We want two fields that describe the pattern itself. On a small patch of sky, treated as flat with angular coordinates $\boldsymbol{\theta} = (\theta_1, \theta_2)$ as in Section T1.5, the natural way is to take the pattern apart into waves. Write each field as a sum of plane waves, $f(\boldsymbol{\theta}) = \int \frac{\mathrm{d}^2\boldsymbol{\ell}}{(2\pi)^2} f(\boldsymbol{\ell})\, e^{i\boldsymbol{\ell}\cdot\boldsymbol{\theta}}$, where the wavevector $\boldsymbol{\ell}$ points at the angle $\varphi_{\boldsymbol{\ell}}$ from $\boldsymbol{e}_1$, and its length ℓ plays the part of the multipole.

Which axes does one wave pick? A single plane wave has one direction of its own, the direction of $\boldsymbol{\ell}$. So for that wave there is a natural pair of axes: the first along $\boldsymbol{\ell}$, the second across it. Read the Stokes numbers of the wave in those axes, which means turning the axes by $\varphi_{\boldsymbol{\ell}}$ and applying Eq. (T1.5). The two numbers we get are called E and B:

$$E(\boldsymbol{\ell}) + iB(\boldsymbol{\ell}) \overset{(1)}{=} e^{-2i\varphi_{\boldsymbol{\ell}}}\big[Q(\boldsymbol{\ell}) + iU(\boldsymbol{\ell})\big], \qquad E(\boldsymbol{\ell}) - iB(\boldsymbol{\ell}) \overset{(2)}{=} e^{2i\varphi_{\boldsymbol{\ell}}}\big[Q(\boldsymbol{\ell}) - iU(\boldsymbol{\ell})\big],$$
$$E(\boldsymbol{\ell}) \overset{(3)}{=} \cos 2\varphi_{\boldsymbol{\ell}}\, Q(\boldsymbol{\ell}) + \sin 2\varphi_{\boldsymbol{\ell}}\, U(\boldsymbol{\ell}), \qquad B(\boldsymbol{\ell}) \overset{(4)}{=} -\sin 2\varphi_{\boldsymbol{\ell}}\, Q(\boldsymbol{\ell}) + \cos 2\varphi_{\boldsymbol{\ell}}\, U(\boldsymbol{\ell}). \quad \text{(T1.23)}$$

(1) Turning the axes by $\varphi_{\boldsymbol{\ell}}$ multiplies $Q + iU$ by $e^{-2i\varphi_{\boldsymbol{\ell}}}$ (T1.5); this holds wave by wave because the turn is the same at every point of the wave.
(2) The same for $Q - iU$, which picks up the opposite phase. In Fourier space $Q(\boldsymbol{\ell})$ and $U(\boldsymbol{\ell})$ are complex, so the second line is a separate statement, not the complex conjugate of the first.
(3) Add the two equations of the first line and divide by two: $e^{\mp 2i\varphi}$ combine into $\cos 2\varphi$ and $\sin 2\varphi$.
(4) Subtract them and divide by $2i$.

In words: E is the part of each wave whose sticks lie along or across its wavevector, and B is the part whose sticks lean at 45° to it. The first row of Figure T1.14 shows one wave of each. This choice of axes uses nothing but the wave itself, so E and B do not depend on how we oriented $\boldsymbol{e}_1, \boldsymbol{e}_2$; they describe the pattern.

Are these the same E and B that weak lensing used, Section T1.6, where they were defined by $\Delta E = (\partial_1^2 - \partial_2^2)Q + 2\partial_1\partial_2 U$ and $\Delta B = -2\partial_1\partial_2 Q + (\partial_1^2 - \partial_2^2)U$ with γ_1, γ_2 in place of Q, U? On one wave each derivative ∂_a becomes a factor $i\ell_a$, with $\ell_1 = \ell\cos\varphi_{\boldsymbol{\ell}}$ and $\ell_2 = \ell\sin\varphi_{\boldsymbol{\ell}}$, so

$$-\ell^2 E(\boldsymbol{\ell}) \overset{(1)}{=} -(\ell_1^2 - \ell_2^2)\, Q(\boldsymbol{\ell}) - 2\ell_1\ell_2\, U(\boldsymbol{\ell}) \overset{(2)}{=} -\ell^2\big[\cos 2\varphi_{\boldsymbol{\ell}}\, Q(\boldsymbol{\ell}) + \sin 2\varphi_{\boldsymbol{\ell}}\, U(\boldsymbol{\ell})\big],$$
$$-\ell^2 B(\boldsymbol{\ell}) \overset{(1)}{=} 2\ell_1\ell_2\, Q(\boldsymbol{\ell}) - (\ell_1^2 - \ell_2^2)\, U(\boldsymbol{\ell}) \overset{(2)}{=} -\ell^2\big[-\sin 2\varphi_{\boldsymbol{\ell}}\, Q(\boldsymbol{\ell}) + \cos 2\varphi_{\boldsymbol{\ell}}\, U(\boldsymbol{\ell})\big]. \quad \text{(T1.24)}$$

(1) The Laplacian becomes $-\ell^2$, $\partial_1^2 - \partial_2^2$ becomes $-(\ell_1^2 - \ell_2^2)$, and $2\partial_1\partial_2$ becomes $-2\ell_1\ell_2$.
(2) $\ell_1^2 - \ell_2^2 = \ell^2(\cos^2\varphi - \sin^2\varphi) = \ell^2\cos 2\varphi$ and $2\ell_1\ell_2 = \ell^2\sin 2\varphi$.

Dividing by $-\ell^2$ gives back (T1.23): the two definitions agree. The derivative form says that E and B at a point depend on Q and U all around it. One stick does not know whether it belongs to an E or a B pattern; only its neighbours do.

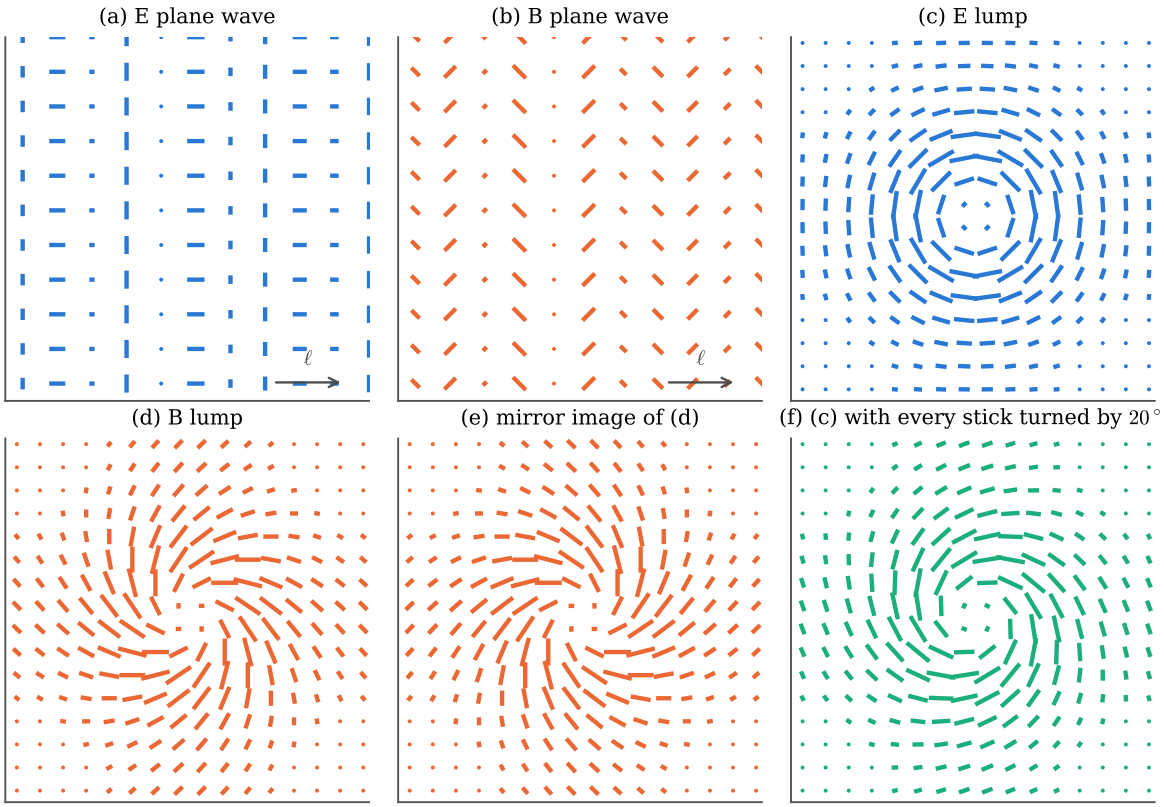

Figure T1.14: Pure E and pure B patterns as fields of sticks (stick length proportional to P). (a) One plane wave of E, wavevector along the first axis (arrow): the sticks lie along the wavevector where the wave is positive and across it where it is negative. (b) The same wave of B: the sticks lean at ±45°. (c) A localised lump of E: rings and spokes. (d) A lump of B: a swirl. (e) The mirror image of (d), reflected top to bottom: it swirls the other way, and it is exactly the B lump with its sign reversed. (f) The E lump of (c) with every stick twisted by 20°: it now swirls, and it is $\cos 40°$ of the E lump plus $\sin 40°$ of a B lump.

Example: what each lump is made of. The script `code/chT1/05_eb_patterns.py` builds the six panels of Figure T1.14 from (T1.23) run backwards, $Q + iU = e^{2i\varphi_\ell}(E + iB)$ wave by wave, and then recovers E and B from the sticks. For the twisted lump of panel (f) the recovered fields are $\cos 40°$ times the original E and $\sin 40°$ times it as B, to a relative error of 2.600×10^{-11}, round-off. That is the rule (T1.22) at work on a whole pattern, and Section T1.10 derives it in general.

Working definition T1.1 (E and B modes)

For each Fourier wave of a polarization pattern, E and B are the Stokes parameters Q and U read in axes aligned with the wavevector: $E(\boldsymbol{\ell}) + iB(\boldsymbol{\ell}) = e^{-2i\varphi_\ell}[Q(\boldsymbol{\ell}) + iU(\boldsymbol{\ell})]$. E sticks lie along or across the wavevector, B sticks at 45° to it. *Operational:* Fourier-transform the Q and U maps, combine them with (T1.23), and on the full sky use the spin-2 harmonic transform of `healpy` (`map2alm` with T, Q, U), which returns $T_{\ell m}, E_{\ell m}, B_{\ell m}$.

T1.9.3 The whole sky

On the whole sphere the plane waves are replaced by spherical harmonics, and the stick-carrying fields need their spin-weighted version. Spin-weighted harmonics ${}_{\pm2}Y_{\ell m}$ are the functions that turn by $e^{\mp 2i\psi}$ when the local axes turn by ψ, just as $Q \pm iU$ do, so they are the natural basis for

$Q \pm iU$; they are built from the ordinary $Y_{\ell m}$ by two derivatives (see the cosmology notes, and [58, 59]). With the sign convention of the cosmology notes and of [58],

$$(Q \pm iU)(\boldsymbol{n}) = -\sum_{\ell \geq 2} \sum_{m=-\ell}^{\ell} \left(E_{\ell m} \pm iB_{\ell m}\right) {}_{\pm 2}Y_{\ell m}(\boldsymbol{n}). \tag{T1.25}$$

The sum starts at $\ell = 2$ because a stick pattern has no monopole or dipole. On small scales this becomes the flat-sky (T1.23), wave by wave, and the overall minus sign is a convention that the flat-sky form hides in its Fourier phases. The temperature has its own coefficients $T_{\ell m}$, the $a_{\ell m}$ of Section T1.2.

The three sets $T_{\ell m}$, $E_{\ell m}$, $B_{\ell m}$ are Gaussian random numbers with mean zero, like the $a_{\ell m}$ of Chapter 7, but now they can be correlated with each other at the same (ℓ, m). For any two of them, $X, Y \in \{T, E, B\}$, the **angular cross-spectrum** is

$$\langle X_{\ell m} Y^*_{\ell' m'} \rangle = \delta_{\ell\ell'}\delta_{mm'}\, C_\ell^{XY}, \qquad \widehat{C}_\ell^{XY} = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} \mathrm{Re}\left(X_{\ell m} Y^*_{\ell m}\right). \tag{T1.26}$$

There are six: TT, EE, BB, TE, EB and TB. On a flat patch the same definition reads $\langle X(\boldsymbol{\ell}) Y^*(\boldsymbol{\ell}')\rangle = (2\pi)^2 \delta^2(\boldsymbol{\ell} - \boldsymbol{\ell}')\, C_\ell^{XY}$. The CAMB fiducial of `code/camb_fiducial.py` returns four of them, TT, EE, BB and TE, and none of EB or TB. The next subsection says why.

T1.9.4 What a mirror does

The event. The fiducial spectra contain no EB and no TB. *What would it take to produce them?* The answer comes from the mirror test of the opening, now done with the formulas.

Reflect the patch of sky in the line $\theta_2 = 0$: the mirror sends the point (θ_1, θ_2) to $(\theta_1, -\theta_2)$. A stick at angle ψ appears in the mirror at $-\psi$. By (T1.21) that leaves $Q = P\cos 2\psi$ unchanged and flips $U = P \sin 2\psi$. So the mirrored sky has $Q^{\mathrm{M}}(\theta_1, \theta_2) = Q(\theta_1, -\theta_2)$, $U^{\mathrm{M}}(\theta_1, \theta_2) = -U(\theta_1, -\theta_2)$ and $T^{\mathrm{M}}(\theta_1, \theta_2) = T(\theta_1, -\theta_2)$. In Fourier space a field flipped in θ_2 has its waves flipped in ℓ_2, so with $\bar{\boldsymbol{\ell}} \equiv (\ell_1, -\ell_2)$, whose angle is $\varphi_{\bar{\ell}} = -\varphi_\ell$,

$$\begin{aligned}
E^{\mathrm{M}}(\boldsymbol{\ell}) &\overset{(1)}{=} \cos 2\varphi_\ell\, Q(\bar{\boldsymbol{\ell}}) - \sin 2\varphi_\ell\, U(\bar{\boldsymbol{\ell}}) \overset{(2)}{=} \cos 2\varphi_{\bar{\ell}}\, Q(\bar{\boldsymbol{\ell}}) + \sin 2\varphi_{\bar{\ell}}\, U(\bar{\boldsymbol{\ell}}) \overset{(3)}{=} E(\bar{\boldsymbol{\ell}}), \\
B^{\mathrm{M}}(\boldsymbol{\ell}) &\overset{(1)}{=} -\sin 2\varphi_\ell\, Q(\bar{\boldsymbol{\ell}}) - \cos 2\varphi_\ell\, U(\bar{\boldsymbol{\ell}}) \overset{(2)}{=} -\left[-\sin 2\varphi_{\bar{\ell}}\, Q(\bar{\boldsymbol{\ell}}) + \cos 2\varphi_{\bar{\ell}}\, U(\bar{\boldsymbol{\ell}})\right] \overset{(3)}{=} -B(\bar{\boldsymbol{\ell}}), \\
T^{\mathrm{M}}(\boldsymbol{\ell}) &= T(\bar{\boldsymbol{\ell}}).
\end{aligned} \tag{T1.27}$$

(1) (T1.23) applied to the mirrored maps: $Q^{\mathrm{M}}(\boldsymbol{\ell}) = Q(\bar{\boldsymbol{\ell}})$ and $U^{\mathrm{M}}(\boldsymbol{\ell}) = -U(\bar{\boldsymbol{\ell}})$.
(2) $\varphi_{\bar{\ell}} = -\varphi_\ell$, so $\cos 2\varphi_\ell = \cos 2\varphi_{\bar{\ell}}$ and $\sin 2\varphi_\ell = -\sin 2\varphi_{\bar{\ell}}$.
(3) (T1.23) again, now at the wavevector $\bar{\boldsymbol{\ell}}$.

A mirror carries E into E and B into $-B$, as panels (d) and (e) of Figure T1.14 show; the script finds the mirrored B lump equal to minus the original to a relative error of 3.400×10^{-11}. On the whole sky the corresponding statement is about the reflection through the centre, $\boldsymbol{n} \to -\boldsymbol{n}$, under which $T_{\ell m} \to (-1)^\ell T_{\ell m}$, $E_{\ell m} \to (-1)^\ell E_{\ell m}$ and $B_{\ell m} \to (-1)^{\ell+1} B_{\ell m}$ [57, 59]: again B has the opposite sign to E and T. E is called a scalar and B a **pseudoscalar**.

Now the spectra. Suppose the laws that produced the sky do not distinguish left from right. Then the mirror image of our sky is exactly as probable as our sky itself, so its spectra are the same as ours. But by (T1.27) its cross-spectra are

$$\begin{aligned}
&C_\ell^{EB,\mathrm{M}} \overset{(1)}{=} -C_\ell^{EB}, \qquad C_\ell^{TB,\mathrm{M}} \overset{(1)}{=} -C_\ell^{TB}, \qquad C_\ell^{XY,\mathrm{M}} \overset{(2)}{=} C_\ell^{XY} \;\; (XY = TT, EE, BB, TE), \\
&C_\ell^{EB} \overset{(3)}{=} -C_\ell^{EB} \implies C_\ell^{EB} = 0, \qquad C_\ell^{TB} = 0.
\end{aligned} \tag{T1.28}$$

(1) Insert $E^{\mathrm{M}}(\boldsymbol{\ell}) = E(\bar{\boldsymbol{\ell}})$, $B^{\mathrm{M}}(\boldsymbol{\ell}) = -B(\bar{\boldsymbol{\ell}})$, $T^{\mathrm{M}}(\boldsymbol{\ell}) = T(\bar{\boldsymbol{\ell}})$ into $\langle X(\boldsymbol{\ell}) Y^*(\boldsymbol{\ell}')\rangle$; one minus sign comes out, and $\bar{\boldsymbol{\ell}}$ has the same length ℓ as $\boldsymbol{\ell}$, so the spectrum is evaluated at the same multipole.
(2) In BB the minus sign appears twice, in the others not at all.
(3) A mirror-symmetric law makes the mirrored sky as probable as ours, so its spectra equal ours; with the first line, C^{EB} equals its own negative.

Four of the six spectra survive the mirror, and two, EB and TB, change sign. In a universe whose physics treats left and right alike, the two parity-odd spectra vanish on average. On one sky they are not exactly zero: $\widehat{C}_\ell^{EB}$ scatters around zero from chance alignments, by an amount set by C^{EE} and C^{BB}, just as $\widehat{C}_\ell$ scatters around C_ℓ.

Key idea: EB and TB detect handedness

Under a mirror T and E keep their sign and B reverses. A universe whose laws are mirror symmetric therefore has $C_\ell^{EB} = C_\ell^{TB} = 0$ on average. A nonzero EB or TB on the sky means that something between the emission and our detector picked a hand: a twist of the polarization by new physics, a twist by our own instrument, or a source whose own structure is handed.

T1.9.5 The same mirror, written with matrices

The mirror of Section T1.9.4 was worked out by following one stick: its angle ψ became $-\psi$, so $Q = P\cos 2\psi$ stayed and $U = P\sin 2\psi$ flipped. The same answer comes out of a short matrix calculation, and that calculation does more: it applies unchanged to the strain of a gravitational wave, and it shows which statements about even and odd are properties of a pattern and which are properties of the axes we happened to choose.

The mirror as a matrix. Put the line of sight along z and the two sky axes $\boldsymbol{e}_1, \boldsymbol{e}_2$ along x and y. The mirror $\theta_2 \to -\theta_2$ is the reflection $(x, y, z) \to (x, -y, z)$, which acts on the components of any arrow as the matrix

$$\mathsf{P}_T = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad \mathsf{P}_T^{\mathsf{T}} = \mathsf{P}_T, \qquad \mathsf{P}_T^2 = \mathbb{1}. \tag{T1.29}$$

The subscript T says that it reflects a transverse direction, across the line of sight, and leaves the direction of travel alone. Reflecting twice changes nothing, which is $\mathsf{P}_T^2 = \mathbb{1}$.

How does a tensor feel the mirror? The simplest tensor is a product of two arrows. Take the electric field of a wave, an arrow with components E_a, and form the table of products $T_{ab} = \langle E_a E_b\rangle$. In the mirror every arrow becomes $\boldsymbol{E}' = \mathsf{P}_T \boldsymbol{E}$, so

$$T'_{ab} \overset{(1)}{=} \langle E'_a E'_b\rangle \overset{(2)}{=} \sum_{c,d} (\mathsf{P}_T)_{ac} (\mathsf{P}_T)_{bd} \langle E_c E_d\rangle \overset{(3)}{=} \left(\mathsf{P}_T\, T\, \mathsf{P}_T^{\mathsf{T}}\right)_{ab},$$

$$T'_{ab} \overset{(4)}{=} s_a s_b\, T_{ab}, \qquad (s_x, s_y, s_z) = (1, -1, 1). \tag{T1.30}$$

(1) The mirrored table is built from the mirrored arrow.
(2) Write each component of $\boldsymbol{E}' = \mathsf{P}_T \boldsymbol{E}$ as a sum, $E'_a = \sum_c (\mathsf{P}_T)_{ac} E_c$; the matrix entries are fixed numbers and come out of the average.
(3) The double sum is the matrix product, with the second factor transposed because its index b sits on the left of $(\mathsf{P}_T)_{bd}$.
(4) P_T is diagonal with entries s_a, so only $c = a$ and $d = b$ survive.

The rule $T' = \mathsf{P}_T T \mathsf{P}_T^{\mathsf{T}}$ holds for every two-index object that turns like a product of two arrows, which includes the strain of space. The last line says it in words: an entry keeps its sign if it carries an even number of y indices and flips if it carries one.

Example: the two polarizations of a gravitational wave. A gravitational wave travelling along z stretches and squeezes space across its direction of travel. Its strain is $h_{ij} = h_+ e^+_{ij} + h_\times e^\times_{ij}$, with the two polarization tensors

$$e^+ = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad e^\times = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{T1.31}$$

The + state stretches along x while it squeezes along y; the × state does the same along the two diagonals (see the cosmology notes). In the mirror,

$$\begin{aligned} \mathsf{P}_T\, e^+\, \mathsf{P}_T^{\mathsf{T}} &\overset{(1)}{=} \begin{pmatrix} 1\cdot 1\cdot 1 & 0 & 0 \\ 0 & (-1)(-1)(-1) & 0 \\ 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix} = e^+, \\ \mathsf{P}_T\, e^\times\, \mathsf{P}_T^{\mathsf{T}} &\overset{(2)}{=} \begin{pmatrix} 0 & (1)(1)(-1) & 0 \\ (-1)(1)(1) & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = -e^\times, \\ \begin{pmatrix} h_+ \\ h_\times \end{pmatrix} &\overset{(3)}{=} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} h_+ \\ h_\times \end{pmatrix}. \end{aligned} \tag{T1.32}$$

(1) (T1.30) entry by entry: each diagonal entry e^+_{aa} is multiplied by $s_a^2 = 1$, so nothing changes.
(2) The only nonzero entries of $e^\times$ are xy and yx, and each carries one y index, so each is multiplied by $s_x s_y = -1$.
(3) The mirrored strain is $h_+ e^+ - h_\times e^\times$: written in the same two tensors, the mirror keeps the amount h_+ and reverses the amount $h_\times$.

Figure T1.15 shows why. A ring of free particles squeezed into an ellipse along x looks the same in a mirror that flips y. An ellipse along the diagonal from lower left to upper right turns, in that mirror, into an ellipse along the other diagonal, which is the × pattern with the opposite sign.

Example: the Stokes numbers as a tensor. The polarization of the microwave light is a two-index object too. The field across the line of sight has the two complex components $E_1 = a_1 e^{i\theta_1}$ and $E_2 = a_2 e^{i\theta_2}$ of (T1.20). The real part of the table of averages $\langle E_a E_b^* \rangle$ is

$$\begin{aligned} \mathrm{Re} \begin{pmatrix} \langle E_1 E_1^* \rangle & \langle E_1 E_2^* \rangle \\ \langle E_2 E_1^* \rangle & \langle E_2 E_2^* \rangle \end{pmatrix} &\overset{(1)}{=} \begin{pmatrix} \langle a_1^2 \rangle & \langle a_1 a_2 \cos(\theta_1 - \theta_2) \rangle \\ \langle a_1 a_2 \cos(\theta_1 - \theta_2) \rangle & \langle a_2^2 \rangle \end{pmatrix} \overset{(2)}{=} \frac{1}{2} \begin{pmatrix} I + Q & U \\ U & I - Q \end{pmatrix} \\ &\overset{(3)}{=} \frac{I}{2} \mathbb{1} + \mathcal{P}, \qquad \mathcal{P} \equiv \frac{1}{2} \begin{pmatrix} Q & U \\ U & -Q \end{pmatrix} \overset{(4)}{=} \frac{Q}{2} e^+ + \frac{U}{2} e^\times. \end{aligned} \tag{T1.33}$$

(1) $E_a E_b^* = a_a a_b e^{i(\theta_a - \theta_b)}$, whose real part is $a_a a_b \cos(\theta_a - \theta_b)$; on the diagonal the phases cancel.
(2) The definitions (T1.20): $\langle a_1^2 \rangle = \frac{1}{2}(I + Q)$, $\langle a_2^2 \rangle = \frac{1}{2}(I - Q)$, and $\langle a_1 a_2 \cos(\theta_1 - \theta_2) \rangle = \frac{1}{2} U$.
(3) Split off the part proportional to the unit matrix; what is left has zero trace.
(4) Compare entry by entry with the 2×2 blocks of (T1.31) that lie across the line of sight.

(The imaginary part of the table, which is antisymmetric, holds the circular polarization V that Thomson scattering does not produce.) The traceless part $\mathcal{P}_{ab}$ is built from e^+ and $e^\times$

exactly as the strain is, with $Q/2$ in place of h_+ and $U/2$ in place of $h_\times$. So the calculation (T1.32) can be copied line by line: the mirror sends $(Q,U) \to (Q,-U)$ at the mirrored point, and the unit-matrix part, the intensity I, does not change. This is what the stick argument of Section T1.9.4 found.

Example: E and B. By (T1.23), E and B are Q and U turned through the angle $2\varphi_\ell$ of each wavevector:

$$\begin{pmatrix} E \\ B \end{pmatrix}(\boldsymbol{\ell}) = R(-2\varphi_\ell)\begin{pmatrix} Q \\ U \end{pmatrix}(\boldsymbol{\ell}), \qquad R(\vartheta) \equiv \begin{pmatrix} \cos\vartheta & -\sin\vartheta \\ \sin\vartheta & \cos\vartheta \end{pmatrix}. \tag{T1.34}$$

Write $D = \mathrm{diag}(1,-1)$ for the action of the mirror on the pair (Q,U). The mirror does two things to a wave: it flips U, and it turns the wavevector $\boldsymbol{\ell}$ into $\bar{\boldsymbol{\ell}} = (\ell_1, -\ell_2)$, whose angle is $\varphi_{\bar\ell} = -\varphi_\ell$. Then

$$\begin{aligned} \begin{pmatrix} E^{\mathrm{M}} \\ B^{\mathrm{M}} \end{pmatrix}(\boldsymbol{\ell}) &\overset{(1)}{=} R(-2\varphi_\ell)\, D \begin{pmatrix} Q \\ U \end{pmatrix}(\bar{\boldsymbol{\ell}}) \overset{(2)}{=} D\, R(2\varphi_\ell) \begin{pmatrix} Q \\ U \end{pmatrix}(\bar{\boldsymbol{\ell}}) \\ &\overset{(3)}{=} D\, R(-2\varphi_{\bar\ell}) \begin{pmatrix} Q \\ U \end{pmatrix}(\bar{\boldsymbol{\ell}}) \overset{(4)}{=} D \begin{pmatrix} E \\ B \end{pmatrix}(\bar{\boldsymbol{\ell}}). \end{aligned} \tag{T1.35}$$

(1) (T1.34) applied to the mirrored maps, whose Fourier coefficients at $\boldsymbol{\ell}$ are $Q(\bar{\boldsymbol{\ell}})$ and $-U(\bar{\boldsymbol{\ell}})$.
(2) A reflection followed by a turn equals the opposite turn followed by the reflection, $R(\vartheta)D = DR(-\vartheta)$. Check it by multiplying: both sides equal $\begin{pmatrix} \cos\vartheta & \sin\vartheta \\ \sin\vartheta & -\cos\vartheta \end{pmatrix}$.
(3) $2\varphi_\ell = -2\varphi_{\bar\ell}$.
(4) (T1.34) again, now at the wavevector $\bar{\boldsymbol{\ell}}$.

E and B transform with the same matrix D as (Q,U) and $(h_+, h_\times)$: E is even and B is odd. This is (T1.27) in two lines. The reason it works is visible in step 2: the mirror flips U and also flips the angle of the wave, and the two flips meet so that E and B come out with D again.

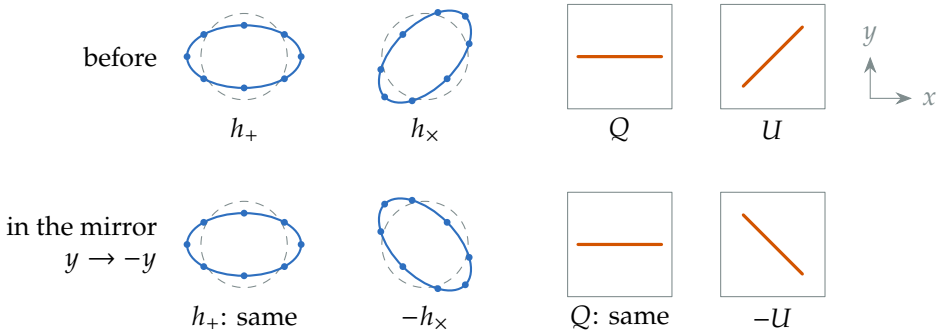

Figure T1.15: One mirror, four objects. Top: a ring of free particles (dashed) deformed by the + and the × polarization of a gravitational wave, and a polarization stick with only Q and with only U. Bottom: the same after the reflection $y \to -y$. The ellipse along x and the stick along x are unchanged. The ellipse and the stick along a diagonal move to the other diagonal, which is the same pattern with its amount reversed.

All in one table. Under the mirror P_T:

	even (sign kept)	odd (sign reversed)
gravitational-wave strain	h_+	$h_\times$
Stokes numbers at a point	$I = T$, Q	U
patterns on the sky	T, E	B

The same matrix is not the same quantity. The table lines up Q, E and h_+ because the mirror acts on each pair with the same matrix diag$(+1, -1)$. That is a statement about the even and odd structure, and nothing more: Q is not E, and h_+ is not E. The difference shows as soon as we use another mirror. Reflect instead in the diagonal line $x = y$, which swaps the two sky axes: its transverse block is $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, and applied to the blocks of (T1.31) it gives $e^+ \to -e^+$ and $e^\times \to e^\times$ (swapping x and y swaps the two diagonal entries of e^+ and leaves $e^\times$ as it was). For that mirror Q and h_+ are odd, and U and $h_\times$ are even. So whether Q is even or odd depends on how the mirror line sits relative to the axes we chose: Q, U and $h_+, h_\times$ are components of one spin-2 tensor in a chosen basis, and the basis decides which component a given mirror flips. E and B were built differently, by reading each wave in axes set by the wave itself, so the answer does not depend on the mirror: every mirror line is the reflection $y \to -y$ seen from turned axes, and E, B do not care about the turn of the axes. E is even and B is odd for every mirror, which is why they, and not Q and U, are the quantities with a definite parity. Nor does the table say that gravitational waves make only E: h_+ and $h_\times$ are the strain in the frame of the wave, and the polarization patterns a gravitational wave leaves on the sky contain both E and B (Section T1.9.6).

Why it matters. A correlation of two quantities picks up the product of their signs. EE, BB, TT and TE multiply even by even or odd by odd and are unchanged by the mirror. EB and TB multiply an even quantity by an odd one and change sign, which is the content of (T1.28). Only physics that tells left from right can make them nonzero on average.

T1.9.6 Where the E modes come from, and how large they are

The CMB is polarized because of Thomson scattering at the last-scattering surface: an electron illuminated more strongly from one direction than from the direction at right angles (a quadrupole in the radiation it sees) scatters light that is linearly polarized [60]; the physics is in the cosmology notes. The quadrupole comes from the flows of the primordial plasma, and a second, smaller dose of polarization was added at reionization, at much larger angular scales.

Which patterns can a density wave produce? A single scalar wave, a plane wave of density in the early universe, has one special direction, its wavevector. Reflect the whole set-up in any plane that contains the wavevector and the line of sight, and nothing changes. By (T1.27) the B part of the pattern it produces must then equal its own negative, so it is zero. Scalar perturbations make only E [59, 61]. A gravitational wave is different: its two polarization states stretch space along crossed axes, and the $\times$ state is not symmetric under that reflection (it changes sign, Eq. (T1.32)), so tensor perturbations make both E and B. This is why B modes became the target of searches for primordial gravitational waves, and why the next sections ask what else can make them.

The fiducial spectra fix the sizes. $D_\ell^{EE} = \ell(\ell+1)C_\ell^{EE}/2\pi$ peaks at $42.4\,\mu\mathrm{K}^2$ near $\ell \approx 990$, so the polarization fluctuations are roughly a tenth of the temperature ones in amplitude. The TE spectrum, with both signs, connects the two. The fiducial BB is not zero, but it contains no primordial gravitational waves: it is the lensing B of Section T1.10.4, which peaks at $D_\ell^{BB} = 0.101\,\mu\mathrm{K}^2$ near $\ell \approx 886$, four hundred times below EE.

T1.10 When power moves from E to B

We now have the rule for one stick, (T1.22): a twist by β multiplies $Q + iU$ by $e^{2i\beta}$. And we have the split of a field of sticks into E and B, with the six spectra C_ℓ^{XY} of (T1.26). That is enough to draw a twisted pattern, as in panel (f) of Figure T1.14. It is not yet enough for data. A CMB

experiment does not compare sticks one by one; it measures the spectra, and the spectra of the sky are known only statistically. The question is what a twist does to the spectra, and how its effect differs from that of anything else that turns E into B.

Think of two radio stations on neighbouring frequencies, a loud one and a nearly silent one. A slightly mistuned receiver lets a little of the loud station into the quiet channel. You hear the leak as extra sound in the quiet channel, but there is a better test than loudness: play the loud station's programme next to the leak and they match, word for word and with the same sign. Now suppose instead the antenna wobbles in the wind, so that the loud programme is added to the quiet channel sometimes with a plus sign and sometimes with a minus sign. You still hear extra sound, as loud as before. But the match with the loud programme averages to zero, because the plus and minus moments cancel. Loudness cannot tell the two leaks apart; the correlation with the source can.

On the sky the loud station is E and the quiet one is B. A twist of every stick by the same angle is the mistuned receiver: it moves a fixed fraction of E into B with a fixed sign, so the new B is correlated with E (and with T, which is correlated with E). Gravitational lensing is the wobbling antenna: it moves E into B through the lensing potential, which is positive in some places and negative in others, so it adds BB power but leaves no EB and no TB on average.

The two leaks in symbols. For one wave, write the mistuned receiver as $B' = sE$ with a fixed number s, and the wobbling antenna as $B' = wE$ with a random w of mean zero and variance σ_w^2, independent of E. The extra power is $\langle |B'|^2 \rangle = s^2 C^{EE}$ in the first case and $\sigma_w^2 C^{EE}$ in the second: equal when $\sigma_w = |s|$, so power cannot tell them apart. The correlation is $\langle B' E^* \rangle = s\, C^{EE}$ in the first case and $\langle w \rangle C^{EE} = 0$ in the second. The dial is the mean of the leak coefficient: a fixed leak has one, a random one does not. Lesson: to identify a twist, measure the correlation EB, not the power BB.

A picture. Plot every mode of the sky as a point in a plane, its E along the horizontal axis and its B along the vertical one. Before any leak the cloud of points is a thin horizontal cigar. A twist turns every point by the same angle, so the cigar tilts, and a tilted cigar is exactly a correlation between the two axes. A random leak pushes each point up or down by a random amount, so the cigar gets fatter but stays horizontal, and a fat horizontal cigar has no correlation.

One idea, many names. A leak with a fixed sign is what an electronics engineer calls coherent cross-talk, and a leak with a random sign incoherent cross-talk; a lock-in amplifier finds a weak signal by correlating with a reference, not by measuring power. In data analysis the same split separates a systematic error, which has a mean and therefore correlates with its cause, from a random one, which only adds variance. The rest of the section turns this into the exact formulas, first for the twist and then for lensing.

T1.10.1 From sticks to harmonic coefficients

What does a uniform twist do to $E_{\ell m}$ and $B_{\ell m}$? Twist every stick of the sky by the same angle β. At every direction $\boldsymbol{n}$, (T1.22) gives $(Q' \pm iU')(\boldsymbol{n}) = e^{\pm 2i\beta}(Q \pm iU)(\boldsymbol{n})$. Insert the harmonic expansion (T1.25) on both sides:

$$
\begin{aligned}
-\sum_{\ell m} \big(E'_{\ell m} \pm iB'_{\ell m}\big)\, {}_{\pm 2}Y_{\ell m}(\boldsymbol{n}) &\overset{(1)}{=} e^{\pm 2i\beta}\Big[-\sum_{\ell m} \big(E_{\ell m} \pm iB_{\ell m}\big)\, {}_{\pm 2}Y_{\ell m}(\boldsymbol{n})\Big] \\
&\overset{(2)}{=} -\sum_{\ell m} e^{\pm 2i\beta} \big(E_{\ell m} \pm iB_{\ell m}\big)\, {}_{\pm 2}Y_{\ell m}(\boldsymbol{n}), \\
E'_{\ell m} \pm iB'_{\ell m} &\overset{(3)}{=} e^{\pm 2i\beta} \big(E_{\ell m} \pm iB_{\ell m}\big). \qquad \text{(T1.36)}
\end{aligned}
$$

(1) The twist rule at each point, with both sides written in the harmonic basis.

(2) β is the same in every direction, so $e^{\pm 2i\beta}$ is a constant and moves inside the sum.
(3) The spin-weighted harmonics are a basis, so two expansions of the same function have the same coefficients.

Now separate E' and B', adding and subtracting the two signs:

$$E'_{\ell m} \overset{(1)}{=} \tfrac{1}{2}\left[e^{2i\beta}(E_{\ell m}+iB_{\ell m}) + e^{-2i\beta}(E_{\ell m}-iB_{\ell m})\right] \overset{(2)}{=} \cos 2\beta\, E_{\ell m} - \sin 2\beta\, B_{\ell m},$$
$$B'_{\ell m} \overset{(3)}{=} \tfrac{1}{2i}\left[e^{2i\beta}(E_{\ell m}+iB_{\ell m}) - e^{-2i\beta}(E_{\ell m}-iB_{\ell m})\right] \overset{(4)}{=} \sin 2\beta\, E_{\ell m} + \cos 2\beta\, B_{\ell m}. \tag{T1.37}$$

(1) Add the + and − versions of (T1.36); the $\pm iB'$ cancel and $2E'$ is left.
(2) Collect: the E terms give $\frac{1}{2}(e^{2i\beta}+e^{-2i\beta}) = \cos 2\beta$; the B terms give $\frac{i}{2}(e^{2i\beta}-e^{-2i\beta}) = \frac{i}{2}\cdot 2i\sin 2\beta = -\sin 2\beta$.
(3) Subtract the two versions; the E' cancel and $2iB'$ is left.
(4) The E terms give $\frac{1}{2i}(e^{2i\beta}-e^{-2i\beta}) = \sin 2\beta$; the B terms give $\frac{i}{2i}(e^{2i\beta}+e^{-2i\beta}) = \cos 2\beta$.

The pair $(E_{\ell m}, B_{\ell m})$ turns like (Q, U) at a point, by the angle 2β, mode by mode and with the same angle for every ℓ and m. The temperature does not change at all, $T'_{\ell m} = T_{\ell m}$, because a twist changes the direction of the polarization and not the intensity. The flat-sky version is the same with $E(\boldsymbol{\ell})$, $B(\boldsymbol{\ell})$ in place of $E_{\ell m}$, $B_{\ell m}$: panel (f) of Figure T1.14, with $2\beta = 40°$, is exactly $\cos 40°$ of E and $\sin 40°$ of B.

T1.10.2 All the rotated spectra

What happens to each of the six spectra? We take them one at a time, starting from a sky that is mirror symmetric before the twist: by (T1.28), $C_\ell^{EB} = C_\ell^{TB} = 0$. Write $c \equiv \cos 2\beta$ and $s \equiv \sin 2\beta$, both real numbers, and use the definition $\langle X_{\ell m} Y^*_{\ell m}\rangle = C_\ell^{XY}$ of (T1.26). The expectation of a sum is the sum of the expectations, and real constants come out of it.

EE: how much E is left?

$$C_\ell^{EE\prime} = \langle E'_{\ell m} E'^*_{\ell m}\rangle \overset{(1)}{=} \left\langle (cE_{\ell m} - sB_{\ell m})(cE^*_{\ell m} - sB^*_{\ell m})\right\rangle$$
$$\overset{(2)}{=} c^2 C_\ell^{EE} - cs\left(C_\ell^{EB} + C_\ell^{BE}\right) + s^2 C_\ell^{BB} \overset{(3)}{=} \cos^2 2\beta\, C_\ell^{EE} + \sin^2 2\beta\, C_\ell^{BB}. \tag{T1.38}$$

(1) Insert E' from (T1.37) and its complex conjugate.
(2) Multiply out and take the expectation term by term.
(3) The sky before the twist has $C_\ell^{EB} = C_\ell^{BE} = 0$.

BB: how much B is there now?

$$C_\ell^{BB\prime} \overset{(1)}{=} \left\langle (sE_{\ell m} + cB_{\ell m})(sE^*_{\ell m} + cB^*_{\ell m})\right\rangle \overset{(2)}{=} s^2 C_\ell^{EE} + sc\left(C_\ell^{EB} + C_\ell^{BE}\right) + c^2 C_\ell^{BB}$$
$$\overset{(3)}{=} \sin^2 2\beta\, C_\ell^{EE} + \cos^2 2\beta\, C_\ell^{BB}. \tag{T1.39}$$

(1) Insert B' from (T1.37).
(2) Multiply out and take expectations.
(3) No EB before the twist.

EB: does the new B remember E?

$$C_\ell^{EB\prime} \overset{(1)}{=} \left\langle (cE_{\ell m} - sB_{\ell m})(sE^*_{\ell m} + cB^*_{\ell m})\right\rangle \overset{(2)}{=} cs\, C_\ell^{EE} + c^2 C_\ell^{EB} - s^2 C_\ell^{BE} - sc\, C_\ell^{BB}$$
$$\overset{(3)}{=} \cos 2\beta \sin 2\beta \left(C_\ell^{EE} - C_\ell^{BB}\right) \overset{(4)}{=} \tfrac{1}{2}\sin 4\beta \left(C_\ell^{EE} - C_\ell^{BB}\right). \tag{T1.40}$$

(1) E' times the complex conjugate of B'.

(2) Multiply out and take expectations.
(3) No EB before the twist; factor out cs.
(4) The double-angle identity $2\sin x\cos x = \sin 2x$ with $x = 2\beta$.

TE and TB: what does the temperature see? The temperature is untouched, so only the second factor changes:

$$C_\ell^{TE\prime} \overset{(1)}{=} \left\langle T_{\ell m}(cE^*_{\ell m} - sB^*_{\ell m})\right\rangle \overset{(2)}{=} c\,C_\ell^{TE} - s\,C_\ell^{TB} \overset{(3)}{=} \cos 2\beta\, C_\ell^{TE},$$
$$C_\ell^{TB\prime} \overset{(1)}{=} \left\langle T_{\ell m}(sE^*_{\ell m} + cB^*_{\ell m})\right\rangle \overset{(2)}{=} s\,C_\ell^{TE} + c\,C_\ell^{TB} \overset{(3)}{=} \sin 2\beta\, C_\ell^{TE}, \qquad C_\ell^{TT\prime} = C_\ell^{TT}. \tag{T1.41}$$

(1) $T'_{\ell m} = T_{\ell m}$, and E', B' from (T1.37), conjugated.
(2) Take the expectations.
(3) No TB before the twist.

Had we kept an EB already present before the twist, the same steps would give $C_\ell^{EB\prime} = \frac{1}{2}\sin 4\beta\,(C_\ell^{EE} - C_\ell^{BB}) + \cos 4\beta\, C_\ell^{EB}$, with the C^{EB} terms of the first two lines adding $\mp \sin 4\beta\, C_\ell^{EB}$ to EE' and BB'; we need this once, in Section T1.12.3.

Key idea: The rotated spectra

A uniform twist β of a parity-symmetric sky gives

$$C_\ell^{EE\prime} = \cos^2 2\beta\, C_\ell^{EE} + \sin^2 2\beta\, C_\ell^{BB}, \qquad C_\ell^{BB\prime} = \sin^2 2\beta\, C_\ell^{EE} + \cos^2 2\beta\, C_\ell^{BB},$$
$$C_\ell^{EB\prime} = \tfrac{1}{2}\sin 4\beta\,\left(C_\ell^{EE} - C_\ell^{BB}\right), \qquad C_\ell^{TE\prime} = \cos 2\beta\, C_\ell^{TE}, \qquad C_\ell^{TB\prime} = \sin 2\beta\, C_\ell^{TE},$$

and leaves C_ℓ^{TT} alone [62, 63]. Power leaves EE and appears in BB; EB and TB appear because the twist has a hand.

T1.10.3 Reading the formulas

Power moves; nothing is lost. Add (T1.38) and (T1.39): $C_\ell^{EE\prime} + C_\ell^{BB\prime} = C_\ell^{EE} + C_\ell^{BB}$, because $\cos^2 + \sin^2 = 1$. The total polarized power at each ℓ is unchanged, as it must be, since a twist does not change the length P of any stick. The fraction $\sin^2 2\beta$ of the E power has moved into B, and the same fraction of the (small) B power has moved into E. Subtract instead, and $C_\ell^{EE\prime} - C_\ell^{BB\prime} = \cos 4\beta\,(C_\ell^{EE} - C_\ell^{BB})$, by $\cos^2 - \sin^2 = \cos(2\cdot 2\beta)$.

EB and TB appear because the twist picks a hand. Before the twist they were zero by the mirror argument. After it they are proportional to $\sin 4\beta$ and $\sin 2\beta$, which change sign with β: twisting the other way gives the other sign, and the mirror image of a sky twisted by β is a sky twisted by $-\beta$. EB follows the shape of $C_\ell^{EE} - C_\ell^{BB}$, which on the real sky is essentially C_ℓ^{EE}, and TB follows the shape of C_ℓ^{TE}, with its changes of sign. These shapes are known from the ΛCDM fit, so a twist is a one-parameter template.

Small twists: linear against quadratic. For $|\beta| \ll 1$ (in radians), $\sin 2\beta \approx 2\beta$ and $\sin 4\beta \approx 4\beta$, so

$$C_\ell^{EB\prime} \approx 2\beta\,\left(C_\ell^{EE} - C_\ell^{BB}\right), \qquad C_\ell^{TB\prime} \approx 2\beta\, C_\ell^{TE}, \qquad C_\ell^{BB\prime} - C_\ell^{BB} \approx 4\beta^2\left(C_\ell^{EE} - C_\ell^{BB}\right). \tag{T1.42}$$

The parity-odd spectra grow like β, the extra BB like β^2. For a small twist the signal is therefore in EB and TB, as in the radio story.

Example 1: a quarter turn of the sticks. $\beta = 45°$: $\cos 2\beta = 0$, $\sin 2\beta = 1$, $\sin 4\beta = 0$. Then $C^{EE\prime} = C^{BB}$, $C^{BB\prime} = C^{EE}$, $C^{TE\prime} = 0$, $C^{TB\prime} = C^{TE}$, and $C^{EB\prime} = 0$. E and B have swapped completely, so the sky looks like a pure-B sky with a TB correlation, and EB is zero because each mode is

again purely of one kind. Panel (a) of Figure T1.14, with every stick turned by 45°, becomes panel (b).

Example 2: a half turn of the sticks. $\beta = 90°$: $\cos 2\beta = -1$, $\sin 2\beta = \sin 4\beta = 0$. Every stick along a wavevector now lies across it, so $E \to -E$ and $B \to -B$. All auto-spectra and EB are unchanged, but $C^{TE\prime} = -C^{TE}$: only the correlation with the temperature notices.

Example 3: the reported angle. $\beta = 0.35°$ is the value reported from Planck by [57]. Then $\sin 2\beta = 1.22\%$ and $\sin^2 2\beta = 1.490 \times 10^{-4}$. Figure T1.16 draws the rotated spectra computed by `code/chT1/06_rotated_spectra.py` from the fiducial spectra. The new EB reaches $D_\ell^{EB} = 0.517\,\mu\mathrm{K}^2$ at $\ell \approx 990$, where EE peaks, and the new TB reaches $\left|D_\ell^{TB}\right| = 1.637\,\mu\mathrm{K}^2$ near $\ell \approx 748$, larger because TE is larger than EE there. The extra BB is a small fraction of the lensing BB: 0.036 of it at $\ell = 100$ and 0.065 at $\ell = 1000$. Only at the very largest scales, $\ell \lesssim 4$, where the reionization peak of EE meets the smallest lensing power, does it exceed lensing, by up to a factor 2.539. A search for β in BB would be fighting lensing at every multipole where the data are good; a search in EB has no lensing to fight.

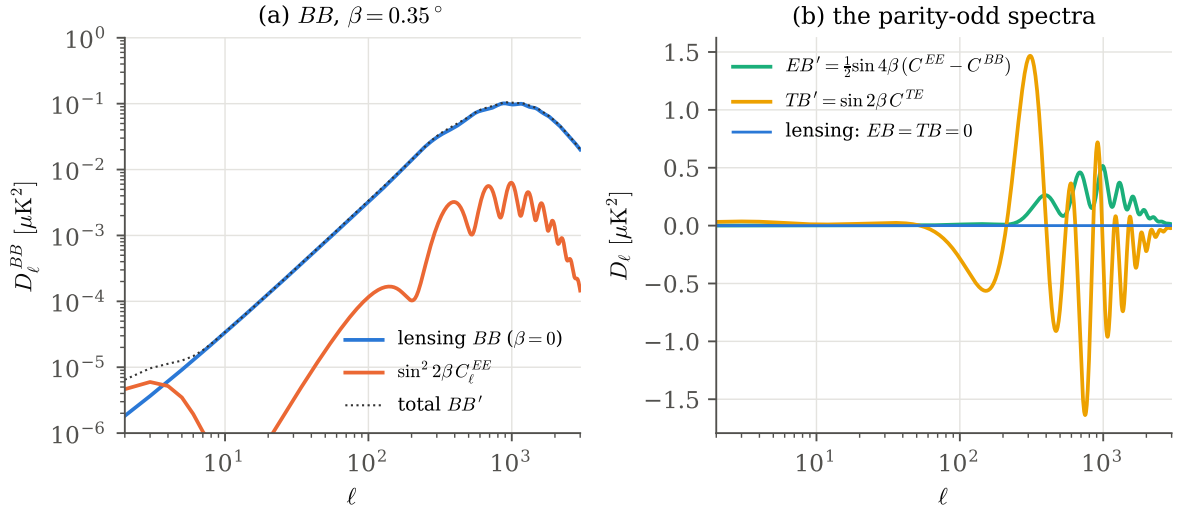

Figure T1.16: The spectra of the fiducial sky twisted by $\beta = 0.35°$. (a) BB: the lensing B modes that the untwisted sky already has (blue), the part moved over from EE by the twist, $\sin^2 2\beta\, C_\ell^{EE}$ (orange), and their sum (dotted), which is indistinguishable from lensing except on the largest scales. (b) The two parity-odd spectra created by the twist: EB follows the shape of EE, and TB follows TE with its changes of sign. Lensing alone leaves both at zero (blue line).

T1.10.4 Lensing: E into B without a hand

Lensing was met twice already: as the remapping $\hat{T}(\boldsymbol{n}) = T(\boldsymbol{n} + \boldsymbol{\nabla}\phi)$ of the temperature by the gradient of the lensing potential ϕ (Section T1.2, where the cosmology notes' ψ is CAMB's ϕ), and in Eq. (T1.7), where the shear made by a single potential was shown to have no B. That second result does not apply here. There, lensing *created* the sticks, and sticks made as second derivatives of one potential have no curl. Here the sticks already exist, created at last scattering as a pure E pattern, and lensing *moves* them: the stick seen in direction $\boldsymbol{n}$ is the one that, without lensing, would have been seen in direction $\boldsymbol{n} + \boldsymbol{\nabla}\phi$. To the accuracy needed here the stick is carried along without being turned [47]. A pure E pattern whose pieces are shifted by different amounts in different places is no longer a pure E pattern. *How much B does that make, and does it have a hand?*

First order in the deflection. The deflection is a few arcminutes, small compared with the scales of the E pattern, so we expand to first order on a flat patch, for each of $X = T, Q, U$:

$$\tilde{X}(\boldsymbol{\theta}) = X(\boldsymbol{\theta} + \boldsymbol{\nabla}\phi) \approx X(\boldsymbol{\theta}) + \boldsymbol{\nabla}\phi \cdot \boldsymbol{\nabla} X(\boldsymbol{\theta}). \tag{T1.43}$$

The correction is a product of two fields. In Fourier space, with the convention of Section T1.9.2, a product becomes a convolution, $(gh)(\boldsymbol{\ell}) = \int \frac{\mathrm{d}^2\boldsymbol{\ell}'}{(2\pi)^2}\, g(\boldsymbol{\ell} - \boldsymbol{\ell}')\, h(\boldsymbol{\ell}')$, and a gradient becomes a factor $i\boldsymbol{\ell}$. Before lensing $B = 0$, so $Q \pm iU = e^{\pm 2i\varphi_{\ell'}} E(\boldsymbol{\ell}')$ by (T1.23). Write $K(\boldsymbol{\ell}, \boldsymbol{\ell}') \equiv (\boldsymbol{\ell} - \boldsymbol{\ell}') \cdot \boldsymbol{\ell}'$. Then

$$\begin{aligned}
\delta(Q \pm iU)(\boldsymbol{\ell}) &\overset{(1)}{=} \int \frac{\mathrm{d}^2\boldsymbol{\ell}'}{(2\pi)^2} \left[i(\boldsymbol{\ell} - \boldsymbol{\ell}')\phi(\boldsymbol{\ell} - \boldsymbol{\ell}') \right] \cdot \left[i\boldsymbol{\ell}'(Q \pm iU)(\boldsymbol{\ell}') \right] \\
&\overset{(2)}{=} -\int \frac{\mathrm{d}^2\boldsymbol{\ell}'}{(2\pi)^2}\, K(\boldsymbol{\ell}, \boldsymbol{\ell}')\, \phi(\boldsymbol{\ell} - \boldsymbol{\ell}')\, e^{\pm 2i\varphi_{\ell'}} E(\boldsymbol{\ell}'), \\
\delta(E \pm iB)(\boldsymbol{\ell}) &\overset{(3)}{=} e^{\mp 2i\varphi_\ell}\, \delta(Q \pm iU)(\boldsymbol{\ell}) \overset{(4)}{=} -\int \frac{\mathrm{d}^2\boldsymbol{\ell}'}{(2\pi)^2}\, K\, \phi(\boldsymbol{\ell} - \boldsymbol{\ell}')\, e^{\pm 2i(\varphi_{\ell'} - \varphi_\ell)} E(\boldsymbol{\ell}'), \\
\tilde{B}(\boldsymbol{\ell}) &\overset{(5)}{=} -\int \frac{\mathrm{d}^2\boldsymbol{\ell}'}{(2\pi)^2}\, K(\boldsymbol{\ell}, \boldsymbol{\ell}')\, \phi(\boldsymbol{\ell} - \boldsymbol{\ell}')\, E(\boldsymbol{\ell}')\, \sin 2(\varphi_{\ell'} - \varphi_\ell).
\end{aligned} \tag{T1.44}$$

(1) The correction term of (T1.43) is the product of $\boldsymbol{\nabla}\phi$ and $\boldsymbol{\nabla}(Q \pm iU)$; transform the product as a convolution, each gradient bringing down i times its own wavevector.
(2) $i \cdot i = -1$; insert $Q \pm iU = e^{\pm 2i\varphi_{\ell'}} E$ for the unlensed, pure-E sky.
(3) The definition (T1.23) of E and B at the wavevector $\boldsymbol{\ell}$, applied to the change.
(4) Combine the two phases.
(5) B was zero, so $\tilde{B} = \delta B = [\delta(E + iB) - \delta(E - iB)]/2i$, and $(e^{ix} - e^{-ix})/2i = \sin x$ with $x = 2(\varphi_{\ell'} - \varphi_\ell)$.

Each lensed B wave collects E waves at other wavevectors $\boldsymbol{\ell}'$, weighted by the lensing potential at the difference $\boldsymbol{\ell} - \boldsymbol{\ell}'$ and by the sine of twice the angle between the two wavevectors. That is the wobbling antenna of the opening: a leak from E into B whose coefficient is the random field ϕ.

Does the new B remember E? Correlate (T1.44) with E or with T:

$$\langle \tilde{B}(\boldsymbol{\ell})\, E^*(\boldsymbol{\ell}'') \rangle \overset{(1)}{=} -\int \frac{\mathrm{d}^2\boldsymbol{\ell}'}{(2\pi)^2}\, K\, \sin 2(\varphi_{\ell'} - \varphi_\ell) \left\langle \phi(\boldsymbol{\ell} - \boldsymbol{\ell}')\, E(\boldsymbol{\ell}')\, E^*(\boldsymbol{\ell}'') \right\rangle \overset{(2)}{=} 0, \tag{T1.45}$$

and in the same way $\langle \tilde{B}\, T^* \rangle = 0$.

(1) Insert (T1.44); the expectation passes inside the integral.
(2) ϕ, E and T are jointly Gaussian with mean zero. The average of a product of three such variables vanishes: changing the sign of all of them leaves their joint distribution unchanged but flips the sign of the product, so its average equals its own negative. This holds even though ϕ is slightly correlated with T.

At the next order the lensed E also has a correction δE, and $\langle \delta E\, \delta B^* \rangle$ contains the integral of $\cos 2(\varphi_{\ell'} - \varphi_\ell) \sin 2(\varphi_{\ell'} - \varphi_\ell)$ against a weight that does not change when $\boldsymbol{\ell}'$ is reflected across $\boldsymbol{\ell}$; the sine changes sign under that reflection, so this term integrates to zero as well. The general reason holds at every order: ϕ is a scalar, a mirror carries a sky lensed by ϕ into the mirrored sky lensed by the mirrored ϕ, and both are equally probable, so the argument of (T1.28) goes through unchanged. Lensing makes B, but no EB and no TB.

How much B power? Multiply (T1.44) by its complex conjugate at $\boldsymbol{\ell}''$ and average. Treat ϕ and E as independent Gaussian fields (their correlation is negligible), so the four-field average

splits into $\langle\phi\phi^*\rangle\langle EE^*\rangle$, each a delta function times a spectrum, as in (T1.26):

$$\begin{aligned}\langle\tilde B(\boldsymbol\ell)\tilde B^*(\boldsymbol\ell'')\rangle &\overset{(1)}{=} \int\frac{\mathrm d^2\boldsymbol\ell'}{(2\pi)^2}\frac{\mathrm d^2\boldsymbol\ell'''}{(2\pi)^2}\,KK'''\,\sin\sin'''\,(2\pi)^2\delta^2(\boldsymbol\ell'-\boldsymbol\ell''')C^{EE}_{\ell'}\,(2\pi)^2\delta^2\big(\boldsymbol\ell-\boldsymbol\ell'-\boldsymbol\ell''+\boldsymbol\ell'''\big)C^{\phi\phi}_{|\boldsymbol\ell-\boldsymbol\ell'|}\\ &\overset{(2)}{=}(2\pi)^2\delta^2(\boldsymbol\ell-\boldsymbol\ell'')\int\frac{\mathrm d^2\boldsymbol\ell'}{(2\pi)^2}\left[(\boldsymbol\ell-\boldsymbol\ell')\cdot\boldsymbol\ell'\right]^2\sin^2 2(\varphi_{\boldsymbol\ell'}-\varphi_{\boldsymbol\ell})\,C^{\phi\phi}_{|\boldsymbol\ell-\boldsymbol\ell'|}\,C^{EE}_{\ell'},\\ C^{BB}_\ell &\overset{(3)}{=}\int\frac{\mathrm d^2\boldsymbol\ell'}{(2\pi)^2}\left[(\boldsymbol\ell-\boldsymbol\ell')\cdot\boldsymbol\ell'\right]^2\sin^2 2(\varphi_{\boldsymbol\ell'}-\varphi_{\boldsymbol\ell})\,C^{\phi\phi}_{|\boldsymbol\ell-\boldsymbol\ell'|}\,C^{EE}_{\ell'}.\end{aligned}\tag{T1.46}$$

(1) Insert (T1.44) twice (the second with integration variable $\boldsymbol\ell'''$ and its factors K''', $\sin'''$), and replace $\langle EE^*\rangle$ and $\langle\phi\phi^*\rangle$ by their delta functions and spectra; the other pairings vanish because ϕ and E are independent with mean zero.

(2) Do the $\boldsymbol\ell'''$ integral with the first delta function, which sets $\boldsymbol\ell'''=\boldsymbol\ell'$; the second then becomes $\delta^2(\boldsymbol\ell-\boldsymbol\ell'')$.

(3) Read off the spectrum from the definition $\langle\tilde B(\boldsymbol\ell)\tilde B^*(\boldsymbol\ell'')\rangle=(2\pi)^2\delta^2(\boldsymbol\ell-\boldsymbol\ell'')C^{BB}_\ell$.

This is the standard first-order lensing B spectrum [47, 64]. Its strength is set by the product $C^{\phi\phi}C^{EE}$ and nothing else: no parameter of new physics, and no hand.

Why is lensing B white on large scales? For ℓ much smaller than the multipoles $\ell'\sim1000$ where E has its power, $\boldsymbol\ell-\boldsymbol\ell'\approx-\boldsymbol\ell'$. Then $K\approx-\ell'^2$, $C^{\phi\phi}_{|\boldsymbol\ell-\boldsymbol\ell'|}\approx C^{\phi\phi}_{\ell'}$, and only the sine still depends on the direction of $\boldsymbol\ell'$. Write $\mathrm d^2\boldsymbol\ell'=\ell'\mathrm d\ell'\,\mathrm d\varphi_{\boldsymbol\ell'}$:

$$C^{BB}_{\ell\to0}\overset{(1)}{=}\int_0^\infty\frac{\ell'\mathrm d\ell'}{(2\pi)^2}\,\ell'^4C^{\phi\phi}_{\ell'}C^{EE}_{\ell'}\int_0^{2\pi}\mathrm d\varphi\,\sin^2 2\varphi\overset{(2)}{=}\frac{1}{4\pi}\int_0^\infty\mathrm d\ell'\,\ell'^5\,C^{\phi\phi}_{\ell'}\,C^{EE}_{\ell'}.\tag{T1.47}$$

(1) Insert the large-ℓ' approximations into (T1.46); the angle between $\boldsymbol\ell'$ and $\boldsymbol\ell$ is now the only angle left.

(2) $\int_0^{2\pi}\sin^2 2\varphi\,\mathrm d\varphi=\pi$, and $\pi/(2\pi)^2=1/4\pi$.

The answer does not depend on ℓ: a flat spectrum, like white noise. Large-scale lensing B modes are a sum of many small-scale E modes, each moved a little, and such a sum has no preferred large scale. Figure T1.17 checks both formulas against CAMB's full calculation. The first-order integral (T1.46) gives between 0.985 and 0.997 times CAMB's lensed BB everywhere between $\ell=20$ and 1500, and the white limit (T1.47) gives $C^{BB}=1.890\times10^{-6}\,\mu\mathrm K^2$, against CAMB's mean $1.940\times10^{-6}\,\mu\mathrm K^2$ over $10\le\ell\le50$. Written as the noise level of a map, that white floor is $\sqrt{C^{BB}}=4.7\,\mu$K-arcmin: an experiment whose polarization noise is below about 5 μK-arcmin sees lensing, not its own noise, as the floor of its B-mode map.

Lensing B is not Gaussian. Equation (T1.44) makes $\tilde B$ a product of two Gaussian fields, and a product of Gaussians is not Gaussian: its four-point function has a part that the power spectrum does not describe, which correlates the errors of different ℓ bins. The same product structure is what allows **delensing** [47]: reconstruct ϕ (by the quadratic estimator of Section T1.6, or from tracers of the matter), take E from the measured map, compute $\tilde B$ from (T1.44) and subtract it. A Gaussian noise could not be removed this way, because nothing in the data predicts it.

T1.10.5 Both on simulated skies

The two derivations make claims about averages over many skies. The script `code/chT1/08_flat_rotation_lensing.py` checks them on 500 simulated flat patches of $17^\circ\times17^\circ$ (256 pixels of 4′ on a side). Each patch is a Gaussian sky with the unlensed T and E of CAMB, correlated through TE, no B, and an independent Gaussian lensing potential with CAMB's $C^{\phi\phi}$. Each sky is processed twice: once twisted by $\beta=2^\circ$, chosen so that the B power it makes is about that

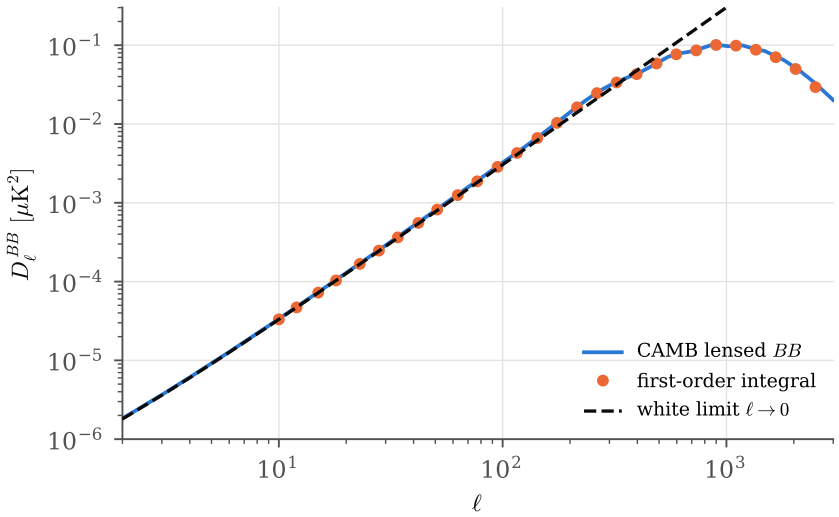

Figure T1.17: The lensing B-mode spectrum. Blue: CAMB's lensed BB for the fiducial model with no gravitational waves. Orange dots: the first-order integral (T1.46) evaluated from CAMB's unlensed EE and lensing potential. Dashed: its large-scale limit (T1.47), a constant C_ℓ^{BB}, which appears as a line of slope two in D_ℓ. The first-order formula holds up to $\ell \approx 1500$; beyond, higher orders in the deflection matter.

of lensing (their median ratio over $100 < \ell < 1500$ is 1.00), and once lensed to first order with (T1.43). For each sky we measure the binned BB, EB and TB in 25 bins between $\ell = 40$ and 2040 and average over the skies.

Figure T1.18 shows the answer. In BB the two are alike, each following its own prediction. In EB and TB they are not: the twist produces the shapes of C^{EE} and C^{TE} from Section T1.10.2, and lensing produces nothing. Quantitatively, the averaged lensing BB divided by the first-order integral is 1.000 ± 0.001 over $100 < \ell < 1500$, and the twisted EB divided by $\frac{1}{2}\sin 4\beta\, C^{EE}$ is 1.0000 ± 0.0004. The lensing EB and TB bin averages scatter around zero by the amount their own Monte Carlo errors allow: the sums of their squared ratios to those errors are 18.1 and 25.3 for 25 bins, where pure chance gives 25 ± 7. The largest lensing EB average is 0.15% of the peak of the twisted EB.

The simulation also shows a property of the twist that is exact sky by sky, not only on average. Since the simulated skies have no B before the twist, $\widehat{C}_\ell^{EB\prime} = \frac{1}{2}\sin 4\beta\, \widehat{C}_\ell^{EE}$ and $\widehat{C}_\ell^{EE\prime} - \widehat{C}_\ell^{BB\prime} = \cos 4\beta\, \widehat{C}_\ell^{EE}$ hold for the measured spectra of each sky, because (T1.37) acts mode by mode. Dividing one by the other, $\widehat{C}_\ell^{EB\prime} = \frac{1}{2}\tan 4\beta\, (\widehat{C}_\ell^{EE\prime} - \widehat{C}_\ell^{BB\prime})$: the twisted EB is predicted by the twisted EE and BB of the same sky, with no reference to any model. The script finds this to hold to 5.100×10^{-16} in every sky. On the real sky, where some B is present before the twist, chance EB adds scatter to this relation; Section T1.12.3 builds the measurement on it.

T1.10.6 The instrument twists too

Every detector that measures Q and U has its own reference axis on the sky. If the true axis is turned by $-\alpha$ from where the analysis believes it is, then by the argument at the end of Section T1.9.1 every measured stick appears twisted by $+\alpha$. The twist of the instrument acts on the maps at the end of the line, after any physical twist β the sky light received on its way, so two twists in a row add: $e^{2i\alpha}e^{2i\beta} = e^{2i(\alpha+\beta)}$. Every formula derived above therefore holds with β replaced by $\alpha + \beta$: $C_\ell^{EB,\mathrm{obs}} = \frac{1}{2}\sin(4\alpha + 4\beta)(C_\ell^{EE} - C_\ell^{BB})$ for the CMB, and likewise for TB, EE and BB. The CMB spectra alone measure the sum and nothing else, so a miscalibrated

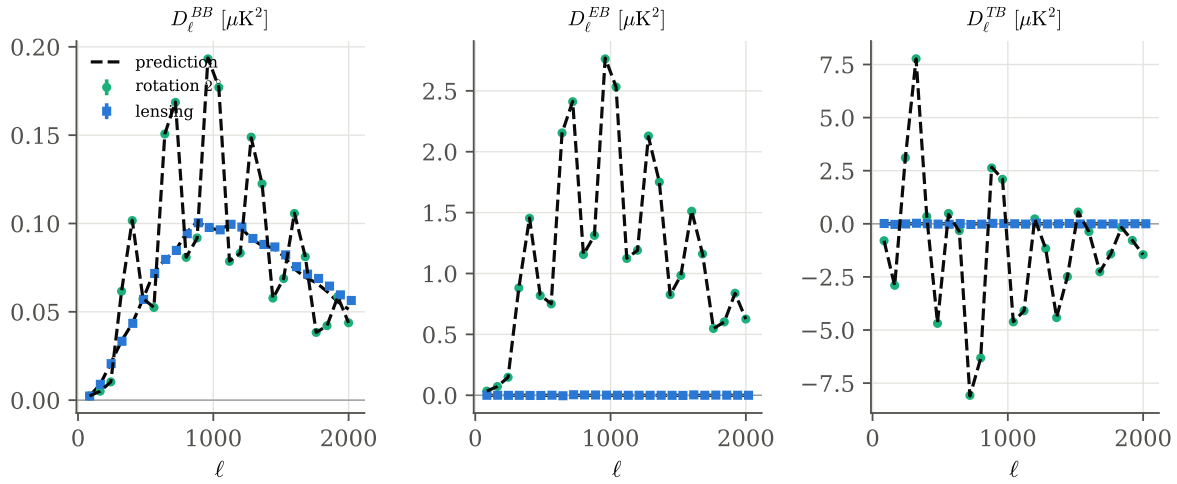

Figure T1.18: A twist and lensing on 500 simulated flat skies. Green circles: skies twisted by 2°; blue squares: the same skies lensed to first order; error bars are the errors of the averages over the skies; dashed: the predictions ($\sin^2 2\beta\, C^{EE}$, $\frac{1}{2}\sin 4\beta\, C^{EE}$, $\sin 2\beta\, C^{TE}$ for the twist; the first-order integral for lensing BB, zero for lensing EB and TB). Both make B power of about the same size. Only the twist makes EB and TB.

polarization angle and a physical twist are exactly degenerate in them. Section T1.12.3 shows how the light of our own Galaxy, which is twisted by α but not by β, breaks this degeneracy.

Watch out: EB alone does not prove new physics

A nonzero EB with the shape of C^{EE} measures $\alpha + \beta$. Without an independent handle on α (a calibration source of known polarization angle, or the Galactic foreground method of Section T1.12.3), an EB signal is first of all a statement about the orientation of the detectors.

T1.11 Where B modes come from

We have met three makers of B so far. Gravitational waves make it at last scattering, because their pattern is not mirror symmetric (Section T1.9.6). Lensing makes it from E, with no hand (Section T1.10.4). A twist makes it from E, with a hand (Section T1.10.2). Each was studied alone. A real B-mode map contains all of them at once, plus the light of our own Galaxy and the imperfections of the instrument, and nothing in the map is labelled. Given a measured excess of B power, or a measured EB, how do we decide what made it?

Imagine a photograph with stains on it, and three ways to examine it. First, look at it through a red, a green and a blue filter. A stain that is equally dark through all three is grey; one that is darker through the red filter is reddish. Second, look at the size of the blotches: some are a centimetre across, some are a fine grain. Third, hold it to a mirror: stains with no shape of their own look the same, but a stain shaped like a swirl or a letter is reversed. No single test sorts every stain, but together the colour, the size and the mirror nearly always do.

The B-mode sky is examined in exactly these three ways. The filters are the observing frequencies. In the temperature units used for the CMB, everything that comes from the CMB itself (gravitational waves, lensing, a twist on the way) has the same amplitude in every channel, a grey stain. The Galaxy is coloured: dust brightens towards high frequency, synchrotron towards low. The blotch size is the multipole ℓ. The mirror is the parity of the spectrum: EB and TB are nonzero only for a source with a hand. One sentence holds the idea of the section:

each source of B leaves fingerprints in frequency, in ℓ and in parity, and the fingerprints are read together.

The colour test in symbols. Take one multipole, $\ell = 80$, and two channels, 150 and 353 GHz. A grey source has the same D_ℓ^{BB} in both. Dust, scaled with the frequency law of Section T1.11.3, has 410 times more power at 353 than at 150 GHz. Measure D_{80}^{BB} in both channels, $x_{150} = g + d$ and $x_{353} = g + 410\,d$, with g the grey part and d the dust at 150 GHz. The naive reading of the 150 GHz channel alone takes all of x_{150} as cosmological. In the cleanest one per cent of the sky, where the dust is weakest, it would be wrong by a large factor: there the dust at 150 GHz is $D_{80}^{BB} = 0.011\,\mu\text{K}^2$, 5.2 times the lensing B and 16.5 times the B of gravitational waves with $r = 0.01$. The good choice uses both channels, $d = (x_{353} - x_{150})/(410 - 1)$ and $g = x_{150} - d$, the two-reading weighting of Section 3.7.4 in its simplest form. Its price is the noise of the 353 GHz channel, which enters g with a weight of only $1/(410 - 1)$ but is large, and the assumption that the dust frequency law is known. Lesson: frequency separates the Galaxy from the CMB, but it cannot separate one grey source from another; for that we need the other two tests.

One idea, many names. Telling sources apart by how they respond to several probes is what an astronomer does with colours, what a particle physicist does with a calorimeter and a tracker together, and what a statistician calls a mixing model: each reading is a sum of sources, each source with its own pattern across the readings. When the patterns are linearly independent, linear algebra separates the sources; the internal linear combination of Section 3.7.4 and the parametric fits of B-mode experiments are both this idea.

We now take the sources one at a time, each with its physical origin and its fingerprints, and then collect them in one table.

T1.11.1 Gravitational waves from the early universe

Origin. Inflation predicts a background of gravitational waves in addition to the density perturbations (see the cosmology notes). Its strength is quoted as the **tensor-to-scalar ratio** r [the primordial power of the gravitational waves divided by that of the curvature perturbations, at the pivot $k_* = 0.05\,\text{Mpc}^{-1}$ of Section T1.2]. As a gravitational wave passes, it stretches the plasma in a quadrupole pattern, and Thomson scattering turns that quadrupole into polarization with both E and B [59, 61]. The best limit is $r < 0.036$ at 95% confidence [65].

Fingerprints. In ℓ, two bumps (blue curve of Figure T1.19, computed with CAMB for $r = 0.01$). The *reionization bump* at $\ell \lesssim 10$ comes from polarization generated when the universe was reionized, late and therefore seen on very large angles. The *recombination bump*, here at $\ell \approx 88$ with $D_\ell^{BB} = 6.590 \times 10^{-4}\,\mu\text{K}^2$, comes from last scattering: it sits at the angle that the horizon at last scattering subtends, because a gravitational wave decays once it is inside the horizon, so waves smaller than the horizon then had already faded. The amplitude is proportional to r. In frequency, grey: the signal is a pattern in the CMB itself, so it has the black-body spectrum of the CMB and the same amplitude in every channel in CMB temperature units. In statistics, Gaussian, like the primordial density field. In parity, symmetric: standard inflation has no hand, so $EB = TB = 0$. (Models with chiral gravitational waves, where one circular polarization of the wave is stronger, would break this [62].)

T1.11.2 Lensing of E

Origin. The remapping of the E pattern by the matter between us and last scattering, derived in Section T1.10.4.

Fingerprints. In ℓ, a broad peak at $\ell \approx 886$, inherited from the peak of EE, and a white spectrum, $C_\ell^{BB} \approx 1.890{\times}10^{-6}\,\mu\text{K}^2$, on large scales (T1.47). At $\ell = 80$ lensing is $D_{80}^{BB} = 0.00205\,\mu\text{K}^2$, about three times the recombination bump of $r = 0.01$; for smaller r the gravitational-wave

bump hides under lensing, which is why delensing matters for future searches. In frequency, grey, since gravity bends all wavelengths alike. In statistics, non-Gaussian (a product of ϕ and E), which is what delensing exploits. In parity, symmetric: $EB = TB = 0$ on average (T1.45).

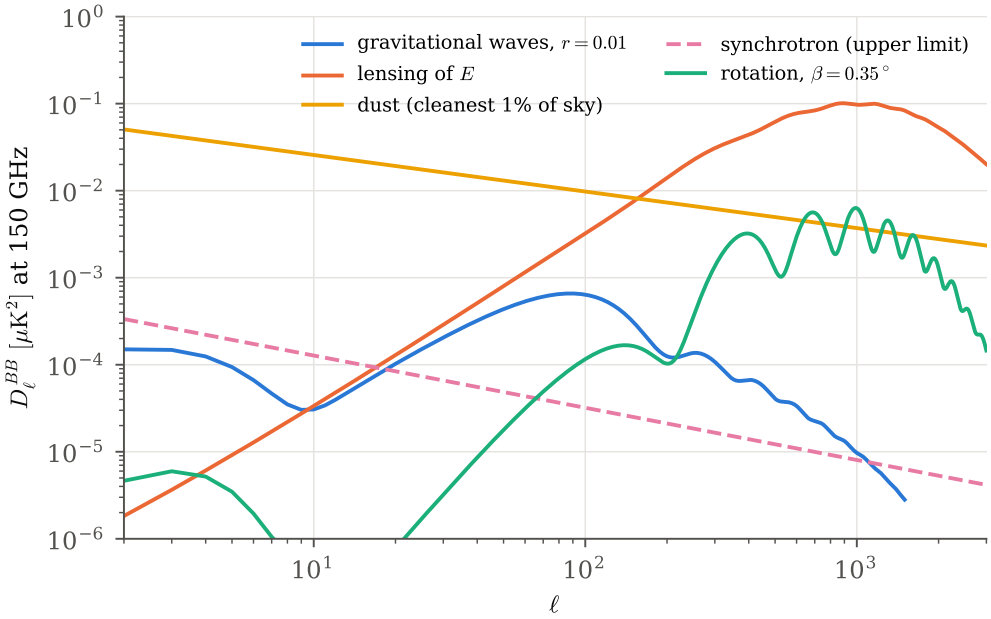

Figure T1.19: The B-mode spectra of the different sources at 150 GHz. Gravitational waves with $r = 0.01$ (blue): the reionization bump at the lowest ℓ and the recombination bump near $\ell \approx 88$. Lensing (orange): white on large scales, peaking near $\ell \approx 886$. Dust (yellow) in the cleanest one per cent of the sky, from the BICEP/Keck model [65], and the 95% upper limit on synchrotron (pink dashed): power laws that fall with ℓ. A twist of $\beta = 0.35°$ (green): the shape of EE, a factor 1.490×10^{-4} down. Over most of the sky the dust is tens of times higher than drawn here.

T1.11.3 The Galaxy: dust and synchrotron

Origin. Two kinds of emission from the Milky Way are polarized [19, 66]. Interstellar *dust* grains are elongated and spin with their long axes across the Galactic magnetic field, so their thermal emission is polarized across the field. *Synchrotron* emission comes from relativistic electrons spiralling around the magnetic field lines, and it is polarized too. Both trace the turbulent, filamentary magnetized gas of the Galaxy, which has structure on every scale.

Fingerprints in ℓ. Power laws, $D_\ell \propto \ell^\alpha$, falling towards small scales. For dust, Planck finds D_ℓ^{EE} and D_ℓ^{BB} both close to $\ell^{-0.42}$ over $40 \le \ell \le 600$, with $BB/EE \approx 0.5$ and a positive TE [66]. For synchrotron the slope is between -0.6 and -1 [65]. A power law that falls with ℓ is unlike both the bumps of gravitational waves and the rising lensing spectrum.

Fingerprints in frequency. This is the strongest test. Dust emits like a black body at $T_d \approx 19.6$ K multiplied by ν^{β_d} with $\beta_d \approx 1.5$ (a modified black body); synchrotron falls like $\nu^{-3.1}$ in brightness temperature [65]. Converted to CMB temperature units, dust rises steeply with frequency and synchrotron falls steeply, and the CMB is flat. Figure T1.20(a), from `code/chT1/07_bmode_sources.py`, plots the B-mode amplitude at $\ell = 80$ against frequency in the cleanest patch of sky: the dust power grows by a factor 410 from 150 to 353 GHz, the synchrotron power (at its upper limit) by a factor 7504 from 150 down to 30 GHz, and the sum of the two is smallest near 90 GHz. This is why CMB experiments put their most sensitive channels near 100 to 150 GHz and add channels on both sides to measure the Galaxy.

Fingerprints in statistics. Neither emission is Gaussian or statistically isotropic. Its amplitude

follows the column of gas along each line of sight, so it is far brighter near the Galactic plane than at high latitude, and its maps are filamentary. Over 71% of the sky Planck measures a dust amplitude $D_{80}^{EE} = 315\,\mu\mathrm{K}^2$ at 353 GHz [66], so $D_{80}^{BB} \approx 0.53 \times 315 \approx 170\,\mu\mathrm{K}^2$, against $4.4\,\mu\mathrm{K}^2$ in the cleanest patch [65]: about forty times more. A Galactic mask is therefore part of every analysis, and the answer depends on which mask.

Fingerprints in parity. The Galaxy can have a hand. The intensity filaments of the dust tend to be aligned with the magnetic field, which makes the dust polarization mostly E-like; where filament and field are misaligned, the misalignment angle has a sign, and the polarization acquires correlations TB and EB [67]. Planck finds a positive dust TB at 353 GHz [66], and [67] predicts a positive dust EB of up to $D_\ell^{EB} \approx 2.5\,\mu\mathrm{K}^2$ at 353 GHz for $100 \lesssim \ell \lesssim 500$ over their mask, with a sign and size that can change with the sky area. This small Galactic hand is the main worry for birefringence measurements (Section T1.12.4).

T1.11.4 Twists: birefringence and Faraday rotation

Cosmic birefringence. A twist of the plane of polarization during the journey from last scattering, by an angle β that is the same for every frequency. Its physical origin is discussed in Section T1.12. Fingerprints: BB, EB and TB with the shapes of Section T1.10.2 (EB follows $C^{EE} - C^{BB}$, TB follows C^{TE}); grey in frequency; Gaussian (it is a fixed linear operation on Gaussian fields); and the only cosmological source that creates EB and TB.

Faraday rotation. A plane of polarization travelling along a magnetic field through an ionized gas is also twisted, by an angle proportional to the square of the wavelength, that is to $1/\nu^2$ [68]; Section T1.12.2 derives this law from the motion of the electrons. A primordial magnetic field of 10^{-9} G today would twist the CMB polarization by about 1° at 30 GHz [68], hence by $(30/150)^2 \times 1° = 0.04°$ at 150 GHz. The twist formulas of Section T1.10 apply channel by channel (with the angle varying across the sky when the field does), so Faraday rotation makes EB and TB like birefringence, but its strong frequency dependence (Figure T1.20(b)) tells it apart: a constant β and an angle falling as ν^{-2} cannot be confused once several channels are compared.

T1.11.5 The instrument

Three imperfections of the telescope matter most [69]. A *miscalibrated polarization angle* α is a twist applied to the maps by the instrument (Section T1.10.6): in the CMB it is exactly degenerate with β, and it is grey only by accident, since each channel, or each detector, has its own α. *Temperature-to-polarization leakage* [a small fraction of the temperature signal read as Q or U, from mismatched gains or bandpasses of the paired detectors] copies the much larger temperature anisotropy into polarization, producing spurious TE and EE, and TB and BB as well, with shapes inherited from C^{TT}. *Beam asymmetry* [the two detectors of a pair seeing slightly different, non-circular patches of sky] does the same with the gradients and second derivatives of the temperature. These effects depend on how the sky was scanned, so they differ between channels, detectors and data splits, and they are hunted with null tests on differences of data splits and corrected with models of the beams [70].

All these fingerprints fit in one table, which is the tool to reach for when a B-mode signal needs a name.

T1.11.6 Reading the fingerprints together

The table is read with three questions, each of which splits the list along a different line. *Does the signal change with frequency?* If it does, it comes from the Galaxy, from Faraday rotation, or from the instrument; if it does not, it comes from the CMB, which leaves gravitational waves, lensing

Taxonomy: Where a B mode comes from: the fingerprints

source	shape in ℓ (BB)	frequency (CMB units)	statistics	EB, TB
gravitational waves (r)	reionization bump at $\ell < 10$, recombination bump near $\ell \approx 80$, amplitude $\propto r$	flat	Gaussian	none
lensing of E	white at low ℓ, broad peak near $\ell \approx 1000$	flat	non-Gaussian, removable by delensing	none on average
dust	power law $D_\ell \propto \ell^{-0.42}$, rising to low ℓ	rises steeply with ν	non-Gaussian, anisotropic	small EB, TB from filament–field misalignment
synchrotron	power law, rising to low ℓ	falls steeply with ν	non-Gaussian, anisotropic	small, if any
cosmic birefringence (β)	$BB = \sin^2 2\beta\, C^{EE}$; EB follows $C^{EE} - C^{BB}$, TB follows C^{TE}	flat	Gaussian	yes: the only cosmological source
Faraday rotation	as birefringence, angle varying over the sky	angle $\propto \nu^{-2}$	follows the magnetized plasma	yes
angle miscalibration (α)	exactly as birefringence	own value per channel or detector	as the CMB	yes
$T \to P$ leakage, beam asymmetry	shapes of C^{TT} and its derivatives	per channel and detector	depends on scan	can be nonzero

and birefringence (and an angle miscalibration that happens to be equal in every channel). *What is its shape in ℓ?* Among the grey sources, the recombination bump near $\ell \approx 80$ marks gravitational waves, the white spectrum rising to a peak near $\ell \approx 1000$ marks lensing, and the shape of C^{EE} marks a twist. *Is it parity-odd?* EB and TB separate the twists (birefringence, Faraday, miscalibration) and the slightly handed dust from everything that preserves parity, which includes gravitational waves and lensing. Here are four cases, worked in the order of the opening: the event, what could have made it, and how each candidate fares.

Case 1: a BB excess at $\ell \approx 80$. *The event:* D_{80}^{BB} at 150 GHz is a few times the lensing prediction. *What could make it?* Gravitational waves (bump there), dust (rising to low ℓ), leakage. *Test each.* Measure the same patch at 353 GHz. Gravitational waves predict the same D_{80}^{BB}; dust predicts 410 times more. Leakage predicts a different answer for each detector set. Only after this does r get a number, from what is left of the 150 GHz power once the dust inferred at 353 GHz is subtracted, as in the colour test of the opening.

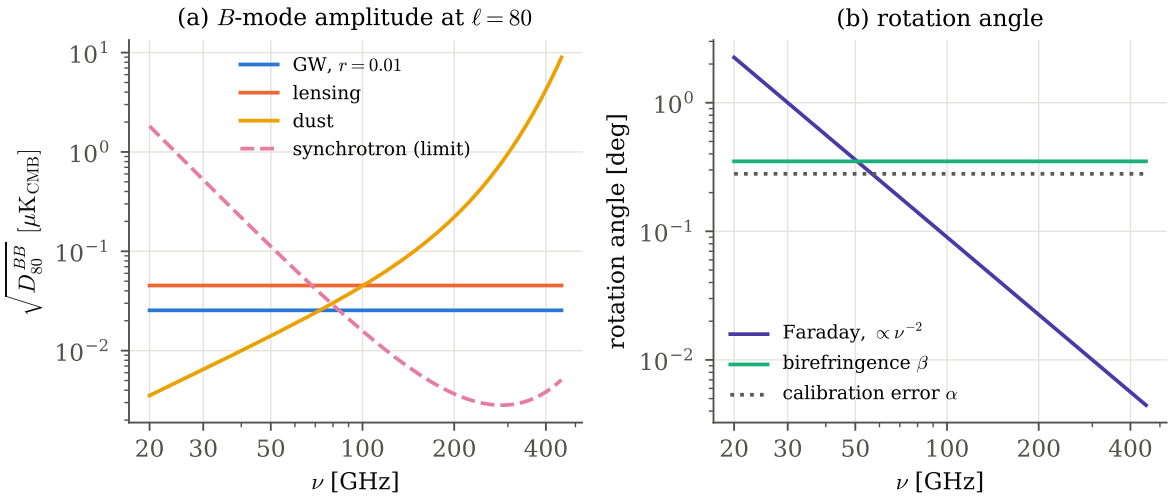

Figure T1.20: The colour test. (a) The rms B-mode amplitude at $\ell = 80$ against observing frequency, in CMB temperature units, for the cleanest patch of sky: gravitational waves ($r = 0.01$) and lensing are flat, dust rises and synchrotron (upper limit) falls; the Galaxy is weakest near 90 GHz. (b) The twist angle against frequency: cosmic birefringence ($\beta = 0.35°$) is flat, Faraday rotation by a 1 nG primordial field falls as ν^{-2}; the dotted line marks the 0.28° calibration uncertainty of Planck, which a single channel cannot distinguish from β.

Case 2: BB power that rises from a flat floor to a peak at $\ell \approx 1000$, the same in every channel. Grey, so cosmological. The shape is that of lensing, and the identification can be confirmed in a way no other source allows: reconstruct ϕ, compute the B it predicts from the measured E with (T1.44), and correlate. If the correlation matches, the power is lensing.

Case 3: an EB with the shape of C^{EE}, equal in all channels. Parity-odd, grey, and with the shape of a twist: the candidates are birefringence and a common angle miscalibration. The CMB cannot tell them apart (Section T1.10.6). Something that is twisted by α but not by β is needed, and Section T1.12.3 finds it in the Galaxy.

Case 4: an EB that is four times larger at 75 GHz than at 150 GHz. A ratio of $(150/75)^2 = 4$ is the ν^{-2} law of Faraday rotation; birefringence would give a ratio of one, dust, which is faint at low frequency, a ratio below one, and synchrotron, which brightens much faster towards low frequency, a ratio of tens. The candidates are Faraday rotation or, if the ratio differs from channel to channel without a pattern, independent miscalibrations of the two channels.

The lesson of the four cases: frequency separates the Galaxy (and Faraday rotation) from the CMB; the shape in ℓ separates gravitational waves from lensing; and EB, TB separate a rotation from everything that preserves parity. A real analysis does all three at once, as one likelihood over all the auto- and cross-spectra of all channels [65].

T1.12 Cosmic birefringence, the instrument and the Galaxy

The previous sections leave us with a precise statement and a problem. The statement: a uniform twist of the CMB polarization by an angle produces $EB = \frac{1}{2}\sin(4 \times \text{angle})\,(C^{EE} - C^{BB})$ and $TB = \sin(2 \times \text{angle})\,C^{TE}$, and nothing else on the sky produces that pattern in every channel. The problem: the angle the CMB measures is $\alpha + \beta$, the twist of the instrument plus the twist of the sky (Section T1.10.6), and from the CMB alone there is no way to split the sum.

Think of a painting in a room that looks crooked to you. Either the painting hangs crooked, or your head is tilted, or both. Looking harder at the painting cannot decide: all you see is the sum of the two tilts. So you look at the door frame next to it. The door frame is close to you, and nothing made it crooked except, possibly, your own head. If the door frame looks straight and the painting crooked, the painting is crooked; if both look crooked by the same amount, it is your head. The method works as long as the door frame really is straight. If the builder hung it slightly crooked, you will misjudge the painting by exactly that amount.

The microwave sky has a door frame. The polarized emission of our Galaxy reaches the telescope after a journey of a few hundred to a few thousand light years, far too short for any cosmological twist to act on it, but it passes through the same detectors as the CMB. It is twisted by α and not by β [71]. The idea of the section, in one sentence: *measure the twist of the Galaxy to get α, measure the twist of the CMB to get $\alpha+\beta$, and take the difference.*

The door frame in symbols. Write the twisted EB of each component to first order in the angles, using (T1.42): the CMB gives $2(\alpha+\beta)\Delta_\ell^{\rm CMB}$ and the dust gives $2\alpha\,\Delta_\ell^{\rm dust}$, where $\Delta_\ell \equiv C_\ell^{EE} - C_\ell^{BB}$ of each. The two dials are α and β; the two patterns across multipoles are $\Delta_\ell^{\rm CMB}$, with its acoustic peaks, and $\Delta_\ell^{\rm dust}$, a smooth power law. Without dust the data are one number times one pattern and fix only $\alpha+\beta$: the naive analysis has one equation for two unknowns. With dust the data are $2\alpha(\Delta_\ell^{\rm dust}+\Delta_\ell^{\rm CMB}) + 2\beta\,\Delta_\ell^{\rm CMB}$, two patterns with two different shapes, and both numbers follow. The price is that β is now the difference of two measured quantities, so its error is at least as large as the larger of their two errors. And the reference is not free: dust bright enough to fix α is also extra scatter in the CMB's own EB. In the forecast of Section T1.12.3 for one channel, the CMB in a dust-free map fixes $\alpha+\beta$ to 0.036°; at 353 GHz the dust fixes α to 0.1129°, but the sum is now known only to 0.271°, and β alone to 0.3717°, ten times worse than the dust-free sum. Lesson: a degeneracy is broken by a second component that sees only one of the two parameters, and the price is paid in the precision of that second component.

One idea, many names. Calibrating an instrument on a source whose answer is known, while measuring an unknown one at the same time, is the oldest trick of experimental physics: a reference star in the same field, a known line in a spectrum, a tag-and-probe sample at a collider. What is special here is that the reference is not known in advance. Only one of its properties is assumed, that the Galaxy itself has no EB, and its own $EE-BB$ is measured from the same data.

We first say what physics could twist the CMB light, and how ordinary matter twists light, then derive the Minami–Komatsu relation that turns the door-frame idea into a measurement, and end with what has been measured and why it is not yet a discovery.

T1.12.1 What could twist the light

A twist is a phase difference between two helicities. Write the two circular polarization states of a wave travelling along $\boldsymbol{e}_3$ as $\boldsymbol{e}_\pm = (\boldsymbol{e}_1 \pm i\boldsymbol{e}_2)/\sqrt{2}$. A wave linearly polarized at angle ψ, with polarization vector $\boldsymbol{\epsilon} = \cos\psi\,\boldsymbol{e}_1 + \sin\psi\,\boldsymbol{e}_2$, is a sum of the two:

$$\frac{e^{-i\psi}\boldsymbol{e}_+ + e^{i\psi}\boldsymbol{e}_-}{\sqrt{2}} \overset{(1)}{=} \tfrac{1}{2}\left[e^{-i\psi}(\boldsymbol{e}_1+i\boldsymbol{e}_2) + e^{i\psi}(\boldsymbol{e}_1-i\boldsymbol{e}_2)\right] \overset{(2)}{=} \cos\psi\,\boldsymbol{e}_1 + \sin\psi\,\boldsymbol{e}_2 = \boldsymbol{\epsilon}. \tag{T1.48}$$

(1) Insert the definitions of $\boldsymbol{e}_\pm$.
(2) Collect: $\frac{1}{2}(e^{-i\psi}+e^{i\psi}) = \cos\psi$ multiplies $\boldsymbol{e}_1$, and $\frac{i}{2}(e^{-i\psi}-e^{i\psi}) = \frac{i}{2}(-2i\sin\psi) = \sin\psi$ multiplies $\boldsymbol{e}_2$.

Now suppose that on its way the + helicity is delayed in phase by β relative to the average, and the − helicity advanced by β, so the left side becomes $(e^{-i(\psi+\beta)}\boldsymbol{e}_+ + e^{i(\psi+\beta)}\boldsymbol{e}_-)/\sqrt{2}$. By the same

identity this is the linear polarization at $\psi + \beta$. A relative phase of 2β between the two helicities is a twist of the plane by β. A medium in which the two helicities travel at different speeds is called birefringent, and a twist of the CMB plane accumulated over its whole journey is called **cosmic birefringence**.

What could make the helicities differ? A pseudoscalar field ϕ that couples to photons through the term $\frac{1}{4} g_{\phi\gamma} \phi F_{\mu\nu} \tilde{F}^{\mu\nu}$ in the Lagrangian, where F is the electromagnetic field tensor, $\tilde{F}$ its dual and $g_{\phi\gamma}$ a coupling constant, does exactly this when ϕ changes in time [72, 73]. The product $F\tilde{F}$ is proportional to $\boldsymbol{E} \cdot \boldsymbol{B}$ of the electromagnetic field, which changes sign in a mirror; multiplied by a pseudoscalar, which also changes sign, it keeps the Lagrangian mirror symmetric, but a background ϕ that evolves in one direction picks a hand. The result is a twist

$$\beta = \tfrac{1}{2} g_{\phi\gamma} \big(\phi_{\rm obs} - \phi_{\rm LSS} \big), \tag{T1.49}$$

set by how much the field changed between last scattering and today, and independent of the frequency of the light [57, 62, 73]. Such "axion-like" fields are candidates for dark matter and dark energy. If the field had always been constant, or did not couple, $\beta = 0$. Because the CMB has travelled for almost the whole age of the universe, it is the most sensitive test: a nonzero β would be a sign of parity violation in the laws of physics beyond the Standard Model. For the data analyst the microphysics matters through three consequences, all met already: β is the same in every channel, it is (for a field that is uniform on the sky) the same in every direction, and its signature is the set of spectra of Section T1.10.2. Equation (T1.49) also says that the early proposals and searches for a twist in the CMB [62, 63] are, in this language, measurements of $g_{\phi\gamma} \Delta\phi$.

Faraday rotation is also a helicity phase difference, caused by free electrons in a magnetic field, but its phase grows with the square of the wavelength (Section T1.11.4). That is the physical reason it is told apart by frequency, while a pseudoscalar twist is not. Both statements can be derived from the motion of a charge pushed by the wave, which is the subject of the next subsection.

T1.12.2 How matter turns light: the electron on a spring

The helicity identity (T1.48) turned the question "what twists the plane of polarization?" into "what gives the two helicities different phases?". For the pseudoscalar field the answer was stated with a citation. For ordinary matter it can be derived from a model every physicist has met, a charge on a spring, and the derivation shows what a twist needs and what it does not need.

Lay a crystal of calcite on a printed page and every letter appears twice. Light polarized along one direction in the crystal travels at one speed, light polarized at right angles to it at another, and the two images are made of the two polarizations. Now put a glass of clear syrup between two polarizing filters, as in the polarimeters that sugar refineries use. The light that leaves the syrup is still linearly polarized, but along a turned direction, and the turn grows with the depth of syrup and with the amount of sugar in it. In white light the turn differs from colour to colour, so the filters show colours. Both materials have two speeds of light. They do different things to the light because the two kinds of light that keep their shape inside them are different: two straight lines in the crystal, two circles, one turning each way, in the syrup, whose sugar molecules are handed. A strong magnet laid along the beam makes plain glass behave like the syrup; Faraday found this in 1845.

In the language of physics: the electrons of a medium are held by springs. In a crystal the springs are stiffer along some directions than others. A magnetic field adds a sideways force on a moving electron that couples its motion along x with its motion along y, with a

sense of rotation. The whole idea in one sentence: *the medium acts on the wave through a matrix, the polarizations that keep their shape are the eigenvectors of that matrix, and a wave that is not an eigenvector changes shape because its two eigen-components drift out of phase.* Whether that change is a rotation depends only on which eigenvectors the matrix has. The naive guess, that a crystal whose axes are turned would turn the light, fails: the crystal's eigenvectors are still straight lines, and a mixture of two straight lines drifting out of phase becomes an ellipse. To turn the plane and keep it a plane, the eigenvectors must be the two helicities.

One idea, many names. A state that is a mixture of two eigenstates with different eigenvalues changes as the eigenstates drift in phase. Two coupled pendulums pass their swinging back and forth this way; a neutrino born as one flavour turns into another; a spin in a magnetic field precesses. Faraday rotation is the precession of the light's polarization about the direction of the field, and the mathematics is that of a two-state system in quantum mechanics.

The electron on a spring. Let a charge q of mass m be bound to an atom, displaced from its rest position by $\boldsymbol{r}$. It feels a restoring force $-m\,\Omega_0^2\boldsymbol{r}$, where Ω_0^2 is a symmetric 3×3 matrix of spring constants divided by the mass, equal to $\omega_0^2\mathbb{1}$ for a spring that is equally stiff in every direction; a friction force $-m\gamma\dot{\boldsymbol{r}}$; the electric field $\boldsymbol{E}(t)$ of the wave; and, if there is one, a steady magnetic field $\boldsymbol{B}_0$. Newton's law is

$$m\ddot{\boldsymbol{r}} = -m\,\Omega_0^2\boldsymbol{r} - m\gamma\dot{\boldsymbol{r}} + q\boldsymbol{E} + q\,\dot{\boldsymbol{r}}\times\boldsymbol{B}_0. \tag{T1.50}$$

(The magnetic field of the wave itself also pushes, but with a force smaller by the speed of the electron over c, which we neglect.) *How does the charge answer a wave of one frequency?* Write the wave as $\boldsymbol{E}e^{-i\omega t}$ and look for the steady answer $\boldsymbol{r}e^{-i\omega t}$, with the physical quantities the real parts. Then $\dot{\boldsymbol{r}}\to -i\omega\boldsymbol{r}$ and $\ddot{\boldsymbol{r}}\to -\omega^2\boldsymbol{r}$. Without $\boldsymbol{B}_0$,

$$\begin{aligned} -m\omega^2\boldsymbol{r} &\overset{(1)}{=} -m\,\Omega_0^2\boldsymbol{r} + im\gamma\omega\,\boldsymbol{r} + q\boldsymbol{E}, \\ \left[\Omega_0^2 - \omega^2\mathbb{1} - i\omega\gamma\mathbb{1}\right]\boldsymbol{r} &\overset{(2)}{=} \frac{q}{m}\boldsymbol{E}, \qquad \boldsymbol{r} \overset{(3)}{=} \frac{q}{m}\left[\Omega_0^2 - \omega^2\mathbb{1} - i\omega\gamma\mathbb{1}\right]^{-1}\boldsymbol{E}. \end{aligned} \tag{T1.51}$$

(1) Insert the oscillating forms into (T1.50) with $\boldsymbol{B}_0 = 0$; the common factor $e^{-i\omega t}$ cancels, and $-m\gamma(-i\omega)\boldsymbol{r} = im\gamma\omega\boldsymbol{r}$.
(2) Move every term with $\boldsymbol{r}$ to the left and divide by m.
(3) Multiply by the inverse matrix, which exists as long as ω is not exactly a resonance of an undamped spring.

With N such charges per unit volume, each displaced by $\boldsymbol{r}$, the medium carries a dipole moment $Nq\boldsymbol{r}$ per unit volume. Writing it as $\varepsilon_0\chi\boldsymbol{E}$ defines the **susceptibility** matrix, and with it the relative permittivity:

$$\chi(\omega) = \omega_p^2\left[\Omega_0^2 - \omega^2\mathbb{1} - i\omega\gamma\mathbb{1}\right]^{-1}, \qquad \varepsilon_r(\omega) = \mathbb{1} + \chi(\omega), \qquad \omega_p^2 \equiv \frac{Nq^2}{\varepsilon_0 m}. \tag{T1.52}$$

The frequency ω_p is the **plasma frequency** of the charges: it measures how many there are and how easily they move.

Which waves can travel? In the medium there are no free charges or currents beyond the bound ones already inside ε_r, so Maxwell's equations read $\nabla\times\boldsymbol{E} = -\partial_t\boldsymbol{B}$ and $\nabla\times\boldsymbol{B} = \mu_0\varepsilon_0\varepsilon_r\,\partial_t\boldsymbol{E}$. Try a plane wave along z, $\boldsymbol{E}\,e^{i(kz-\omega t)}$, for which $\nabla\times$ becomes $ik\,\hat{\boldsymbol{z}}\times$ and ∂_t becomes $-i\omega$:

$$\begin{aligned} \boldsymbol{B} &\overset{(1)}{=} \frac{k}{\omega}\,\hat{\boldsymbol{z}}\times\boldsymbol{E}, \\ ik\,\frac{k}{\omega}\,\hat{\boldsymbol{z}}\times(\hat{\boldsymbol{z}}\times\boldsymbol{E}) &\overset{(2)}{=} -\frac{i\omega}{c^2}\,\varepsilon_r\boldsymbol{E}, \\ \frac{c^2k^2}{\omega^2}\,\boldsymbol{E}_\perp &\overset{(3)}{=} \varepsilon_r\boldsymbol{E}, \qquad \left[\varepsilon_{r\perp} - n^2\mathbb{1}\right]\boldsymbol{E}_\perp \overset{(4)}{=} 0, \qquad n \equiv \frac{ck}{\omega}. \end{aligned} \tag{T1.53}$$

(1) The first Maxwell equation: $ik\,\hat{\boldsymbol{z}} \times \boldsymbol{E} = i\omega \boldsymbol{B}$.
(2) The second, with $\boldsymbol{B}$ from the first line inserted and $\mu_0\varepsilon_0 = 1/c^2$.
(3) The vector identity $\hat{\boldsymbol{z}} \times (\hat{\boldsymbol{z}} \times \boldsymbol{E}) = \hat{\boldsymbol{z}}(\hat{\boldsymbol{z}} \cdot \boldsymbol{E}) - \boldsymbol{E} = -\boldsymbol{E}_\perp$, the part of $\boldsymbol{E}$ across z; then multiply by ic^2/ω.
(4) In both media below ε_r does not mix z with x and y. The z row then reads $\varepsilon_{r,zz}E_z = 0$, so $E_z = 0$, and the x, y rows form a 2×2 problem with the transverse block $\varepsilon_{r\perp}$.

This is an eigenvalue problem. *The polarizations that can travel unchanged are the eigenvectors of $\varepsilon_{r\perp}$, and their refractive indices squared are its eigenvalues.* A medium is **birefringent** when the two eigenvalues differ. Away from a resonance the friction γ can be dropped, the matrix is then Hermitian in both cases below, and the indices are real; a nonzero γ makes them complex, which is absorption, and absorption that differs between the two eigenvectors is called dichroism. Figure T1.21 shows the idea as a sum of the two eigen-polarizations, and Figure T1.22 follows the shape step by step through the medium.

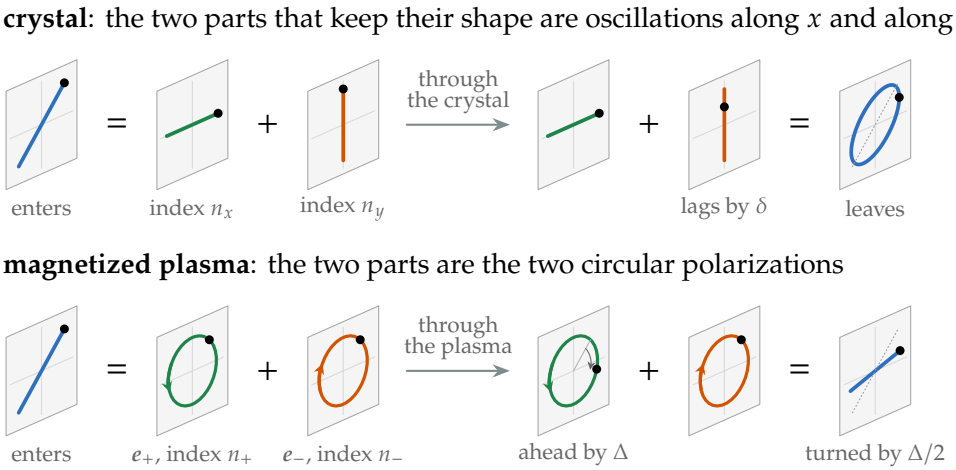

Figure T1.21: What a birefringent medium does: split the wave into the two polarizations that keep their shape, let them drift apart in phase, and add them up again. The dot in each box is the tip of that part of the field at one instant. Top: in a crystal the parts are oscillations along x and y; they enter in step, so their sum is the 45° line, and after the crystal the y part lags by δ (its dot has not yet reached the end when the x dot has), so the sum traces an ellipse instead of a line. Bottom: in a magnetized plasma the parts are the two circular polarizations turning in opposite senses; their sum is a straight line pointing midway between the two dots. One part gets ahead by Δ, the midway direction moves by $\Delta/2$, and the line leaves turned by $\Delta/2$ (dotted: the entering direction).

Case A: a crystal. Let the springs have different stiffness along x and y, $\Omega_0^2 = \mathrm{diag}(\omega_{0x}^2, \omega_{0y}^2, \omega_{0z}^2)$, with no magnetic field and no friction. Every matrix in (T1.52) is then diagonal, and so is

$$\varepsilon_{r\perp} = \begin{pmatrix} 1 + \dfrac{\omega_p^2}{\omega_{0x}^2 - \omega^2} & 0 \\ 0 & 1 + \dfrac{\omega_p^2}{\omega_{0y}^2 - \omega^2} \end{pmatrix}. \tag{T1.54}$$

Its eigenvectors are $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{y}}$, with indices n_x^2 and n_y^2 equal to the two diagonal entries; they differ when $\omega_{0x} \neq \omega_{0y}$. This is **linear birefringence**: a wave polarized along x or along y crosses the crystal unchanged. *What happens to a wave at* 45°*?* At the entrance it is $\boldsymbol{E} = \frac{E_0}{\sqrt{2}}(\hat{\boldsymbol{x}} + \hat{\boldsymbol{y}})$. Each part

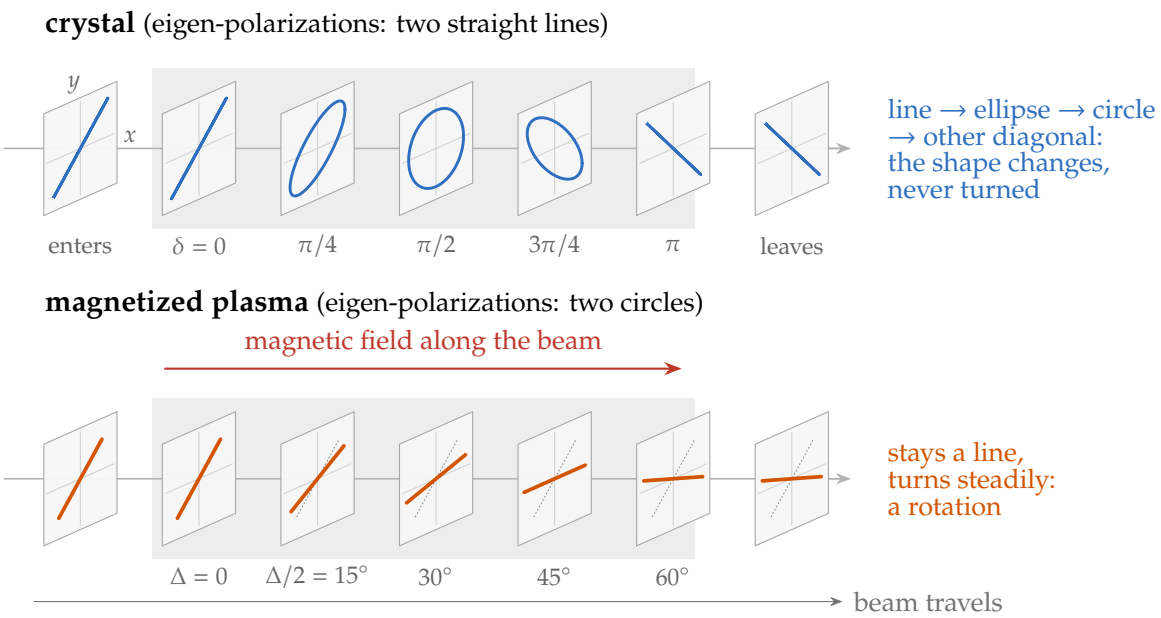

Figure T1.22: The same two media followed step by step along the beam, for a wave that enters linearly polarized at 45°. Each tilted frame is the plane at right angles to the beam at one depth inside the medium (shaded), and shows the curve traced there by the tip of the electric field. In a crystal the two waves that keep their shape are straight lines along x and y; as they drift apart in phase by δ, the line opens into an ellipse, then a circle, then closes again along the other diagonal, but it is never turned. In a magnetized plasma the two waves that keep their shape are the two circular polarizations; as they drift apart by Δ, the wave stays a straight line and turns steadily, by $\Delta/2$ (dotted: the entering direction).

travels with its own wavenumber $k = n\omega/c$, so after a length L

$$\boldsymbol{E}(L) \overset{(1)}{=} \frac{E_0}{\sqrt{2}}\left(\hat{\boldsymbol{x}}\, e^{in_x\omega L/c} + \hat{\boldsymbol{y}}\, e^{in_y\omega L/c}\right) \overset{(2)}{=} e^{in_x\omega L/c}\,\frac{E_0}{\sqrt{2}}\left(\hat{\boldsymbol{x}} + \hat{\boldsymbol{y}}\, e^{i\delta}\right), \qquad \delta \equiv (n_y - n_x)\frac{\omega L}{c},$$
$$Q \overset{(3)}{=} \tfrac{1}{2}E_0^2 - \tfrac{1}{2}E_0^2 = 0, \qquad U \overset{(4)}{=} 2\cdot\tfrac{1}{2}E_0^2\cos(0-\delta) = E_0^2\cos\delta. \tag{T1.55}$$

(1) Each eigenvector picks up its own phase $kL = n\omega L/c$ and keeps its direction.
(2) Take out the phase of the x part, which is common to the whole wave and invisible in the Stokes numbers.
(3) The definition (T1.20) with $a_1 = a_2 = E_0/\sqrt{2}$.
(4) The same with the phase difference $\theta_1 - \theta_2 = -\delta$.

The tip of the real field traces $E_x \propto \cos\omega t$, $E_y \propto \cos(\omega t - \delta)$: a line for $\delta = 0$, an ellipse with its axes along the two diagonals, a circle at $\delta = \pi/2$, and a line along the other diagonal at $\delta = \pi$ (Figure T1.24(a)). Q stays zero and the linear polarization $|U| = E_0^2\,|\cos\delta|$ shrinks and comes back, while the circular part V, set aside since Section T1.9.1, grows as $\sin\delta$. The stick is never turned; the light becomes partly circular. Even the plate with $\delta = \pi$ that sends the 45° line to −45° is not a rotation: it sends a stick at ψ from the x axis to $-\psi$, so a stick at 10° goes to −10° and one at 30° to −30°. That is a mirror in the x axis, not the same turn for every stick.

Case B: electrons in a magnetic field. Now let the springs be equally stiff in every direction, $\Omega_0^2 = \omega_0^2\mathbb{1}$, and put a steady field $\boldsymbol{B}_0 = B_0\hat{\boldsymbol{z}}$ along the direction of the wave. The only new force in (T1.50) is the magnetic one, $q\,\dot{\boldsymbol{r}} \times \boldsymbol{B}_0 = qB_0\,(\dot{y}, -\dot{x}, 0)$: a charge moving along x is pushed along $-y$, one moving along y is pushed along $+x$. The field therefore *couples* the two directions: the motion along y feeds the equation for x, and the motion along x feeds the equation for y.

The two equations, written out. Insert the oscillating forms $\boldsymbol{r}e^{-i\omega t}$ and $\boldsymbol{E}e^{-i\omega t}$ as before, so that $\dot{x} \to -i\omega x$ and $\dot{y} \to -i\omega y$. The x and y rows of (T1.50) become

$$
\begin{aligned}
-m\omega^2 x &\overset{(1)}{=} -m\omega_0^2 x + im\gamma\omega\, x + qE_x + qB_0(-i\omega y),\\
-m\omega^2 y &\overset{(2)}{=} -m\omega_0^2 y + im\gamma\omega\, y + qE_y - qB_0(-i\omega x),\\
a\,x + i\omega\omega_c\, y &\overset{(3)}{=} \frac{q}{m}E_x, \qquad -i\omega\omega_c\, x + a\, y \overset{(3)}{=} \frac{q}{m}E_y, \qquad a \equiv \omega_0^2 - \omega^2 - i\omega\gamma, \qquad \omega_c \equiv \frac{qB_0}{m},\\
M\begin{pmatrix} x \\ y \end{pmatrix} &\overset{(4)}{=} \frac{q}{m}\begin{pmatrix} E_x \\ E_y \end{pmatrix}, \qquad M = \begin{pmatrix} a & i\omega\omega_c \\ -i\omega\omega_c & a \end{pmatrix}.
\end{aligned}
\tag{T1.56}
$$

(1) The x component: spring, friction and electric force as in Case A, plus the x component of the magnetic force, $qB_0\dot{y}$ with $\dot{y} = -i\omega y$.
(2) The y component: the same, plus the y component of the magnetic force, $-qB_0\dot{x}$ with $\dot{x} = -i\omega x$.
(3) Move every term with x or y to the left and divide by m. In the first equation $-qB_0(-i\omega y)/m$ on the left is $+i\omega\omega_c\, y$; in the second, $+qB_0(-i\omega x)/m$ on the left is $-i\omega\omega_c\, x$.
(4) Write the two equations as one matrix equation: the first equation is the first row of M, the second is the second row.

Without the field ($\omega_c = 0$) M is a times the unit matrix and x and y answer separately. The field adds two off-diagonal entries of opposite sign, an antisymmetric part, which a crystal cannot produce because its spring matrix is symmetric. The quantity ω_c is the **cyclotron frequency**, the rate at which the charge would circle the field line; its sign is set by the charge and the direction of the field.

Which polarizations keep their shape? They are the eigenvectors of M, because $\chi = \omega_p^2 M^{-1}$ by (T1.52) and a matrix and its inverse share their eigenvectors. Find them the standard way, from the eigenvalues:

$$
\begin{aligned}
\det(M - \lambda\mathbb{1}) &\overset{(1)}{=} (a-\lambda)^2 - (i\omega\omega_c)(-i\omega\omega_c) \overset{(2)}{=} (a-\lambda)^2 - \omega^2\omega_c^2 = 0 \quad \Rightarrow \quad \lambda_\pm \overset{(3)}{=} a \mp \omega\omega_c,\\
(M - \lambda_\pm\mathbb{1})\begin{pmatrix} 1 \\ s \end{pmatrix} &\overset{(4)}{=} \begin{pmatrix} \pm\omega\omega_c + i\omega\omega_c\, s \\ -i\omega\omega_c \pm \omega\omega_c\, s \end{pmatrix} = 0 \quad \Rightarrow \quad s \overset{(5)}{=} \pm i, \qquad \boldsymbol{e}_\pm = \frac{\hat{\boldsymbol{x}} \pm i\hat{\boldsymbol{y}}}{\sqrt{2}},\\
n_\pm^2 &\overset{(6)}{=} 1 + \frac{\omega_p^2}{\omega_0^2 - \omega^2 \mp \omega\omega_c} \qquad (\gamma = 0).
\end{aligned}
\tag{T1.57}
$$

(1) The determinant of a 2×2 matrix: product of the diagonal minus product of the off-diagonal entries.
(2) $(i)(-i) = 1$.
(3) $(a-\lambda)^2 = \omega^2\omega_c^2$, so $a - \lambda = \pm\omega\omega_c$.
(4) Apply $M - \lambda_\pm\mathbb{1}$, whose diagonal entries are $a - \lambda_\pm = \pm\omega\omega_c$, to a vector with first entry 1 and second entry s.
(5) The first row gives $\pm 1 + is = 0$, so $s = \pm i$; the second row gives the same. Normalised, the eigenvectors are exactly the helicity vectors of (T1.48).
(6) $\varepsilon_{r\perp} = \mathbb{1} + \omega_p^2 M^{-1}$ has eigenvalues $1 + \omega_p^2/\lambda_\pm$ on these same vectors, and these are $n_\pm^2$ by (T1.53).

The two waves that keep their shape are the two helicities, with different indices $n_+ \neq n_-$ as soon as $\omega_c \neq 0$. This is **circular birefringence**. *What happens to a linear polarization?* By (T1.48), a stick at angle ψ is the equal mixture $(e^{-i\psi}\boldsymbol{e}_+ + e^{i\psi}\boldsymbol{e}_-)/\sqrt{2}$. After a length L each helicity has

picked up its own phase $\phi_\pm = n_\pm \omega L/c$, and with $\Delta \equiv \phi_+ - \phi_-$ and $\bar\phi \equiv \frac{1}{2}(\phi_+ + \phi_-)$,

$$\frac{e^{-i\psi}e^{i\phi_+}\boldsymbol{e}_+ + e^{i\psi}e^{i\phi_-}\boldsymbol{e}_-}{\sqrt{2}} \overset{(1)}{=} e^{i\bar\phi}\,\frac{e^{-i(\psi-\Delta/2)}\boldsymbol{e}_+ + e^{i(\psi-\Delta/2)}\boldsymbol{e}_-}{\sqrt{2}} \overset{(2)}{=} e^{i\bar\phi}\left[\cos(\psi-\tfrac{\Delta}{2})\,\hat{\boldsymbol{x}} + \sin(\psi-\tfrac{\Delta}{2})\,\hat{\boldsymbol{y}}\right]. \tag{T1.58}$$

(1) Write $\phi_\pm = \bar\phi \pm \Delta/2$ and take out the common phase $e^{i\bar\phi}$.
(2) (T1.48) with ψ replaced by $\psi - \Delta/2$.

The wave leaves still linearly polarized, with the same strength, and its plane turned by $-\Delta/2$: half the phase difference of the two helicities, as found in Section T1.12.1, and the same turn for every starting angle ψ (Figure T1.24(b)). The sense of the turn is set by the sign of ω_c, that is by the sign of the charge and the direction of the field. This is a rotation, a twist of every stick by the same angle, and it is the rule (T1.22) with $\beta = -\Delta/2$.

How does the angle depend on frequency? Take free electrons in an ionized gas: no spring, $\omega_0 = 0$, charge $q = -e$, and no friction. Then $n_\pm^2 = 1 - \omega_p^2/[\omega(\omega \pm \omega_c)]$, and the gas is transparent only above the plasma frequency. For radio and microwave light crossing interstellar or intergalactic gas the plasma and cyclotron frequencies are in the kilohertz range or below, far beneath the gigahertz of the light, so we expand in the small ratios ω_p/ω and ω_c/ω:

$$\begin{aligned} n_\pm &\overset{(1)}{=} \left[1 - \frac{\omega_p^2}{\omega^2}\left(1 \pm \frac{\omega_c}{\omega}\right)^{-1}\right]^{1/2} \overset{(2)}{=} 1 - \frac{\omega_p^2}{2\omega^2}\left(1 \mp \frac{\omega_c}{\omega}\right), \\ \Delta &\overset{(3)}{=} (n_+ - n_-)\frac{\omega L}{c} \overset{(4)}{=} \frac{\omega_p^2 \omega_c}{\omega^3}\,\frac{\omega L}{c} = \frac{\omega_p^2\,\omega_c\,L}{c\,\omega^2} \overset{(5)}{=} \frac{\omega_p^2\,\omega_c\,L}{4\pi^2 c^3}\,\lambda^2. \end{aligned} \tag{T1.59}$$

(1) Take ω^2 out of $\omega(\omega \pm \omega_c)$ and the square root of $n_\pm^2$.
(2) To first order, $(1 \pm x)^{-1} \approx 1 \mp x$ and $(1 - y)^{1/2} \approx 1 - y/2$; products of the two small ratios beyond $\omega_p^2\omega_c/\omega^3$ are dropped.
(3) The definition of Δ with $\phi_\pm = n_\pm \omega L/c$.
(4) In the difference of the two indices the terms $1 - \omega_p^2/2\omega^2$ cancel; what is left is $+\omega_p^2\omega_c/2\omega^3$ in n_+ and $-\omega_p^2\omega_c/2\omega^3$ in n_-, which differ by $\omega_p^2\omega_c/\omega^3$.
(5) $\omega = 2\pi c/\lambda$, so $1/\omega^2 = \lambda^2/(4\pi^2c^2)$.

The index difference falls as ω^{-3}, the path in wavelengths grows as ω, and the phase difference, hence the angle $|\Delta|/2$, grows as λ^2. That is the law of **Faraday rotation**. Inserting $\omega_p^2 = n_e e^2/(\varepsilon_0 m_e)$ for n_e electrons per unit volume and $|\omega_c| = eB_\parallel/m_e$, and adding up the contributions of a gas whose density and field change along the path, the angle is

$$\frac{|\Delta|}{2} = \mathrm{RM}\,\lambda^2, \qquad \mathrm{RM} = \frac{e^3}{8\pi^2\varepsilon_0 m_e^2 c^3}\int n_e B_\parallel \,\mathrm{d}l = 0.812\,\mathrm{rad\,m^{-2}} \int \frac{n_e}{\mathrm{cm^{-3}}}\,\frac{B_\parallel}{\mu\mathrm{G}}\,\frac{\mathrm{d}l}{\mathrm{pc}}, \tag{T1.60}$$

the standard rotation measure, which is what [68] evaluate for a primordial field. The λ^2 law is the high-frequency limit. Figure T1.24(c) compares it with the exact indices of (T1.57) for a plasma with $\omega_c = 0.2\,\omega_p$: at ten times the plasma frequency the exact angle exceeds the law by 0.54%, at three times by 6.6%, and near the plasma frequency the law fails. For the CMB, more than a million times above the plasma frequency of the gas it crosses, the law is exact for all practical purposes.

Case C: cosmic birefringence. The medium is now empty space filled with the slowly changing pseudoscalar field ϕ of (T1.49). With the coupling $\frac{1}{4}g_{\phi\gamma}\phi F_{\mu\nu}\tilde F^{\mu\nu}$, Maxwell's equations again have the two helicities as the waves that keep their shape, and again give them different

phases. The difference is how that phase depends on frequency. For a field changing in time at the rate $\dot{\phi}$, the two helicities with the same wavenumber have frequencies that differ by $g_{\phi\gamma}\dot{\phi}$, the same amount for every wavelength [72, 73]. Equivalently, at one frequency their wavenumbers differ by a fixed amount. Over the journey from last scattering the phase difference adds up to $g_{\phi\gamma}(\phi_{\rm obs} - \phi_{\rm LSS})$, and by (T1.58) the plane turns by half of it, which is the twist β of (T1.49) (its sign depends on the conventions for $g_{\phi\gamma}$ and for the angle). In Faraday rotation the splitting of the two indices, $n_+ - n_- \propto \omega^{-3}$, falls faster than the path in wavelengths grows, and the angle goes as λ^2; here the splitting of the wavenumbers is a constant, $n_+ - n_- \propto \omega^{-1}$, which exactly cancels the growth of the path in wavelengths, and the angle is the same at every frequency. This is the difference between the Faraday row and the birefringence row of the table in Section T1.11.5, a λ^2 law against a constant, and it is the reason the colour test of Figure T1.20(b) can separate them. Figure T1.23 shows the two cases side by side for two colours.

(a) Faraday rotation
red light (twice the wavelength) turns four times as far: $\propto \lambda^2$

(b) cosmic birefringence
every colour turns by the same angle β

Figure T1.23: Two colours of light, both entering linearly polarized along the dotted line, after crossing (a) a magnetized plasma and (b) the pseudoscalar field of cosmic birefringence. Blue is the shorter wavelength, red the wavelength twice as long. In (a) the red line turns four times as far as the blue, because the Faraday angle grows as λ^2. In (b) the two lines lie on top of each other (red dashed over blue): the angle β is the same at every wavelength.

Birefringence is not dispersion. Birefringence means two different eigenvalues at one frequency: two polarizations travel at two speeds. Dispersion means one eigenvalue that changes with frequency: different colours travel at different speeds. Because χ in (T1.52) depends on ω, the Lorentz model has both, and the Faraday law needs both: the two indices differ, and their difference changes with frequency. Dispersion alone, such as $n^2 = 1 - \omega_p^2/\omega^2$ in a plasma without a magnetic field, delays a pulse but leaves every polarization as it was, because both eigenvalues move together.

medium	what makes the two indices differ	waves that keep their shape	a 45° line becomes
crystal	springs of different stiffness	lines along x, y	an ellipse, not turned
magnetized plasma	the force $q\,\dot{\boldsymbol{r}} \times \boldsymbol{B}_0$	the two helicities	a line turned by $\propto \lambda^2$
pseudoscalar field	$\phi F\tilde{F}$ with $\dot{\phi} \neq 0$	the two helicities	a line turned by β, any λ

T1.12.3 The Galaxy as a reference: the Minami–Komatsu relation

The observed spectra. A map at one frequency contains the CMB, the Galactic foreground ("fg"), and noise. By Figure T1.25, the foreground is twisted by α and the CMB by $\alpha + \beta$, so by (T1.37)

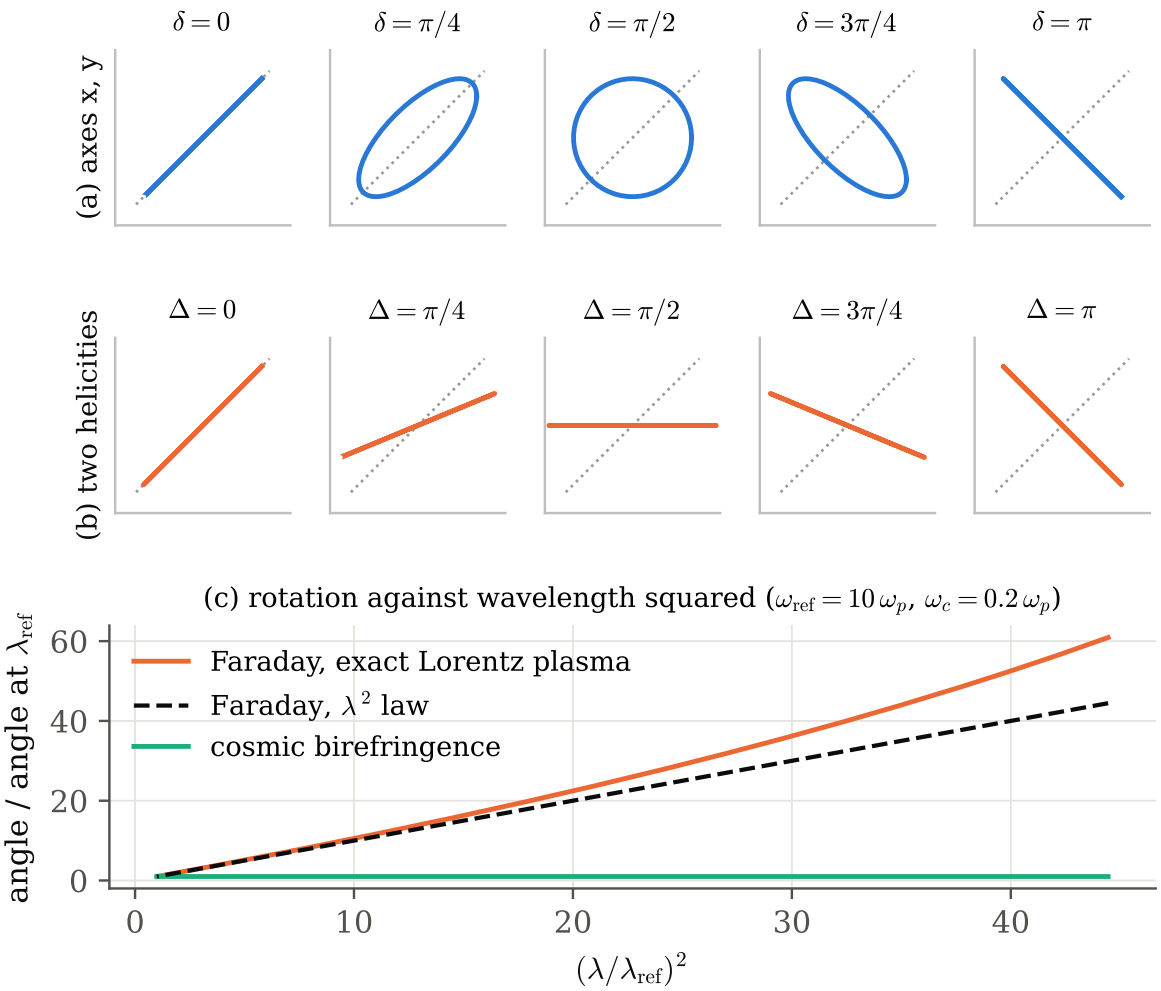

Figure T1.24: Linear against circular birefringence. A wave enters linearly polarized at 45° (dotted). (a) In a crystal, after a phase difference δ between the x and y parts, the tip of the electric field traces an ellipse, then a circle, then the line along the other diagonal; the axis of the ellipse never turns. (b) With the two helicities as the travelling waves, a phase difference Δ leaves the light linearly polarized and turns the line by $\Delta/2$. (c) The angle of turn against the square of the wavelength, each normalised to its value at a reference wavelength: Faraday rotation in a cold magnetized plasma from the exact Lorentz-model indices (orange), its high-frequency λ^2 law (dashed), and cosmic birefringence, the same at every wavelength (green). The exact curve leaves the λ^2 law only as the frequency approaches the plasma frequency.

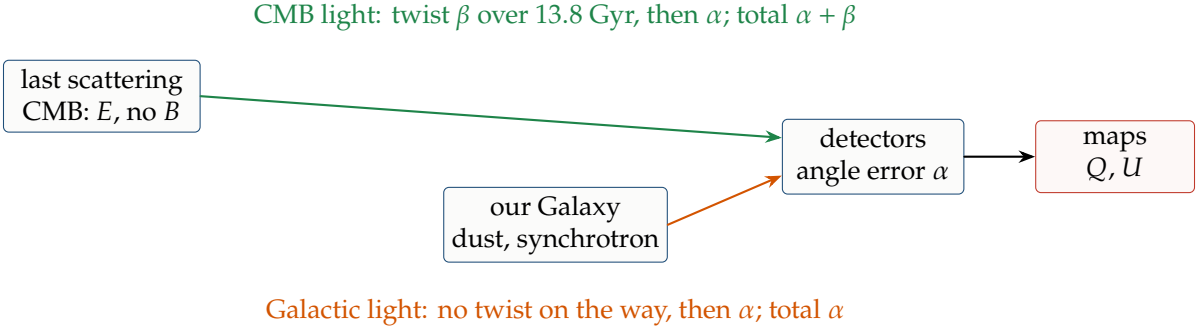

Figure T1.25: The door frame of the microwave sky. CMB light (green) is twisted by β on its long journey and then by the detector angle error α; light from the Galaxy (orange) travels too short a distance to be twisted by β and receives only α. The maps contain both, so the twists of the two components can be measured separately.

applied to each,

$$E^{\rm o}_{\ell m} + iB^{\rm o}_{\ell m} = e^{2i\alpha}\left(E^{\rm fg}_{\ell m} + iB^{\rm fg}_{\ell m}\right) + e^{2i(\alpha+\beta)}\left(E^{\rm CMB}_{\ell m} + iB^{\rm CMB}_{\ell m}\right) + \text{noise}. \tag{T1.61}$$

Assume, as [57, 71] do in their baseline, that neither the foreground nor the CMB has an EB of its own, and that the CMB, the foreground and the noise are uncorrelated, so the cross terms between them vanish on average. Each component then contributes to the averaged spectra exactly as in Section T1.10.2, with its own angle. Writing $\Delta^X_\ell \equiv C^{EE,X}_\ell - C^{BB,X}_\ell$ for the component X, and leaving out the noise, which has $EE = BB$ and no EB,

$$\begin{aligned} C^{EB,\rm o}_\ell &\overset{(1)}{=} \tfrac{1}{2}\sin 4\alpha\, \Delta^{\rm fg}_\ell + \tfrac{1}{2}\sin(4\alpha+4\beta)\,\Delta^{\rm CMB}_\ell, \\ C^{EE,\rm o}_\ell - C^{BB,\rm o}_\ell &\overset{(2)}{=} \cos 4\alpha\, \Delta^{\rm fg}_\ell + \cos(4\alpha+4\beta)\,\Delta^{\rm CMB}_\ell. \end{aligned} \tag{T1.62}$$

(1) (T1.40) for each component, with the angle α for the foreground and $\alpha+\beta$ for the CMB.
(2) $C^{EE\prime} - C^{BB\prime} = \cos 4\beta\,(C^{EE} - C^{BB})$ from Section T1.10.3, again with each component's own angle; the noise has $C^{EE} = C^{BB}$ and drops out.

Removing the unknown foreground. We do not know $\Delta^{\rm fg}_\ell$; modelling the Galaxy is exactly what we want to avoid. But it appears in both lines with known coefficients, so it can be eliminated:

$$\begin{aligned} C^{EB,\rm o}_\ell - \tfrac{1}{2}\tan 4\alpha\left(C^{EE,\rm o}_\ell - C^{BB,\rm o}_\ell\right) &\overset{(1)}{=} \tfrac{1}{2}\left[\sin(4\alpha+4\beta) - \tan 4\alpha\cos(4\alpha+4\beta)\right]\Delta^{\rm CMB}_\ell \\ &\overset{(2)}{=} \frac{\sin(4\alpha+4\beta)\cos 4\alpha - \sin 4\alpha\cos(4\alpha+4\beta)}{2\cos 4\alpha}\,\Delta^{\rm CMB}_\ell \\ &\overset{(3)}{=} \frac{\sin 4\beta}{2\cos 4\alpha}\,\Delta^{\rm CMB}_\ell. \end{aligned} \tag{T1.63}$$

(1) Insert both lines of (T1.62); the foreground terms are $\frac{1}{2}\sin 4\alpha\,\Delta^{\rm fg} - \frac{1}{2}\tan 4\alpha\cos 4\alpha\,\Delta^{\rm fg} = 0$, since $\tan 4\alpha\cos 4\alpha = \sin 4\alpha$.
(2) Put both terms over the common denominator $\cos 4\alpha$.
(3) The subtraction formula $\sin(A+B)\cos A - \sin A\cos(A+B) = \sin B$ with $A = 4\alpha$, $B = 4\beta$.

Rearranged, this is the relation of [71] (their eq. 9 without the noise and intrinsic-EB terms):

$$C^{EB,\rm o}_\ell = \frac{\tan 4\alpha}{2}\left(C^{EE,\rm o}_\ell - C^{BB,\rm o}_\ell\right) + \frac{\sin 4\beta}{2\cos 4\alpha}\left(C^{EE,\rm CMB}_\ell - C^{BB,\rm CMB}_\ell\right). \tag{T1.64}$$

Read it in words. The first term uses the *observed* $EE - BB$ of the map, foreground and all, and its coefficient depends only on α: everything in the map has been twisted by α. The second term uses the *theoretical* CMB spectra from the ΛCDM fit, and its coefficient carries β: only the CMB has the extra twist. Where the foreground is negligible, $C^{EE,\rm o} - C^{BB,\rm o} \approx \cos(4\alpha+4\beta)\Delta^{\rm CMB}$ has the same shape as the second template and the two terms cannot be separated; that is the degeneracy of Section T1.10.6 again. Where the foreground contributes, the observed $EE - BB$ has a different shape in ℓ (a power law added to the acoustic peaks) and a different size in each frequency channel, and the two coefficients are separately measurable. With no foreground at all and $\beta = 0$, (T1.64) reduces to the sky-by-sky relation $\widehat{C}^{EB} = \frac{1}{2}\tan 4\alpha(\widehat{C}^{EE} - \widehat{C}^{BB})$ verified on simulations in Section T1.10.5.

How well can it work? Figure T1.26 gives a size, from a Fisher forecast in `code/chT1/09_alpha_beta_fisher.py`. The set-up is one frequency channel covering 70% of the sky with white noise of 50 μK-arcmin and a 5′ beam, $51 \le \ell \le 1500$, the CMB fiducial, and Planck's dust over 71% of the sky [66]; the data are the EB spectrum (T1.62), with the cosmic-variance error of each $\widehat{C}^{EB}_\ell$, $[C^{EE}_\ell C^{BB}_\ell/(2\ell+1)f_{\rm sky}]^{1/2}$ with total spectra, as in Chapter 10. With the CMB alone the Fisher matrix is singular: only the sum is measured, $\sigma(\alpha+\beta) = 0.036°$, the band in the figure.

At 143 GHz the dust is faint: it hardly disturbs the CMB, which still fixes $\sigma(\alpha+\beta) = 0.038°$, but it anchors α only weakly, and the band closes into a long, thin ellipse with $\sigma(\beta) = 0.8578°$. At 353 GHz, where the dust is 549 times brighter in power than at 143 GHz, the dust anchors α well, $\sigma(\alpha) = 0.1129°$, but over 70% of the sky its EE and BB exceed those of the CMB at every multipole used, so it also swamps the CMB's EB with chance scatter: the sum is known only to $0.271°$, and $\sigma(\beta) = 0.3717°$. One channel faces a trade-off, too little dust to calibrate or so much that it blurs the CMB. In both cases α and β are strongly anti-correlated (correlation coefficients -0.999 and -0.924), because $\alpha+\beta$ is better measured than β itself, and $\beta = (\alpha+\beta) - \alpha$. The real analyses combine several channels, each with its own α_ν and a single β, which is how [57] reach $\sigma(\beta) = 0.14°$; their posterior shows the same anti-correlation. The forecast assumes the dust spectra are known; the measurement does not need them, because (T1.64) uses the observed $EE - BB$.

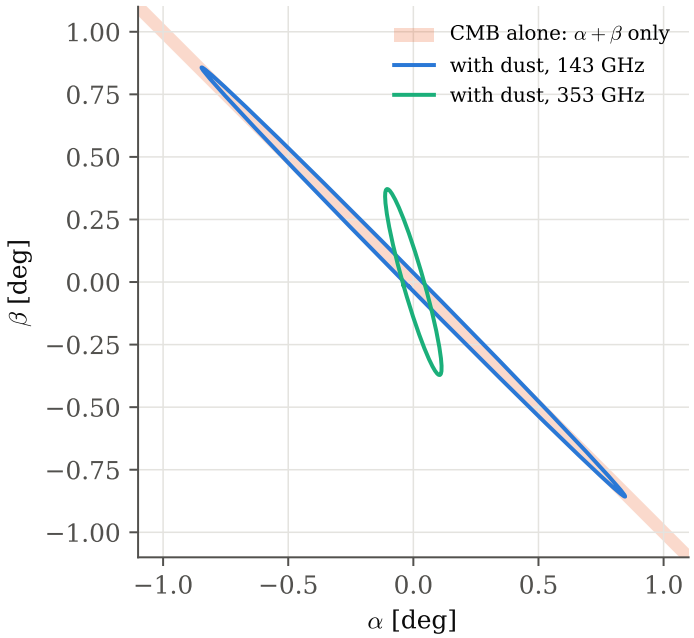

Figure T1.26: Fisher forecast for the detector angle α and the birefringence angle β from the EB spectrum of one channel. With the CMB alone only $\alpha+\beta$ is measured (shaded band, 1σ). Adding the dust of the same map, twisted by α only, closes the band into an ellipse (1σ). At 143 GHz, where the dust is faint, the ellipse is long and stays inside the band: the CMB still fixes the sum, and the dust pins α only weakly. At 353 GHz the bright dust pins α tightly, so the ellipse is short in α, but the same dust adds scatter to the CMB's EB, so the ellipse is wider than the band and β is still uncertain by about a third of a degree.

When the door frame is crooked. The method assumes the Galaxy has no EB of its own. Suppose instead the dust has an intrinsic EB, and write it, as [57] do, as if the dust were twisted at the source by an angle γ: $C_\ell^{EB,\mathrm{dust}} = \frac{1}{2}\sin 4\gamma\, \Delta_\ell^{\mathrm{dust}}$. Then the dust in the map is twisted by $\alpha+\gamma$ in total, and

$$\hat{\alpha} \overset{(1)}{=} \alpha+\gamma, \qquad \hat{\alpha}+\hat{\beta} \overset{(2)}{=} \alpha+\beta \quad\Longrightarrow\quad \hat{\beta} \overset{(3)}{=} \beta-\gamma. \tag{T1.65}$$

(1) The method reads the total twist of the foreground as the detector angle.
(2) The CMB still fixes the sum of the detector angle and its own twist, which the method splits as $\hat{\alpha}+\hat{\beta}$.
(3) Subtract the first equation from the second.

The estimate of β is off by exactly the dust's own handedness. Since the dust TB and TE are both positive, the misalignment picture of Section T1.11.3 predicts $\gamma > 0$, so an analysis that

assumes $\gamma = 0$ would underestimate β [57]; but the size and even the sign of the dust EB can change with the sky area [67].

T1.12.4 What has been measured, and why it is not yet a detection

The measurements. With the detector angles fixed at their ground calibration, the Planck team found an angle of $0.31^\circ \pm 0.05^\circ$ (statistical) $\pm 0.28^\circ$ (systematic), where the second error is the calibration uncertainty of α [57]. Applying the relation (T1.64) to the Planck 2018 maps at 100, 143, 217 and 353 GHz, fitting one β and four α_ν, [57] found

$$\beta = 0.35^\circ \pm 0.14^\circ \quad (68\%), \tag{T1.66}$$

which excludes zero at 99.2% confidence, a 2.4σ result, with the calibration uncertainty no longer in the error. Repeating the analysis on the reprocessed Planck data (PR4) gave $\beta = 0.30^\circ \pm 0.11^\circ$ for nearly the full sky, with values that decrease as the Galactic mask is enlarged [74]. Adding WMAP and the Planck low-frequency channels, 23 to 353 GHz, gave

$$\beta = 0.342^{\circ\,+0.094^\circ}_{\;-0.091^\circ} \quad (68\%), \tag{T1.67}$$

excluding zero at 99.987% confidence, 3.6σ, with no evidence that β depends on frequency [75]. The independence of frequency argues against Faraday rotation, whose angle would change by a factor $(353/23)^2 \approx 240$ across that range.

Why is it not yet a detection? Treat it as an inference problem, in the order used throughout the book. *The event:* an EB (and TB) with the shape of a twist, at the level of three to four standard deviations, after the detector angles were fitted using the Galaxy. *What could have produced it?* Four candidates.

1. *Chance.* With a 3.6σ result, a fluctuation of the noise and of the cosmic variance is unlikely, but particle physics and cosmology reserve the word "discovery" for 5σ, because many analyses are performed and systematic errors are often underestimated (Chapter 4).
2. *A crooked door frame.* An intrinsic dust EB shifts the estimate to $\beta - \gamma$ (T1.65). Its size is not known well enough: the dust EB predicted from filament misalignment is of the same order as the effect [67], and the dependence of β on the mask found by [74] is what a foreground effect would produce. Those authors chose not to assign cosmological significance to the value until the foreground polarization is better understood.
3. *The instrument.* Leakage from temperature to polarization and beam effects can create EB and TB (Section T1.11.5). The analyses correct for them with beam models and test the corrections on simulations [57], but the corrections are themselves models.
4. *New physics.* A twist (T1.49) by a pseudoscalar field, $g_{\phi\gamma}\Delta\phi$ of about 10^{-2} radians [57].

Only the last is interesting, and only the last is grey, uniform over the sky and independent of the mask. A detection therefore needs evidence that removes the others: experiments with an independent calibration of α (artificial polarized sources, or well-measured astrophysical ones), a better model of the dust EB from its correlation with TB and TE [67], and agreement between instruments with different detectors and scan strategies.

How this is used in real research: How the measurement is made

The published analyses work with the cross-spectra of maps that share no noise: the two half-mission maps of each frequency channel, in all combinations of channels, so that noise bias drops out [57]. The spectra are measured on the masked sky with a pseudo-C_ℓ code

(NaMaster) that corrects for the mask, which otherwise leaks E into B and mixes multipoles (the MASTER method of Chapter 8). Equation (T1.64), written for every pair of channels, is turned into a Gaussian likelihood whose covariance is estimated from the observed spectra, and α_ν, β are sampled with an MCMC (Chapter 9). The pipeline is validated on end-to-end simulations with no twist, which must return β consistent with zero. Our forecast replaces all of this with one channel, a known dust spectrum and a Fisher matrix; it gives the sizes, not the result. Chapter 13 measures the twist on the Planck SMICA maps, where only the sum $\alpha + \beta$ is accessible because a component-separated map has had its Galaxy removed.

One chain of reasoning runs from the sticks to the published angle. Polarization is a field of headless sticks; its split into E and B is a split by behaviour in a mirror; ordinary physics leaves the parity-odd spectra at zero; a uniform twist moves power from E to B and, unlike lensing, leaves a hand behind in EB and TB; and the twist of the instrument is told from the twist of the sky only by a component, the Galaxy, that sees one of them and not the other.

Recap

- The polarization stick is $Q + iU = Pe^{2i\psi}$; a twist by β multiplies it by $e^{2i\beta}$, and turning the axes by α multiplies it by $e^{-2i\alpha}$.
- E and B are Q and U read in axes aligned with each wavevector; E is mirror symmetric, B changes sign, so a mirror-symmetric universe has $EB = TB = 0$.
- Scalar perturbations make only E; gravitational waves make E and B.
- A uniform twist rotates $(E_{\ell m}, B_{\ell m})$ by 2β and gives $C^{EE\prime} = \cos^2 2\beta\, C^{EE} + \sin^2 2\beta\, C^{BB}$, $C^{BB\prime} = \sin^2 2\beta\, C^{EE} + \cos^2 2\beta\, C^{BB}$, $C^{EB\prime} = \frac{1}{2}\sin 4\beta (C^{EE} - C^{BB})$, $C^{TE\prime} = \cos 2\beta\, C^{TE}$, $C^{TB\prime} = \sin 2\beta\, C^{TE}$; total polarized power is conserved.
- Lensing also turns E into B, $C^{BB} = \int \frac{\mathrm{d}^2\ell'}{(2\pi)^2}[\boldsymbol{\ell}' \cdot (\boldsymbol{\ell} - \boldsymbol{\ell}')]^2 \sin^2 2\Delta\varphi\, C^{\phi\phi} C^{EE}$, white at low ℓ ($\approx 4.7\,\mu$K-arcmin), but leaves $EB = TB = 0$: no hand.
- Fingerprints of B: frequency separates the Galaxy and Faraday rotation from the CMB; the ℓ shape separates gravitational waves from lensing; EB, TB separate twists from parity-preserving sources.
- A detector angle error α adds to β; the Galaxy is twisted by α only, which gives the Minami–Komatsu relation (T1.64); dust EB shifts the result to $\beta - \gamma$.
- Measured: $\beta = 0.35^\circ \pm 0.14^\circ$ (Planck 2018), $0.30^\circ \pm 0.11^\circ$ (PR4), $0.342^\circ{}^{+0.094^\circ}_{-0.091^\circ}$ (WMAP + Planck); not yet a detection because of the dust EB and instrumental systematics.

Chapter summary

The cosmological model is the first step of the book's pipeline. For every choice of the six ΛCDM numbers it fixes the expected value of each summary that the later chapters estimate from data, and never the sky itself. The route is short enough to hold in the head. The Friedmann equation gives the expansion rate $E(z)$, and one integral of $1/E$ gives the distances D_A and D_L. The primordial spectrum $\mathcal{P}_\zeta = A_s(k/k_*)^{n_s - 1}$ is carried to the sky by the radiation transfer function, $C_\ell = \frac{2}{\pi}\int k^2 \mathrm{d}k\, P_\zeta\, g_{T\ell}^2$, and to the matter field by growth and the matter transfer function, $P_\delta(k, a_0) = P_\delta(k, a_\mathrm{i})\, T^2[D_+(a_0)/D_+(a_\mathrm{i})]^2$. The data are one draw from each: the $a_{\ell m}$ with variance C_ℓ, the Fourier modes $\delta_{\boldsymbol{k}}$ with variance $P_\delta(k)$. Weak lensing adds a third field built from the same matter: projected along the line of sight with the lensing efficiency $g(\chi)$,

it becomes the convergence κ, whose power spectrum $C_\ell^{\kappa\kappa}$ is a Limber integral of P_δ, and it is read off galaxy shapes through the shear γ, buried under shape noise. The CMB light is also polarized, a field of headless sticks split into a mirror-symmetric E and a mirror-odd B: ordinary physics leaves $EB = TB = 0$, gravitational waves and lensing make B without a hand, and a uniform twist of the polarization, by new physics (β) or by a miscalibrated detector (α), moves power from E to B and creates EB and TB.

What carries into the inference chapters is how these predictions move when the parameters move. The finite-difference responses $R_i(\ell)$ of Eq. (T1.1) are the derivatives of the Fisher matrix, two nearly parallel responses are a degeneracy, and the line between linear and halofit $P(k)$ is where the Gaussian description of the matter field stops. Conventions are the fixed factors that decide whether a script reproduces these numbers. The table lists what to carry forward, what each item means in practice, and where it is used.

concept	operational meaning	used later in
model as a machine	six numbers into CAMB, expected statistics out; call it through `code/camb_fiducial.py` for the fiducial spectra	Chapters 7 to 10
one realisation	the sky is one draw; each $a_{\ell m}$ has variance C_ℓ, and $\widehat{C}_\ell$ scatters about C_ℓ as $\chi^2_{2\ell+1}/(2\ell+1)$	Chapters 7 and 8
distances and $H(z)$	$E(z)$ from the density parameters, then D_A, D_L by one integral; the model mean of supernova and BAO data	Chapters 3 and 5
conventions	raw C_ℓ vs D_ℓ; $\mu\mathrm{K}^2$; $A_s = \frac{25}{4}A_S^2$; h^{-1}Mpc; $\phi \equiv \psi$	every CMB and LSS script
fractional response $R_i(\ell)$	central difference of C_ℓ over $\pm1\sigma$, divided by $2C_\ell$; times C_ℓ/δ_i it is $\partial C_\ell/\partial\theta_i$	Chapter 10
degeneracy	two nearly parallel response curves (A_s and τ above $\ell \approx 30$); a near-singular Fisher matrix and a ridge in the chain	Chapters 9 and 10
linear vs halofit $P(k)$	agree on large scales, differ by 10% at $k \approx 0.15\,h\,\mathrm{Mpc}^{-1}$ at $z = 0$; beyond that the field is non-Gaussian	Chapters 7 and 12
$\xi(r)$ and the BAO bump	Fourier partner of $P(k)$; a peak near $r_s(z_{\mathrm{drag}})$, a standard ruler	Chapters 7 and 12
σ_8	top-hat variance of the linear field at $8\,h^{-1}$Mpc; a check that $P(k)$ is normalised correctly	Chapters 7 and 10
f_{NL}	amplitude of the primordial bispectrum; invisible to C_ℓ and $P(k)$	Chapter 12
κ, γ, E/B	projected density and its spin-2 tidal stretch (Section T1.5); lensing makes only E, so B is a null test	Chapter 12
$C_\ell^{\kappa\kappa}$ and shape noise	Limber integral of $[g/a]^2 P_\delta$ (CAMB lensing windows); measured power $C_\ell^{ij} + \delta_{ij}\sigma_\epsilon^2/\bar{n}_i$	Chapters 10 and 12
S_8 and nuisances	cosmic shear fixes $\sigma_8\Omega_m^\alpha$, $\alpha \approx 0.55$; photo-z, shear bias, intrinsic alignment, baryons are marginalised	Chapters 9, 10 and 12
E, B and parity	Q, U read along each wavevector; B changes sign in a mirror, so $EB = TB = 0$ unless something picks a hand (Section T1.9.4)	Chapters T3 and 13
rotated spectra	a twist β gives $EB = \frac{1}{2}\sin 4\beta\,(C^{EE} - C^{BB})$, $TB = \sin 2\beta\, C^{TE}$, BB gains $\sin^2 2\beta\, C^{EE}$; a detector angle error α enters as $\alpha + \beta$	Chapter 13
lensing B modes	$C^{BB} = \int [\boldsymbol{\ell}' \cdot (\boldsymbol{\ell} - \boldsymbol{\ell}')]^2 \sin^2 2\Delta\varphi\, C^{\phi\phi} C^{EE}$; white at low ℓ, peak near $\ell \approx 1000$; no EB, TB; non-Gaussian	Chapters 10 and 13
B-mode fingerprints	frequency (Galaxy vs CMB), ℓ shape (gravitational waves vs lensing), parity (EB, TB: twists vs the rest); table in Section T1.11.5	Chapter 13
Minami–Komatsu relation	the Galaxy is twisted by α only: $C^{EB,\mathrm{o}} = \frac{1}{2}\tan 4\alpha\,(C^{EE,\mathrm{o}} - C^{BB,\mathrm{o}}) + \frac{\sin 4\beta}{2\cos 4\alpha}(C^{EE} - C^{BB})^{\mathrm{CMB}}$; dust EB biases β to $\beta - \gamma$	Chapter 13

Reading the literature. The physics of every object above is developed in the cosmology notes. The Boltzmann code used throughout is CAMB [8]. The parameter values and errors are those of Planck 2018 [25]. The non-linear correction is the halofit version of [41], and the first detection of the BAO bump in the galaxy correlation function is [42]. For weak lensing, the standard reviews are [43] and [44], CMB lensing is reviewed in [47] and measured in [48], and the Stage-III cosmic-shear results are [45, 49, 50]. For CMB polarization, the E/B decomposition is due to [58, 59], with a gentle introduction in [60]; gravitational-wave B modes are predicted in [61], lensing B modes in [64], and experimental systematics are catalogued in [69]. The physics of cosmic birefringence is in [62, 72, 73]; the method that uses the Galaxy to calibrate the detector angles is [71], applied in [57, 74, 75], with the dust EB caveat of [67]. The polarized foregrounds are characterised in [66] and the current limit on r is [65].

Chapter T2

Astrophysics for the Data Analyst

Where this chapter is going

Two black holes orbit each other. Every half orbit the pair looks the same again, a dumbbell turning in space, and a turning dumbbell shakes spacetime. The shaking spreads out as a wave, the wave carries energy, and the energy comes out of the orbit. So the two holes sink closer, circle faster, and shake spacetime harder. The wave that reaches us rises in pitch and in loudness until the holes merge: a *chirp*. In the band of the space detector LISA a light black hole can circle a heavy one millions of times before the end, and each circle adds a predictable amount to the phase of the wave. If the pair lives inside a cloud of dark matter, the light hole feels a drag and sinks a little faster than it would in empty space. After a million orbits a tiny drag becomes a phase lag of many radians, and a phase lag is something a detector can measure.

Turning that lag into a number with an error bar is a statistics problem, and Chapter 10 solves it: the likelihood of a signal buried in noise, the matched filter, the Fisher matrix and the forecast. Every one of those calculations needs a short list of physical objects. It needs the signal, written as a Fourier transform $\tilde{h}(f)$ whose phase $\Psi(f)$ depends on the masses, the arrival time t_c and the phase ϕ_c. It needs the noise, as one function $S_n(f)$ of frequency. It needs the numbers that connect them, the factors $4/5$ and $3/10$ that turn a real source on the sky into an average one. And it needs the form in which any departure from the vacuum chirp enters the phase: a power of the frequency, βf^b. None of these is a matter of convention. Each follows from two physical facts, Einstein's equation for a weak gravitational field and the energy that a gravitational wave carries, together with Newton's law of gravity for the orbit; everything else can be derived from them.

Figure T2.1 shows how the ideas feed into each other. A small ripple h on flat spacetime obeys a wave equation and has exactly two polarisations, h_+ and $h_\times$, each of which stretches a ring of free masses in one direction while squeezing it in the other (Section T2.1). A source makes such a ripple only if its mass distribution changes shape: the total mass and the motion of the centre of mass are fixed by conservation laws, so the first thing that can radiate is the quadrupole, and for a binary it radiates at twice the orbital frequency (Section T2.2). The energy the wave carries away drives the chirp: one formula for $\dot{f}$, a time to merger t_c and a phase at merger ϕ_c (Section T2.4). Its Fourier transform, found by the stationary-phase approximation, is the template $\tilde{h}(f)$ of every forecast (Section T2.5). Corrections from general relativity and from the environment of the binary enter the Fourier phase as extra powers of f, which is what makes one forecast cover many kinds of physics (Section T2.6). A detector compares the light travel times along two arms, and so measures one combination of h_+ and $h_\times$ with weights that depend on where the source sits on the sky (Section T2.3). Finally, LISA's own noise, from photon counting, from stray forces on its test masses and from millions of unresolved Galactic

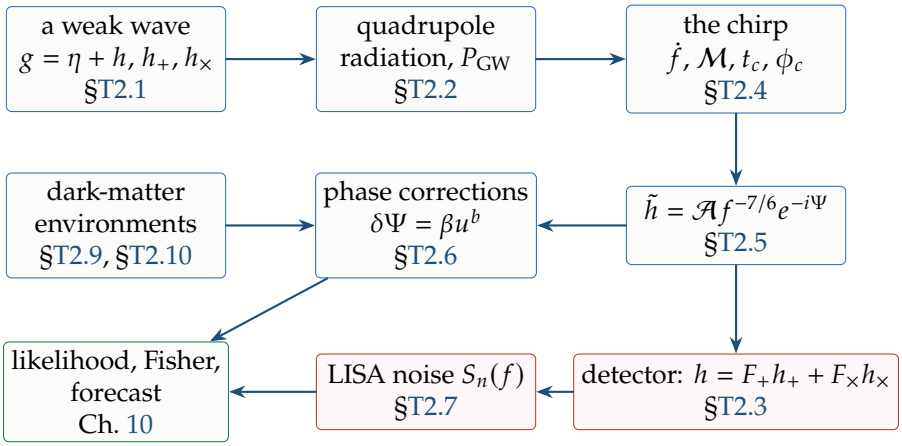

Figure T2.1: How the pieces of the chapter connect. Blue boxes are the physics of the source: a weak wave, how a moving mass makes one, how the orbit shrinks, and what the wave looks like in the frequency domain, including the small power-law terms that an environment adds to its phase. Red boxes are the detector: how it turns a wave into one number per instant, and what noise it adds. The green box is the statistics of Chapter 10, which takes the signal model and the noise spectrum and runs the chain backwards to learn about the source.

binaries, is summarised by the spectrum $S_n(f)$ (Section T2.7). Table T2.1 lists every symbol, where it is derived, and where Chapter 10 uses it.

The same reading applies to the other astrophysical data in the book. The dark-matter environments that change the chirp are built from their own physical inputs in Sections T2.9 and T2.10. Distances from standard candles, the distance ladder, selection effects and galaxy surveys follow in Section T2.11 onwards. Each time the question is the same: what physical object is there, what is measured, what is the noise, and which statistical tool turns the measurement into physics. In the language of the book's pipeline (Chapter 0), the gravitational-wave case reads as follows. The physical model is the binary and its environment. The data set is the strain time series. What matters in it is the phase of the wave. The sampling distribution is that of the detector noise, fixed by $S_n(f)$. Inference then asks the question of Chapter 5: given the recorded data, which masses, distance and environmental strength could have produced it, and how plausible is the noise realisation each of them requires?

T2.1 What a gravitational wave is

In Newton's theory gravity acts at once. Move the Sun, and the Earth feels the new pull in the same instant, however far away it is. Relativity forbids this: no influence travels faster than light. So when a mass distribution changes, say two black holes swing round each other, the news of the change must spread outwards at a finite speed, as a ripple in the gravitational field. Far from the source the ripple is tiny, and it passes through everything in its way, detectors included.

Three questions decide whether such a ripple can be measured and how. *What is the ripple, as a mathematical object? How many independent kinds of ripple are there? And what does one do to the things it passes through?* The answers are short. The ripple is a small correction $h_{\mu\nu}$ to the flat metric of spacetime; it obeys a wave equation with speed c; it comes in exactly two kinds, called h_+ and $h_\times$; and its only effect on a set of free masses is to change the distances between them, stretching along one direction while squeezing along the perpendicular one. A detector is a device that measures such changes of distance.

T2.1.1 The inputs

As in the derivation of the Poisson law in Chapter 2, we first say what goes in. Four things do. Two are physics, one is a statement about coordinates, and one is a physical result we import.

1. *Physical: the field is weak.* Far from the source spacetime is nearly flat. We write the metric as
$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}, \qquad \eta_{\mu\nu} = \mathrm{diag}(-1,1,1,1), \qquad |h_{\mu\nu}| \ll 1, \tag{T2.1}$$
with coordinates $x^\mu = (ct, x, y, z)$, and keep everything to first order in h. Indices are raised and lowered with η.

2. *Physical: Einstein's equation, to first order in h.* Define the **trace-reversed perturbation** $\bar{h}_{\mu\nu} = h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h$, with $h = \eta^{\mu\nu}h_{\mu\nu}$ [the same ten numbers, recombined so that the field equation becomes simple]. If the coordinates are chosen so that $\partial^\mu \bar{h}_{\mu\nu} = 0$ (the **Lorenz gauge**), Einstein's equation linearised in h reads
$$\Box\, \bar{h}_{\mu\nu} = -\frac{16\pi G}{c^4} T_{\mu\nu}, \qquad \Box \equiv -\frac{1}{c^2}\frac{\partial^2}{\partial t^2} + \nabla^2, \tag{T2.2}$$
where $T_{\mu\nu}$ is the energy–momentum tensor of the matter [76, Sec. 1.1]. It is the twin of the equation $\Box A^\mu = -\mu_0 J^\mu$ for the electromagnetic potentials in the Lorenz gauge, with the energy–momentum of matter in place of the electric current.

3. *Mathematical: coordinates are labels.* Relabelling the points of spacetime by $x^\mu \to x^\mu + \xi^\mu(x)$, with a small ξ, changes the components of the metric but not the spacetime. To first order it changes $h_{\mu\nu} \to h_{\mu\nu} - \partial_\mu \xi_\nu - \partial_\nu \xi_\mu$. Anything measurable, such as the distance a ruler records between two free masses, is unchanged.

4. *Physical: the energy flux.* A gravitational wave carries energy; the formula for the flux is imported from general relativity in Section T2.1.4 and stated there.

Several things often listed as facts about gravitational waves are *not* inputs: that they travel at c, that they are transverse, that there are two polarisations, and the pattern in which they move test masses. All four are derived below.

T2.1.2 Waves in empty space, and how many kinds there are

The wave equation. Far from the source there is no matter, $T_{\mu\nu} = 0$, and (T2.2) becomes $\Box \bar{h}_{\mu\nu} = 0$. Written out, $\partial_t^2 \bar{h}_{\mu\nu} = c^2 \nabla^2 \bar{h}_{\mu\nu}$: each of the ten components obeys the ordinary wave equation with speed c. So a disturbance in the gravitational field travels at the speed of light, and nothing more had to be assumed to get this.

A plane wave. Any solution is a superposition of plane waves, so it is enough to study one,
$$\bar{h}_{\mu\nu} = \mathrm{Re}\left[\varepsilon_{\mu\nu}\, e^{ik_\alpha x^\alpha}\right], \qquad k^\alpha = \left(\frac{\omega}{c}, \boldsymbol{k}\right), \tag{T2.3}$$
with a constant symmetric matrix $\varepsilon_{\mu\nu}$ of amplitudes. Inserting it into $\Box \bar{h}_{\mu\nu} = 0$ brings down $-k_\alpha k^\alpha = \omega^2/c^2 - |\boldsymbol{k}|^2$, which must vanish: $\omega = c|\boldsymbol{k}|$, the dispersion relation of a wave moving at c.

How many of the ten amplitudes are real? A symmetric 4×4 matrix has ten entries. Not all of them describe something physical, because some can be changed by relabelling coordinates (input 3). We count them for a wave travelling along z, so that $k^\alpha = (K, 0, 0, K)$ and $k_\alpha = (-K, 0, 0, K)$ with $K = \omega/c$.

First, the Lorenz condition. The gauge condition $\partial^\mu \bar{h}_{\mu\nu} = 0$ becomes $k^\mu \varepsilon_{\mu\nu} = 0$, that is $K\varepsilon_{0\nu} + K\varepsilon_{3\nu} = 0$, or

$$\varepsilon_{3\nu} = -\varepsilon_{0\nu} \qquad (\nu = 0, 1, 2, 3). \tag{T2.4}$$

Four conditions, so six amplitudes are left.

Second, the relabelling that is still allowed. A relabelling with $\Box\xi_\mu = 0$ does not spoil the Lorenz condition, because, using input 3 and its trace-reversed form,

$$\begin{aligned} \delta\bar{h}_{\mu\nu} &\overset{(1)}{=} -\partial_\mu\xi_\nu - \partial_\nu\xi_\mu + \eta_{\mu\nu}\,\partial^\alpha\xi_\alpha, \\ \partial^\mu\delta\bar{h}_{\mu\nu} &\overset{(2)}{=} -\Box\xi_\nu - \partial_\nu\partial^\mu\xi_\mu + \partial_\nu\partial^\alpha\xi_\alpha \overset{(3)}{=} -\Box\xi_\nu. \end{aligned} \tag{T2.5}$$

(1) The trace of $\delta h_{\mu\nu} = -\partial_\mu\xi_\nu - \partial_\nu\xi_\mu$ is $\delta h = -2\partial^\alpha\xi_\alpha$, so $\delta\bar{h}_{\mu\nu} = \delta h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}\delta h$ gains the last term.
(2) Take ∂^μ of each term; $\partial^\mu\partial_\mu = \Box$, and $\partial^\mu\eta_{\mu\nu} = \partial_\nu$.
(3) The last two terms cancel.

So any ξ_μ that itself solves the wave equation is still allowed. Take one with the same wave vector, $\xi_\mu = \mathrm{Re}[-i\zeta_\mu e^{ik_\alpha x^\alpha}]$, with four constants ζ_μ; then $\partial_\nu\xi_\mu = \mathrm{Re}[k_\nu\zeta_\mu e^{ik\cdot x}]$, and the first line of (T2.5) shifts the amplitudes by

$$\delta\varepsilon_{\mu\nu} = -k_\mu\zeta_\nu - k_\nu\zeta_\mu + \eta_{\mu\nu}\,(k^\alpha\zeta_\alpha), \qquad k^\alpha\zeta_\alpha = K(\zeta_0 + \zeta_3). \tag{T2.6}$$

Look at what the four constants can do. $\delta\varepsilon_{01} = -k_0\zeta_1 = K\zeta_1$, so ζ_1 can cancel ε_{01}; likewise ζ_2 cancels ε_{02}. $\delta\varepsilon_{03} = -k_0\zeta_3 - k_3\zeta_0 = K(\zeta_3 - \zeta_0)$, and the trace changes by $\eta^{\mu\nu}\delta\varepsilon_{\mu\nu} = -2k\cdot\zeta + 4k\cdot\zeta = 2K(\zeta_0 + \zeta_3)$. The combinations $\zeta_3 - \zeta_0$ and $\zeta_3 + \zeta_0$ are independent, so they cancel ε_{03} and the trace. Four constants, four conditions: we can always reach

$$\varepsilon_{01} = \varepsilon_{02} = \varepsilon_{03} = 0, \qquad \eta^{\mu\nu}\varepsilon_{\mu\nu} = 0. \tag{T2.7}$$

What is left. Combine (T2.7) with the Lorenz condition (T2.4). For $\nu = 1, 2$: $\varepsilon_{31} = \varepsilon_{32} = 0$. For $\nu = 3$: $\varepsilon_{33} = -\varepsilon_{03} = 0$. For $\nu = 0$: $\varepsilon_{00} = -\varepsilon_{30} = 0$. Only ε_{11}, ε_{12} and ε_{22} survive, and the zero trace, $-\varepsilon_{00} + \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33} = 0$, forces $\varepsilon_{22} = -\varepsilon_{11}$. Two numbers remain. Since the trace is zero, $\bar{h}_{\mu\nu} = h_{\mu\nu}$, and the wave is

$$h_{ij}^{\mathrm{TT}}(t, z) = \begin{pmatrix} h_+ & h_\times & 0 \\ h_\times & -h_+ & 0 \\ 0 & 0 & 0 \end{pmatrix} \left(t - \frac{z}{c}\right), \qquad h_{0\mu}^{\mathrm{TT}} = 0. \tag{T2.8}$$

We wrote $h_+(t - z/c)$ and $h_\times(t - z/c)$ for arbitrary wave forms, because a superposition of plane waves with the same direction is any function of $t - z/c$. Ten amplitudes, minus four Lorenz conditions, minus four allowed relabellings, leave two: the **plus** and **cross polarisations** [76, Sec. 1.2].

Working definition T2.1 (transverse-traceless gauge)

For a wave travelling along a unit vector $\hat{\boldsymbol{n}}$, the **TT gauge** is the choice of coordinates in which $h_{0\mu} = 0$, $h_{ij}\hat{n}_j = 0$ [no component along the direction of travel] and $h_{ii} = 0$ [no overall expansion]. In it the wave is the 2×2 matrix $\left(\begin{smallmatrix} h_+ & h_\times \\ h_\times & -h_+ \end{smallmatrix}\right)$ in the plane perpendicular to $\hat{\boldsymbol{n}}$. *Operationally:* given any symmetric 3×3 matrix M and the transverse unit vectors $\boldsymbol{p}, \boldsymbol{q}$, its TT part has $h_+ = \frac{1}{2}(M_{pp} - M_{qq})$ and $h_\times = M_{pq}$, where $M_{pq} = p_i M_{ij} q_j$.

The operational recipe in the box is just (T2.8) read backwards: keep the block of M in the plane spanned by $\boldsymbol{p}$ and $\boldsymbol{q}$, and subtract half its trace from the diagonal so that it becomes traceless, which leaves $\frac{1}{2}(M_{pp} - M_{qq})$ on the diagonal and M_{pq} off it. We use it in Section T2.2.

Example: turning the axes. The labels + and × refer to the axes x, y we chose in the transverse plane. Suppose we turn those axes by an angle α about the direction of travel. The 2×2 block of (T2.8) is $h_+\sigma_3 + h_\times\sigma_1$, with $\sigma_3 = \left(\begin{smallmatrix}1&0\\0&-1\end{smallmatrix}\right)$ and $\sigma_1 = \left(\begin{smallmatrix}0&1\\1&0\end{smallmatrix}\right)$. Its components in the turned axes are $R^{\mathsf T}hR$ with R the rotation matrix by α, and

$$R^{\mathsf T}\sigma_3 R \overset{(1)}{=} \cos 2\alpha\,\sigma_3 - \sin 2\alpha\,\sigma_1, \qquad R^{\mathsf T}\sigma_1 R \overset{(1)}{=} \sin 2\alpha\,\sigma_3 + \cos 2\alpha\,\sigma_1,$$
$$h'_+ \overset{(2)}{=} h_+\cos 2\alpha + h_\times \sin 2\alpha, \qquad h'_\times \overset{(2)}{=} -h_+\sin 2\alpha + h_\times\cos 2\alpha. \tag{T2.9}$$

(1) Multiply out with $R = \left(\begin{smallmatrix}\cos\alpha & -\sin\alpha\\ \sin\alpha & \cos\alpha\end{smallmatrix}\right)$ and use $\cos^2\alpha - \sin^2\alpha = \cos 2\alpha$, $2\sin\alpha\cos\alpha = \sin 2\alpha$.
(2) Collect the coefficients of σ_3 (the new h_+) and of σ_1 (the new $h_\times$).

The polarisations mix with *twice* the angle. A turn by 45° turns a pure h_+ into a pure $h_\times$, and a turn by 90° only flips the sign; a turn by 180° changes nothing. This is the signature of a field of spin two, and it is why the orientation of the detector and the orientation of the source on the sky enter the detected signal through angles 2ϕ and 2ψ (Section T2.3).

T2.1.3 What a wave does to free masses

Do the masses move? Place a free test mass at rest at some point and let the wave (T2.8) pass. The mass follows a geodesic, $\mathrm{d}^2x^\mu/\mathrm{d}\tau^2 = -\Gamma^\mu_{\alpha\beta}(\mathrm{d}x^\alpha/\mathrm{d}\tau)(\mathrm{d}x^\beta/\mathrm{d}\tau)$. While it is at rest only $\mathrm{d}x^0/\mathrm{d}\tau$ is nonzero, so its acceleration is set by Γ^i_{00} alone:

$$\frac{\mathrm{d}^2x^i}{\mathrm{d}\tau^2} \overset{(1)}{=} -\Gamma^i_{00}\left(\frac{\mathrm{d}x^0}{\mathrm{d}\tau}\right)^2, \qquad \Gamma^i_{00} \overset{(2)}{=} \tfrac12\left(2\partial_0 h_{i0} - \partial_i h_{00}\right) \overset{(3)}{=} 0. \tag{T2.10}$$

(1) Only the $\alpha=\beta=0$ term survives when the spatial velocity is zero.
(2) The Christoffel symbol to first order in h, $\Gamma^i_{\alpha\beta} = \tfrac12(\partial_\alpha h_{i\beta} + \partial_\beta h_{i\alpha} - \partial_i h_{\alpha\beta})$, at $\alpha=\beta=0$.
(3) In the TT gauge every $h_{0\mu}$ vanishes, (T2.8).

So the mass stays at rest, and keeps its coordinates, for as long as the wave lasts. The TT coordinates are, in effect, painted onto the free masses. Yet something does change: the distance between two masses, as a ruler or a light signal would measure it.

The distances do change. Take one mass at the origin and another at coordinates $\boldsymbol{x}_0$, a distance much smaller than the wavelength so that h_{ij} is the same all the way between them. The proper distance follows from $\mathrm{d}s^2 = (\delta_{ij}+h_{ij})\mathrm{d}x^i\mathrm{d}x^j$. To first order the matrix $\delta_{ij}+h_{ij}$ is a perfect square,

$$\mathrm{d}s^2 \overset{(1)}{=} \mathrm{d}\boldsymbol{x}^{\mathbb T}(\mathbb 1 + h)\,\mathrm{d}\boldsymbol{x} \overset{(2)}{=} \mathrm{d}\boldsymbol{x}^{\mathbb T}\left(\mathbb 1 + \tfrac12 h\right)^2\mathrm{d}\boldsymbol{x} \overset{(3)}{=} \left|\mathrm{d}\boldsymbol{X}\right|^2, \qquad \boldsymbol{X} \equiv \left(\mathbb 1 + \tfrac12 h\right)\boldsymbol{x}. \tag{T2.11}$$

(1) The spatial part of the TT metric, in matrix form.
(2) $(\mathbb 1 + \frac12 h)^2 = \mathbb 1 + h + \frac14 h^2$, and h^2 is second order.
(3) h is symmetric, so $\mathrm{d}\boldsymbol{x}^{\mathsf T}(\mathbb 1+\frac12 h)^2\mathrm{d}\boldsymbol{x}$ is the squared length of the vector $(\mathbb 1+\frac12 h)\mathrm{d}\boldsymbol{x}$.

So $\boldsymbol{X}$ are ordinary Cartesian coordinates, the ones a ruler would give, and the mass that sits at fixed $\boldsymbol{x}_0$ is found at

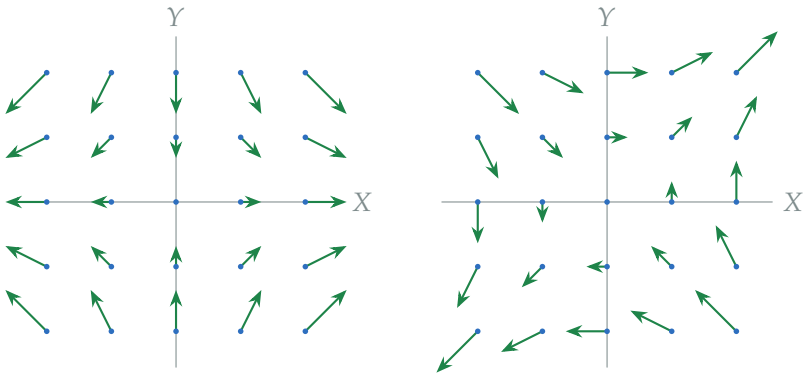
$$X_i(t) = x_{0,i} + \tfrac12\, h_{ij}(t)\, x_{0,j}, \qquad \frac{\delta L}{L} = \tfrac12\, h_{ij}\hat n_i \hat n_j, \tag{T2.12}$$

where $L = |\boldsymbol{x}_0|$ and $\hat{\boldsymbol{n}} = \boldsymbol{x}_0/L$. The second form is the fractional change of the distance, read off by projecting the displacement onto $\hat{\boldsymbol{n}}$. A mass on the x axis is pushed out by $\frac12 h_+ L$ while one on the y axis is pulled in by the same amount: the factor $\frac12$ in $\delta L/L = \frac12 h$ is the one the detector formulas of Section T2.3 start from.

The same thing as a tidal force. Differentiate (T2.12) twice in time. Since $\boldsymbol{x}_0$ is fixed,

$$\ddot{X}_i = \tfrac{1}{2}\,\ddot{h}_{ij}\,x_{0,j} = \tfrac{1}{2}\,\ddot{h}_{ij}\,X_j + O(h^2). \tag{T2.13}$$

Read as Newtonian mechanics in the ruler coordinates $\boldsymbol{X}$, each mass feels an acceleration proportional to its distance from the centre, $\frac{1}{2}\ddot{h}_{ij}X_j$. That is exactly the form of a tidal acceleration. The Moon's tidal field on the Earth is $-(\partial_i\partial_j\Phi)X_j$: it stretches the oceans along the line to the Moon and squeezes them across it, and its matrix has zero trace because $\nabla^2\Phi = 0$ in empty space. The wave plays the role of $\partial_i\partial_j\Phi$ with $\partial_i\partial_j\Phi \to -\frac{1}{2}\ddot{h}_{ij}$; this matrix is also traceless, also stretches one way while squeezing the other, but it oscillates, travels at c, and acts only across its direction of travel. In general relativity (T2.13) is the equation of geodesic deviation, $\ddot{\xi}^i = -c^2 R^i{}_{0j0}\xi^j$, with the curvature of the wave $R_{i0j0} = -\ddot{h}_{ij}/(2c^2)$ [76, Sec. 1.3].



$\ddot{h}_+ > 0$: stretch along X $\qquad$ $\ddot{h}_\times > 0$: stretch along the diagonal

Figure T2.2: The wave as a tidal field. Each dot is a free mass in the plane perpendicular to the direction of travel, and each arrow the acceleration $\frac{1}{2}\ddot{h}_{ij}X_j$ it feels at one instant. Left, a pure h_+ wave: masses are pushed out along X and pulled in along Y, with no push at the centre. Right, a pure $h_\times$ wave: the same pattern turned by 45°. Half a period later every arrow reverses.

Key idea: A gravitational wave changes distances, not positions

In the TT gauge free masses keep their coordinates, but the proper distance between two of them, separated by L along $\hat{\boldsymbol{n}}$, changes by $\delta L/L = \frac{1}{2}h_{ij}\hat{n}_i\hat{n}_j$. Equivalently, in ruler coordinates each mass feels the tidal acceleration $\frac{1}{2}\ddot{h}_{ij}X_j$: a traceless, transverse, oscillating squeeze.

Example: a ring of free masses. Put masses on a circle of radius R in the plane perpendicular to the wave, at $\boldsymbol{x}_0 = R(\cos\theta, \sin\theta)$, and let $h_+(t) = h\cos\omega t$ with $h_\times = 0$. By (T2.12),

$$X \overset{(1)}{=} R\cos\theta\,\big(1 + \tfrac{1}{2}h\cos\omega t\big), \qquad Y \overset{(1)}{=} R\sin\theta\,\big(1 - \tfrac{1}{2}h\cos\omega t\big),$$
$$\frac{X^2}{a^2} + \frac{Y^2}{b^2} \overset{(2)}{=} 1, \qquad a = R\big(1 + \tfrac{1}{2}h\cos\omega t\big), \quad b = R\big(1 - \tfrac{1}{2}h\cos\omega t\big). \tag{T2.14}$$

(1) $h_{xx} = h_+$, $h_{yy} = -h_+$, $h_{xy} = h_\times = 0$ in (T2.12).
(2) Divide X by a and Y by b; $\cos^2\theta + \sin^2\theta = 1$.

The ring becomes an ellipse with semi-axes along x and y, stretched along x and squeezed along y for half a period, then the other way round. To first order the area $\pi ab = \pi R^2(1 - \frac{1}{4}h^2\cos^2\omega t)$ does not change: the traceless squeeze moves masses around without compressing the region they enclose. With $h_\times$ instead, $X = R\cos\theta + \frac{1}{2}h_\times R\sin\theta$ and $Y = R\sin\theta + \frac{1}{2}h_\times R\cos\theta$, and the

ellipse has its axes along the diagonals. The script `12_ring_masses.py` draws both cases with the amplitude exaggerated to $h = 0.35$ (Figure T2.3), and checks that the $h_\times$ pattern is the h_+ pattern turned by 45°, as (T2.9) says.

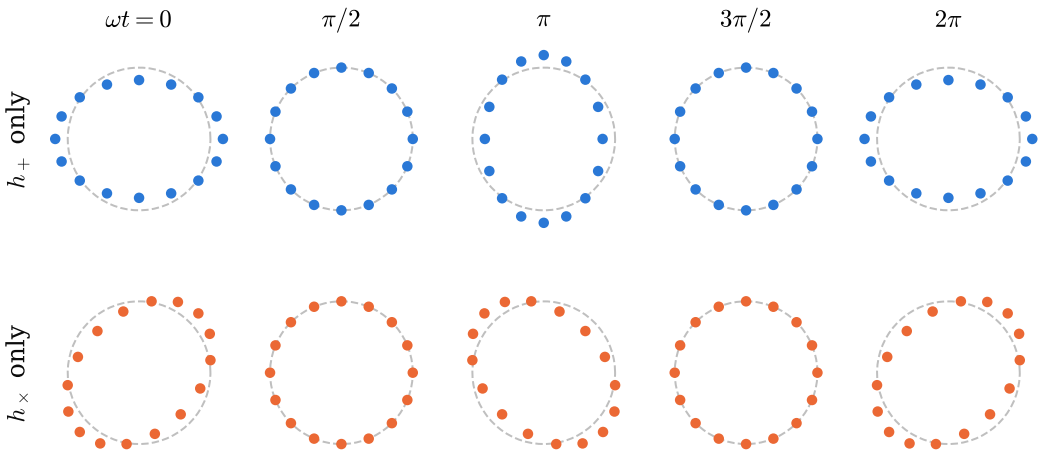


Figure T2.3: A ring of sixteen free masses (dots) as a wave travelling out of the page passes, at five phases of one period; the dashed circle is the ring without the wave. Top row, a pure plus wave: the ring is stretched along the horizontal and squeezed along the vertical, then the reverse. Bottom row, a pure cross wave: the same breathing along the diagonals. The real amplitude is some 10^{19} times smaller than drawn.

Example: how large is the effect? For a ground-based detector with arms of $L = 4\,\mathrm{km}$ and a wave of $h = 10^{-21}$, (T2.12) gives $\delta L = \frac{1}{2}hL = 2 \times 10^{-18}\,\mathrm{m}$, a few thousandths of the size of a proton. For LISA, with $L = 2.5 \times 10^{9}\,\mathrm{m}$ and $h = 10^{-20}$, $\delta L = \frac{1}{2} \times 10^{-20} \times 2.5 \times 10^{9} \approx 10^{-11}\,\mathrm{m}$, about ten picometres. The longer the arm, the larger the displacement for the same strain, which is one reason to fly a detector in space. The other is that on the ground the seismic shaking of the Earth swamps everything below a few hertz.

Watch out: Coordinates that do not move

"In the TT gauge the masses do not move" and "the wave changes the distance between them" are both true. The first is a statement about labels, which the TT gauge attaches to the free masses themselves. The second is the physics. Every measurable effect must be computed as a proper distance or a light travel time, as in (T2.11), never read off from a change of coordinates.

T2.1.4 The energy a wave carries

A wave that can push masses around can do work, so it carries energy. Energy in general relativity is subtle, because the gravitational field has no energy density at a single point: at any one point a freely falling observer sees no field at all. What is well defined is the energy averaged over a region several wavelengths across. This is our fourth input, imported from general relativity [76, Sec. 1.4]: the energy crossing unit area per unit time, for a wave in the TT gauge, is

$$\mathcal{F} = \frac{c^3}{32\pi G}\left\langle \dot{h}^{\mathrm{TT}}_{ij}\dot{h}^{\mathrm{TT}}_{ij}\right\rangle = \frac{c^3}{16\pi G}\left\langle \dot{h}_+^2 + \dot{h}_\times^2\right\rangle, \tag{T2.15}$$

where the angle brackets average over several periods, and the second form follows from (T2.8), since $h_{ij}h_{ij} = h_+^2 + h_\times^2 + h_\times^2 + h_+^2$. Its form is that of the electromagnetic Poynting flux of a

radiation field, $\varepsilon_0 c\langle E^2\rangle$ with $E = -\dot{A}$. The flux is quadratic in the field because energy is, and it contains the time derivative because a static strain, like a static potential, carries nothing away.

Example: why a strain of 10^{-21} is a lot of energy. The constant in front of (T2.15) is enormous:

$$\frac{c^3}{16\pi G} \overset{(1)}{=} \frac{(3.0\times10^8)^3}{16\pi\times 6.67\times10^{-11}}\,\frac{\mathrm{kg}}{\mathrm{s}} \overset{(2)}{=} 8.0\times10^{33}\,\mathrm{kg\,s^{-1}}.$$

(1) c in $\mathrm{m\,s^{-1}}$ and G in $\mathrm{m^3\,kg^{-1}\,s^{-2}}$; the units combine to $\mathrm{kg\,s^{-1}}$, which times $\dot{h}^2$ in $\mathrm{s^{-2}}$ gives $\mathrm{W\,m^{-2}}$.

(2) $2.7\times10^{25}/3.35\times10^{-9} = 8.0\times10^{33}$.

Take the first detected wave near its peak, $h_+ = h\cos 2\pi f t$ with $h \approx 10^{-21}$ and $f \approx 250\,\mathrm{Hz}$. Then $\langle \dot{h}_+^2\rangle = \frac{1}{2}(2\pi f h)^2 = \frac{1}{2}(1.6\times10^{-18}\,\mathrm{s^{-1}})^2 = 1.2\times10^{-36}\,\mathrm{s^{-2}}$, and $\mathcal{F} \approx 8.0\times10^{33}\times1.2\times10^{-36} \approx 10^{-2}\,\mathrm{W\,m^{-2}}$. For a fraction of a second, the Earth received more energy per square metre in gravitational waves than it receives in light from any star in the night sky. Yet the strain was 10^{-21}. Spacetime is stiff: the factor c^3/G means a large energy flux produces only a minute deformation, and, the other way round, a measurable deformation needs a violent source.

Where this is used. The two polarisations and the factor $\frac{1}{2}$ in $\delta L/L$ are what a detector turns into the single strain $h(t) = F_+h_+ + F_\times h_\times$ of Section T2.3. That strain is the signal part of the data stream $d(t) = h(t) + n(t)$ with which Section 10.8 begins, and the energy flux (T2.15) drives the chirp of Section T2.4, whose phase is what Section 10.9 measures.

T2.2 Why radiation starts at the quadrupole

A radio antenna radiates because electrons slosh back and forth along it: the electric dipole moment, charge times separation, oscillates. Two black holes on an orbit look at first sight like the same thing, two "charges" swinging round each other, so we might expect them to radiate like a rotating dipole, at the orbital frequency. They do not. The gravitational wave of a binary comes out at *twice* the orbital frequency, and it is weaker than a dipole estimate by a factor $(v/c)^2$. Both facts have one cause. The "charge" of gravity is mass, it has only one sign, and it is the same mass that sets the inertia of the body. As a result the two quantities that make up the monopole and the dipole of the field, the total mass and the position of the centre of mass, cannot oscillate: they are protected by conservation laws.

The question, in words: *starting from the field equation of Section T2.1, which part of a moving mass distribution produces a wave far away, how large is the wave, and how much power does it carry off?* For a binary the answers are the waveform h_+, $h_\times$ that every template in Chapter 10 is built on, and the power P_{GW} that drives the chirp of Section T2.4.

T2.2.1 The field far from a slow source

Inputs. We keep the inputs of Section T2.1: the weak-field metric (T2.1) and the linearised field equation (T2.2), $\Box\bar{h}_{\mu\nu} = -(16\pi G/c^4)T_{\mu\nu}$. We add three about the source.

1. *Physical: small and slow.* The source has size d and internal speeds $v \ll c$. It then changes on a time scale d/v, so it emits at wavelengths $\lambda \sim c\,d/v \gg d$.
2. *Physical: energy and momentum are conserved,* $\partial_\mu T^{\mu\nu} = 0$, and the source is Newtonian, $T^{00} = \rho c^2$ with ρ the mass density. For a binary held together by its own gravity this is true only once the energy of the gravitational field is counted as well. The full theory shows that the leading-order result derived below is unchanged by that [76, Sec. 3.1].

3. *Mathematical: the retarded solution.* The solution of $\Box\psi = -4\pi s$ that contains only outgoing waves is $\psi(t,\boldsymbol{x}) = \int s(t-|\boldsymbol{x}-\boldsymbol{x}'|/c, \boldsymbol{x}')/|\boldsymbol{x}-\boldsymbol{x}'|\,\mathrm{d}^3x'$, the retarded potential familiar from electrodynamics. Applied to each component of (T2.2),

$$\bar{h}_{\mu\nu}(t,\boldsymbol{x}) = \frac{4G}{c^4}\int \frac{T_{\mu\nu}\big(t-|\boldsymbol{x}-\boldsymbol{x}'|/c,\ \boldsymbol{x}'\big)}{|\boldsymbol{x}-\boldsymbol{x}'|}\,\mathrm{d}^3x'. \tag{T2.16}$$

Far away. The detector sits at distance $r = |\boldsymbol{x}| \gg d$ in the direction $\hat{\boldsymbol{n}} = \boldsymbol{x}/r$. For a point $\boldsymbol{x}'$ of the source, $|\boldsymbol{x}-\boldsymbol{x}'| = r - \hat{\boldsymbol{n}}\cdot\boldsymbol{x}' + O(d^2/r)$. In the denominator of (T2.16) the correction is negligible and we write $1/r$. In the time argument it is not automatically negligible, because it multiplies a rapidly varying function:

$$T_{\mu\nu}\Big(t - \frac{r}{c} + \frac{\hat{\boldsymbol{n}}\cdot\boldsymbol{x}'}{c}, \boldsymbol{x}'\Big) = T_{\mu\nu}(t_r,\boldsymbol{x}') + \frac{\hat{n}_i x_i'}{c}\,\partial_t T_{\mu\nu}(t_r,\boldsymbol{x}') + \frac{\hat{n}_i\hat{n}_j x_i' x_j'}{2c^2}\,\partial_t^2 T_{\mu\nu}(t_r,\boldsymbol{x}') + \ldots, \tag{T2.17}$$

with $t_r = t - r/c$ the **retarded time**. Each term is smaller than the one before by about $(d/c)/(d/v) = v/c$: the time light takes to cross the source, divided by the time the source takes to change. This is the **multipole expansion**, and the slow-motion input says it converges quickly.

Which terms can change in time? Apply (T2.17) to the 00 component, with $T_{00} = \rho c^2$:

$$\bar{h}_{00} = \frac{4G}{c^2 r}\Big[M + \frac{\hat{n}_i}{c}\dot{M}_i + \frac{\hat{n}_i\hat{n}_j}{2c^2}\ddot{M}_{ij} + \ldots\Big]_{t_r}, \qquad M = \int\rho, \quad M_i = \int\rho\, x_i, \quad M_{ij} = \int\rho\, x_i x_j, \tag{T2.18}$$

where every integral is over the source at the retarded time. The three moments are the mass, the mass dipole and the second mass moment. Take them one at a time.

The monopole. Mass conservation, the $\nu = 0$ part of input 2, is the continuity equation $\partial_t\rho + \partial_k(\rho v_k) = 0$. Integrated over a volume enclosing the source, the divergence becomes a flux through a surface where there is no matter, so $\dot{M} = 0$. The first term is the static Newtonian potential $4GM/(c^2 r)$ and carries no wave.

The dipole. Using the continuity equation again,

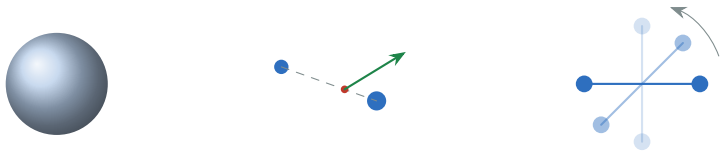
$$\dot{M}_i \overset{(1)}{=} \int x_i\,\partial_t\rho\,\mathrm{d}^3x \overset{(2)}{=} -\int x_i\,\partial_k(\rho v_k)\,\mathrm{d}^3x \overset{(3)}{=} \int \rho\, v_k\,\partial_k x_i\,\mathrm{d}^3x \overset{(4)}{=} \int \rho\, v_i\,\mathrm{d}^3x = P_i, \tag{T2.19}$$

(1) Differentiate under the integral; the integration region is fixed.
(2) Continuity equation.
(3) Integrate by parts; the surface term vanishes outside the source.
(4) $\partial_k x_i = \delta_{ik}$. The result is the total momentum P_i.

Momentum conservation, the $\nu = i$ part of input 2, gives $\dot{P}_i = 0$, so $\ddot{M}_i = 0$: $\dot{M}_i$ is constant. The second term of (T2.18) is the field of a mass whose centre moves at constant velocity, and that does not radiate either. In electromagnetism the dipole moment is $\sum q\,\boldsymbol{x}$, whose derivative $\sum q\,\boldsymbol{v}$ is not a conserved quantity, because different particles carry different charge per unit mass. In gravity every body's "charge" is its mass, the very quantity that sets its momentum, so the dipole is tied to the centre of mass and frozen.

The quadrupole. Nothing stops $\ddot{M}_{ij}$ from oscillating. The first time-dependent term, and so the first radiating one, is the second moment of the mass. A spinning symmetric top has a constant M_{ij} and stays silent; a dumbbell rotating about an axis through its middle does not, and radiates.

The wave itself. The radiation lives in the spatial components $\bar{h}_{ij}$. At leading order in v/c we keep only the first term of (T2.17), so $\bar{h}_{ij} = (4G/c^4 r)\int T_{ij}(t_r,\boldsymbol{x}')\,\mathrm{d}^3x'$. The integral of the



mass M conserved: no wave

centre of mass moves uniformly: no wave

shape M_{ij} changes twice per turn: waves

Figure T2.4: The three lowest moments of a mass distribution. The total mass (left) cannot change. The mass dipole is the total mass times the position of the centre of mass (middle, red dot), which can only move at constant velocity. The second moment (right) describes the shape; for a rotating dumbbell, drawn at three instants an eighth of a turn apart, it returns to the same value after half a turn, so it oscillates at twice the rotation frequency.

stresses T_{ij} is not obviously related to the mass distribution, but conservation turns it into one:

$$\frac{1}{c^2}\frac{\mathrm{d}^2}{\mathrm{d}t^2}\int T^{00}x_ix_j\,\mathrm{d}^3x \overset{(1)}{=} \int x_ix_j\,\partial_0\partial_0 T^{00}\,\mathrm{d}^3x \overset{(2)}{=} \int x_ix_j\,\partial_k\partial_l T^{kl}\,\mathrm{d}^3x$$
$$\overset{(3)}{=} \int T^{kl}\,\partial_k\partial_l(x_ix_j)\,\mathrm{d}^3x \overset{(4)}{=} 2\int T^{ij}\,\mathrm{d}^3x. \tag{T2.20}$$

(1) $x^0 = ct$, so $\partial_0 = c^{-1}\partial_t$.
(2) From $\partial_\mu T^{\mu\nu} = 0$: $\partial_0 T^{00} = -\partial_k T^{k0}$ and $\partial_0 T^{0k} = -\partial_l T^{lk}$, so $\partial_0\partial_0 T^{00} = -\partial_k\partial_0 T^{0k} = \partial_k\partial_l T^{kl}$.
(3) Integrate by parts twice; both surface terms vanish outside the source.
(4) $\partial_l(x_ix_j) = \delta_{il}x_j + x_i\delta_{jl}$ and then ∂_k of that is $\delta_{il}\delta_{jk} + \delta_{ik}\delta_{jl}$; both terms give T^{ij} because T is symmetric.

With $T^{00} = \rho c^2$ the left side is $\ddot{M}_{ij}$, so $\int T_{ij} = \frac{1}{2}\ddot{M}_{ij}$ and $\bar{h}_{ij} = (2G/c^4 r)\ddot{M}_{ij}(t_r)$. Far from the source the wave is locally a plane wave travelling along $\hat{\boldsymbol{n}}$, and its physical content is its TT part, obtained with the recipe of the working definition in Section T2.1: keep the components in the plane perpendicular to $\hat{\boldsymbol{n}}$ and remove their trace. Removing the trace means that M_{ij} may as well be replaced by its traceless part, the **mass quadrupole**

$$Q_{ij} = \int \rho\left(x_ix_j - \tfrac{1}{3}\delta_{ij}|\boldsymbol{x}|^2\right)\mathrm{d}^3x, \qquad h_{ij}^{\mathrm{TT}}(t,\boldsymbol{x}) = \frac{2G}{c^4 r}\left[\ddot{Q}_{ij}(t - r/c)\right]^{\mathrm{TT}}. \tag{T2.21}$$

This is the **quadrupole formula** for the wave [76, Sec. 3.3]. In terms of the transverse unit vectors $\boldsymbol{p}$, $\boldsymbol{q}$ and the recipe of the working definition, $h_+ = \frac{G}{c^4 r}\left(\ddot{Q}_{pp} - \ddot{Q}_{qq}\right)$ and $h_\times = \frac{2G}{c^4 r}\ddot{Q}_{pq}$.

Key idea: The quadrupole formula

Far from a slow source, the wave is $h_{ij}^{\mathrm{TT}} = (2G/c^4 r)\,[\ddot{Q}_{ij}(t - r/c)]^{\mathrm{TT}}$, with Q_{ij} the traceless second moment of the mass. Mass and momentum conservation forbid monopole and dipole radiation, so the quadrupole is the leading term, and each further multipole is suppressed by another factor v/c.

T2.2.2 The circular binary

The quadrupole of a binary. Two masses m_1, m_2 at positions $\boldsymbol{x}_1$, $\boldsymbol{x}_2$, centre of mass at rest at the origin. With $M = m_1 + m_2$, the separation $\boldsymbol{x} = \boldsymbol{x}_1 - \boldsymbol{x}_2$ and the **reduced mass** $\mu = m_1m_2/M$, the positions are $\boldsymbol{x}_1 = (m_2/M)\boldsymbol{x}$ and $\boldsymbol{x}_2 = -(m_1/M)\boldsymbol{x}$, and

$$M_{ij} = m_1x_{1i}x_{1j} + m_2x_{2i}x_{2j} = \left(\frac{m_1m_2^2}{M^2} + \frac{m_2m_1^2}{M^2}\right)x_ix_j = \mu\,x_ix_j, \tag{T2.22}$$

so the binary radiates like a single body of mass μ on the relative orbit. For a circular orbit of radius r in the xy plane, $\boldsymbol{x} = r(\cos\omega t, \sin\omega t, 0)$, and Kepler's third law $\omega^2 = GM/r^3$ links ω and r. The components we need are

$$M_{xx} \overset{(1)}{=} \mu r^2 \cos^2\omega t \overset{(2)}{=} \tfrac{1}{2}\mu r^2(1+\cos 2\omega t), \qquad M_{yy} \overset{(2)}{=} \tfrac{1}{2}\mu r^2(1-\cos 2\omega t), \qquad M_{xy} \overset{(2)}{=} \tfrac{1}{2}\mu r^2 \sin 2\omega t,$$
$$\ddot{M}_{xx} \overset{(3)}{=} -2\mu r^2\omega^2 \cos 2\omega t = -\ddot{M}_{yy}, \qquad \ddot{M}_{xy} \overset{(3)}{=} -2\mu r^2\omega^2 \sin 2\omega t, \tag{T2.23}$$

and every component with a z is zero or constant.

(1) $x_x = r\cos\omega t$.
(2) $\cos^2\theta = \frac{1}{2}(1+\cos 2\theta)$, $\sin^2\theta = \frac{1}{2}(1-\cos 2\theta)$, $\sin\theta\cos\theta = \frac{1}{2}\sin 2\theta$.
(3) Two time derivatives of $\cos 2\omega t$ or $\sin 2\omega t$ bring down $-(2\omega)^2$; the constants drop out.

Everything oscillates at 2ω. The mass distribution of the pair, a dumbbell, looks the same after half a turn, so the wave frequency is twice the orbital one:

$$f_{\mathrm{GW}} = 2f_{\mathrm{orb}} = \frac{\omega}{\pi}. \tag{T2.24}$$

From here on f without a label means the wave frequency f_{GW}.

The two polarisations seen from an angle. Let the observer look at the binary from the direction $\hat{\boldsymbol{n}} = (0, \sin\iota, \cos\iota)$, where ι is the **inclination**, the angle between the orbital axis and the line of sight. Two transverse unit vectors are $\boldsymbol{p} = (1,0,0)$ and $\boldsymbol{q} = (0, \cos\iota, -\sin\iota)$. Then $\ddot{M}_{pp} = \ddot{M}_{xx}$, $\ddot{M}_{qq} = \cos^2\iota\,\ddot{M}_{yy}$ and $\ddot{M}_{pq} = \cos\iota\,\ddot{M}_{xy}$, because the z components do not contribute. By (T2.21) at distance D,

$$h_+ \overset{(1)}{=} \frac{G}{c^4 D}\left(\ddot{M}_{xx} - \cos^2\iota\,\ddot{M}_{yy}\right) \overset{(2)}{=} -\frac{4G\mu r^2\omega^2}{c^4 D}\,\frac{1+\cos^2\iota}{2}\,\cos 2\omega t_r,$$
$$h_\times \overset{(1)}{=} \frac{2G}{c^4 D}\cos\iota\,\ddot{M}_{xy} \overset{(2)}{=} -\frac{4G\mu r^2\omega^2}{c^4 D}\,\cos\iota\,\sin 2\omega t_r. \tag{T2.25}$$

(1) The recipe $h_+ = \frac{G}{c^4 D}(\ddot{M}_{pp} - \ddot{M}_{qq})$, $h_\times = \frac{2G}{c^4 D}\ddot{M}_{pq}$, with M in place of Q since their difference is a multiple of δ_{ij}, which the TT recipe removes.
(2) Insert (T2.23): $\ddot{M}_{xx} - \cos^2\iota\,\ddot{M}_{yy} = -2\mu r^2\omega^2(1+\cos^2\iota)\cos 2\omega t$.

Seen face on ($\iota = 0$) the two polarisations have equal size and are a quarter cycle apart: the wave is circularly polarised, as the rotating dumbbell suggests. Seen edge on ($\iota = 90^\circ$) only h_+ is left, at half the face-on size: the dumbbell seen from the side only grows and shrinks.

The amplitude as a function of the wave frequency. Kepler's law gives $r^2\omega^2 = (GM)^{2/3}\omega^{2/3}$, and $\omega = \pi f$. So the common factor in (T2.25) is

$$A \equiv \frac{4G\mu r^2\omega^2}{c^4 D} \overset{(1)}{=} \frac{4G\mu (GM)^{2/3}(\pi f)^{2/3}}{c^4 D} \overset{(2)}{=} \frac{4(G\mathcal{M})^{5/3}(\pi f)^{2/3}}{c^4 D}, \qquad \mathcal{M} \equiv \mu^{3/5}M^{2/5} = \frac{(m_1 m_2)^{3/5}}{(m_1+m_2)^{1/5}}. \tag{T2.26}$$

(1) $r = (GM/\omega^2)^{1/3}$, so $r^2\omega^2 = (GM)^{2/3}\omega^{2/3}$.
(2) $G\mu\,G^{2/3}M^{2/3} = G^{5/3}\mu M^{2/3}$, and $\mu M^{2/3} = (\mu^{3/5}M^{2/5})^{5/3} = \mathcal{M}^{5/3}$.

The masses enter only through the **chirp mass** $\mathcal{M}$; Section T2.4 finds the same combination in the rate of the chirp. This amplitude is the one used for the Fourier-domain waveform in Section T2.5, where it becomes the constant $\mathcal{A}$ of (T2.56); it is the time-domain amplitude quoted by Eda et al. [77, eq. (21)].

Example: the size of the wave from a known source. For a GW150914-like binary, $\mathcal{M} = 28\,M_\odot$, so $G\mathcal{M}/c^3 = 28 \times 4.93\,\mu\text{s} = 1.38 \times 10^{-4}\,\text{s}$, at $D = 410\,\text{Mpc} = 1.27 \times 10^{25}\,\text{m}$ and $f = 250\,\text{Hz}$. Write (T2.26) with the masses as times, $A = 4(G\mathcal{M}/c^3)^{5/3}(\pi f)^{2/3}\, c/D$:

$$A \overset{(1)}{=} 4 \times \left(1.38 \times 10^{-4}\right)^{5/3} \times (785)^{2/3} \times \frac{3.0 \times 10^8}{1.27 \times 10^{25}} \overset{(2)}{=} 4 \times 3.7 \times 10^{-7} \times 85 \times 2.4 \times 10^{-17} \approx 3 \times 10^{-21}.$$

(1) $(G\mathcal{M})^{5/3}/c^4 = (G\mathcal{M}/c^3)^{5/3} c^5/c^4$, and $\pi \times 250 = 785\,\text{s}^{-1}$.
(2) $10^{-3.86\times 5/3} = 10^{-6.43} = 3.7 \times 10^{-7}$; $785^{2/3} = 85$; $c/D = 2.4 \times 10^{-17}\,\text{s}^{-1}$.

This is the strain of order 10^{-21} used in Section T2.1.4. For the intermediate mass-ratio benchmark of Section T2.4 ($\mathcal{M} \approx 19\,M_\odot$) at 75 Mpc and $f = 20\,\text{mHz}$ the same steps give $A \approx 1.6 \times 10^{-23}$. It is the millions of cycles, not the instantaneous size, that make such a source detectable.

T2.2.3 The power

From the flux. The power leaving the binary is the flux (T2.15) integrated over a sphere of radius D. Over one period, $\langle \sin^2 \rangle = \langle \cos^2 \rangle = \frac{1}{2}$, and each time derivative of (T2.25) brings down 2ω, so $\langle \dot{h}_+^2 + \dot{h}_\times^2 \rangle = \frac{1}{2}(2\omega A)^2 \left[\frac{1}{4}(1+\cos^2\iota)^2 + \cos^2\iota\right]$. The bracket is the angular pattern of the radiation (Figure T2.5). It does not depend on the observer's azimuth, because a circular orbit seen from a different azimuth is the same orbit seen at a different moment. With $x = \cos\iota$ and $\mathrm{d}\Omega = \mathrm{d}\phi\,\mathrm{d}x$,

$$\begin{aligned} P_{\text{GW}} &\overset{(1)}{=} \int \frac{c^3}{16\pi G} \langle \dot{h}_+^2 + \dot{h}_\times^2 \rangle D^2\,\mathrm{d}\Omega \overset{(2)}{=} \frac{c^3 D^2}{16\pi G} \cdot 2\omega^2 A^2 \cdot 2\pi \int_{-1}^{1} \left[\frac{(1+x^2)^2}{4} + x^2\right] \mathrm{d}x \\ &\overset{(3)}{=} \frac{c^3 D^2}{16\pi G} \cdot 2\omega^2 A^2 \cdot \frac{16\pi}{5} \overset{(4)}{=} \frac{2}{5} \frac{c^3}{G} \omega^2 (DA)^2 \overset{(5)}{=} \frac{32}{5} \frac{G}{c^5} \mu^2 r^4 \omega^6. \end{aligned} \tag{T2.27}$$

(1) Flux times area, summed over all directions.
(2) $\frac{1}{2}(2\omega A)^2 = 2\omega^2 A^2$; the ϕ integral gives 2π.
(3) $\int_{-1}^{1}(1+x^2)^2 \mathrm{d}x = 2 + \frac{4}{3} + \frac{2}{5} = \frac{56}{15}$ and $\int_{-1}^{1} x^2 \mathrm{d}x = \frac{2}{3}$, so the integral is $\frac{1}{4} \cdot \frac{56}{15} + \frac{2}{3} = \frac{14}{15} + \frac{10}{15} = \frac{8}{5}$, and $2\pi \cdot \frac{8}{5} = \frac{16\pi}{5}$.
(4) $\frac{2 \cdot 16\pi}{16\pi \cdot 5} = \frac{2}{5}$.
(5) $DA = 4G\mu r^2 \omega^2/c^4$ from (T2.26), so $(DA)^2 = 16G^2\mu^2 r^4 \omega^4/c^8$; then $\frac{2}{5} \cdot 16 = \frac{32}{5}$, $c^3/c^8 = c^{-5}$ and $G^2/G = G$.

The angular integral $\int [\frac{1}{4}(1+x^2)^2 + x^2]\mathrm{d}\Omega = 16\pi/5$ is worth remembering; divided by 4π it is the average $\frac{4}{5}$ that reappears in the sky-averaged waveform of Section T2.5.

From the quadrupole directly. The same integral can be done once and for all for any source. Insert (T2.21) into (T2.15). The TT recipe is a projection, applying it twice changes nothing, and for a traceless symmetric matrix it gives

$$\begin{aligned} [\ddot{Q}]^{\text{TT}}_{ij} [\ddot{Q}]^{\text{TT}}_{ij} &\overset{(1)}{=} \ddot{Q}_{ij}\ddot{Q}_{ij} - 2\,\hat{n}_i \ddot{Q}_{ik}\ddot{Q}_{kj}\hat{n}_j + \tfrac{1}{2}\left(\hat{n}_i \ddot{Q}_{ij}\hat{n}_j\right)^2, \\ \frac{1}{4\pi}\int [\ddot{Q}]^{\text{TT}}_{ij}[\ddot{Q}]^{\text{TT}}_{ij}\,\mathrm{d}\Omega &\overset{(2)}{=} \ddot{Q}_{ij}\ddot{Q}_{ij}\left(1 - \frac{2}{3} + \frac{2}{15}\cdot\frac{1}{2}\right) = \frac{2}{5}\ddot{Q}_{ij}\ddot{Q}_{ij}, \\ P_{\text{GW}} &\overset{(3)}{=} \frac{c^3 r^2}{32\pi G}\left(\frac{2G}{c^4 r}\right)^2 \cdot 4\pi \cdot \frac{2}{5}\left\langle \ddot{Q}_{ij}\ddot{Q}_{ij}\right\rangle = \frac{G}{5c^5}\left\langle \dddot{Q}_{ij}\dddot{Q}_{ij}\right\rangle. \end{aligned} \tag{T2.28}$$

(1) With the projector $P_{ij} = \delta_{ij} - \hat{n}_i\hat{n}_j$ onto the transverse plane, the recipe is $[Q]^{\text{TT}} = PQP - \frac{1}{2}P\,\text{tr}(PQ)$. Squaring and taking the trace, with $P^2 = P$ and $\text{tr}P = 2$, gives $\text{tr}(PQPQ) - \text{tr}(PQ)^2 + \frac{1}{4}\cdot 2\,\text{tr}(PQ)^2 = \text{tr}(PQPQ) - \frac{1}{2}\text{tr}(PQ)^2$. Multiplying out $P = \mathbb{1} - \hat{\boldsymbol{n}}\hat{\boldsymbol{n}}^{\mathsf{T}}$ gives $\text{tr}(PQPQ) = \text{tr}Q^2 - 2\,\hat{\boldsymbol{n}}\cdot Q^2\hat{\boldsymbol{n}} + (\hat{\boldsymbol{n}}\cdot Q\hat{\boldsymbol{n}})^2$, and $\text{tr}(PQ) = -\hat{\boldsymbol{n}}\cdot Q\hat{\boldsymbol{n}}$ because $\text{tr}\,Q = 0$.

(2) Average over directions with $\langle \hat{n}_i \hat{n}_j \rangle = \frac{1}{3}\delta_{ij}$ and $\langle \hat{n}_i \hat{n}_j \hat{n}_k \hat{n}_l \rangle = \frac{1}{15}(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk})$; for a traceless symmetric Q the second gives $\langle (\hat{\boldsymbol{n}} \cdot Q\hat{\boldsymbol{n}})^2 \rangle = \frac{2}{15}\mathrm{tr}Q^2$.

(3) The flux (T2.15) with $\dot{h}^{\mathrm{TT}} = (2G/c^4 r)[\ddot{Q}]^{\mathrm{TT}}$, times r^2, integrated over 4π; $\frac{c^3}{32\pi G} \cdot \frac{4G^2}{c^8} \cdot 4\pi \cdot \frac{2}{5} = \frac{G}{5c^5}$.

For the binary, the third derivatives of (T2.23) are $\dddot{Q}_{xx} = -\dddot{Q}_{yy} = 4\mu r^2\omega^3 \sin 2\omega t$ and $\dddot{Q}_{xy} = -4\mu r^2\omega^3 \cos 2\omega t$, so

$$\ddot{Q}_{ij}\ddot{Q}_{ij} = \ddot{Q}_{xx}^2 + \ddot{Q}_{yy}^2 + 2\ddot{Q}_{xy}^2 = (4\mu r^2\omega^3)^2\big(2\sin^2 + 2\cos^2\big)(2\omega t) = 32\,\mu^2 r^4 \omega^6, \tag{T2.29}$$

and (T2.28) gives $P_{\mathrm{GW}} = \frac{32}{5}(G/c^5)\mu^2 r^4\omega^6$ again [76, Sec. 4.1]. Two routes, one answer: the first summed the radiation over directions by hand, the second did the same sum for a general traceless matrix.

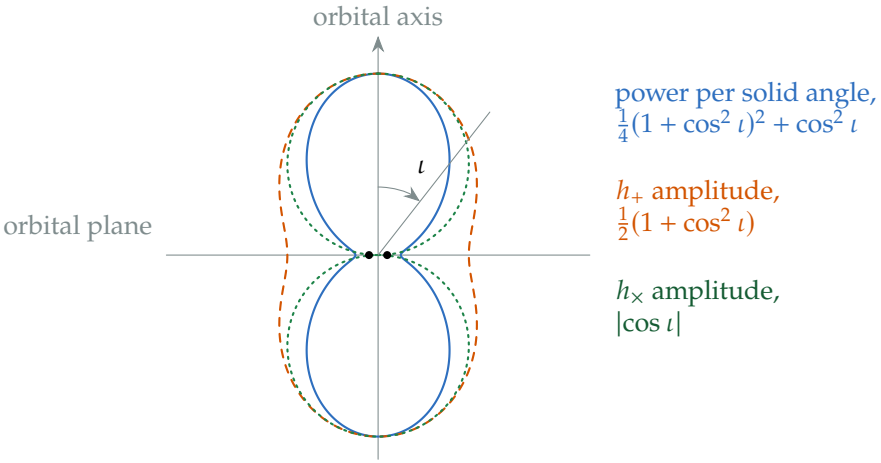


Figure T2.5: How a circular binary radiates in different directions, in units of the face-on value; the distance from the centre along a direction at angle ι from the orbital axis is the quantity named on the right. Along the axis both polarisations are full size and the power is largest. In the orbital plane $h_\times$ vanishes, h_+ is halved, and the power per solid angle drops from $\frac{1}{4}\cdot 2^2 + 1 = 2$ to $\frac{1}{4}$, an eighth of its value on the axis.

Example: how much weaker than a dipole? Suppose, against the conservation laws, that a binary could radiate like an electric dipole. Larmor's formula, $P = q^2a^2/(6\pi\varepsilon_0 c^3)$, with $q^2/(4\pi\varepsilon_0)$ replaced by $G\mu^2$ and the acceleration $a = r\omega^2$, would give $P_{\mathrm{dip}} \sim G\mu^2 r^2\omega^4/c^3$. The quadrupole power is $P_{\mathrm{GW}} \sim G\mu^2 r^4\omega^6/c^5$, so

$$\frac{P_{\mathrm{GW}}}{P_{\mathrm{dip}}} \sim \frac{r^2\omega^2}{c^2} = \frac{v^2}{c^2}.$$

Quadrupole radiation is one power of $(v/c)^2$ weaker than dipole radiation would be. In theories of gravity in which bodies carry an extra "charge" that is not proportional to their mass, dipole radiation does appear, and because it is relatively stronger at low speeds, it shows up at low frequency. Section T2.6 shows that it enters the phase of the wave as the power $f^{-7/3}$.

Where this is used. The amplitude (T2.26) and its dependence on the inclination (T2.25) set the size of every template in Chapter 10: through the constant $\mathcal{A}$ of (T2.56) they fix the signal-to-noise ratio of Section 10.8.3, and through the factor $\frac{4}{5}$ they enter the sky-averaged forecasts of Section 10.11. The power (T2.27) drives the chirp of Section T2.4, whose phase is what Section 10.9 measures.

T2.3 How a detector turns a wave into one number

A wave arrives with two polarisations, $h_+(t)$ and $h_\times(t)$, defined with respect to axes in the plane perpendicular to its direction of travel (Section T2.1). A detector records one time series. LIGO records the difference between the lengths of its two arms, read from the interference of laser light that has run up and down each of them; LISA does the same with laser links between spacecraft millions of kilometres apart. Every likelihood in Chapter 10 compares that one recorded number with a template, so we need the exact rule that maps $(h_+, h_\times)$ onto it.

The questions, in words: *how does a change in the light travel time along one arm follow from h_{ij}? How do two arms combine into one strain? How strongly does the result depend on where the source sits on the sky and how its orbit is turned? And what changes when the arm is so long that the wave changes while the light is still in flight?* The answers produce three numbers that appear without explanation in most papers: the $\frac{4}{5}$ of the inclination average, the $\frac{1}{5}$ of the sky average, and LISA's $\frac{3}{10}$, together with the transfer frequency $f_* = c/(2\pi L)$.

T2.3.1 One arm: the light travel time

The simplest case first. Put one free mass at the origin and one at $x = L$, the arm along x, and let a wave travel along z with a wavelength much longer than L, so that $h_{xx} = h_+$ is the same along the whole arm while the light is in flight. Light moves on $\mathrm{d}s^2 = 0$. Along the arm only $\mathrm{d}t$ and $\mathrm{d}x$ change, so with the TT metric

$$0 \overset{(1)}{=} -c^2\mathrm{d}t^2 + (1 + h_{xx})\,\mathrm{d}x^2 \;\Rightarrow\; c\,\mathrm{d}t \overset{(2)}{=} \sqrt{1 + h_{xx}}\,\mathrm{d}x \overset{(3)}{=} \Big(1 + \tfrac{1}{2}h_{xx}\Big)\mathrm{d}x,$$

$$T_{\mathrm{round}} \overset{(4)}{=} \frac{2L}{c}\Big(1 + \tfrac{1}{2}h_{xx}\Big), \qquad \frac{\delta T_{\mathrm{round}}}{2L/c} = \tfrac{1}{2}h_{xx}. \tag{T2.30}$$

(1) The TT line element (T2.8) along the x axis, with $\mathrm{d}y = \mathrm{d}z = 0$.
(2) Solve for $c\,\mathrm{d}t$.
(3) $\sqrt{1+\epsilon} = 1 + \frac{1}{2}\epsilon$ to first order.
(4) Integrate from 0 to L and back. The end masses keep their TT coordinates (Section T2.1.3), so the coordinate length is L both ways.

The light takes longer exactly as if the arm had grown by $\delta L/L = \frac{1}{2}h_{xx}$, which is the proper-distance result (T2.12) again: a light clock and a ruler agree. For an arm along any unit vector $\hat{\boldsymbol{a}}$, the same steps give $\delta L/L = \frac{1}{2}h_{ij}\hat{a}_i\hat{a}_j$, written $\frac{1}{2}h_{aa}$ for short.

Two arms. A Michelson interferometer sends light along two arms $\hat{\boldsymbol{u}}$ and $\hat{\boldsymbol{v}}$ of equal length and compares the return times. Common changes cancel; the difference survives. The strain the instrument reports is the length difference divided by the arm length [78, eq. (5)], [79, eq. (11)]:

$$h(t) \equiv \frac{\delta L_u - \delta L_v}{L} = \tfrac{1}{2}\big(h_{uu} - h_{vv}\big) = D_{ij}h_{ij}, \qquad D_{ij} \equiv \tfrac{1}{2}\big(\hat{u}_i\hat{u}_j - \hat{v}_i\hat{v}_j\big). \tag{T2.31}$$

The matrix D, the **detector tensor**, is all the geometry of the instrument that matters while the arms are short compared with the wavelength. For a wave of plus polarisation coming straight down onto a right-angle detector with arms along x and y, $h_{uu} = h_+$ and $h_{vv} = -h_+$, so $h = h_+$: one arm grows while the other shrinks, and the two effects add in the difference. That is why the interferometer has two arms at right angles.

T2.3.2 Antenna patterns: where on the sky, and how turned

The general rule. Let the wave come from the direction $\hat{\boldsymbol{n}}$ (so it travels along $-\hat{\boldsymbol{n}}$), and let $\boldsymbol{p}$, $\boldsymbol{q}$ be the axes in the transverse plane with respect to which h_+ and $h_\times$ are defined. By (T2.8) the

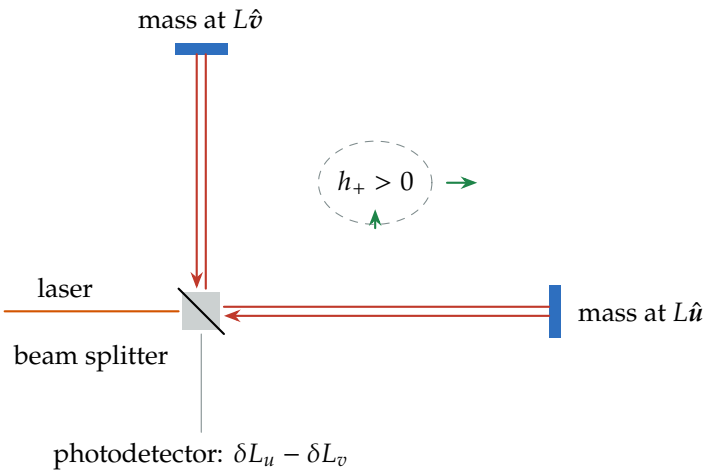

Figure T2.6: A Michelson interferometer. Laser light is split, runs along two perpendicular arms to free masses (blue) and back, and the two beams are recombined. The recombined light measures the difference of the two round-trip times. A plus wave arriving from above, at the instant drawn, lengthens the horizontal arm and shortens the vertical one (small ellipse), so the two changes add up in the difference.

wave is $h_{ij} = h_+ e^+_{ij} + h_\times e^\times_{ij}$ with $e^+ = \boldsymbol{p}\boldsymbol{p}^\mathsf{T} - \boldsymbol{q}\boldsymbol{q}^\mathsf{T}$ and $e^\times = \boldsymbol{p}\boldsymbol{q}^\mathsf{T} + \boldsymbol{q}\boldsymbol{p}^\mathsf{T}$. Inserting it in (T2.31),

$$h(t) = F_+\, h_+(t) + F_\times\, h_\times(t), \qquad F_A = D_{ij}\, e^A_{ij} \quad (A = +, \times), \tag{T2.32}$$

the form used for every detector [78, eq. (24)].

Working definition T2.2 (antenna pattern functions)

F_+ and $F_\times$ are the weights with which a detector adds the two polarisations of a wave into its one output, $h = F_+ h_+ + F_\times h_\times$ [numbers between −1 and 1, fixed by the arm directions, the source direction and the orientation of the polarisation axes]. *Operationally:* $F_A = D_{ij} e^A_{ij}$ with the detector tensor $D = \frac{1}{2}(\hat{\boldsymbol{u}}\hat{\boldsymbol{u}}^\mathsf{T} - \hat{\boldsymbol{v}}\hat{\boldsymbol{v}}^\mathsf{T})$.

A right-angle detector. Take arms along x and y and a source at polar angle θ and azimuth ϕ in the detector's frame. Choose first the natural transverse axes, $\boldsymbol{p}_0 = \hat{\boldsymbol{\theta}} = (\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta)$ and $\boldsymbol{q}_0 = \hat{\boldsymbol{\phi}} = (-\sin\phi, \cos\phi, 0)$. With $D = \frac{1}{2}\mathrm{diag}(1, -1, 0)$,

$$\begin{aligned} F^0_+ &\overset{(1)}{=} \tfrac{1}{2}\left(p_x^2 - q_x^2 - p_y^2 + q_y^2\right) \overset{(2)}{=} \tfrac{1}{2}\left(\cos^2\theta\cos^2\phi - \sin^2\phi - \cos^2\theta\sin^2\phi + \cos^2\phi\right) \\ &\overset{(3)}{=} \tfrac{1}{2}(1 + \cos^2\theta)\cos 2\phi, \\ F^0_\times &\overset{(1)}{=} p_x q_x - p_y q_y \overset{(2)}{=} -\cos\theta\cos\phi\sin\phi - \cos\theta\sin\phi\cos\phi \overset{(3)}{=} -\cos\theta\sin 2\phi. \end{aligned} \tag{T2.33}$$

(1) $D_{ij}e^A_{ij} = \frac{1}{2}(e^A_{xx} - e^A_{yy})$, with $e^+_{xx} = p_x^2 - q_x^2$ and $e^\times_{xx} = 2p_x q_x$.
(2) Insert the components of $\boldsymbol{p}_0$ and $\boldsymbol{q}_0$.
(3) $\cos^2\phi - \sin^2\phi = \cos 2\phi$ and $2\sin\phi\cos\phi = \sin 2\phi$.

If the wave's own axes are turned by an angle ψ, the **polarisation angle**, from $(\boldsymbol{p}_0, \boldsymbol{q}_0)$, the rule (T2.9) for turning axes rewrites the wave in the $(\boldsymbol{p}_0, \boldsymbol{q}_0)$ frame as $h_+\cos 2\psi - h_\times \sin 2\psi$ and $h_+\sin 2\psi + h_\times\cos 2\psi$. Collecting the coefficients of h_+ and $h_\times$,

$$\begin{aligned} F_+ &= \tfrac{1}{2}(1 + \cos^2\theta)\cos 2\phi\cos 2\psi - \cos\theta\sin 2\phi\sin 2\psi, \\ F_\times &= -\tfrac{1}{2}(1 + \cos^2\theta)\cos 2\phi\sin 2\psi - \cos\theta\sin 2\phi\cos 2\psi, \end{aligned} \tag{T2.34}$$

which is [80, eq. (6)] and [79, eq. (15a)]; their $F_\times$ has the opposite overall sign, a matter of which way ψ is counted, which no average or signal-to-noise ratio can see. The detector is deaf in four directions in its own plane, $\theta = 90°$ and $\phi = 45°, 135°, \ldots$, along the bisectors of the arms, where both arms are stretched equally. It is most sensitive straight overhead. Figure T2.7 maps $F_+^2 + F_\times^2$, which does not depend on ψ.

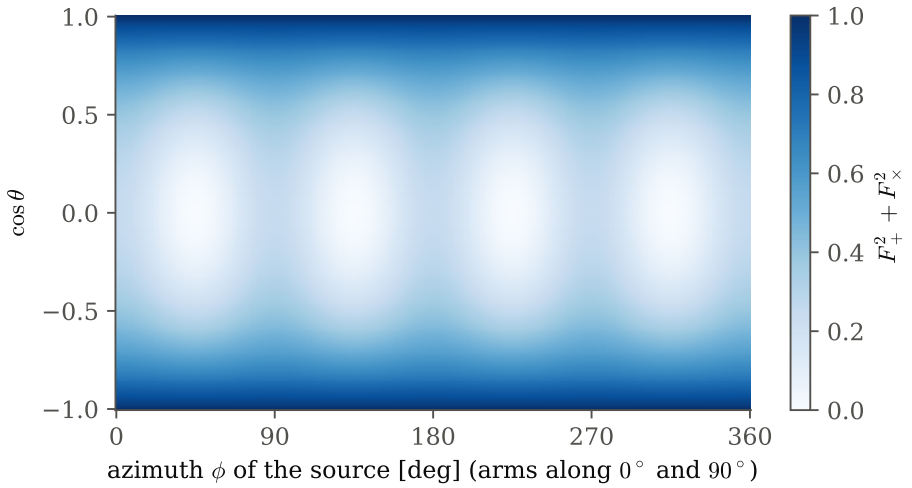

Figure T2.7: The sensitivity of a right-angle interferometer over the sky, $F_+^2 + F_\times^2$, as a function of the source's azimuth and of the cosine of its polar angle. It is largest above and below the detector ($\cos\theta = \pm 1$), and drops to zero at four points in the plane of the arms ($\cos\theta = 0$, $\phi = 45°$, $135°$, $225°$, $315°$), where the wave stretches both arms equally.

Example: a source overhead and a source in the plane of the arms. For a source straight overhead, $\theta = 0$, (T2.34) gives

$$F_+ \overset{(1)}{=} \cos 2\phi \cos 2\psi - \sin 2\phi \sin 2\psi \overset{(2)}{=} \cos(2\phi + 2\psi),$$
$$F_\times \overset{(1)}{=} -\cos 2\phi \sin 2\psi - \sin 2\phi \cos 2\psi \overset{(2)}{=} -\sin(2\phi + 2\psi),$$

(1) $\cos\theta = 1$, so $\frac{1}{2}(1 + \cos^2\theta) = 1$.
(2) The addition rules for $\cos(a + b)$ and $\sin(a + b)$.

so $F_+^2 + F_\times^2 = 1$ whatever the orientation: overhead, the detector catches the full wave, and turning the polarisation axes only moves the signal from one polarisation to the other. For a source in the plane of the arms, in the direction of the x arm ($\theta = 90°$, $\phi = 0$), we get $F_+ = \frac{1}{2}\cos 2\psi$ and $F_\times = -\frac{1}{2}\sin 2\psi$, so $F_+^2 + F_\times^2 = \frac{1}{4}$: the wave travels along the x arm, which it cannot stretch because the wave is transverse, and only the y arm responds, with its weight $\frac{1}{2}$ in the difference (T2.31).

The sky and polarisation average. For forecasts the source's position and orientation are not known, so the response is averaged over all of them, with the source direction uniform on the sphere and ψ uniform. Take $\langle F_+^2 \rangle$ in three steps, one angle at a time:

$$\langle F_+^2 \rangle_\psi \overset{(1)}{=} \tfrac{1}{2}\Big[\tfrac{1}{4}(1 + \cos^2\theta)^2 \cos^2 2\phi + \cos^2\theta \sin^2 2\phi\Big],$$
$$\langle F_+^2 \rangle_{\psi,\phi} \overset{(2)}{=} \tfrac{1}{4}\Big[\tfrac{1}{4}(1 + \cos^2\theta)^2 + \cos^2\theta\Big],$$
$$\langle F_+^2 \rangle \overset{(3)}{=} \tfrac{1}{4}\Big[\tfrac{1}{4} \cdot \tfrac{28}{15} + \tfrac{1}{3}\Big] = \tfrac{1}{4} \cdot \tfrac{12}{15} = \tfrac{1}{5}. \qquad \text{(T2.35)}$$

(1) Square (T2.34); over a full turn of ψ, $\langle\cos^2 2\psi\rangle = \langle\sin^2 2\psi\rangle = \frac{1}{2}$ and $\langle\cos 2\psi \sin 2\psi\rangle = 0$, so the cross term drops.
(2) The same averages over ϕ.
(3) A direction uniform on the sphere has $x = \cos\theta$ uniform on $[-1, 1]$, so $\langle(1 + x^2)^2\rangle = \frac{1}{2}\int_{-1}^{1}(1 + 2x^2 + x^4)\mathrm{d}x = 1 + \frac{1}{3} + \frac{1}{5} = \frac{28}{15}$ and $\langle x^2\rangle = \frac{1}{3}$.

The same steps give $\langle F_\times^2\rangle = \frac{1}{5}$, and $\langle F_+ F_\times\rangle = 0$. This is the $\frac{1}{5}$ of [80, eq. (7)]. The bracket in the second line is the same function $\frac{1}{4}(1 + \cos^2)^2 + \cos^2$ that described the radiation pattern of a binary in Section T2.2: a detector receives from each direction in the same pattern as a rotating quadrupole emits into it, because both are the TT part of a quadrupolar tensor.

The inclination average. The source has its own orientation. By (T2.25) a circular binary at inclination ι has $h_+ = A\frac{1}{2}(1 + \cos^2\iota)\cos\Phi$ and $h_\times = A\cos\iota\sin\Phi$ (up to an overall sign), where Φ is the wave's phase. Averaged over ψ, F_+^2 and $F_\times^2$ have the same mean and no correlation, so the mean squared signal is $\langle F_+^2\rangle A^2[\frac{1}{4}(1 + \cos^2\iota)^2 + \cos^2\iota]$, and averaging over orientations of the orbit, $x = \cos\iota$ uniform,

$$\left\langle \tfrac{1}{4}(1 + x^2)^2 + x^2 \right\rangle_x = \tfrac{1}{4}\cdot\tfrac{28}{15} + \tfrac{1}{3} = \tfrac{7}{15} + \tfrac{5}{15} = \tfrac{4}{5}. \tag{T2.36}$$

This is the $\frac{4}{5}$ in the sky-averaged waveform $\tilde{h} = \sqrt{4/5}\,\mathcal{A}f^{-7/6}e^{-i\Psi}$ of [81, eq. (44)] and [80, eq. (16)], and divided into $16\pi/5$ over 4π it is the same angular integral that gave the binary's total power. For a ground-based detector the two averages combine to $\frac{4}{5}\cdot\frac{1}{5} = \frac{4}{25}$ in power, $\frac{2}{5}$ in amplitude, the factor quoted in the LIGO literature.

T2.3.3 LISA at low frequency: 60° arms and two channels

LISA's three spacecraft form an equilateral triangle (Figure T2.8), so two arms meeting at a spacecraft make 60°, not 90°. *How much does that cost?* Let $\hat{\boldsymbol{e}}_1$ be the unit vector along the bisector of the two arms and $\hat{\boldsymbol{e}}_2$ the perpendicular one in their plane, so that with $\alpha = 60°$ the opening angle,

$$\hat{\boldsymbol{u}} = \cos\tfrac{\alpha}{2}\,\hat{\boldsymbol{e}}_1 + \sin\tfrac{\alpha}{2}\,\hat{\boldsymbol{e}}_2, \qquad \hat{\boldsymbol{v}} = \cos\tfrac{\alpha}{2}\,\hat{\boldsymbol{e}}_1 - \sin\tfrac{\alpha}{2}\,\hat{\boldsymbol{e}}_2,$$
$$2D = \hat{\boldsymbol{u}}\hat{\boldsymbol{u}}^{\mathsf{T}} - \hat{\boldsymbol{v}}\hat{\boldsymbol{v}}^{\mathsf{T}} \overset{(1)}{=} 2\cos\tfrac{\alpha}{2}\sin\tfrac{\alpha}{2}\left(\hat{\boldsymbol{e}}_1\hat{\boldsymbol{e}}_2^{\mathsf{T}} + \hat{\boldsymbol{e}}_2\hat{\boldsymbol{e}}_1^{\mathsf{T}}\right) \overset{(2)}{=} \sin\alpha\left(\hat{\boldsymbol{e}}_1\hat{\boldsymbol{e}}_2^{\mathsf{T}} + \hat{\boldsymbol{e}}_2\hat{\boldsymbol{e}}_1^{\mathsf{T}}\right). \tag{T2.37}$$

(1) Multiply out: the $\hat{\boldsymbol{e}}_1\hat{\boldsymbol{e}}_1^{\mathsf{T}}$ and $\hat{\boldsymbol{e}}_2\hat{\boldsymbol{e}}_2^{\mathsf{T}}$ terms are the same in both and cancel; the mixed terms add.
(2) $2\sin\frac{\alpha}{2}\cos\frac{\alpha}{2} = \sin\alpha$.

For $\alpha = 90°$ the bracket is the detector tensor of a right-angle interferometer whose arms lie along $(\hat{\boldsymbol{e}}_1 \pm \hat{\boldsymbol{e}}_2)/\sqrt{2}$. So a 60° interferometer is a right-angle interferometer, turned by 45° relative to its bisector, with every response multiplied by $\sin 60° = \sqrt{3}/2$: the factor in [79, eq. (14)]. Turning does not change a sky average, so each 60° channel has $\langle F_+^2\rangle = \frac{3}{4}\cdot\frac{1}{5} = \frac{3}{20}$. The three arms of the triangle provide two such independent channels at low frequency, the second equivalent to the first turned by 45° [79, eqs. (12), (15b)], and the sensitivity-curve literature sums them: $R = 2\times\frac{3}{20} = \frac{3}{10}$ [80, eqs. (8)–(9)]. The script `13_lisa_response.py` checks all of these averages by quadrature over the sky and ψ and finds 0.2 and 0.2 for a right-angle detector, 0.15 for one 60° channel, 0.8 for the inclination average and $3.2\,\pi$ for the angular integral of the binary's power.

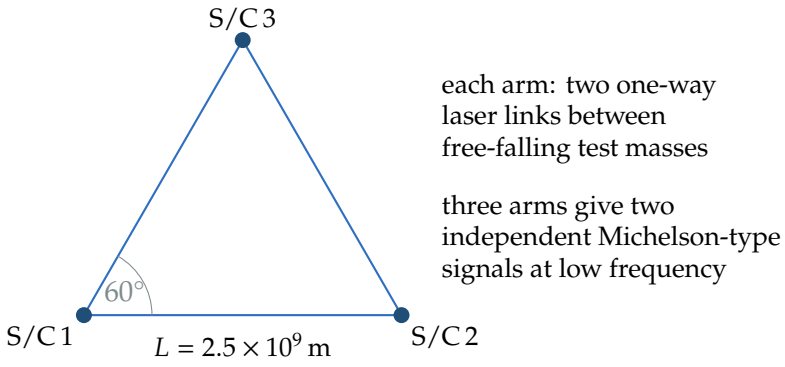

Figure T2.8: The LISA constellation. Three spacecraft form an equilateral triangle; each side carries laser links in both directions. Two arms meeting at a spacecraft act as a Michelson interferometer whose arms make 60° rather than 90°. At low frequency the three arms carry two independent combinations, written as detectors I and II in [79, eqs. (11)–(12)].

T2.3.4 Long arms: the transfer frequency

LISA's arms are $L = 2.5\times10^9$ m long, and light needs $L/c = 8.3$ s to cross one. A wave of 10 mHz has a period of 100 s, so it changes noticeably while the light is in flight, and (T2.30), which froze h during the trip, must be redone.

The simplest case: a wave arriving perpendicular to the arm. Then $h_{xx} = h(t)$ is the same at every point of the arm but changes in time. Light reflected at the far end at time t_m left at $t_m - L/c$ and returns at $t_m + L/c$. Following the steps of (T2.30) with h evaluated at the moment the light passes, for $h(t) = h_0 \cos 2\pi f t$,

$$\delta T_{\text{round}} \overset{(1)}{=} \frac{1}{2}\int_{t_m-L/c}^{t_m+L/c} h_0 \cos(2\pi f t')\,\mathrm{d}t' \overset{(2)}{=} \frac{h_0}{4\pi f}\left[\sin 2\pi f\left(t_m+\frac{L}{c}\right) - \sin 2\pi f\left(t_m-\frac{L}{c}\right)\right]$$
$$\overset{(3)}{=} \frac{h_0}{2\pi f}\cos(2\pi f t_m)\,\sin\frac{2\pi f L}{c} \overset{(4)}{=} \frac{L}{c}\,h(t_m)\,\mathrm{sinc}\left(\frac{f}{f_*}\right), \qquad f_* \equiv \frac{c}{2\pi L}, \tag{T2.38}$$

(1) Each element $\mathrm{d}x = c\,\mathrm{d}t'$ of the path adds $\frac{1}{2}h(t')\,\mathrm{d}t'$ to the travel time, by step (3) of (T2.30).
(2) The integral of cos is $\sin/(2\pi f)$.
(3) $\sin a - \sin b = 2\cos\frac{a+b}{2}\sin\frac{a-b}{2}$, with $\frac{a+b}{2} = 2\pi f t_m$ and $\frac{a-b}{2} = 2\pi f L/c$.
(4) Multiply and divide by $2\pi f L/c = f/f_*$, with $\mathrm{sinc}\,z \equiv \sin z/z$.

For $f \ll f_*$, sinc $\to 1$ and we are back at $\delta T = (L/c)h$, i.e. $\delta L/L = \frac{1}{2}h$. The **transfer frequency** f_* is where the wave's phase advances by one radian while the light crosses one arm:

$$f_* = \frac{c}{2\pi L} = \frac{3.0\times10^8\ \mathrm{m\,s^{-1}}}{2\pi\times 2.5\times10^9\ \mathrm{m}} = 19.1\ \mathrm{mHz}. \tag{T2.39}$$

At $f = \pi f_* = c/(2L) = 59.96$ mHz the wave completes exactly one cycle during the round trip, the stretching on the way out is undone by the squeezing on the way back, and the arm sees nothing. Above f_*, $|\mathrm{sinc}(f/f_*)| \le f_*/f$, so the response in power falls at least as $(f_*/f)^2$.

Example: how much is lost at 10 and at 100 millihertz. At $f = 10$ mHz, $f/f_* = 0.52$ and sinc(0.52) = sin(0.52)/0.52 = 0.497/0.52 = 0.96, so the response in power is $0.96^2 = 0.91$ of its low-frequency value: hardly any loss. At $f = 100$ mHz, $f/f_* = 5.24$ and sinc(5.24) = sin(5.24)/5.24 = −0.866/5.24 = −0.17, a power response of 0.027, below the bound $(f_*/f)^2 = 0.036$. A tenfold rise in frequency has cost a factor thirty in power, which the noise curve of Section T2.7 will show as a rising high-frequency wall.

Any direction. If the wave travels along $\hat{\boldsymbol{k}}$ and the arm points along $\hat{\boldsymbol{a}}$, the light moving outwards meets the wave at the position $\boldsymbol{x} = \hat{\boldsymbol{a}}\, c(t' - t_0)$, where the wave's phase is $2\pi f(t' - \hat{\boldsymbol{k}} \cdot \boldsymbol{x}/c) = 2\pi f[(1 - \hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{a}})t' + \text{const}]$. The light rides with the wave if $\hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{a}} = 1$ and meets it head on if -1, so the phase runs at the Doppler-shifted rate $2\pi f(1 - \hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{a}})$ along the outward leg and $2\pi f(1 + \hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{a}})$ on the way back. The integral over one leg of duration L/c is therefore

$$\int_{t_0}^{t_0+L/c} e^{2\pi i f(1\mp\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{a}})t'}\,\mathrm{d}t' = \frac{L}{c}\, e^{2\pi i f(1\mp\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{a}})(t_0+L/2c)}\,\operatorname{sinc}\!\left[\frac{f}{2f_*}\left(1 \mp \hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{a}}\right)\right], \tag{T2.40}$$

the same calculation as (T2.38) for half the path and a shifted frequency. Putting both legs of both arms into (T2.31) gives the frequency-dependent $F_+(f)$ and $F_\times(f)$ of a LISA channel. The script averages $|F_+(f)|^2$ over the sky and polarisation for one 60° Michelson and doubles it for the two channels:

Listing T2.1: The light-travel integrals of one arm, and the sky-averaged response (`code/chT2/13_lisa_response.py`)

```

The function `leg` is (T2.40) with the light time L/c set to one, so that $2\pi f = f/f_*$. `arm_transfer` adds the outward and return legs and divides by the round-trip time, so it tends to one at low frequency. The loop forms $F_+(f)$ for each sky direction and polarisation angle and averages its squared modulus with the quadrature weights `W`.

Figure T2.9 shows the result. At low frequency it is 0.3, the $\frac{3}{10}$ found above. At f_* it has dropped to 0.708 of that (the fit $R(f) = \frac{3}{10}/[1 + 0.6(f/f_*)^2]$ of [80, eq. (9)] gives 0.625), and well above f_* it falls as $f^{-2.009}$, the f^{-2} of the single-arm argument. Between about $2f_*$ and $10f_*$ our single-Michelson response wiggles around the fit by up to 66.42%: these are the zeros of the individual arm responses, partly filled in by the sky average. The fit smooths them over, and the full response used in research analyses adds the third, high-frequency channel of the triangle [80].

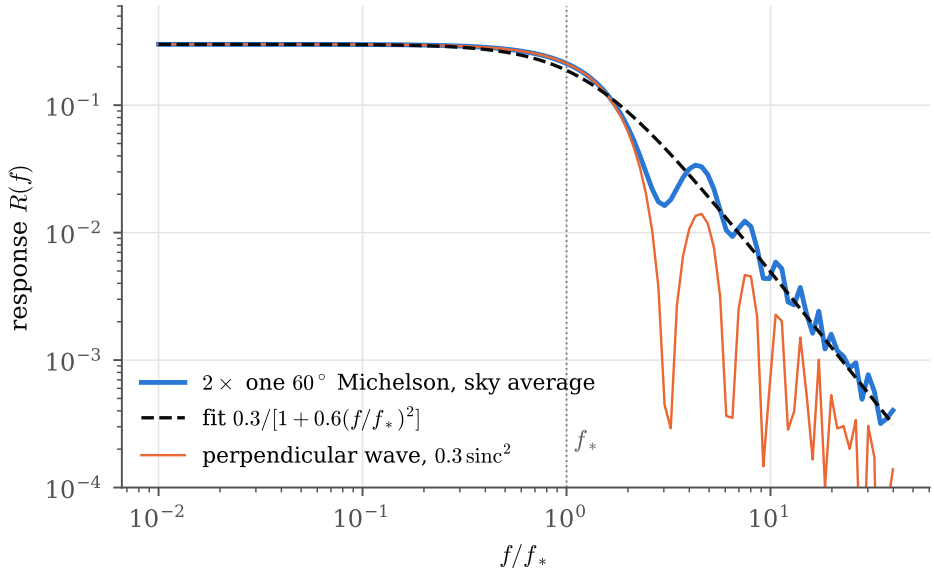

Figure T2.9: The sky- and polarisation-averaged response of LISA against frequency in units of $f_* = c/(2\pi L)$. Blue: computed from the light-travel integrals (T2.40) for one 60° Michelson channel and doubled for two channels. Dashed: the fit of Robson et al. Orange: a wave arriving perpendicular to the arms, whose response $\mathrm{sinc}^2(f/f_*)$ vanishes whenever a whole number of cycles fits into the round trip. Averaging over directions fills in those zeros, but the f^{-2} fall above f_* remains.

Key idea: The numbers that turn a source into an average source

A detector reports $h = F_+ h_+ + F_\times h_\times$. Averaged over the sky and the polarisation angle, a right-angle interferometer has $\langle F_+^2 \rangle = \langle F_\times^2 \rangle = \frac{1}{5}$; a 60° channel has $\frac{3}{4}$ of that, $\frac{3}{20}$, and LISA's two channels together $\frac{3}{10}$. Averaging a circular binary over its inclination multiplies the signal power by $\frac{4}{5}$. Above the transfer frequency $f_* = c/(2\pi L)$ the wave changes while the light is in flight and the response falls as f^{-2}.

What the sky average leaves out. LISA orbits the Sun, so a source's signal is Doppler shifted back and forth over a year, and the triangle rotates, so the antenna patterns (T2.34) change slowly with time [79, eqs. (16)–(17)]. The phase is modulated by $2\pi f R \sin\theta_S \cos(2\pi t/\mathrm{yr} - \phi_S)$, with $R = 1\,\mathrm{AU}/c = 499\,\mathrm{s}$ and (θ_S, ϕ_S) the source's sky position [79, eq. (33)]. At $f = 10\,\mathrm{mHz}$ the amplitude of this modulation is $2\pi \times 0.01 \times 499 \approx 31\,\mathrm{rad}$, so it is easily measured, and it is how LISA locates sources on the sky. The sky-averaged response drops that information and replaces the real, moving detector by an average one. For forecasts of an environment, which acts on the phase evolution and not on the sky position, the averaged response is adequate, and the signal-to-noise ratios it gives are good to a factor of about two [80].

Where this is used. The response rule (T2.32) is what turns a template into the predicted data stream in the detection problem of Section 10.8. The averages $\frac{4}{5}$ and $\frac{3}{10}$ are the ones built into the sky-averaged waveform and the sensitivity curve of Section T2.7, which Section 10.11.1 checks against its source; f_* and the high-frequency fall of the response set the shape of that curve above about 20 mHz.

T2.4 Why a compact binary chirps

Take two black holes, masses m_1 and m_2, on a circular orbit of radius r. Section T2.2 showed that the pair radiates gravitational waves at twice its orbital frequency, with the power $P_{\text{GW}} = \frac{32}{5}(G/c^5)\mu^2 r^4 \omega^6$ of (T2.27), and the energy flux of Section T2.1.4 says that this power is real energy leaving the system. The pair therefore has less and less orbital energy, so it must sit deeper in its own potential well, on a smaller orbit. A smaller orbit is a faster orbit, and since $P_{\text{GW}} \propto r^4\omega^6 \propto r^{-5}$, a faster orbit radiates far more strongly. The process runs away: the orbit shrinks ever faster, and the frequency of the wave rises ever faster until the holes merge. Played as sound, the signal is a rising whistle, a **chirp**.

Every statistics calculation with such a signal starts from one question: *given the two masses and the frequency f of the wave we see today, how fast is f rising, and how long is left before the merger?* The answer is a single formula for $\dot{f}$. The time to merger, the number of cycles, the phase of the wave and the end of the inspiral all follow from it.

T2.4.1 The inputs

As with the Poisson process of Chapter 2, we first separate what goes in from what comes out. Four things go in, and only the first two are new.

1. *Physical: Newtonian circular orbits.* The two bodies obey Newton's gravity and move on a circle. The two-body problem reduces, as usual, to one body of reduced mass $\mu = m_1 m_2/M$ circling a fixed mass $M = m_1 + m_2$, with Kepler's third law $\omega^2 = GM/r^3$ for the orbital angular frequency ω.
2. *Physical: slow evolution.* One orbit takes much less time than the orbit takes to shrink noticeably. So at each moment the orbit is a circle of the current radius, and the orbital energy simply drains into the waves, $\mathrm{d}E/\mathrm{d}t = -P_{\text{GW}}$. We check this with numbers at the end of the section.
3. *Derived earlier: the radiated power $P_{\text{GW}} = \frac{32}{5}(G/c^5)\mu^2 r^4\omega^6$ of (T2.27), which came from the linearised field equation and the energy flux in Section T2.2, and the wave frequency $f = \omega/\pi$ of (T2.24).*
4. *Mathematical: $r(t)$ is smooth, so we may differentiate it.*

That only one combination of the masses matters is *not* an input; it comes out of the derivation.

T2.4.2 From the radiated power to the chirp

Energy and power as functions of the wave frequency. The frequency is what the detector measures, so we trade r for f using Kepler, $r = (GM/\omega^2)^{1/3}$ with $\omega = \pi f$:

$$E \overset{(1)}{=} -\frac{GM\mu}{2r} \overset{(2)}{=} -\frac{\mu}{2}(\pi GMf)^{2/3}, \tag{T2.41}$$

$$P_{\text{GW}} \overset{(3)}{=} \frac{32}{5}\frac{G}{c^5}\mu^2(GM)^{4/3}(\pi f)^{10/3} \overset{(4)}{=} \frac{32}{5}\frac{c^5}{G}\left(\frac{\pi G\mathcal{M}f}{c^3}\right)^{10/3}, \qquad \mathcal{M} \equiv \mu^{3/5}M^{2/5} = \frac{(m_1m_2)^{3/5}}{(m_1+m_2)^{1/5}}. \tag{T2.42}$$

(1) Kinetic plus potential energy of a circular orbit: $\frac{1}{2}\mu v^2 - GM\mu/r$ with $v^2 = GM/r$.
(2) $1/r = (\omega^2/GM)^{1/3}$, so $GM/r = (GM)^{2/3}\omega^{2/3}$.
(3) $r^4\omega^6 = (GM)^{4/3}\omega^{-8/3}\omega^6 = (GM)^{4/3}\omega^{10/3}$.

(4) Collect the masses: $\mu^2 M^{4/3} = (\mu^{3/5} M^{2/5})^{10/3}$, and the powers of G and c rearrange as $G^{7/3}/c^5 = (c^5/G)(G/c^3)^{10/3}$.

The combination $\mathcal{M}$ is the chirp mass of (T2.26): it appeared there in the amplitude of the wave and appears here again, on its own, in step (4).

The chirp rate. Energy balance says $\mathrm{d}E/\mathrm{d}t = -P_{\mathrm{GW}}$. Since E depends on time only through f, $\mathrm{d}E/\mathrm{d}t = (\mathrm{d}E/\mathrm{d}f)\,\dot{f}$, so

$$\dot{f} \overset{(1)}{=} \frac{P_{\mathrm{GW}}}{|\mathrm{d}E/\mathrm{d}f|} \overset{(2)}{=} \frac{\frac{32}{5}\frac{G^{7/3}}{c^5}\mu^2 M^{4/3}(\pi f)^{10/3}}{\frac{\mu}{3}(\pi G M)^{2/3} f^{-1/3}} \overset{(3)}{=} \frac{96}{5}\,\pi^{8/3}\Big(\frac{G\mathcal{M}}{c^3}\Big)^{5/3} f^{11/3}. \tag{T2.43}$$

(1) Energy balance, with $\mathrm{d}E/\mathrm{d}f < 0$ (a higher frequency is a more bound orbit).
(2) P_{GW} from step (3) of (T2.42); $\mathrm{d}E/\mathrm{d}f = -\frac{\mu}{3}(\pi G M)^{2/3} f^{-1/3}$ from (T2.41).
(3) One μ cancels; $\mu M^{4/3}/M^{2/3} = \mu M^{2/3} = \mathcal{M}^{5/3}$, $G^{7/3}/G^{2/3} = G^{5/3}$ so $G^{5/3}/c^5 = (G/c^3)^{5/3}$, and $\pi^{10/3}/\pi^{2/3} \cdot f^{10/3} f^{1/3} = \pi^{8/3} f^{11/3}$.

Key idea: The Newtonian chirp

A circular binary radiating quadrupole waves sweeps up in frequency at the rate $\dot{f} = \frac{96}{5}\pi^{8/3}(G\mathcal{M}/c^3)^{5/3} f^{11/3}$. At this order the masses enter only through the chirp mass $\mathcal{M} = (m_1 m_2)^{3/5}/(m_1 + m_2)^{1/5}$, so the data measure $\mathcal{M}$ first and the separate masses only through smaller corrections.

The product $G\mathcal{M}/c^3$ has units of time. For the Sun it is $GM_\odot/c^3 = 4.93\,\mu\mathrm{s}$, which is the handiest number in gravitational-wave astronomy: a mass in solar units times $4.93\,\mu$s is that mass as a time.

Frequency against time, and the number of cycles. Since $\mathrm{d}t = \mathrm{d}f/\dot{f}$, the time left before the frequency runs off to infinity (the formal coalescence time t_c) is

$$\tau(f) \equiv t_c - t \overset{(1)}{=} \int_f^\infty \frac{\mathrm{d}f'}{\dot{f}(f')} \overset{(2)}{=} \frac{5}{96}\pi^{-8/3}\Big(\frac{G\mathcal{M}}{c^3}\Big)^{-5/3} \cdot \frac{3}{8} f^{-8/3} = \frac{5}{256}\Big(\frac{G\mathcal{M}}{c^3}\Big)^{-5/3}(\pi f)^{-8/3}, \tag{T2.44}$$

(1) Time is the integral of $\mathrm{d}f/\dot{f}$ along the sweep.
(2) $\int_f^\infty f'^{-11/3}\mathrm{d}f' = \frac{3}{8}f^{-8/3}$; then $\frac{5}{96}\cdot\frac{3}{8} = \frac{5}{256}$ and $\pi^{-8/3} f^{-8/3} = (\pi f)^{-8/3}$.

and inverting, $f(\tau) = \frac{1}{8\pi}\big(G\mathcal{M}/c^3\big)^{-5/8}\big(5/\tau\big)^{3/8}$ [80, eq. (24)]. The number of wave cycles between f_1 and f_2 is $N = \int f\,\mathrm{d}t = \int f\,\mathrm{d}f/\dot{f}$:

$$N(f_1, f_2) = \frac{1}{32\pi^{8/3}}\Big(\frac{G\mathcal{M}}{c^3}\Big)^{-5/3}\big(f_1^{-5/3} - f_2^{-5/3}\big), \tag{T2.45}$$

from $\int f^{-8/3}\mathrm{d}f = -\frac{3}{5}f^{-5/3}$ and $\frac{3}{5}\cdot\frac{5}{96} = \frac{1}{32}$. The low-frequency end dominates: most cycles are spent where the binary is slow.

Where the inspiral ends. In Newton's theory circular orbits exist all the way down. In general relativity they stop being stable inside the **innermost stable circular orbit** (ISCO), $r_{\mathrm{ISCO}} = 6GM/c^2$, three Schwarzschild radii; inside it the small body plunges. Kepler's law there gives $\omega^2 = c^6/(216\,G^2M^2)$, so

$$f_{\mathrm{ISCO}} = \frac{c^3}{6^{3/2}\pi G M} \approx 4.4\,\mathrm{kHz} \times \frac{M_\odot}{M}. \tag{T2.46}$$

Papers on dark-matter environments stop their inspirals here [77, 81], and so do we.

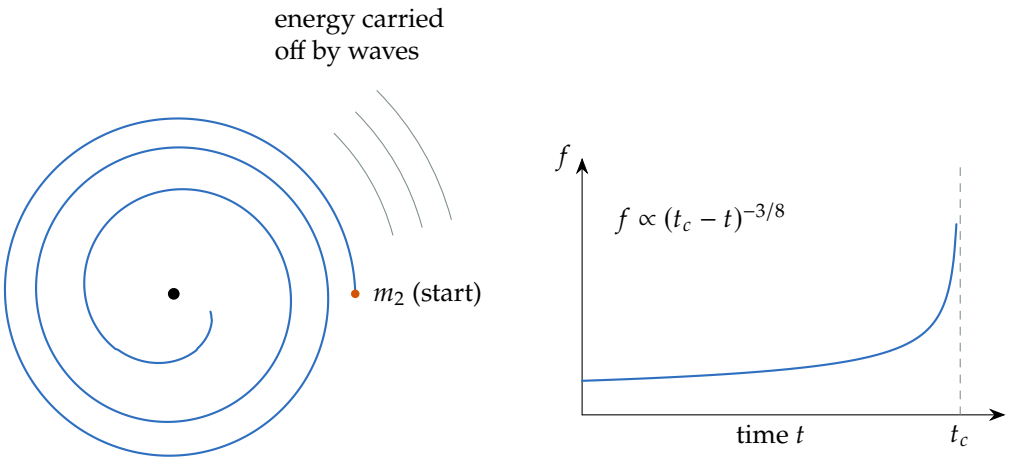

Figure T2.10: The chirp. Left: the light body's path around the heavy one (dot) for a Newtonian inspiral, the last three turns, drawn to scale in shape ($r \propto (\phi_c - \phi)^{2/5}$, which follows from $r \propto \tau^{1/4}$ and $\phi \propto \tau^{5/8}$); each turn is tighter and quicker than the last. Right: the wave frequency of (T2.44) inverted, rising slowly for a long time and then very fast just before t_c.

T2.4.3 The phase of the wave, and the two numbers that fix it

The detector does not record the frequency; it records the wave, $h(t) = A(t)\cos\phi(t)$ for one polarisation, with the amplitude $A \propto f^{2/3}$ of (T2.26) and a phase $\phi(t)$ whose rate of change is the angular frequency, $\dot\phi = 2\pi f$. So the phase is the integral of the frequency history. Write $T_{\mathcal{M}} \equiv G\mathcal{M}/c^3$, the chirp mass as a time, and $\tau = t_c - t$. The inverse of (T2.44) is $2\pi f(\tau) = \frac{1}{4}T_{\mathcal{M}}^{-5/8}5^{3/8}\tau^{-3/8}$, and since $\mathrm{d}\tau = -\mathrm{d}t$,

$$\phi(t) \overset{(1)}{=} \phi_c - \int_0^\tau 2\pi f(\tau')\,\mathrm{d}\tau' \overset{(2)}{=} \phi_c - \tfrac{1}{4}T_{\mathcal{M}}^{-5/8}5^{3/8}\cdot\tfrac{8}{5}\,\tau^{5/8} \overset{(3)}{=} \phi_c - 2\Big(\frac{\tau}{5T_{\mathcal{M}}}\Big)^{5/8}, \tag{T2.47}$$

(1) The phase grows by $2\pi f\,\mathrm{d}t$ in each moment. Integrating backwards from the end, where it reaches the value ϕ_c, the phase at time t is ϕ_c minus everything still to come.

(2) $\int_0^\tau \tau'^{-3/8}\mathrm{d}\tau' = \frac{8}{5}\tau^{5/8}$.

(3) $\frac{1}{4}\cdot\frac{8}{5}\cdot 5^{3/8} = \frac{2}{5}\cdot 5^{3/8} = 2\cdot 5^{-5/8}$, and $5^{-5/8}T_{\mathcal{M}}^{-5/8}\tau^{5/8} = (\tau/5T_{\mathcal{M}})^{5/8}$.

which is [82, eq. (17)]. Two integration constants appeared on the way, and both are now parameters of the signal.

The time of coalescence t_c is the moment at which the Newtonian frequency (T2.44) would formally run off to infinity. The real inspiral ends a little earlier, at the ISCO, but t_c is a convenient label for "when it all happens". Changing t_c by Δ slides the whole signal along the time axis, $h(t) \to h(t-\Delta)$, without changing its shape.

The phase at coalescence ϕ_c is the value of the phase at t_c. Since the wave phase is twice the orbital phase, changing ϕ_c by δ is the same as having started the two bodies at a different place on their orbit, turned by $\delta/2$ about the orbital axis. It does not change t_c, the masses or the frequency history; it only shifts the crests of the wave.

Why they are nuisance parameters. Neither number says anything about the physics of the source. t_c records when, on our clocks, the binary happened to merge; ϕ_c records where the two bodies happened to be on their orbit at that moment. Both are pure accident, both are unknown before the data arrive, and both must nevertheless be in the template: a template whose crests sit half a cycle away from the signal's crests correlates with it negatively, however right its masses. In the language of Chapter 5 they are **nuisance parameters**, unknowns we must fit or integrate over but do not care about. Section 10.8.4 shows that both can be searched

over almost for free, the phase with two filters and the arrival time with one Fourier transform, and Section T2.5 shows why: in the frequency domain they enter the phase only as the straight line $2\pi f t_c - \phi_c$.

T2.4.4 Examples: the benchmark binaries of the book

Two systems recur in the dark-matter literature and in Chapter 10. In both, a light black hole falls into a much heavier one. Binaries are named by their mass ratio $q = m_2/m_1$: comparable-mass binaries have $q \sim 1$, **intermediate mass-ratio inspirals** (IMRIs) roughly $q \sim 10^{-2}$–10^{-4}, and **extreme mass-ratio inspirals** (EMRIs) $q \lesssim 10^{-4}$; the boundary is a convention, and papers place it differently [81, 83]. A small q is what makes these systems good probes. By (T2.43), $\dot{f} \propto \mathcal{M}^{5/3} \approx m_2\, m_1^{2/3}$ when $m_2 \ll m_1$, so a light companion spirals in slowly and completes a huge number of orbits inside the environment.

The numbers. Every number quoted in the examples below comes from a few lines of `01_chirp.py`, which apply (T2.46), (T2.44), (T2.45) and (T2.43) to a pair of masses:

Listing T2.2: From two masses to the end of the inspiral (`code/chT2/01_chirp.py`)

```
28    Mc, M = chirp_mass(m1, m2), m1 + m2
29    fi = f_isco(M)
30    t_isco = tau_of_f(fi, Mc)                    # time left at the ISCO frequency
31    f4 = f_of_tau(t_isco + T4, Mc)               # frequency 4 years before the ISCO
32    N4 = cycles(f4, fi, Mc)
33    adiab = fdot_vac(fi, Mc) / fi**2             # fractional change of f per cycle
```

Line 29 is the ISCO frequency. Line 30 is the time left at that frequency, (T2.44). Line 31 adds four years to that time and inverts, giving the frequency four years before the ISCO. Line 32 counts the cycles between the two frequencies, and line 33 is the slow-evolution number checked in the last example. The helper functions (`tau_of_f`, `cycles`, and so on) sit in `lib_lisa.py` and are one-line transcriptions of the equations above.

Example: the EMRI of Kim et al. A $1\,M_\odot$ black hole falls into a $10^4\,M_\odot$ one [81, Sec. III F]. Kim et al. call it an IMRI; with $q = 10^{-4}$ it sits on the boundary, and we call it the EMRI. The chirp mass is

$$\mathcal{M} = \frac{(10^4 \cdot 1)^{3/5}}{(10^4 + 1)^{1/5}} \approx \frac{10^{2.4}}{10^{0.8}} = 10^{1.6} \approx 40\,M_\odot,$$

and the code gives $\mathcal{M} = 39.81\,M_\odot$. By (T2.46) the inspiral ends at $f_{\rm ISCO} = 4.4\,\text{kHz}/10^4 \approx 0.4397\,\text{Hz}$, inside the LISA band ($10^{-4}$–1 Hz). Four years earlier, from (T2.44), the frequency was 13.84 mHz, and by (T2.45) the binary completes $N = 2.787 \times 10^6$ wave cycles in those four years.

Example: the IMRI of Eda et al. and Coogan et al. A $1.4\,M_\odot$ object falls into a $10^3\,M_\odot$ black hole [77, 84]. Now $\mathcal{M} = 19.39\,M_\odot$ and $f_{\rm ISCO} = 4.391\,\text{Hz}$, above LISA's band: the last stretch of this inspiral is invisible to LISA. Four years before the ISCO the frequency is 21.7 mHz, and $N = 4.382 \times 10^6$ cycles follow. Figure T2.11 shows both frequency tracks.

Example: a GW150914-like binary passing through the LISA band. Robson, Cornish and Liu note that a binary like the first LIGO detection, five years before merger, sweeps from 16 to 29 mHz during a four-year mission [80, Sec. 2]. We can check this with (T2.44). Take $m_1 = 36$,

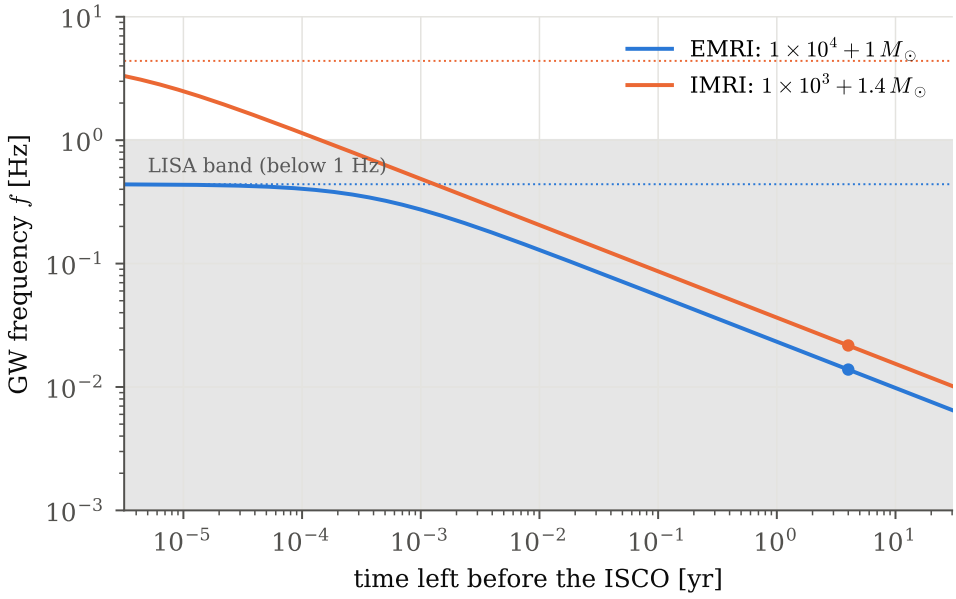

Figure T2.11: Frequency against the time left before the ISCO for the two benchmark binaries. Far from the end both tracks are straight lines of slope $-3/8$ on these log axes; close to the end they flatten onto f_{ISCO} (dotted). Dots mark the frequency four years before the ISCO. The shaded band is LISA's frequency range: the IMRI leaves it before its ISCO, the EMRI does not.

$m_2 = 29\,M_\odot$, so $\mathcal{M} = 28.1\,M_\odot$ and $G\mathcal{M}/c^3 = 28.1 \times 4.93\,\mu\mathrm{s} = 1.38 \times 10^{-4}\,\mathrm{s}$. Five years before merger, $\tau = 1.58 \times 10^8\,\mathrm{s}$, and

$$f \overset{(1)}{=} \frac{1}{8\pi\, G\mathcal{M}/c^3}\left(\frac{5\,G\mathcal{M}/c^3}{\tau}\right)^{3/8} \overset{(2)}{=} \frac{1}{3.47 \times 10^{-3}\,\mathrm{s}}\left(4.37 \times 10^{-12}\right)^{3/8}$$
$$\overset{(3)}{=} 288\,\mathrm{Hz} \times 5.5 \times 10^{-5} \approx 16\,\mathrm{mHz}.$$

(1) The inverse of (T2.44).
(2) $8\pi \times 1.38 \times 10^{-4} = 3.47 \times 10^{-3}$ and $5 \times 1.38 \times 10^{-4}/1.58 \times 10^8 = 4.37 \times 10^{-12}$.
(3) $(4.37 \times 10^{-12})^{3/8} = 10^{-11.36 \times 3/8} = 10^{-4.26}$.

The same steps with $\tau = 1\,\mathrm{yr}$ give 29 mHz. The code returns 15.83 and 28.94 mHz, and the binary completes 2.534×10^6 cycles in between.

Example: checking the slow-evolution input. Input 2 assumed the orbit barely changes during one cycle. The fractional change of f during one cycle (duration $1/f$) is $\dot{f}/f^2 = \frac{96}{5}\pi^{8/3}(G\mathcal{M}f/c^3)^{5/3}$, largest at the ISCO. The code gives 6.839×10^{-5} for the EMRI and 9.550×10^{-4} for the IMRI. Even on the last orbit the frequency changes by less than a part in a thousand per cycle, so treating the orbit as a slowly shrinking circle is safe [82, eq. (25)].

What a million cycles buys. A template that drifts out of step with the signal by a single cycle, out of millions, no longer matches it. So the data pin down whatever sets the number of cycles very precisely [82, Sec. I]. By (T2.45), $N \propto \mathcal{M}^{-5/3}$, so a fractional change $\delta\mathcal{M}/\mathcal{M}$ shifts the count by $\delta N = \frac{5}{3} N\, \delta\mathcal{M}/\mathcal{M}$. Requiring $\delta N \lesssim 1$ gives $\delta\mathcal{M}/\mathcal{M} \lesssim 3/(5N)$, of order 10^{-7} for the EMRI. This is only a rough estimate: noise, a finite signal-to-noise ratio and correlations with other parameters weaken it, and the Fisher matrix of Chapter 10 does the calculation properly. For this EMRI with five years of data and signal-to-noise ratio 15, Kim et al. find $\mathcal{M} = 39.8^{+0.0012}_{-0.0006}\,M_\odot$ (95% range), a fractional error of about 2×10^{-5} [81, Fig. 4]. The parameters

that only set the amplitude, such as the distance, are measured with fractional errors of order one over the signal-to-noise ratio. This difference is the reason an environment is detectable at all: it acts on the phase, the most precisely measured part of the signal.

Watch out: Which mass is measured

The wave reaches us stretched by the cosmological redshift z, and a stretched chirp from mass $\mathcal{M}$ is indistinguishable from an unstretched chirp from mass $(1+z)\mathcal{M}$. The data measure the *detector-frame* (redshifted) chirp mass $(1+z)\mathcal{M}$, and (T2.43)–(T2.46) must be used with it [80, Sec. 2]. For the nearby benchmark binaries $z \ll 1$ and the difference is negligible.

Where this is used. The chirp rate (T2.43) and the binding energy (T2.41) are the vacuum baseline that Section 10.10.1 perturbs when an environment drains extra energy; the frequency four years before the ISCO and the cycle counts fix the band and the benchmark source of Section 10.11.2; and t_c, ϕ_c are the two nuisance parameters that Section 10.8.4 maximises over and that the Fisher matrix of Section 10.9 carries alongside the masses.

T2.5 The chirp in the frequency domain

The detector records a time series, but the likelihood of Section 10.8.2 is written in the frequency domain. There the stationary noise of the detector is simple: different Fourier components are independent, each with a variance set by the noise spectrum $S_n(f)$, and the log-likelihood is $-\frac{1}{2}(d-h\,|\,d-h)$ with the noise-weighted inner product $(a\,|\,b) = 4\,\mathrm{Re}\int_0^\infty \tilde{a}\tilde{b}^*/S_n\,\mathrm{d}f$. So the statistics needs the Fourier transform of the chirp of Section T2.4, as a formula in which the masses, the arrival time t_c and the phase ϕ_c appear explicitly.

A chirp makes this easy. At each moment it has one frequency, and it passes through each frequency once. So we ask in words: *which part of the time series builds the Fourier component at frequency f?* The answer is: essentially only the stretch during which the chirp's own frequency is close to f. At all other times the chirp and the probe wave $e^{-2\pi i f t}$ run at different rates, their product oscillates, and the oscillations cancel in the integral. Only near the moment t_f at which the chirp's frequency equals f do the two stay in step long enough to add up. Turning this sentence into a formula is the **stationary-phase approximation** (SPA) [82, eq. (21)].

T2.5.1 The Fourier convention, and why only positive frequencies count

The book's convention, used in every chapter, is

$$\tilde{h}(f) = \int_{-\infty}^{\infty} h(t)\, e^{-2\pi i f t}\,\mathrm{d}t, \qquad h(t) = \int_{-\infty}^{\infty} \tilde{h}(f)\, e^{2\pi i f t}\,\mathrm{d}f, \tag{T2.48}$$

with f in cycles per second, so that no factors of 2π stand in front of the integrals. A detector output is a real number at every instant, and that fixes the negative frequencies in terms of the positive ones:

$$\tilde{h}(-f) \overset{(1)}{=} \int h(t)\, e^{+2\pi i f t}\,\mathrm{d}t \overset{(2)}{=} \left[\int h(t)\, e^{-2\pi i f t}\,\mathrm{d}t\right]^* \overset{(3)}{=} \tilde{h}(f)^*. \tag{T2.49}$$

(1) The definition at $-f$.
(2) $h(t)$ is real, so complex-conjugating the integrand only flips the sign in the exponent.
(3) The definition at $+f$.

For example, the tone $\cos 2\pi f_0 t = \frac{1}{2}e^{2\pi i f_0 t} + \frac{1}{2}e^{-2\pi i f_0 t}$ has $\tilde{h}(f) = \frac{1}{2}\delta(f - f_0) + \frac{1}{2}\delta(f + f_0)$: half its weight sits at $+f_0$ and half, the complex conjugate, at $-f_0$. Since the negative half carries no new information, every quantity built from a real signal can be written with $f > 0$ only, at the price of a factor two. That is where the 4 in the inner product comes from: the 2 of the one-sided noise spectrum of Section 10.8.2 times the 2 from folding $-f$ onto $+f$. So it is enough to know $\tilde{h}(f)$ for $f > 0$.

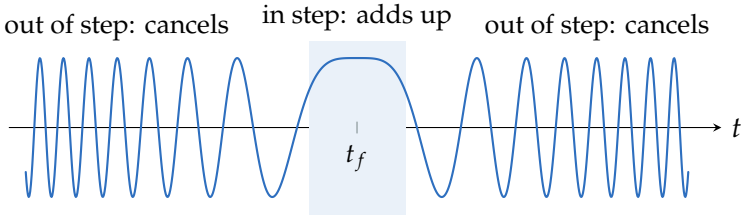

Figure T2.12: The real part of the integrand $e^{i[\phi(t)-2\pi f t]}$ near the moment t_f at which the chirp has frequency f, for a chirp whose frequency rises linearly: the phase difference grows like $(t - t_f)^2$. In the shaded window, of width about $1/\sqrt{\dot{f}}$, the integrand barely turns and its contributions add. Outside, positive and negative lobes alternate faster and faster and cancel.

T2.5.2 The stationary-phase formula

Inputs. The signal is $h(t) = A(t)\cos\phi(t)$, with an amplitude that changes slowly compared with the phase ($\dot{A}/A \ll \dot{\phi}$) and a frequency $\dot{\phi}/2\pi$ that changes slowly, $\ddot{\phi} \ll \dot{\phi}^2$. The second condition is $\dot{f}/f^2 \ll 1$, the slow-evolution number already checked in Section T2.4. We want $\tilde{h}(f)$ for $f > 0$.

Two exponentials. Writing the cosine as $\cos\phi = \frac{1}{2}(e^{i\phi} + e^{-i\phi})$,

$$\tilde{h}(f) = \frac{1}{2}\int A(t)\, e^{i[\phi(t)-2\pi f t]}\,\mathrm{d}t + \frac{1}{2}\int A(t)\, e^{-i[\phi(t)+2\pi f t]}\,\mathrm{d}t. \tag{T2.50}$$

The second integral is negligible. Its phase $\phi(t) + 2\pi f t$ always grows, at the rate $\dot{\phi} + 2\pi f \geq 2\pi f$, so its integrand turns steadily and its positive and negative lobes cancel. Integrating by parts once shows how well: $\int A e^{i\theta}\mathrm{d}t = [A e^{i\theta}/(i\dot{\theta})] - \int(\mathrm{d}/\mathrm{d}t)(A/i\dot{\theta})\, e^{i\theta}\mathrm{d}t$, so the integral is of order $A/(2\pi f)$, the amplitude times the time the integrand needs to turn once. We will see that the first integral is of order $A/\sqrt{\dot{f}}$; the ratio is $\sqrt{\dot{f}}/f = (\dot{f}/f^2)^{1/2} \ll 1$.

Where the first integral comes from. Call its phase $\vartheta(t) \equiv \phi(t) - 2\pi f t$. It is *stationary*, $\dot{\vartheta} = 0$, where $\dot{\phi} = 2\pi f$: at the moment t_f when the chirp's own frequency equals f. Near that moment Taylor-expand, $\vartheta(t) = \vartheta(t_f) + 0\cdot(t - t_f) + \frac{1}{2}\ddot{\phi}(t_f)(t - t_f)^2 + \ldots$, the linear term vanishing by the definition of t_f, and freeze the slowly varying amplitude at $A(t_f)$. Then

$$\begin{aligned}\tilde{h}(f) &\overset{(1)}{=} \frac{1}{2}A(t_f)\, e^{i\vartheta(t_f)}\int_{-\infty}^{\infty} e^{\frac{i}{2}\ddot{\phi}(t_f)\,s^2}\,\mathrm{d}s \overset{(2)}{=} \frac{1}{2}A(t_f)\, e^{i\vartheta(t_f)}\sqrt{\frac{2\pi}{\ddot{\phi}(t_f)}}\; e^{i\pi/4} \\ &\overset{(3)}{=} \frac{1}{2}A(t_f)\,\dot{f}(t_f)^{-1/2}\, e^{-i\Psi(f)}, \qquad \Psi(f) \equiv 2\pi f t_f - \phi(t_f) - \frac{\pi}{4}.\end{aligned} \tag{T2.51}$$

(1) The expansion with $s = t - t_f$. The limits can be taken to $\pm\infty$, because far from t_f the integrand oscillates ever faster and contributes nothing more (Figure T2.12).

(2) The Fresnel integral, derived just below: $\int e^{ias^2/2}\mathrm{d}s = \sqrt{2\pi/a}\, e^{i\pi/4}$ for $a > 0$, here with $a = \ddot{\phi}(t_f) > 0$ because the frequency rises.

(3) $\ddot{\phi} = 2\pi\dot{f}$, so $\sqrt{2\pi/\ddot{\phi}} = \dot{f}^{-1/2}$. Collecting the phases, $\vartheta(t_f) + \frac{\pi}{4} = \phi(t_f) - 2\pi f t_f + \frac{\pi}{4} = -\Psi(f)$.

The Fresnel integral. The integrand $e^{ias^2/2}$ has modulus one everywhere, so the integral converges only because of the cancellations. Make that explicit by adding a small damping $e^{-\epsilon s^2}$, $\epsilon > 0$, and letting $\epsilon \to 0$ at the end. With $b \equiv \epsilon - ia/2$,

$$\int_{-\infty}^{\infty} e^{-\epsilon s^2 + ias^2/2}\,\mathrm{d}s \overset{(1)}{=} \int_{-\infty}^{\infty} e^{-bs^2}\,\mathrm{d}s \overset{(2)}{=} \sqrt{\frac{\pi}{b}} \xrightarrow{\epsilon\to 0} \sqrt{\frac{\pi}{-ia/2}} \overset{(3)}{=} \sqrt{\frac{2\pi}{a}}\, e^{i\pi/4}. \tag{T2.52}$$

(1) Definition of b; its real part ϵ is positive, so the integral converges absolutely.

(2) The Gaussian integral $\int e^{-bs^2}\mathrm{d}s = \sqrt{\pi/b}$, familiar for real $b > 0$. Both sides are analytic functions of b in the half-plane $\mathrm{Re}\, b > 0$ (with the square root positive for real b), and two analytic functions that agree on the positive real axis agree everywhere in that half-plane.

(3) $-i = e^{-i\pi/2}$, so $1/(-i) = e^{i\pi/2}$ and its square root is $e^{i\pi/4}$; the branch is the one that is continuous from $\mathrm{Re}\, b > 0$, where $\arg b \to -\pi/2$ and $\arg\sqrt{1/b} \to +\pi/4$.

The real and imaginary parts are the classic Fresnel integrals, $\int \cos(as^2/2)\mathrm{d}s = \int \sin(as^2/2)\mathrm{d}s = \sqrt{\pi/a}$; the phase $e^{i\pi/4}$ says they are equal.

How accurate is it? The width of the window that contributes is set by the Gaussian factor in step (1): $|t - t_f| \lesssim 1/\sqrt{\ddot{\phi}} \sim 1/\sqrt{\dot{f}}$. During that window the chirp completes about $f/\sqrt{\dot{f}} = (\dot{f}/f^2)^{-1/2}$ cycles, which is large precisely when the slow-evolution number is small. The first neglected term of the Taylor expansion, $\frac{1}{6}\dddot{\phi}\,(t - t_f)^3$, is of size $\dddot{\phi}/\ddot{\phi}^{3/2}$ across the window; with $\ddot{\phi} = 2\pi\ddot{f}$ and $\ddot{f} = \frac{11}{3}\dot{f}^2/f$ for the Newtonian chirp, that is again of order $(\dot{f}/f^2)^{1/2}$. So the same condition makes the orbit adiabatic and the SPA accurate.[1]

What the phase knows. Differentiate Ψ and use $\dot{\phi}(t_f) = 2\pi f$:

$$\frac{\mathrm{d}\Psi}{\mathrm{d}f} \overset{(1)}{=} 2\pi t_f + 2\pi f\frac{\mathrm{d}t_f}{\mathrm{d}f} - \dot{\phi}(t_f)\frac{\mathrm{d}t_f}{\mathrm{d}f} \overset{(2)}{=} 2\pi t(f), \qquad \frac{\mathrm{d}^2\Psi}{\mathrm{d}f^2} \overset{(3)}{=} \frac{2\pi}{\dot{f}}. \tag{T2.53}$$

(1) Product rule on $2\pi f t_f$ and chain rule on $\phi(t_f)$, since t_f depends on f.

(2) The last two terms cancel because $\dot{\phi}(t_f) = 2\pi f$. We write $t(f) \equiv t_f$.

(3) $\mathrm{d}t/\mathrm{d}f = 1/\dot{f}$.

In words: the slope of the Fourier phase is the time at which frequency f arrives, and its curvature is 2π divided by the chirp rate. Whatever changes how fast the binary sweeps, an environment included, changes Ψ through (T2.53). Section T2.10 applies exactly this equation to a binary that is losing energy to its surroundings as well as to waves.

The Newtonian waveform. Integrate (T2.53) with $t(f) = t_c - \tau(f)$ from (T2.44):

$$\begin{aligned}\Psi(f) &\overset{(1)}{=} 2\pi f t_c - 2\pi\int \tau(f)\,\mathrm{d}f + \text{const} \overset{(2)}{=} 2\pi f t_c + 2\pi\cdot\frac{3}{5}\cdot\frac{5}{256}\left(\frac{G\mathcal{M}}{c^3}\right)^{-5/3}\pi^{-8/3}f^{-5/3} + \text{const}\\ &\overset{(3)}{=} 2\pi f t_c - \phi_c - \frac{\pi}{4} + \frac{3}{128}\left(\frac{\pi G\mathcal{M}f}{c^3}\right)^{-5/3}.\end{aligned} \tag{T2.54}$$

(1) Integrate $\mathrm{d}\Psi/\mathrm{d}f = 2\pi t_c - 2\pi\tau(f)$ once.

[1] Cutler and Flanagan, Eda et al. and Kim et al. define the Fourier transform with $e^{+2\pi i f t}$ and therefore write $e^{+i\Psi(f)}$. The function $\Psi(f)$ is the same; the two conventions give complex-conjugate $\tilde{h}$, and the inner product, the signal-to-noise ratio and the Fisher matrix, which contain only $\mathrm{Re}\,\tilde{a}\tilde{b}^*$, are unchanged.

(2) $\tau = \frac{5}{256}(G\mathcal{M}/c^3)^{-5/3}\pi^{-8/3}f^{-8/3}$ and $\int f^{-8/3}\mathrm{d}f = -\frac{3}{5}f^{-5/3}$.
(3) $2\pi\cdot\frac{3}{256}\pi^{-8/3} = \frac{3}{128}\pi^{-5/3}$; the integration constant is named after the phase at coalescence, $-\phi_c - \pi/4$.

This agrees with [82, eq. (24)], where the last term is written $\frac{3}{4}(8\pi\mathcal{M}f)^{-5/3}$ ($G = c = 1$); $\frac{3}{4}\cdot 8^{-5/3} = \frac{3}{4}\cdot\frac{1}{32} = \frac{3}{128}$. The phase constant $-\phi_c - \pi/4$ and the term $2\pi f t_c$ are exactly the two nuisance parameters of Section T2.4.3, and in the frequency domain they enter only as a straight line in f: a shift of the arrival time is a phase that grows linearly with frequency.

The amplitude. For the amplitude we need $A(t_f)$, the face-on amplitude of (T2.26) at frequency f, with the distance now the luminosity distance D_L, and $\dot f$ from (T2.43). With $T_\mathcal{M} = G\mathcal{M}/c^3$,

$$\tfrac{1}{2}A\,\dot f^{-1/2} \overset{(1)}{=} \frac{1}{2}\cdot 4T_\mathcal{M}^{5/3}(\pi f)^{2/3}\frac{c}{D_L}\cdot\left(\frac{96}{5}\right)^{-1/2}\pi^{-4/3}T_\mathcal{M}^{-5/6}f^{-11/6} \overset{(2)}{=} \sqrt{\frac{5}{24}}\,\pi^{-2/3}\,T_\mathcal{M}^{5/6}\,\frac{c}{D_L}\,f^{-7/6}, \tag{T2.55}$$

(1) $A = 4(G\mathcal{M})^{5/3}(\pi f)^{2/3}/(c^4 D_L) = 4T_\mathcal{M}^{5/3}(\pi f)^{2/3}c/D_L$, and $\dot f^{-1/2} = (\frac{96}{5})^{-1/2}\pi^{-4/3}T_\mathcal{M}^{-5/6}f^{-11/6}$.
(2) $2(\frac{5}{96})^{1/2} = (\frac{20}{96})^{1/2} = (\frac{5}{24})^{1/2}$; $\pi^{2/3-4/3} = \pi^{-2/3}$; $T_\mathcal{M}^{5/3-5/6} = T_\mathcal{M}^{5/6}$; $f^{2/3-11/6} = f^{-7/6}$.

so that

$$\tilde h(f) = \mathcal{A}\,f^{-7/6}e^{-i\Psi(f)}, \qquad \mathcal{A} = \sqrt{\frac{5}{24}}\,\pi^{-2/3}\left(\frac{G\mathcal{M}}{c^3}\right)^{5/6}\frac{c}{D_L}, \tag{T2.56}$$

the amplitude of Robson et al. [80, eq. (20)] and of Kim et al. [81, eq. (45)], written out; the time-domain amplitude is that of Eda et al. [77, eq. (21)]. A real source is not face-on, and the detector does not see both polarisations equally. By (T2.25) the polarisations of a circular binary have amplitudes $\frac{1}{2}(1+x^2)$ and x times A, with $x = \cos\iota$, and Section T2.3 showed that averaging over the orientation of the orbit multiplies the signal power by $\frac{4}{5}$, (T2.36), while the average over sky position and polarisation is put into the noise curve (Section T2.7). Hence the sky-averaged waveform $\tilde h = \sqrt{4/5}\,\mathcal{A}f^{-7/6}e^{-i\Psi}$ used in the forecasts [81, eq. (44)].

Key idea: The signal model of the forecasts

In the stationary-phase approximation a slowly chirping binary has $\tilde h(f) = \frac{1}{2}A(t_f)\dot f^{-1/2}e^{-i\Psi(f)}$, with $\mathrm{d}\Psi/\mathrm{d}f = 2\pi t(f)$ and $\mathrm{d}^2\Psi/\mathrm{d}f^2 = 2\pi/\dot f$. For the Newtonian chirp this is $\mathcal{A}f^{-7/6}e^{-i\Psi}$ with $\Psi = 2\pi f t_c - \phi_c - \pi/4 + \frac{3}{128}(\pi G\mathcal{M}f/c^3)^{-5/3}$: four parameters, $\ln\mathcal{A}$, $\mathcal{M}$, t_c and ϕ_c.

T2.5.3 Checking the formula numerically

A stellar-mass chirp lasts seconds, so its Fourier transform can be computed directly and compared with (T2.51). The script `02_spa_check.py` builds a Newtonian chirp with $\mathcal{M} = 10\,M_\odot$ from 20 Hz to 1 kHz, 4.729 s long, sampled at 4096 Hz:

Listing T2.3: A Newtonian chirp in the time domain (`code/chT2/02_spa_check.py`)

```
t = np.arange(-tau0, -tau1, 1 / fs)            # time from coalescence (t_c = 0)
tau = -t
f_t = (1 / (8 * np.pi * m)) * (5 * m / tau) ** (3 / 8)     # f(t), Newtonian
phi_t = -2 * (tau / (5 * m)) ** (5 / 8)                     # GW phase, phi_c = 0
A_t = (f_t / f0) ** (2 / 3)                                 # amplitude ~ f^{2/3}
# cosine ramps: 0.3 s at the start (f near 20 Hz), 2 ms at the end (f > 360 Hz),
# so the band 30-150 Hz used for the comparison is untouched by the window
win = np.ones_like(t)
r0, r1 = t < t[0] + 0.3, t > t[-1] - 2e-3
```

```
win[r0] = 0.5 * (1 - np.cos(np.pi * (t[r0] - t[0]) / 0.3))
win[r1] = 0.5 * (1 - np.cos(np.pi * (t[-1] - t[r1]) / 2e-3))
h = A_t * np.cos(phi_t) * win
```

Lines 28–29 are the inverse of (T2.44) and its time integral, $\phi(t) = \phi_c - 2[\tau/(5G\mathcal{M}/c^3)]^{5/8}$ [82, eq. (22)]. The amplitude $\propto f^{2/3}$ follows the quadrupole formula (the overall scale is irrelevant here). The cosine ramps at the two ends switch the signal on and off gently. An abrupt start would add the transform of a step, which rings across all frequencies. The ramps are kept short and placed at the ends of the sweep, so the band we compare, 30–150 Hz, is untouched. The prediction is then four lines:

Listing T2.4: The stationary-phase prediction (`code/chT2/02_spa_check.py`)

```
# SPA prediction
band = (f > 30) & (f < 150)
fb = f[band]
tf = -tau_of_f(fb, Mc)
phif = -2 * (tau_of_f(fb, Mc) / (5 * m)) ** (5 / 8)
Psi = 2 * np.pi * fb * tf - phif - np.pi / 4
Hspa = 0.5 * (fb / f0) ** (2 / 3) / np.sqrt(fdot_vac(fb, Mc)) * np.exp(-1j * Psi)
```

Here `tf` is t_f from (T2.44), `phif` is $\phi(t_f)$, and line 50 is (T2.51). Figure T2.13 shows the result. In the comparison band the modulus agrees with the FFT to within 3.655%, and the phase difference has an rms of 0.01296 rad while Ψ itself changes by 168.4 rad across the band. The small ripples that remain are the leftovers of switching the signal on and off, not a failure of the approximation.

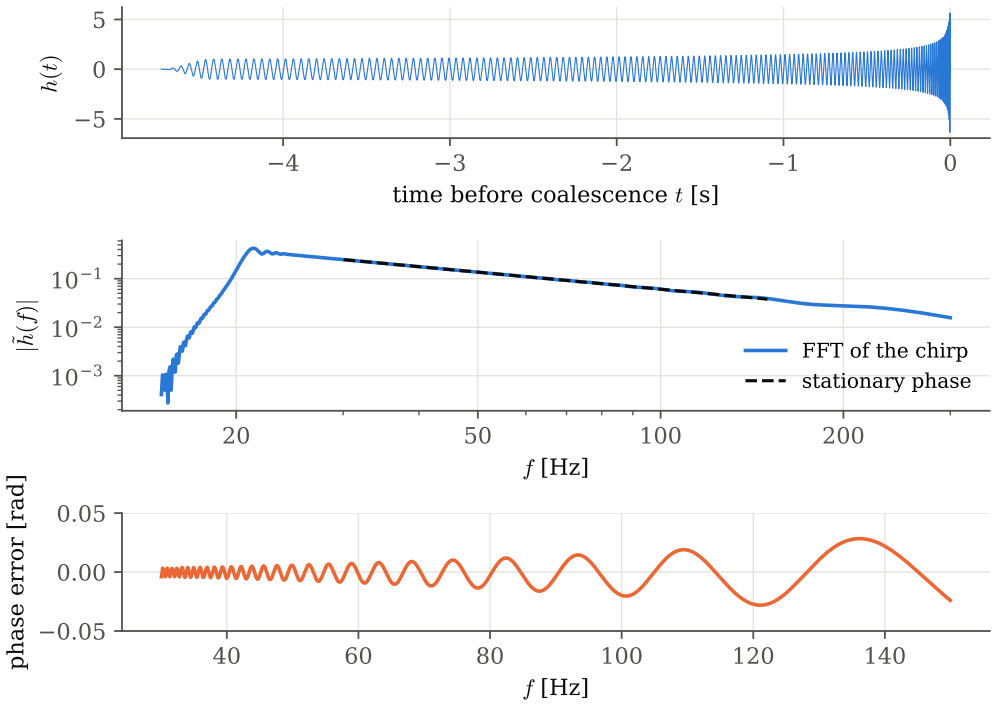

Figure T2.13: The stationary-phase formula against a direct FFT. Top: the chirp in time, its amplitude and frequency rising towards coalescence. Middle: $|\tilde{h}|$ from the FFT and from (T2.51), which fall together as $f^{-7/6}$ in the band; the FFT drops at 20 Hz, where the signal starts. Bottom: the phase of the FFT minus the predicted $-\Psi(f)$, a few hundredths of a radian.

Example: two phases that are easy to confuse. Papers on environments plot the *time-domain* phase left before merger, $\Phi(f) = 2\pi \int_t^{t_c} f \, \mathrm{d}t$, which is 2π times the number of cycles [84], [81, eq. (48)]. The Fisher matrix uses the Fourier phase $\Psi(f)$. For the Newtonian chirp, (T2.45) with $f_2 \to \infty$ gives $\Phi(f) = \frac{1}{16}x$, with $x \equiv (\pi G\mathcal{M}f/c^3)^{-5/3}$. With $t_c = \phi_c = 0$, the phase at time t_f is $\phi(t_f) = -\Phi(f)$, so

$$\Psi(f) + \frac{\pi}{4} \overset{(1)}{=} 2\pi f\, t_f - \phi(t_f) \overset{(2)}{=} -2\pi f\, \tau(f) + \Phi(f) \overset{(3)}{=} -\frac{10}{256}\, x + \frac{16}{256}\, x = \frac{3}{128}\, x.$$

(1) Definition of Ψ in (T2.51).

(2) $t_f = -\tau(f)$ and $\phi(t_f) = -\Phi(f)$, since the phase still to come is $\Phi(f)$ and the phase reaches $\phi_c = 0$ at t_c.

(3) $2\pi f\tau = 2\pi \cdot \frac{5}{256}(G\mathcal{M}/c^3)^{-5/3}\pi^{-8/3}f^{-5/3} = \frac{10}{256}x$, and $\frac{1}{16} = \frac{16}{256}$.

So Ψ carries $\frac{3}{8}$ of the time-domain phase, because the term $2\pi f t_f$ removes the part a shift of the arrival time can absorb. For the EMRI four years before the ISCO, $\Phi \approx 2\pi \times 2.787 \times 10^6$ while the f-dependent part of Ψ is about three eighths of that. Both phases are correct; they answer different questions, and a dephasing quoted in one cannot be compared with a phase error in the other without this conversion.

Where this is used. The waveform (T2.56) with the phase (T2.54) is the signal model of Section 10.9.2, extended there by the post-Newtonian terms derived in Section T2.6. The fact that t_c and ϕ_c enter Ψ only as $2\pi f t_c - \phi_c$ is what lets Section 10.8.4 search all arrival times with one inverse Fourier transform. The relations (T2.53) are the bridge from any change of the sweep rate to a change of the phase, used in Section 10.10.1, and Section 10.12.1 carries out the conversion between the two kinds of phase.

T2.6 Corrections to the phase: post-Newtonian orders and the ppE form

The chirp of Section T2.4 rests on Newton's law of gravity and on the quadrupole formula, both of which are the first term of an expansion in v/c. Far from merger that is excellent. Near the ISCO the orbital speed is $v = c/\sqrt{6} \approx 0.4c$, and the corrections are tens of per cent. Even far from merger, a correction of a few per cent to the rate of the inspiral is not small in the only currency that matters for a matched filter: over a million cycles, a few per cent is tens of thousands of cycles, and a template that slips by one cycle has lost the signal (Section T2.4). Other physics acts the same way. A cloud of dark matter, a disc of gas, or a departure from general relativity each changes how fast the binary loses energy, by a fraction that depends on the frequency.

So the question is: *if the binding energy or the radiated power differs from its Newtonian value by a small fractional term, how does that change the Fourier phase $\Psi(f)$, and which power of f does each kind of correction produce?* The answer is one rule. A correction that scales as v^p relative to the Newtonian term adds to Ψ a term proportional to $f^{(p-5)/3}$, with a coefficient we can compute once and for all. General-relativistic corrections have $p = 2, 3, 4, \ldots$; environments and some modifications of gravity have negative p. The rule turns the whole zoo of corrections into one family, $\delta\Psi = \beta u^b$, which is the form the forecast of Chapter 10 uses.

T2.6.1 The expansion parameter

Measure the speed of the orbit by the observable wave frequency. For a Newtonian circular orbit, Kepler's law gives the orbital speed $v_{\mathrm{orb}} = r\omega = (GM\omega)^{1/3}$, and with $\omega = \pi f$ from

(T2.24),

$$v \equiv \left(\frac{\pi G M f}{c^3}\right)^{1/3} = \frac{v_{\rm orb}}{c}, \qquad x \equiv v^2, \tag{T2.57}$$

with $M = m_1 + m_2$ the total mass. A correction of relative size v^{2k} is called **kPN** (post-Newtonian) order, so 1PN means v^2, 1.5PN means v^3. Using f rather than the orbital radius r is deliberate: r depends on the coordinates used to describe the strong-field region, while the frequency of the wave at the detector does not [82, Sec. III A]. Two mass combinations will appear: the **symmetric mass ratio** $\eta = m_1 m_2/M^2 = \mu/M$ [$\frac{1}{4}$ for equal masses, about m_2/m_1 when one body is much lighter], and the chirp mass, $\mathcal{M} = \eta^{3/5} M$. The reduced frequency of the Newtonian phase is then

$$u \equiv \frac{\pi G \mathcal{M} f}{c^3} = \eta^{3/5} v^3, \qquad u^{-5/3} = \eta^{-1} v^{-5}. \tag{T2.58}$$

T2.6.2 From the energy and the flux to the phase

Inputs. The orbit is still circular and evolves slowly, so energy balance $\mathrm{d}E/\mathrm{d}t = -\mathcal{F}$ holds at each moment, with $E(v)$ the binding energy and $\mathcal{F}(v)$ the power radiated, now allowed to carry corrections. In the Newtonian limit, by (T2.41) and (T2.42) written in terms of v,

$$E_{\rm N} = -\tfrac{1}{2}\mu c^2 v^2, \qquad \mathcal{F}_{\rm N} = \frac{32}{5}\frac{c^5}{G}\eta^2 v^{10}. \tag{T2.59}$$

(For E: $\frac{1}{2}\mu(\pi G M f)^{2/3} = \frac{1}{2}\mu c^2 v^2$. For the power: $u^{10/3} = \eta^2 v^{10}$ by (T2.58).)

The time. Energy balance gives $\mathrm{d}t = -\mathrm{d}E/\mathcal{F} = -(\mathrm{d}E/\mathrm{d}v)\,\mathrm{d}v/\mathcal{F}$. Write the corrections to $\mathrm{d}E/\mathrm{d}v$ and $\mathcal{F}$ together as one bracket,

$$\frac{\mathrm{d}t}{\mathrm{d}v} = -\frac{E'(v)}{\mathcal{F}(v)} = -\frac{E'_{\rm N}}{\mathcal{F}_{\rm N}}\left[1 + c_p v^p + \dots\right] = \frac{5GM}{32c^3\eta}\, v^{-9}\left[1 + c_p v^p + \dots\right], \tag{T2.60}$$

because $-E'_{\rm N}/\mathcal{F}_{\rm N} = \mu c^2 v \,/\, \left(\frac{32}{5}\frac{c^5}{G}\eta^2 v^{10}\right) = \frac{5}{32}\frac{G\mu}{c^3\eta^2} v^{-9}$ and $\mu = \eta M$. The bracket may contain several terms; each acts separately at first order, so we follow one, $c_p v^p$.

The phase. From (T2.53), $\mathrm{d}\Psi/\mathrm{d}f = 2\pi t(f) = 2\pi t_c - 2\pi\tau(f)$, where $\tau = t_c - t$ is the time left. So $\Psi = 2\pi f t_c - \phi_c - \frac{\pi}{4} - 2\pi\int^f \tau\,\mathrm{d}f'$, with the integration constants named as in (T2.54). We need τ as a function of v, and $\mathrm{d}f$ in terms of $\mathrm{d}v$:

$$\begin{aligned}
\tau(v) &\overset{(1)}{=} \int_v^\infty \frac{\mathrm{d}t}{\mathrm{d}v'}\,\mathrm{d}v' \overset{(2)}{=} \frac{5GM}{32c^3\eta}\left[\frac{v^{-8}}{8} + c_p\frac{v^{p-8}}{8-p}\right], \qquad \mathrm{d}f \overset{(3)}{=} \frac{3c^3 v^2}{\pi G M}\,\mathrm{d}v, \\
-2\pi\int \tau\,\mathrm{d}f &\overset{(4)}{=} -\frac{15}{16\eta}\int\left[\frac{v^{-6}}{8} + c_p\frac{v^{p-6}}{8-p}\right]\mathrm{d}v \overset{(5)}{=} \frac{15}{16\eta}\left[\frac{v^{-5}}{40} + c_p\frac{v^{p-5}}{(8-p)(5-p)}\right] \\
&\overset{(6)}{=} \frac{3}{128\,\eta\,v^5}\left[1 + \frac{40\,c_p}{(8-p)(5-p)}\,v^p\right].
\end{aligned} \tag{T2.61}$$

(1) The time left is the integral of $\mathrm{d}t$ from the current speed to the end, where $v \to \infty$ formally, as in (T2.44).

(2) $\int_v^\infty v'^q \mathrm{d}v' = v^{q+1}/(-q-1)$ for $q < -1$; here $q = -9$ and $q = p - 9$, which needs $p < 8$.

(3) $f = c^3 v^3/(\pi G M)$ from (T2.57).

(4) Multiply: $2\pi \cdot \frac{5GM}{32c^3\eta} \cdot \frac{3c^3}{\pi G M} = \frac{15}{16\eta}$, and $v^{-8}v^2 = v^{-6}$.

(5) $\int v^q \mathrm{d}v = v^{q+1}/(q+1)$: for $q = -6$ this is $-v^{-5}/5$ and for $q = p-6$ it is $-v^{p-5}/(5-p)$, which needs $p \neq 5$. The two minus signs cancel the one in front; the constants of integration join ϕ_c.

(6) Factor out the Newtonian term: $\frac{15}{16}\cdot\frac{1}{40}=\frac{3}{128}$, and the ratio of the two coefficients is $\frac{1/((8-p)(5-p))}{1/40}$.

For $p=0$ only the Newtonian term is left, $\frac{3}{128}\eta^{-1}v^{-5}=\frac{3}{128}u^{-5/3}$, which is (T2.54) again. A correction $c_p v^p$ in the rate of the inspiral therefore becomes a phase term

$$\delta\Psi=\frac{3}{128}\,u^{-5/3}\,\frac{40\,c_p}{(8-p)(5-p)}\,v^p\;\propto\;f^{(p-5)/3}. \tag{T2.62}$$

At $p=5$ the integral in step (5) is a logarithm instead of a power; this is why the 2.5PN term of the phase contains $\ln f$.

T2.6.3 The 1PN and 1.5PN phase

The inputs from general relativity. The binding energy to 1PN order and the flux to 1.5PN order are standard results, which Cutler and Flanagan quote in terms of the orbital radius r in a particular coordinate system [82, eqs. (35)–(37)], [85]. In units $G=c=1$,

$$\Omega^2=\frac{M}{r^3}\Big[1-(3-\eta)\frac{M}{r}\Big],\qquad E=-\frac{\mu M}{2r}\Big[1-\frac{7-\eta}{4}\frac{M}{r}\Big], \tag{T2.63}$$

and the flux is $\frac{32}{5}\eta^2(M\Omega)^{10/3}[1-(\frac{1247}{336}+\frac{35}{12}\eta)\frac{M}{r}+4\pi(\frac{M}{r})^{3/2}]$. The first expression is the square of their eq. (35), to the same order. The 4π is the **tail**: part of the outgoing wave scatters off the curved spacetime around the binary on its way out, and the scattered part interferes with the rest.

Rewritten in v. With $v^2=(M\Omega)^{2/3}$,

$$\begin{aligned}
v^2 &\overset{(1)}{=}\frac{M}{r}\Big[1-(3-\eta)\frac{M}{r}\Big]^{1/3}\overset{(2)}{=}\frac{M}{r}\Big[1-\Big(1-\frac{\eta}{3}\Big)\frac{M}{r}\Big],\qquad \frac{M}{r}\overset{(3)}{=}v^2\Big[1+\Big(1-\frac{\eta}{3}\Big)v^2\Big],\\
E &\overset{(4)}{=}-\frac{\mu}{2}v^2\Big[1+\Big(1-\frac{\eta}{3}\Big)v^2-\frac{7-\eta}{4}v^2\Big]\overset{(5)}{=}-\frac{\mu}{2}v^2\Big[1-\frac{9+\eta}{12}v^2\Big].
\end{aligned} \tag{T2.64}$$

(1) $(M\Omega)^{2/3}=(M^2/r^3)^{1/3}[\dots]^{1/3}=(M/r)[\dots]^{1/3}$.
(2) $(1-\epsilon)^{1/3}=1-\epsilon/3$.
(3) Invert to first order: if $v^2=y(1-ky)$ then $y=v^2(1+kv^2)$.
(4) Insert into E; in the 1PN bracket $M/r=v^2$ is enough.
(5) $1-\frac{\eta}{3}-\frac{7}{4}+\frac{\eta}{4}=-\frac{3}{4}-\frac{\eta}{12}=-\frac{9+\eta}{12}$.

The flux is already written with $(M\Omega)^{10/3}=v^{10}$ in front, and inside its bracket $M/r=v^2$ to the order needed. So, restoring c,

$$E'(v)=-\mu c^2 v\Big[1-\frac{9+\eta}{6}v^2\Big],\qquad \mathcal{F}=\frac{32}{5}\frac{c^5}{G}\eta^2v^{10}\Big[1-\Big(\frac{1247}{336}+\frac{35}{12}\eta\Big)v^2+4\pi v^3\Big], \tag{T2.65}$$

where E' comes from differentiating $v^2-\frac{9+\eta}{12}v^4$ to $2v-\frac{9+\eta}{3}v^3$.

The bracket of (T2.60). Dividing,

$$\frac{E'/E'_{\rm N}}{\mathcal{F}/\mathcal{F}_{\rm N}}\overset{(1)}{=}\Big[1-\frac{9+\eta}{6}v^2\Big]\Big[1+\Big(\frac{1247}{336}+\frac{35}{12}\eta\Big)v^2-4\pi v^3\Big]\overset{(2)}{=}1+\Big(\frac{743}{336}+\frac{11}{4}\eta\Big)v^2-4\pi v^3, \tag{T2.66}$$

(1) $1/(1-\epsilon)=1+\epsilon$ to first order, applied to the flux bracket.
(2) Multiply out to order v^3: $\frac{1247}{336}-\frac{9}{6}=\frac{1247-504}{336}=\frac{743}{336}$ and $\frac{35}{12}-\frac{1}{6}=\frac{33}{12}=\frac{11}{4}$.

so $c_2 = \frac{743}{336} + \frac{11}{4}\eta$ and $c_3 = -4\pi$. The rule (T2.61) gives the factors $\frac{40}{6\cdot3} = \frac{20}{9}$ for $p = 2$ and $\frac{40}{5\cdot2} = 4$ for $p = 3$:

$$\Psi(f) = 2\pi f t_c - \phi_c - \frac{\pi}{4} + \frac{3}{128}\,u^{-5/3}\Big[1 + \frac{20}{9}\Big(\frac{743}{336} + \frac{11}{4}\eta\Big)x - 16\pi x^{3/2}\Big], \tag{T2.67}$$

with $x = v^2$. This is Cutler and Flanagan's restricted post-Newtonian phase [82, eq. (42)], in our sign convention, and it is the waveform used in Section 10.9.2. The same bracket inverted gives the chirp rate, $\dot f \propto 1 - (\frac{743}{336} + \frac{11}{4}\eta)x + 4\pi x^{3/2}$, their eq. (38). The symmetric mass ratio η appears for the first time at 1PN: it is the post-Newtonian terms that let the data separate m_1 from m_2 once $\mathcal{M}$ is known.

Example: how many cycles each term is worth. Count cycles instead of phase: the number of wave cycles is $N = \int f\,\mathrm{d}t = \int f(\mathrm{d}t/\mathrm{d}v)\,\mathrm{d}v$, and with (T2.60) and $f = c^3v^3/(\pi GM)$,

$$N(v_1, v_2) = \frac{5}{32\pi\eta}\int_{v_1}^{v_2} v^{-6}\big[1 + c_2v^2 + c_3v^3\big]\mathrm{d}v = \frac{5}{32\pi\eta}\Big[\frac{v^{-5}}{5} + c_2\frac{v^{-3}}{3} + c_3\frac{v^{-2}}{2}\Big]_{v_2}^{v_1}. \tag{T2.68}$$

The first term is (T2.45) again. The script `14_pn_cycles.py` evaluates the three terms separately (Figure T2.14). For a pair of $1.4\,M_\odot$ neutron stars observed from 10 Hz to the ISCO by a ground-based detector, the Newtonian term gives 16 034 cycles, the 1PN term 441 and the tail −211, in agreement with the counts Blanchet tabulates for the same band (about 1.6×10^4, 441 and −211) [85]. For the book's intermediate mass-ratio benchmark in its last four years (v from 0.06954 to 0.4082), the counts are 4.38×10^6, 77 847 and −44 949; for the EMRI, 2.79×10^6, 1.66×10^5 and -1.69×10^5. Tens of thousands of cycles from each correction: no template can leave them out. Even the GW150914-like binary crossing the LISA band years before merger, at $v \approx 0.03$, gains 5 521 cycles from the 1PN term.

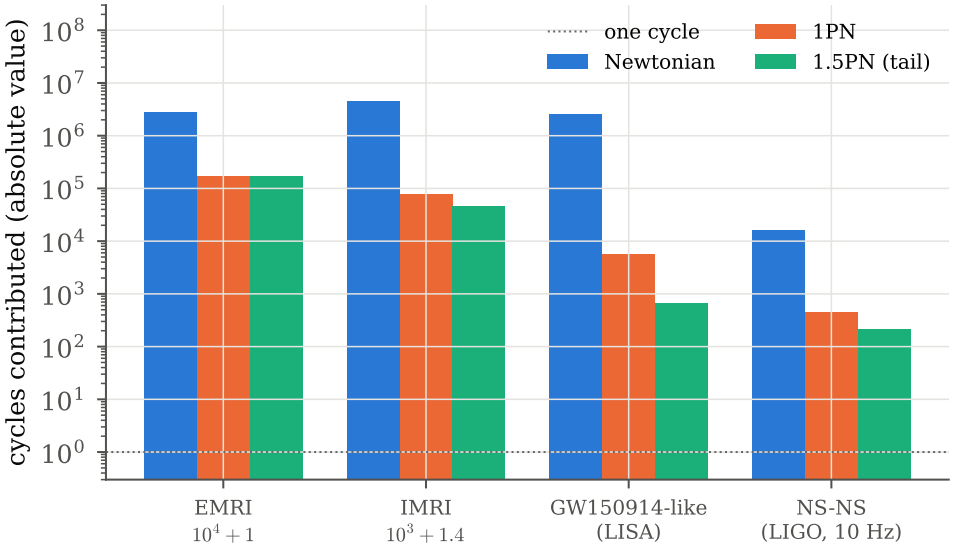

Figure T2.14: Number of wave cycles contributed by the Newtonian term and by the 1PN and 1.5PN (tail) corrections, for the four binaries named below the bars, each in its observation window. The dotted line marks one cycle, the slip that ruins a matched filter. Every correction is worth hundreds to hundreds of thousands of cycles.

Watch out: Post-Newtonian series for extreme mass ratios

For the EMRI the 1PN and 1.5PN counts are almost equal and opposite, each about six per cent of the total. Near the ISCO, $v \approx 0.4$, successive terms of the series shrink only slowly, so truncating it at 1.5PN leaves an error of many cycles. Research templates for extreme mass ratios therefore come from black-hole perturbation theory (the small body moving in the exact geometry of the large one, corrected by its own field) rather than from the post-Newtonian series; the power-law structure derived here is used to describe small *changes* to such a template, not the template itself.

T2.6.4 Every correction is a power of the frequency: the ppE form

The rule (T2.62) applies to any small correction that scales as a power of v, whatever its origin. In terms of the reduced frequency u of (T2.58), $v^p = \eta^{-p/5} u^{p/3}$, so a correction of relative order v^p becomes

$$\delta\Psi = \beta\, u^b, \qquad b = \frac{p-5}{3}, \tag{T2.69}$$

with all the constants, including the powers of η, in β. For the general-relativistic terms $p = 2k$ at kPN order, so $b = (2k-5)/3$: -1 at 1PN, $-2/3$ at 1.5PN, $-1/3$ at 2PN. A term that grows *at low frequency* faster than the Newtonian $-\frac{5}{3}$ must come from a correction with $p < 0$, one that is relatively more important when the binary is wide and slow. Yunes and Pretorius proposed to test general relativity with exactly this family: the **parameterised post-Einsteinian** (ppE) waveform

$$\tilde{h}(f) = \tilde{h}_{\mathrm{GR}}(f)\,\bigl(1 + \alpha u^a\bigr)\, e^{-i\beta u^b}, \tag{T2.70}$$

in our sign convention, where (α, a) change the amplitude and (β, b) the phase, and general relativity is $\alpha = \beta = 0$ [86, eq. (1)]. (Yunes and Pretorius write the powers of $(\pi G\mathcal{M}f/c^3)^{1/3}$, so each of their exponents is three times ours.) The environments of Section T2.10 fit into the same family: a dark-matter spike adds a drag whose power relative to the radiated one falls as f^{-n}, which by (T2.69) with $p = -3n$ is $b = -\frac{5}{3} - n$, (T2.94).

Example: dipole radiation, $b = -7/3$. In some alternatives to general relativity, such as the Brans–Dicke theory, a compact body carries a scalar "charge" that is not proportional to its mass, and the binary emits dipole radiation as well. By the estimate at the end of Section T2.2, dipole power relative to quadrupole power scales as $(v/c)^{-2}$. So $\mathcal{F} = \mathcal{F}_{\mathrm{N}}(1 + Bv^{-2})$, the bracket of (T2.60) gains $-Bv^{-2}$, $p = -2$, and $b = (-2-5)/3 = -\frac{7}{3}$: Yunes and Pretorius's Brans–Dicke case [86]. A "-1PN" term, it is largest at the lowest frequencies, which is why a long, slow inspiral in the LISA band is a sensitive test of it.

Example: a massive graviton, $b = -1$. If the graviton had a mass m_g, waves of energy hf would travel at the group velocity $v_g = c\sqrt{1 - m_g^2c^4/(hf)^2} \approx c\,[1 - m_g^2c^4/(2h^2f^2)]$, and low frequencies would arrive late. Over a distance D the delay is $\Delta t(f) = (D/c)\, m_g^2c^4/(2h^2f^2) = Dc/(2\lambda_g^2 f^2)$, with $\lambda_g = h/(m_g c)$ the graviton's Compton wavelength. The arrival time of frequency f is what the slope of the Fourier phase measures, $\mathrm{d}\Psi/\mathrm{d}f = 2\pi t(f)$ by (T2.53), so

$$\delta\Psi(f) \overset{(1)}{=} 2\pi \int \Delta t(f)\,\mathrm{d}f \overset{(2)}{=} 2\pi\,\frac{Dc}{2\lambda_g^2}\int f^{-2}\,\mathrm{d}f \overset{(3)}{=} -\frac{\pi Dc}{\lambda_g^2}\,f^{-1} + \text{const}, \tag{T2.71}$$

(1) Integrate the extra delay once, as in (T2.54).
(2) Insert $\Delta t(f)$.
(3) $\int f^{-2}\mathrm{d}f = -f^{-1}$; the constant joins ϕ_c.

a term $\propto f^{-1}$, so $b = -1$, the ppE massive-graviton case [86]. It has the same exponent as the 1PN term, which is why a graviton mass and the mass ratio are partly degenerate in a fit, a correlation Section 10.11.4 meets in another guise.

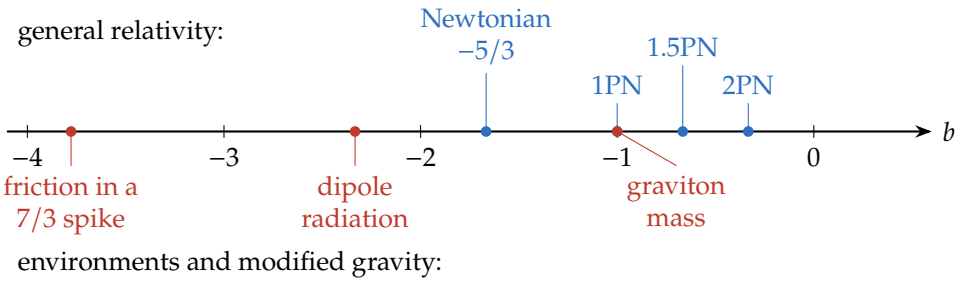

Figure T2.15: The exponent b of the term βu^b that each effect adds to the Fourier phase. General-relativistic corrections (blue, above the line) sit at $b = (2k - 5)/3$ and climb towards zero as the PN order k grows. Effects that matter most when the binary is wide and slow (red, below) have $b < -5/3$: dipole radiation at $-7/3$, dynamical friction in a dark-matter spike of slope $7/3$ at $-34/9$. A graviton mass lands on the same exponent as the 1PN term.

Key idea: A correction v^p becomes a phase term $f^{(p-5)/3}$

If the binding energy or the radiated power differs from its Newtonian value by a relative term $c_p v^p$, the Fourier phase gains $\delta\Psi = \frac{3}{128} u^{-5/3} \cdot \frac{40 c_p}{(8-p)(5-p)} v^p \propto u^{(p-5)/3}$. General relativity's kPN terms have $p = 2k$; environments and dipole radiation have $p < 0$. Any such effect is a ppE term βu^b, with the exponent b naming the physics and β its strength.

Where this is used. The phase (T2.67) is the signal model of Section 10.9.2, and the exponents of its terms are what make its Fisher matrix in Section 10.9.3 a set of weighted averages of powers of f. The rule (T2.69) is the general form behind Section 10.10.1, where an environment is a power law in the phase, and behind Section 10.11.3, which computes the error on β for every exponent b at once; the specific exponents of dark-matter environments are derived in Section T2.10.

T2.7 What LISA measures, and what hides the signal

LISA will be three spacecraft flying in a triangle $L = 2.5$ million kilometres on a side, trailing the Earth around the Sun (Figure T2.8). Each spacecraft shields test masses that fall freely, and laser links measure the distance between test masses on different spacecraft. By (T2.12) a gravitational wave of strain h changes an arm's length by about $\frac{1}{2} hL$. For $h \sim 10^{-20}$ that is about 10^{-11} m, ten picometres over millions of kilometres. The whole instrument is designed around measuring such changes, and its noise is the floor under which a signal can hide.

For the statistics, LISA is summarised by a single function. The data are the signal plus noise, $d = h(\boldsymbol{\theta}) + n$. For a given $\boldsymbol{\theta}$, the likelihood of Section 10.8.2 asks how plausible the particular noise realisation $n = d - h(\boldsymbol{\theta})$ is, and for stationary Gaussian noise that plausibility is set, one Fourier component at a time, by the noise power at that frequency. So the likelihood weights each frequency by the inverse of the noise power there, and the Fisher matrix of Chapter 10 inherits that weight. The question is therefore physical: *at each frequency, how large is the noise, where does it come from, and how large would a gravitational wave have to be to produce the same output?* The answer is the sensitivity curve $S_n(f)$ [80].

T2.7.1 A noise spectrum as a physical quantity

The statistics of a noise spectrum, how it describes the correlations of a stationary random process and how it is estimated from data, is developed in Sections 10.8.2 and 10.8.5. Here we need only what it means physically. Pass the noise $n(t)$ through a narrow filter that keeps only frequencies between f and $f + \Delta f$, and measure the mean square of what comes out. The **one-sided power spectral density** $S_n(f)$ is that mean square divided by Δf:

$$\left\langle n^2 \right\rangle_{[f,f+\Delta f]} = S_n(f)\,\Delta f, \qquad \left\langle n^2 \right\rangle = \int_0^\infty S_n(f)\,\mathrm{d}f. \tag{T2.72}$$

"One-sided" means that only positive frequencies are counted, the negative ones having been folded onto them as in Section T2.5. Its square root, the **amplitude spectral density** $\sqrt{S_n}$, is in units of the measured quantity per $\sqrt{\text{Hz}}$: a displacement noise of $15\,\text{pm}\,\text{Hz}^{-1/2}$ means that, averaged over one second (a band of about 1 Hz), the length reading scatters by about 15 pm. Two noises from independent causes add in power, $S = S_1 + S_2$, because the mean square of a sum of uncorrelated terms is the sum of their mean squares. And if a noise in one quantity is converted into another by a linear, frequency-dependent factor, as a force becomes a displacement, the spectrum is multiplied by the squared modulus of that factor.

T2.7.2 From test-mass jitter and photon counting to strain sensitivity

The two instrumental noises. Two processes limit the arm-length measurement [80, eqs. (10)–(11)]:

$$\begin{aligned} P_{\text{OMS}}(f) &= (1.5\times10^{-11}\,\text{m})^2\left[1+\left(\frac{2\,\text{mHz}}{f}\right)^4\right]\text{Hz}^{-1},\\ P_{\text{acc}}(f) &= (3\times10^{-15}\,\text{m}\,\text{s}^{-2})^2\left[1+\left(\frac{0.4\,\text{mHz}}{f}\right)^2\right]\left[1+\left(\frac{f}{8\,\text{mHz}}\right)^4\right]\text{Hz}^{-1}. \end{aligned} \tag{T2.73}$$

The first is **optical metrology** noise, the error with which the laser interferometry reads the length of one link: about $15\,\text{pm}\,\text{Hz}^{-1/2}$, flat in frequency apart from a rise below 2 mHz. The second is **acceleration noise**: stray forces on the free-falling test masses, from impacts of residual gas molecules, electrostatic and magnetic forces on the slightly charged and magnetised masses, and the pressure of thermal radiation from their housing, push each of them around by about $3\times10^{-15}\,\text{m}\,\text{s}^{-2}\,\text{Hz}^{-1/2}$.

Example: where 15 picometres comes from. Most of the metrology noise is photon *shot noise*, the graininess of light, and its size follows from counting photons. A laser of about 2 W leaves one spacecraft through a telescope of diameter $D \approx 0.3\,\text{m}$. Diffraction spreads the beam by an angle $\theta \approx \lambda/D = 1.064\,\mu\text{m}/0.3\,\text{m} = 3.5\times10^{-6}$, so after $L = 2.5\times10^9\,\text{m}$ the spot has a radius of about $\theta L \approx 9\,\text{km}$, and the receiving telescope, of radius 0.15 m, catches a fraction of order $(0.15/9000)^2 \approx 3\times10^{-10}$ of it: a received power $P_r \approx 6\times10^{-10}\,\text{W}$. Each photon carries $hc/\lambda = 1.9\times10^{-19}\,\text{J}$, so about $\dot N = P_r\lambda/hc \approx 3\times10^9$ photons arrive per second. A phase measured by counting N photons is uncertain by $1/\sqrt{N}$ radians, the Poisson fluctuation of the count (Chapter 2), and a phase $\delta\varphi$ is a length $\lambda\,\delta\varphi/2\pi$. Per second of averaging,

$$\delta x \approx \frac{\lambda}{2\pi}\frac{1}{\sqrt{\dot N\times 1\,\text{s}}} = \frac{1.06\times10^{-6}\,\text{m}}{2\pi}\times\frac{1}{\sqrt{3\times10^9}} \approx 3\times10^{-12}\,\text{m},$$

a few picometres per $\sqrt{\text{Hz}}$, the same order as the $15\,\text{pm}\,\text{Hz}^{-1/2}$ allocated to all the metrology noise together. Counting statistics does not depend on how fast the signal varies, so shot noise is white in displacement. The arm length helps the signal ($\delta L \propto L$) but hurts the light budget ($P_r \propto L^{-2}$); 2.5 million kilometres is a compromise between the two.

Why acceleration noise is divided by $(2\pi f)^4$. A force noise becomes a displacement noise by integrating twice in time, and integration in time is division by frequency:

$$\ddot{x}(t) = a(t) \quad \Rightarrow \quad (2\pi i f)^2 \tilde{x}(f) \overset{(1)}{=} \tilde{a}(f) \quad \Rightarrow \quad P_x(f) \overset{(2)}{=} \frac{P_a(f)}{(2\pi f)^4}. \tag{T2.74}$$

(1) Fourier transform with the book's convention (T2.48): each time derivative becomes a factor $2\pi i f$.
(2) The spectrum is multiplied by the squared modulus of the conversion factor; $|(2\pi i f)^2|^2 = (2\pi f)^4$.

A random push of given strength moves a mass far if it keeps pushing the same way for a long time, that is at low frequency, and hardly at all if it reverses quickly. So acceleration noise is harmless at high frequency and dominates at low frequency, rising as f^{-4} in power.

Adding up the noise in one Michelson channel. Follow one arm, with test mass A at the vertex spacecraft and test mass B at the far one, and let $x_A(t)$, $x_B(t)$ be their random displacements along the arm (positive in the direction from A to B). Light leaves A at $t - 2L/c$, is sent back from B at $t - L/c$ and returns to A at t. The measured round-trip length changes by

$$\begin{aligned}
\delta\ell(t) &\overset{(1)}{=} \big[x_B(t - L/c) - x_A(t - 2L/c)\big] + \big[x_B(t - L/c) - x_A(t)\big], \\
\tilde{\delta\ell}(f) &\overset{(2)}{=} 2e^{-2\pi i f L/c}\, \tilde{x}_B - \big(1 + e^{-4\pi i f L/c}\big)\tilde{x}_A, \\
P_{\delta\ell} &\overset{(3)}{=} 4P_x + \big|1 + e^{-4\pi i f L/c}\big|^2 P_x \overset{(4)}{=} 4P_x + 4\cos^2\!\Big(\frac{2\pi f L}{c}\Big)P_x = 4\Big(1 + \cos^2\frac{f}{f_*}\Big)P_x.
\end{aligned} \tag{T2.75}$$

(1) The outward leg is lengthened by B's displacement when the light arrives and shortened by A's when it left; the return leg likewise, with A's displacement at the end.
(2) A delay by T multiplies a Fourier transform by $e^{-2\pi i f T}$, as in a time shift (Section 10.8.4).
(3) A and B jitter independently with the same spectrum P_x, so their contributions add in power; $|2e^{-i\cdot}|^2 = 4$.
(4) $|1 + e^{-i\theta}|^2 = 2 + 2\cos\theta = 4\cos^2(\theta/2)$ with $\theta = 4\pi f L/c$, and $2\pi f L/c = f/f_*$.

The far mass counts four times because the light touches it twice at the same moment; the vertex mass counts at two moments $2L/c$ apart, which add in step at low frequency and cancel when the round trip is half a period. A Michelson channel is the difference of two such arms, and in LISA each arm has its own test mass at the vertex, so the acceleration noise of the channel is $8(1 + \cos^2 f/f_*)P_{\rm acc}/(2\pi f)^4$: sixteen units at low frequency. The metrology noise enters once per one-way link, two links per arm, two arms: $4P_{\rm OMS}$. The signal in the same channel is the round-trip difference $2L\, D_{ij}h_{ij}$ of Section T2.3, so dividing the noise by $(2L)^2$ expresses it as an equivalent strain:

$$P_n(f) = \frac{4P_{\rm OMS} + 8\big(1 + \cos^2\frac{f}{f_*}\big)\frac{P_{\rm acc}}{(2\pi f)^4}}{4L^2} = \frac{1}{L^2}\Big[P_{\rm OMS} + 2\Big(1 + \cos^2\frac{f}{f_*}\Big)\frac{P_{\rm acc}}{(2\pi f)^4}\Big], \tag{T2.76}$$

which is Robson et al.'s eq. (12), with its "four contributions from the optical metrology noise and sixteen from the test mass acceleration noise" [80].

The noise that is cancelled before it is counted. There is a third noise, far larger than both: the laser's own frequency jitter. Even a stabilised laser wanders in frequency by about one part in 10^{13} per $\sqrt{\rm Hz}$, and a Michelson interferometer is immune to that only if its two arms are equally long, so that both beams carry the same old laser light back to be compared. LISA's

arms differ by about one per cent, some 2.5×10^{7} m, so the jitter would appear as a length noise of order $10^{-13}\times2.5\times10^{7}\,\mathrm{m}\approx2.5\,\mu\mathrm{m}$ per $\sqrt{\mathrm{Hz}}$, some 10^{5} times the signal. LISA therefore records every one-way link separately and, on the ground, adds the records with time shifts chosen so that the laser noise cancels exactly, synthesising an equal-arm Michelson after the fact. This is **time-delay interferometry**. What survives it is the test-mass and metrology noise counted above.

From the noise in the channel to the sensitivity curve. P_n is the noise of one channel expressed as a strain, but a real wave is not optimally oriented: on average over the sky and polarisation the channels respond to only a fraction $R(f)$ of the wave's power, $\frac{3}{10}$ at low frequency for the two channels together and falling above f_* (Section T2.3). It is conventional to move that factor from the signal onto the noise [80, eq. (2)]: the **sensitivity curve** is the noise divided by the response. With the fit $R(f)=\frac{3}{10}/[1+0.6(f/f_*)^2]$, checked in Figure T2.9,

$$S_n(f)=\frac{P_n(f)}{R(f)}=\frac{10}{3L^2}\left[P_{\mathrm{OMS}}(f)+2\left(1+\cos^2\frac{f}{f_*}\right)\frac{P_{\mathrm{acc}}(f)}{(2\pi f)^4}\right]\left[1+\frac{6}{10}\left(\frac{f}{f_*}\right)^2\right]+S_c(f). \tag{T2.77}$$

At $f\ll f_*$ the factor $2(1+\cos^2)$ is 4, the simpler form of Robson et al.'s eq. (1) [80]; the code uses the full factor.

The Galactic confusion noise. The last term in (T2.77) is not instrumental. Our Galaxy contains tens of millions of binaries of white dwarfs radiating at millihertz frequencies. A four-year observation divides the frequency axis into bins of width $1/T\approx8\,\mathrm{nHz}$, and below a few millihertz there are more binaries than bins. They cannot be separated from one another, and their sum acts as an extra noise [80, Sec. 1]:

$$S_c(f)=A\,f^{-7/3}\,e^{-f^{\alpha}+\beta f\sin(\kappa f)}\left[1+\tanh(\gamma(f_k-f))\right]\mathrm{Hz}^{-1}, \tag{T2.78}$$

with $A=9\times10^{-45}$ and, for four years, $(\alpha,\beta,\kappa,\gamma,f_k)=(0.138,-221,521,1680,1.13\,\mathrm{mHz})$ [80, eq. (14)].

Why $f^{-7/3}$? The power law follows from the chirp. Suppose white-dwarf binaries form at a steady rate at low frequency and then drift upwards in frequency at the rate $\dot f\propto f^{11/3}$ of (T2.43). In a steady state the number of binaries crossing any frequency per unit time is the same at every f, like a steady flow of traffic: $(\mathrm{d}N/\mathrm{d}f)\,\dot f=\text{const}$, so $\mathrm{d}N/\mathrm{d}f\propto f^{-11/3}$. Where binaries move quickly they are few. Each binary contributes a mean-square strain $\propto A^2\propto f^{4/3}$, by (T2.26). Summing the power of all binaries in a band, as (T2.72) sums the power of a noise,

$$S_c(f)\propto\frac{\mathrm{d}N}{\mathrm{d}f}\,A^2\propto f^{-11/3}\,f^{4/3}=f^{-7/3}. \tag{T2.79}$$

The other factors of the fit describe where this simple picture fails. Above the knee f_k there is less than about one binary per bin, so the binaries can be fitted and subtracted one by one, and the tanh switches the confusion off. The longer LISA observes, the finer the bins, the more binaries are resolved, and the lower the knee moves (it is 2.58 mHz after six months). The confusion noise is also not stationary: it rises and falls during the year as the antenna pattern of Section T2.3 sweeps across the Galactic centre. The fit is its average.

Working definition T2.3 (sensitivity curve)

The **sensitivity curve** $S_n(f)$ is the one-sided noise power spectral density of the detector divided by its sky- and polarisation-averaged response, plus any unresolved foreground [the noise expressed as the strain power a gravitational wave would need to produce the

same output]. *Operationally:* in the inner product $(a\,|\,b) = 4\,\mathrm{Re}\int \tilde{a}\tilde{b}^*/S_n\,\mathrm{d}f$ use $S_n(f)$ of (T2.77) together with the angle-averaged waveform $\tilde{h} = \sqrt{4/5}\,\mathcal{A} f^{-7/6} e^{-i\Psi}$.

Figure T2.16 shows the three pieces. Acceleration noise dominates below 3.077 mHz (by hand: setting $P_{\rm OMS} = 4P_{\rm acc}/(2\pi f)^4$ without the correction factors gives $(2\pi f)^4 = 4\times 9\times 10^{-30}/2.25\times10^{-22} = 1.6\times10^{-7}\,\mathrm{s}^{-4}$, i.e. $f = 3.2$ mHz). The confusion noise exceeds the instrument between 0.4101 and 1.908 mHz. Above $f_* = 19.09$ mHz the falling response makes the curve rise again. The best sensitivity, $\sqrt{S_n} = 1.178\times10^{-20}\,\mathrm{Hz}^{-1/2}$, is reached near 7.256 mHz.

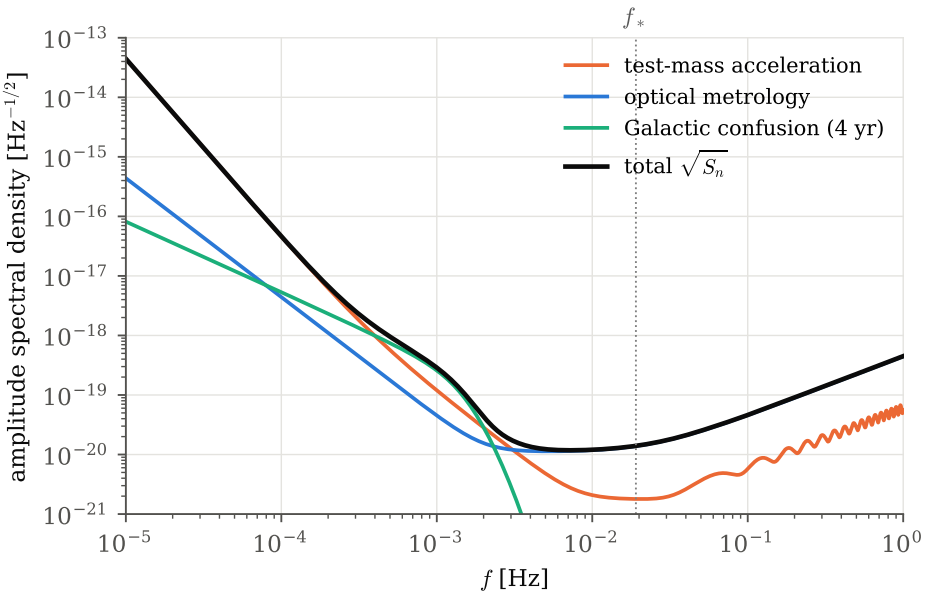

Figure T2.16: The LISA sensitivity curve and its three ingredients, as amplitude spectral densities $\sqrt{S}$. Test-mass acceleration noise falls steeply with frequency, optical metrology noise is flat and then rises above f_* (dotted) where the arms respond less, and the Galactic confusion noise fills the gap around a millihertz. The thick curve is the total used throughout the book.

The curve is a short function in `lib_lisa.py`:

108 def Sn_lisa(f, confusion=True):
109     """Sky-averaged LISA S_n(f) [1/Hz]: instrument (their eq. 13) + confusion (eq. 14)."""
110     oms, acc, conf = lisa_components(f)
111     return oms + acc + (conf if confusion else 0.0)
```

The factor `resp` on line 102 is $\frac{10}{3L^2}[1 + 0.6(f/f_*)^2]$, the conversion from displacement noise to strain sensitivity. Line 103 is the metrology term of (T2.77), line 104 the acceleration term with its f^{-4} and the full factor $2(1+\cos^2)$, and line 105 hands back the confusion fit. `Sn_lisa` adds the three; with `confusion=False` it is the instrument alone.

T2.7.3 How loud is a source?

With the noise in hand, the signal-to-noise ratio of Chapter 0 is $\rho^2 = (h\,|\,h) = 4\int |\tilde h|^2/S_n\,\mathrm{d}f$. For the angle-averaged waveform of Section T2.5, $|\tilde h|^2 = \frac{4}{5}\mathcal{A}^2 f^{-7/3}$ (with $\mathcal{A}$ the amplitude of (T2.56)), and it is useful to rewrite the integral so that a plot shows it:

$$\rho^2 \overset{(1)}{=} \frac{16}{5}\int \frac{\mathcal{A}^2 f^{-7/3}}{S_n(f)}\,\mathrm{d}f \overset{(2)}{=} \int \left(\frac{h_c(f)}{h_n(f)}\right)^2 \mathrm{d}\ln f, \qquad h_c \equiv 2f|\tilde h(f)|, \quad h_n \equiv \sqrt{f S_n(f)}. \tag{T2.80}$$

(1) Insert $|\tilde h|^2 = \frac{4}{5}\mathcal{A}^2 f^{-7/3}$; $4\cdot\frac{4}{5} = \frac{16}{5}$ [80, eq. (18)].
(2) $4|\tilde h|^2\mathrm{d}f/S_n = (2f|\tilde h|)^2/(fS_n)\cdot \mathrm{d}f/f$, and $\mathrm{d}f/f = \mathrm{d}\ln f$.

Both h_c, the **characteristic strain**, and h_n are dimensionless. On log–log axes the height of a source's track above the noise curve shows how much signal-to-noise ratio each decade of frequency contributes. A track below the curve can still be detected if it is long enough, because the integral adds up many frequencies.

Example: the three benchmark sources. The script `03_lisa_noise.py` evaluates (T2.80) on the four-year stretch of each binary of Section T2.4. Kim et al. place the EMRI at $D_L = 203\,\mathrm{Mpc}$, where five years of data give a signal-to-noise ratio of about 15 [81, Sec. III F]. For our four years we place it where $\rho = 14$, which is $D_L = 199.8\,\mathrm{Mpc}$, close to their distance. The IMRI at 75 Mpc, the distance out to which Coogan et al. find dark-matter environments measurable [84], reaches $\rho = 12.1$ between 21.7 mHz and the 1 Hz end of the band. The GW150914-like binary at 410 Mpc reaches only $\rho = 3.89$: on its own LISA would not claim it, which is why such sources are studied together with ground-based detectors. Figure T2.17 shows the tracks. Since $h_c \propto f\cdot f^{-7/6} = f^{-1/6}$, each inspiral is an almost flat line that ends where the binary reaches its ISCO or leaves the band.

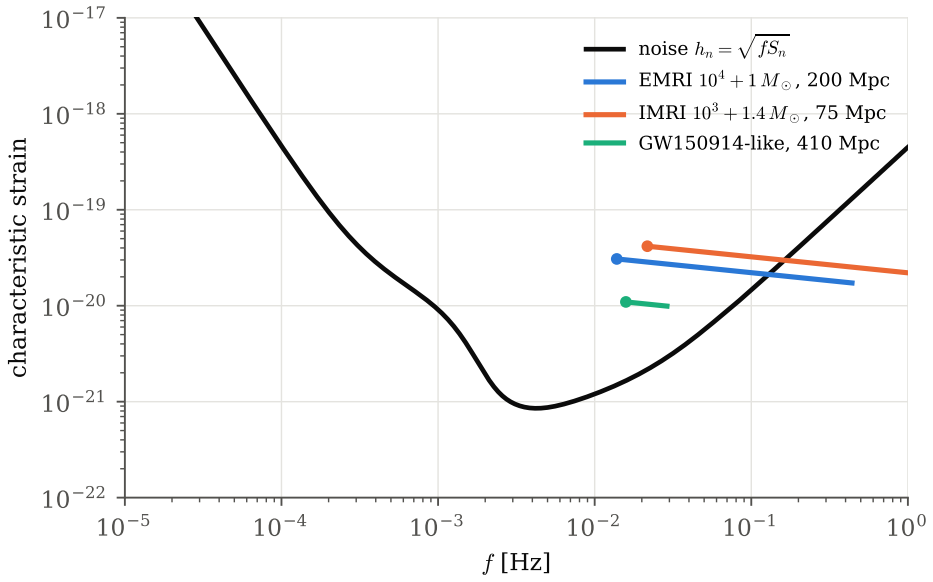

Figure T2.17: Characteristic strain of the three benchmark binaries during four years of observation (dots mark the start), over the LISA noise amplitude $h_n = \sqrt{fS_n}$. The squared ratio of the two curves, integrated over $\ln f$, is the squared signal-to-noise ratio (T2.80). The EMRI and the IMRI sit well above the noise over a decade or more of frequency; the GW150914-like binary is short and sits only several times above it.

Watch out: Three conventions for one curve

The literature plots $\sqrt{P_n}$ (noise only), $\sqrt{S_n} = \sqrt{P_n/R}$ (noise over response) and $h_n = \sqrt{fS_n}$ (dimensionless), and quotes the low-frequency response as 3/10 (two channels) or 3/20 (one) [80, Sec. 1]. Each is correct with the matching signal. Pair S_n with the angle-averaged waveform $\sqrt{4/5}\,\mathcal{A}f^{-7/6}$, or P_n with the full detector response, and never mix them: a mismatch changes every signal-to-noise ratio and Fisher error by a constant factor that nothing else in the calculation will reveal.

Where this is used. The curve (T2.77) is the $S_n(f)$ of the noise-weighted inner product of Section 10.8.2, and with it of every likelihood, matched filter and Fisher matrix in Chapter 10; Section 10.11.1 checks it against the published figure, and Section 10.11.2 uses the signal-to-noise ratio (T2.80) to place the benchmark source. In real data S_n is not known in advance but estimated, which is the subject of Sections 10.8.5 and 10.8.6; the non-stationary confusion noise is one reason why that estimate is hard.

T2.8 The symbols, where they come from, and where they are used

Every gravitational-wave object that Chapter 10 takes as given has a short derivation above. The table that follows gives each symbol in a few words, the equation or section where it was derived, and the part of Chapter 10 in which it does its work. The rows follow the chain of Figure T2.1: the wave, the source, the chirp, the frequency domain, the corrections, the detector and its noise.

The rows are links of one chain of reasoning. Einstein's equation for a weak field gave a wave with two polarisations that changes distances by $\frac{1}{2}h$. Mass and momentum conservation made the quadrupole the first source of such waves, and the energy they carry made a binary chirp. The stationary-phase approximation turned the chirp into a Fourier-domain template whose phase is a sum of powers of f, two of whose terms, $2\pi f t_c - \phi_c$, are nuisances, and whose other terms, Newtonian, post-Newtonian or environmental, carry the physics. The detector added its geometry, through F_+, $F_\times$ and the averages $\frac{4}{5}$ and $\frac{3}{10}$, and its noise, through $S_n(f)$. Nothing in the list is a convention to be taken on trust; each entry can be recomputed from the two physical inputs of Section T2.1 and Newton's law of gravity.

Recap

- A weak gravitational wave is a transverse, traceless ripple h_{ij} moving at c, with two polarisations h_+, $h_\times$ that mix under rotations with twice the angle; it changes the distance between free masses by $\delta L/L = \frac{1}{2}h_{ij}\hat{n}_i\hat{n}_j$, a travelling tidal squeeze.
- Conservation of mass and momentum forbids monopole and dipole radiation, so slow sources radiate through $\ddot{Q}_{ij}$: $h_{ij}^{\mathrm{TT}} = (2G/c^4 r)[\ddot{Q}_{ij}]^{\mathrm{TT}}$ and $P = (G/5c^5)\langle\dddot{Q}\dddot{Q}\rangle$. A circular binary radiates at $f = 2f_{\mathrm{orb}}$ with amplitude $4(G\mathcal{M})^{5/3}(\pi f)^{2/3}/(c^4 D)$ and power $\frac{32}{5}(G/c^5)\mu^2 r^4\omega^6$.
- A detector outputs $h = F_+h_+ + F_\times h_\times$. Averages: $\frac{1}{5}$ over sky and polarisation, $\frac{3}{4}$ for 60° arms, $\frac{3}{10}$ for LISA's two channels, $\frac{4}{5}$ over inclination. Above $f_* = c/(2\pi L) = 19\,\mathrm{mHz}$ the response falls as f^{-2}.
- Energy balance gives the chirp $\dot{f} \propto \mathcal{M}^{5/3}f^{11/3}$; integrating it gives the time to merger, the number of cycles and the phase, with the nuisance constants t_c and ϕ_c.

symbol	meaning	derived in	used in Chapter 10
h_+, $h_\times$	the two polarisations of a wave, in the transverse plane	(T2.8)	§10.8
$\delta L/L = \frac{1}{2}h_{aa}$	fractional change of an arm's length, read by light travel time	(T2.12), (T2.30)	§10.8
F_+, $F_\times$; D_{ij}	antenna patterns: weights of the polarisations in the detector output; detector tensor	(T2.32), (T2.34)	§10.8
$\frac{1}{5}$, $\frac{3}{20}$, $R = \frac{3}{10}$	sky- and polarisation-averaged response: right-angle, one 60° channel, two LISA channels	(T2.35), (T2.37)	§10.11.1
$\frac{4}{5}$	inclination average of a circular binary's signal power	(T2.36)	§10.11.1, §10.11.2
$f_* = c/2\pi L$	transfer frequency; response falls as f^{-2} above it	(T2.38)	§10.11.1
M, μ, η	total mass, reduced mass, symmetric mass ratio μ/M	§T2.2, (T2.57)	§10.9.2
$\mathcal{M}$	chirp mass $\mu^{3/5}M^{2/5}$, the mass the Newtonian signal depends on	(T2.26), (T2.42)	§10.9.2, §10.9.4
$f = 2f_{\rm orb}$	wave frequency, twice the orbital one	(T2.24)	throughout
A; $\mathcal{A}$	time-domain amplitude; Fourier amplitude of $\tilde{h} = \mathcal{A}f^{-7/6}e^{-i\Psi}$	(T2.26), (T2.56)	§10.8.3, §10.9.2
ι, ψ	inclination of the orbit; polarisation angle	(T2.25), (T2.34)	§10.11.1
$P_{\rm GW}$, $E(f)$	radiated power; orbital binding energy	(T2.27), (T2.41)	§10.10.1
$\dot{f}$	chirp rate $\frac{96}{5}\pi^{8/3}(G\mathcal{M}/c^3)^{5/3}f^{11/3}$	(T2.43)	§10.10.1
$\tau(f)$, N, $f_{\rm ISCO}$	time left to coalescence; number of cycles; end of the inspiral	(T2.44), (T2.45), (T2.46)	§10.11.2
t_c, ϕ_c	time and phase of coalescence: nuisance parameters	(T2.47), §T2.4.3	§10.8.4, §10.9.4
$\tilde{h}(f)$	Fourier transform, $\int h\, e^{-2\pi i f t}\mathrm{d}t$; $\tilde{h}(-f) = \tilde{h}(f)^*$	(T2.48), (T2.49)	§10.8.2
$\Psi(f)$	Fourier phase of the chirp, from the stationary-phase approximation	(T2.51), (T2.54)	§10.9.2
$\Psi' = 2\pi t(f)$, $\Psi'' = 2\pi/\dot{f}$	what the phase knows: arrival time and chirp rate	(T2.53)	§10.10.1
$\Phi(f)$	time-domain phase still to come; Ψ carries $\frac{3}{8}$ of it	§T2.5 (example)	§10.12.1
v, x, u	PN parameter $(\pi GMf/c^3)^{1/3}$, $x = v^2$, reduced frequency $\pi G\mathcal{M}f/c^3$	(T2.57), (T2.58)	§10.9.2
1PN, 1.5PN terms	corrections $\frac{20}{9}(\frac{743}{336}+\frac{11}{4}\eta)x$ and $-16\pi x^{3/2}$	(T2.67)	§10.9.2
β, b	ppE amplitude and exponent of a phase term βu^b; $b = (p-5)/3$	(T2.69), (T2.94)	§10.10, §10.11.3
$S_n(f)$	one-sided noise spectrum divided by the response: the sensitivity curve	(T2.72), (T2.77)	§10.8.2, §10.11.1
$P_{\rm OMS}$, $P_{\rm acc}$, S_c	metrology, test-mass acceleration and Galactic confusion noise	(T2.73), (T2.76)	§10.11.1
h_c, h_n, ρ	characteristic strain, noise amplitude, signal-to-noise ratio	(T2.80)	§10.11.2

Table T2.1: The gravitational-wave symbols of Chapter 10: what each one is, the equation or section that derives it, and the section of Chapter 10 that uses it.

- The stationary-phase approximation, a Taylor expansion of the phase plus a Fresnel integral, gives $\tilde{h} = \mathcal{A} f^{-7/6} e^{-i\Psi}$ with $\Psi' = 2\pi t(f)$ and $\Psi'' = 2\pi/\dot{f}$, checked against an FFT.
- A relative correction v^p to the energy or flux adds $\propto f^{(p-5)/3}$ to Ψ: the 1PN and 1.5PN terms of the standard template, dipole radiation at $b = -7/3$, a graviton mass at $b = -1$, environments at $b = -5/3 - n$, all of the ppE form βu^b.
- LISA's noise is shot noise (flat in displacement) and test-mass acceleration noise (divided by $(2\pi f)^4$), counted through the round trips of a Michelson channel and divided by the response to give $S_n(f)$, plus the $f^{-7/3}$ confusion noise of unresolved Galactic binaries.

T2.9 Dark matter around black holes

The signal model of Sections T2.5 and T2.6 describes a binary in empty space: a chirp whose Fourier phase $\Psi(f)$ (T2.54) is fixed by the chirp mass $\mathcal{M}$ (T2.42) and the coalescence constants t_c, ϕ_c (Section T2.4.3), and to which any extra physics adds a power of the frequency, βu^b (T2.69). This section and the next supply the extra physics that the forecasts of Chapter 10 test. Here we ask where dark matter around a black hole comes from and how dense it becomes; Section T2.10 finds the forces it exerts on the orbit and the exponent b they produce.

Near the Sun, dark matter has a density of about $0.01\,M_\odot\,\mathrm{pc}^{-3}$. Spread at that density over a sphere the size of the EMRI orbit of Section T2.4, about 30 Schwarzschild radii of a $10^4\,M_\odot$ hole or $3\times10^{-8}\,\mathrm{pc}$, it amounts to $\frac{4}{3}\pi(3\times10^{-8})^3\times0.01 \approx 10^{-24}\,M_\odot$. No orbit could feel that. A survey of environmental effects on inspirals concludes exactly this: for most sources, galactic dark matter at ordinary densities is irrelevant [87, Sec. IX]. If a gravitational wave is to show dark matter, something must have packed it around the black hole at densities some eighteen orders of magnitude higher. The black hole itself can do it. So the question is: *how does a black hole that grows at the centre of a dark-matter halo rearrange the dark matter around it, and how dense does it become where the companion orbits?*

T2.9.1 The halo far away

Far from any black hole, simulations of cold dark matter find the **Navarro–Frenk–White** (NFW) profile

$$\rho_{\mathrm{NFW}}(r) = \frac{\rho_s}{(r/r_s)(1+r/r_s)^2}, \tag{T2.81}$$

which falls as r^{-1} inside the scale radius r_s and as r^{-3} outside it [88], [89, eq. (1)]. The inner r^{-1} is called a **cusp**. A halo has no sharp edge, so it is labelled by the mass inside a conventional one. The reference density is the **critical density** $\rho_{\mathrm{crit}} = 3H_0^2/(8\pi G)$, the mean density at which a universe expanding at today's rate H_0 would be spatially flat, about $1.3\times10^{-7}\,M_\odot\,\mathrm{pc}^{-3}$ for $h = 0.674$. The edge r_{200} is the radius within which the mean density of the halo is $200\rho_{\mathrm{crit}}$, and M_{200} is the mass inside it. Since that mass is $200\rho_{\mathrm{crit}}$ times the volume $\frac{4}{3}\pi r_{200}^3$, the mass fixes the edge, $r_{200} = [3M_{200}/(800\pi\rho_{\mathrm{crit}})]^{1/3}$. The second label is the concentration $c = r_{200}/r_s$, which then fixes $r_s = r_{200}/c$. What remains is ρ_s, and it follows from the enclosed mass:

$$M(<r) \overset{(1)}{=} 4\pi\rho_s r_s^3 \int_0^{r/r_s} \frac{x\,\mathrm{d}x}{(1+x)^2} \overset{(2)}{=} 4\pi\rho_s r_s^3 \Big[\ln\Big(1+\frac{r}{r_s}\Big) - \frac{r/r_s}{1+r/r_s}\Big],$$
$$\rho_s \overset{(3)}{=} \rho_{\mathrm{crit}}\,\frac{200}{3}\,\frac{c^3}{\ln(1+c) - c/(1+c)} \equiv \rho_{\mathrm{crit}}\,\delta_c. \tag{T2.82}$$

(1) $M = \int_0^r 4\pi r'^2 \rho \, \mathrm{d}r'$ with $x = r'/r_s$; the factor x^2/x leaves x.
(2) $\frac{x}{(1+x)^2} = \frac{1}{1+x} - \frac{1}{(1+x)^2}$ integrates to $\ln(1+x) + \frac{1}{1+x} - 1 = \ln(1+x) - \frac{x}{1+x}$.
(3) Evaluate step (2) at $r = r_{200} = c r_s$ and set it equal to $200\rho_{\mathrm{crit}} \cdot \frac{4}{3}\pi r_{200}^3$: $4\pi\rho_s r_s^3 \left[\ln(1+c) - \frac{c}{1+c} \right] = \frac{800\pi}{3} \rho_{\mathrm{crit}} \, c^3 r_s^3$. The factor r_s^3 cancels, and dividing by $4\pi[\dots]$ gives ρ_s [89, eq. (2)].

Take a dwarf-galaxy halo with $M_{200} = 10^8 \, M_\odot$. The concentration–mass relation of Correa et al. at redshift zero [90, eq. (19)] gives $c = 13.49$, and then $r_{200} = 9.82\,\mathrm{kpc}$, $r_s = 0.7279\,\mathrm{kpc}$, $\delta_c = 9.39 \times 10^4$ and $\rho_s = 0.01184 \, M_\odot \, \mathrm{pc}^{-3}$ (with $h = 0.674$). These are ordinary galactic numbers. The interesting physics is inside, where the black hole dominates.

T2.9.2 The spike: what slow growth of a black hole does

Suppose a black hole of mass M grows at the centre of the cusp slowly, over many orbital periods of the surrounding dark matter. Each dark-matter particle feels the potential deepen gradually and moves inward to a tighter orbit. Dark matter piles up around the hole. The simplest orbits, circles, already give the answer.

Inputs. (i) Physical: the growth is **adiabatic** [slow compared with the orbital period of the dark matter at the radius considered], so a particle on a circular orbit stays on a circular orbit and keeps its angular momentum, which is conserved in any spherical potential. (ii) Physical: orbits do not cross. Every circular orbit shrinks, but an orbit that started inside another stays inside it, so the shells keep their order, and the mass inside each orbit is the same before and after. (iii) Physical: before the growth the gravity at radius r_i comes from the dark matter inside it; afterwards the gravity at the new radius r_f comes from the hole alone. The last input needs a word. The compressed dark matter inside r_f weighs the same $M_i(r_i)$ it weighed before the growth, and the radii of interest are those where that is much less than M; there the hole's pull dominates and the dark matter's own pull is a small correction.

The mass inside the old orbit. For an initial cusp $\rho_i = \rho_0 (r/r_0)^{-\gamma_i}$ with $\gamma_i < 3$, adding up thin shells gives

$$M_i(r_i) = \int_0^{r_i} 4\pi r^2 \rho_0 \left(\frac{r}{r_0}\right)^{-\gamma_i} \mathrm{d}r = \frac{4\pi\rho_0 r_0^{\gamma_i}}{3-\gamma_i} \, r_i^{3-\gamma_i} \propto r_i^{3-\gamma_i}.$$

Same angular momentum, smaller orbit. Equating the angular momentum before and after, and then following the mass of a shell to its new radius,

$$\begin{aligned} G\, M_i(r_i)\, r_i &\overset{(1)}{=} G\, M\, r_f \quad \Rightarrow \quad r_f \overset{(2)}{=} \frac{M_i(r_i)\, r_i}{M} \propto r_i^{4-\gamma_i}, \\ \rho_f(r_f) &\overset{(3)}{=} \rho_i(r_i) \, \frac{r_i^2}{r_f^2} \, \frac{\mathrm{d}r_i}{\mathrm{d}r_f} \overset{(4)}{=} \frac{\rho_i(r_i)}{4-\gamma_i} \, \frac{r_i^3}{r_f^3} \propto r_i^{3-\gamma_i} \, r_f^{-3} \overset{(5)}{=} r_f^{\frac{3-\gamma_i}{4-\gamma_i} - 3} = r_f^{-\frac{9-2\gamma_i}{4-\gamma_i}}. \end{aligned} \tag{T2.83}$$

(1) For a circular orbit $v^2 = GM_{\mathrm{enc}}/r$, so the squared angular momentum per unit mass is $L^2 = r^2 v^2 = GM_{\mathrm{enc}}\, r$. Before the growth $M_{\mathrm{enc}} = M_i(r_i)$; after it $M_{\mathrm{enc}} = M$ by input (iii). L^2 is the same by input (i).
(2) Solve for r_f and use $M_i(r_i) \propto r_i^{3-\gamma_i}$.
(3) By input (ii) the shell between r_i and $r_i + \mathrm{d}r_i$ becomes the shell between r_f and $r_f + \mathrm{d}r_f$ with the same mass: $4\pi r_i^2 \rho_i \, \mathrm{d}r_i = 4\pi r_f^2 \rho_f \, \mathrm{d}r_f$. Divide by $4\pi r_f^2 \mathrm{d}r_f$.
(4) From step (2), $\mathrm{d}r_f/\mathrm{d}r_i = (4-\gamma_i)\, r_f/r_i$, so $\mathrm{d}r_i/\mathrm{d}r_f = r_i/[(4-\gamma_i) r_f]$.
(5) Step (2) inverted, $r_i \propto r_f^{1/(4-\gamma_i)}$, and $\rho_i \propto r_i^{-\gamma_i}$. The exponent is $\frac{3-\gamma_i}{4-\gamma_i} - 3 = \frac{3-\gamma_i-12+3\gamma_i}{4-\gamma_i} = \frac{2\gamma_i-9}{4-\gamma_i}$.

Key idea: The dark-matter spike

A black hole that grows slowly inside a cusp $\rho \propto r^{-\gamma_i}$ compresses it into a **spike** $\rho_{\rm sp}(r) = \rho_{\rm sp}(r_{\rm sp}/r)^{\gamma_{\rm sp}}$ with $\gamma_{\rm sp} = (9-2\gamma_i)/(4-\gamma_i)$. An NFW cusp ($\gamma_i = 1$) gives $\gamma_{\rm sp} = 7/3$; the range $0 \le \gamma_i \le 2$ gives $2.25 \le \gamma_{\rm sp} \le 2.5$.

The circular-orbit argument is a sketch, but it gives the same exponent as the full calculation, which follows the whole phase-space distribution of the dark matter through the growth using all the adiabatic invariants [91], [81, eqs. (1)–(6)]. The full calculation changes two things that matter here.

The spike has a hole in the middle. General relativity adds one input to the Newtonian picture: a particle that falls in from far away with angular momentum per unit mass below $4GM/c$ has no turning point and crosses the horizon [92]. The circular orbit that carries exactly this angular momentum has radius $4GM/c^2 = 2r_h$ ($r_h = 2GM/c^2$), and no orbit is stable inside the innermost stable circular orbit (ISCO) at $6GM/c^2 = 3r_h$. A particle whose orbit dips below these radii is swallowed within one orbit, so the spike holds nothing there. The papers place the cutoff at $3r_h$ [77, Sec. II B], at $4GM/c^2$ [84], or smooth it with a factor $(1 - 2r_h/r)^{\gamma_{\rm sp}}$ [81, eq. (6)]. A fully relativistic calculation lets the spike reach closer to the hole and makes it denser there [92], [83, Sec. II].

The slope depends on how the dark matter moved before. Real orbits are not all circles. A particle on an eccentric orbit that started far out can spend part of its time deep inside, so the mass inside r_f collects contributions from many initial radii, and the one-to-one map $r_i \mapsto r_f$ of (T2.83) is lost. For an initially uniform core, Eda et al. quote the gentler $\rho \propto r^{-3/2}$ [77, Sec. II B]. The reason fits in one line. A core has nearly the same density of particles in phase space for all its slow particles, and slow growth does not change that phase-space density (Liouville's theorem with adiabatic invariants). After the growth, the particles bound at radius r have speeds up to the escape speed $v_{\rm esc} = \sqrt{2GM/r}$, so the density is that constant phase-space density times the volume $\frac{4}{3}\pi v_{\rm esc}^3$ of a ball in velocity space: $\rho \propto v_{\rm esc}^3 \propto r^{-3/2}$. The same exponent will appear for a wave falling freely into the hole, (T2.85) below, for a related reason: in both cases the speeds near the hole scale as $r^{-1/2}$. Finally, mergers with other black holes, or scattering off stars, can erase a spike altogether [84], which is why the slope $\gamma_{\rm sp}$ is treated as a parameter to measure rather than a prediction.

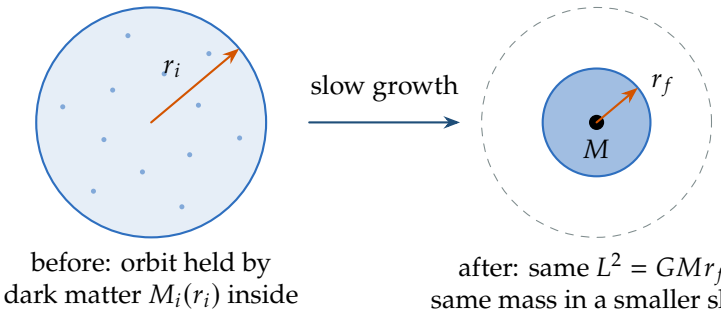

Figure T2.18: Adiabatic compression. Left: a dark-matter orbit of radius r_i in the original cusp, held by the dark matter inside it. Right: after the hole has grown, the same orbit, with the same angular momentum, sits at a smaller radius r_f (the dashed circle is the old one). The same mass now fills a smaller volume, so the density rises, more steeply the closer to the hole.

Fixing the normalisation. The slope says nothing about how high the spike is: (T2.83) is a proportionality. Eda et al. wanted a height fixed by the black-hole mass alone, so that a single number, M, would set the whole profile inside a given halo [77, Sec. II B]. They impose two

conditions. The first is continuity: the spike joins the NFW profile at the radius r_{sp} where it begins, so $\rho_{\mathrm{sp}} = \rho_{\mathrm{NFW}}(r_{\mathrm{sp}})$. The second needs the idea of a **radius of influence** r_{infl}, the radius out to which the black hole's gravity is comparable with that of the dark matter around it. The usual definition counts mass: r_{infl} is where the dark matter inside weighs twice the hole, $M_{\mathrm{DM}}(< r_{\mathrm{infl}}) = 2M$. Eda et al. then take the spike to occupy the inner fifth of that region, $r_{\mathrm{sp}} = 0.2\, r_{\mathrm{infl}}$ [77, eqs. (4)–(5)]. Both the factor 2 and the factor 0.2 are definitions, chosen to mark where the hole's influence ends; they are not consequences of a law, and a different choice moves the spike's height.

The condition in our notation. With $r_{\mathrm{infl}} = 5r_{\mathrm{sp}}$, the dark matter inside $5r_{\mathrm{sp}}$ is the spike from the inner cutoff r_{min} ($3r_h$ for Eda et al.) out to r_{sp}, plus the undisturbed NFW halo from r_{sp} to $5r_{\mathrm{sp}}$:

$$\underbrace{\frac{4\pi\rho_{\mathrm{sp}} r_{\mathrm{sp}}^{\gamma_{\mathrm{sp}}}}{3-\gamma_{\mathrm{sp}}}\left(r_{\mathrm{sp}}^{3-\gamma_{\mathrm{sp}}} - r_{\mathrm{min}}^{3-\gamma_{\mathrm{sp}}}\right)}_{\text{spike}} + \underbrace{M_{\mathrm{NFW}}(<5r_{\mathrm{sp}}) - M_{\mathrm{NFW}}(<r_{\mathrm{sp}})}_{\text{halo, from (T2.82)}} = 2M. \tag{T2.84}$$

The spike term is $\int_{r_{\mathrm{min}}}^{r_{\mathrm{sp}}} 4\pi r^2 \rho_{\mathrm{sp}} (r_{\mathrm{sp}}/r)^{\gamma_{\mathrm{sp}}} \mathrm{d}r$, done as for M_i above; the halo terms are step (2) of (T2.82) at the two radii. Since continuity fixes ρ_{sp} once r_{sp} is known, (T2.84) is one equation for one unknown, r_{sp}. The script `04_dm_profile.py` solves it by root finding:

Listing T2.6: The spike radius from the mass condition (`code/chT2/04_dm_profile.py`)

```
49 def mass_condition(rsp):
50     m_in = 4*np.pi * nfw(rsp) * rsp**gsp * (rsp**(3-gsp) - rmin**(3-gsp)) / (3-gsp)
51     return m_in + (M_nfw(5 * rsp) - M_nfw(rsp)) - 2 * M
52 rsp = brentq(mass_condition, 1e-4, 1e3)
53 rho_sp = nfw(rsp)
```

Line 50 is the spike term of (T2.84), with ρ_{sp} replaced by `nfw(rsp)` (continuity). Line 51 adds the halo term and subtracts $2M$, so the root of `mass_condition` is the r_{sp} we want. For the $10^4\, M_\odot$ hole in the $10^8\, M_\odot$ halo the root is $r_{\mathrm{sp}} = 3.759\,\mathrm{pc}$, and then $\rho_{\mathrm{sp}} = 2.269\, M_\odot\,\mathrm{pc}^{-3}$.

Coogan et al.'s shortcut. Coogan et al. keep $r_{\mathrm{sp}} = 0.2\, r_{\mathrm{infl}}$ and $M_{\mathrm{DM}}(< r_{\mathrm{infl}}) = 2M$ but count the mass with the spike power law alone, from the centre, and treat ρ_{sp} as a free parameter instead of tying it to a halo:

$$2M \overset{(1)}{=} \frac{4\pi\rho_{\mathrm{sp}} r_{\mathrm{sp}}^{\gamma_{\mathrm{sp}}}}{3-\gamma_{\mathrm{sp}}} r_{\mathrm{infl}}^{3-\gamma_{\mathrm{sp}}} \overset{(2)}{=} \frac{4\pi\rho_{\mathrm{sp}} r_{\mathrm{sp}}^{\gamma_{\mathrm{sp}}}}{3-\gamma_{\mathrm{sp}}} 5^{3-\gamma_{\mathrm{sp}}} r_{\mathrm{sp}}^{3-\gamma_{\mathrm{sp}}} \quad\Rightarrow\quad r_{\mathrm{sp}} \overset{(3)}{=} \left[\frac{(3-\gamma_{\mathrm{sp}})\, 0.2^{3-\gamma_{\mathrm{sp}}} M}{2\pi\rho_{\mathrm{sp}}}\right]^{1/3}.$$

(1) The spike mass inside r_{infl}, the spike term of (T2.84) with $r_{\mathrm{min}} \to 0$ and upper limit r_{infl}.
(2) $r_{\mathrm{infl}} = 5r_{\mathrm{sp}}$.
(3) The powers of r_{sp} add to r_{sp}^3; divide by $4\pi\rho_{\mathrm{sp}} 5^{3-\gamma_{\mathrm{sp}}}/(3-\gamma_{\mathrm{sp}})$, and $1/5 = 0.2$.

This is their formula for r_{sp} [84, eq. (2)]. The two rules side by side:

	Eda et al.	Coogan et al.
height ρ_{sp}	$\rho_{\mathrm{NFW}}(r_{\mathrm{sp}})$ (continuity)	free parameter
mass inside $5r_{\mathrm{sp}}$	spike above $3r_h$ + NFW, (T2.84)	spike power law from $r = 0$
result	$r_{\mathrm{sp}} = 3.759\,\mathrm{pc}$ ($M = 10^4\, M_\odot$, our halo)	$r_{\mathrm{sp}} = 0.54\,\mathrm{pc}$ ($M = 10^3\, M_\odot$, $\rho_{\mathrm{sp}} = 226\, M_\odot\,\mathrm{pc}^{-3}$)

Example: why Coogan et al. use ρ_6. With their rule, $\rho_{\rm sp}$ is a poor parameter for a measurement. Write $r_{\rm sp} = (kM/\rho_{\rm sp})^{1/3}$ with $k = (3-\gamma_{\rm sp})0.2^{3-\gamma_{\rm sp}}/2\pi$. The density at a fixed radius r is

$$\rho(r) \overset{(1)}{=} \rho_{\rm sp}\Big(\frac{r_{\rm sp}}{r}\Big)^{\gamma_{\rm sp}} \overset{(2)}{=} \rho_{\rm sp}\Big(\frac{kM}{\rho_{\rm sp}}\Big)^{\gamma_{\rm sp}/3} r^{-\gamma_{\rm sp}} \overset{(3)}{=} \rho_{\rm sp}^{1-\gamma_{\rm sp}/3}(kM)^{\gamma_{\rm sp}/3}\, r^{-\gamma_{\rm sp}}.$$

(1) The spike profile.
(2) Insert $r_{\rm sp}$.
(3) Collect powers of $\rho_{\rm sp}$: $\rho_{\rm sp}^{1} \cdot \rho_{\rm sp}^{-\gamma_{\rm sp}/3}$.

For $\gamma_{\rm sp} = 7/3$ the exponent is $1 - \frac{7}{9} = \frac{2}{9}$: the density felt by the binary grows only as $\rho_{\rm sp}^{2/9}$, so a factor of ten in $\rho_{\rm sp}$ moves the density at the orbit by $10^{2/9} \approx 1.7$. The gravitational wave only senses the density near the orbit, at 10^{-8}–10^{-7} pc for these systems. So Coogan et al. parametrise the spike by ρ_6, the density at the fixed radius $r_6 = 10^{-6}$ pc close to the orbits, $\rho = \rho_6(r_6/r)^{\gamma_{\rm sp}}$ [84, eqs. (3)–(4)].

Their benchmark in the new parameter. For $m_1 = 10^3\,M_\odot$ and $\rho_{\rm sp} = 226\,M_\odot\,{\rm pc}^{-3}$, their rule gives $r_{\rm sp} = [\frac{2}{3} \times 0.2^{2/3} \times 10^3/(2\pi \times 226)]^{1/3}\,{\rm pc} = 0.544\,{\rm pc}$, and then

$$\rho_6 = \rho_{\rm sp}\Big(\frac{r_{\rm sp}}{r_6}\Big)^{\gamma_{\rm sp}} = 226 \times \left(5.44 \times 10^5\right)^{7/3} M_\odot\,{\rm pc}^{-3} = 5.45 \times 10^{15}\,M_\odot\,{\rm pc}^{-3}.$$

Why a pivot radius helps. Suppose the data fix the density $\rho(r_o)$ at the orbit, $r_o \approx 10^{-8}$ pc, and nothing else. Write the profile through an amplitude ρ_A at some radius r_A, $\ln\rho(r_o) = \ln\rho_A + \gamma_{\rm sp}\ln(r_A/r_o)$. Holding $\ln\rho(r_o)$ fixed, a change $\delta\gamma$ of the slope must be compensated by $\delta\ln\rho_A = -\ln(r_A/r_o)\,\delta\gamma$. With the amplitude at $r_A = r_{\rm sp} \approx 0.5$ pc the lever arm is $\ln(5\times10^7) \approx 18$: a slope uncertainty of 0.01 drags the amplitude by 18%, and the two are almost perfectly correlated. With the amplitude at $r_A = r_6$ the lever arm is $\ln 100 \approx 4.6$, four times shorter, and the correlation is correspondingly weaker. Moving r_A all the way to the place where the data carry their information would remove it entirely. This is the choice of a pivot scale in cosmology, and the straight-line example of Section 10.4.3 shows that the decorrelating pivot sits at the information-weighted mean of the variable along which the line is drawn; Chapter 10 reads these correlations off a Fisher matrix.

T2.9.3 Ultralight dark matter: a wave falling into the hole

If dark matter is a very light boson of mass μ, its quantum nature can show on astrophysical scales. Two comparisons of lengths decide when.

Particle or wave? A particle of momentum μv is also a wave of de Broglie wavelength $\lambda_{\rm dB} = 2\pi\hbar/(\mu v)$, and a wave cannot be squeezed into a region smaller than its wavelength. If $\lambda_{\rm dB}$ is much shorter than the region r we look at, the wave can be built into packets much smaller than r that move like particles along orbits; if it is longer, there is no way to say where along the orbit the dark matter is, and only the wave description makes sense. Up to the factor 2π, the dividing line is $\mu v r/\hbar \sim 1$: particles for $\mu v r/\hbar \gg 1$, a wave otherwise.

Does the wave see the horizon? The second length is the Compton wavelength $\hbar/(\mu c)$, the wavelength of the field's oscillation in time, to be compared with the size r_h of the hole. A wave meets the hole roughly as light meets an obstacle. If its wavelength is much shorter than the obstacle, it behaves like a ray and simply falls in. If its wavelength is much longer, it hardly resolves the horizon: most of it is reflected by the gravitational potential around the hole, and only a small part is absorbed per encounter. The reflected wave interferes with the incoming one, and the density shows standing-wave nodes.

For the speed we take $v = 1000\,\mathrm{km\,s^{-1}}$, which is $c/300$. Near the hole the typical speed is not fixed; it grows inward as the orbital speed $\sqrt{GM/r}$ does, from the $\sim 10\,\mathrm{km\,s^{-1}}$ dispersion of a dwarf galaxy to near c at the horizon. A value of $c/300$ is near the top of the range of dispersions that Hui et al. consider around black holes [93, eq. (1.5)]; a smaller v only raises the boson mass at which the wave regime ends ($\mu \propto 1/v$ below) and moves the self-gravity radius outward ($r_{\mathrm{sg}} \propto 1/v^2$ below). The hole is the $10^4\,M_\odot$ one, for which $r_h = 9.571 \times 10^{-10}\,\mathrm{pc}$.

Example: where the wave regime begins. With $\hbar c = 1.97 \times 10^{-7}\,\mathrm{eV\,m}$ and $r_h = 2.95 \times 10^7\,\mathrm{m}$, the condition $\mu v r_h/\hbar = 1$ reads

$$\mu c^2 = \frac{\hbar c}{(v/c)\,r_h} = \frac{1.97 \times 10^{-7}\,\mathrm{eV\,m}}{3.3 \times 10^{-3} \times 2.95 \times 10^7\,\mathrm{m}} \approx 2 \times 10^{-12}\,\mathrm{eV},$$

and the code gives $2.003 \times 10^{-12}\,\mathrm{eV}$. Heavier dark matter is particle-like everywhere outside the hole. Dropping the factor v/c gives the mass at which the Compton wavelength equals the horizon, $\mu c^2 = \hbar c/r_h = 6.681 \times 10^{-15}\,\mathrm{eV}$. Hui et al. sort boson masses by this comparison [93, Sec. 1]. Above it the field falls straight into the hole. Below it, part of the wave is reflected near the hole and the profile develops nodes.

How far the black hole rules. Close to the hole its gravity dominates; far away the dark matter's own gravity does. The boundary, the **self-gravity radius** r_{sg}, is where the hole stops controlling the motion. The idea is to compare two energies per unit mass: the kinetic energy of the dark matter, of order v^2, and the depth of the hole's potential, GM/r. Far out $v^2 > GM/r$: the dark matter moves too fast for the hole to hold it, and its motion is set by the halo. Close in $GM/r > v^2$: the hole binds it. The boundary is where the two are equal. The virial theorem for dark matter of mass M_{sg} moving with dispersion v in the hole's potential says exactly this: $2\langle T\rangle + \langle V\rangle = M_{\mathrm{sg}}v^2 - GMM_{\mathrm{sg}}/r_{\mathrm{sg}} = 0$, so

$$r_{\mathrm{sg}} = \frac{GM}{v^2} = \frac{r_h}{2}\left(\frac{c}{v}\right)^2 = 4.5 \times 10^4\,r_h \qquad (v = 1000\,\mathrm{km\,s^{-1}}).$$

Hui et al. define the radius by $r_h/r_{\mathrm{sg}} = (v/c)^2$ [93, eq. (1.5)], that is $r_{\mathrm{sg}} = 2GM/v^2$, twice as large, about $10^5 r_h$. The factor 2 is the choice between the circular speed, $v^2 = GM/r$, and the escape speed, $v^2 = 2GM/r$, as the speed that marks the boundary; neither is more correct. We use the round value $r_{\mathrm{sg}} = 10^5 r_h$. How much does the choice matter? Inside r_{sg} the density follows $r^{-3/2}$ (below), and at r_{sg} it joins the spike $r^{-7/3}$. The density at an orbit inside r_{sg} is then $\rho_{\mathrm{sp}}(r_{\mathrm{sp}}/r_{\mathrm{sg}})^{7/3}(r_{\mathrm{sg}}/r)^{3/2} \propto r_{\mathrm{sg}}^{-5/6}$, so moving r_{sg} by a factor 2.2 changes the density at the orbit by $2.2^{5/6} \approx 1.9$. That is small next to the eighteen orders of magnitude we are explaining, and in the forecasts the overall density is a free parameter anyway. Inside r_{sg} the dark matter is a test field on the black-hole spacetime.

The field falling into the hole. *The question.* Hui et al. asked what a field of mass μ does once it is inside r_{sg}, where only the hole's gravity acts on it and the horizon swallows whatever reaches it [93, Sec. 2]. Hancock and Witek asked the same for a massive vector (Proca) field [94, Sec. V]. Their answer, for the heavier masses $\mu r_h \gtrsim 1$ ($\hbar = c = 1$ from here to the end of the paragraph), is [93, eq. (2.17)]

$$\chi(t, r) \propto r^{1/4}\, e^{-i\mu t}\, e^{-2i\mu\sqrt{r r_h}}, \tag{T2.85}$$

where $\chi = r\phi$ is r times the field ϕ. We now derive it far from the horizon, where gravity is weak.

Symbols. The field is complex, ϕ, and the physical (real) field is $\phi + \phi^*$. A field that oscillates as $e^{-i\mu t}$ is an oscillator of frequency μ, whose energy density is $\frac{1}{2}(\dot\phi^2_{\rm real} + \mu^2\phi^2_{\rm real}) = \frac{1}{2}\mu^2(2|\phi|)^2$, so $\rho \approx 2\mu^2|\phi|^2$ [93, eq. (2.12)], and $\rho \propto |\chi|^2/r^2$.

The equation. Far from the horizon the field's equation (the Klein–Gordon equation on the Schwarzschild spacetime) reduces to the Schrödinger equation for a particle of mass μ in the Newtonian potential $-GM/r = -r_h/(2r)$, with the fast factor $e^{-i\mu t}$ split off. Dark matter that starts at rest far away has zero energy in that equation, and for the spherically symmetric part of the field the usual substitution $\chi = r\phi$ removes the first derivative. The radial equation is

$$\chi'' + k(r)^2\chi = 0, \qquad k(r)^2 = 2\mu^2\,\frac{GM}{r} = \mu^2\,\frac{r_h}{r}. \tag{T2.86}$$

In words: $k(r) = \mu v_{\rm ff}$, with $v_{\rm ff} = \sqrt{2GM/r} = \sqrt{r_h/r}$ the speed of a particle dropped from rest far away. The local wavenumber is the de Broglie wavenumber of freely falling dark matter.

A slowly changing wave. Where k changes little over one wavelength, try a wave with a slowly varying amplitude $A(r)$ and a phase that accumulates the local wavenumber, $\chi = A\,e^{-iS}$ with $S' = k$:

$$\chi'' + k^2\chi \overset{(1)}{=} \big(A'' - 2iA'k - iAk' - Ak^2\big)e^{-iS} + k^2Ae^{-iS} \overset{(2)}{=} \big[A'' - i(2A'k + Ak')\big]e^{-iS} = 0,$$

$$\text{so}\quad 2A'k + Ak' \overset{(3)}{=} 0 \quad\Leftrightarrow\quad (A^2k)' = 0 \quad\Rightarrow\quad A \propto k^{-1/2} \overset{(4)}{=} r^{1/4}.$$

(1) Differentiate twice: $\chi' = (A' - iAk)e^{-iS}$, $\chi'' = (A'' - 2iA'k - iAk' - Ak^2)e^{-iS}$.
(2) The Ak^2 terms cancel.
(3) Drop A'', which is smaller than the kept terms by a factor of order $1/(kr)^2 = 1/(\mu^2 r r_h)$, small when $\mu r_h \gtrsim 1$ and $r \gg r_h$; the imaginary part must vanish. Multiplying by A shows $2AA'k + A^2k' = (A^2k)'$.
(4) $k \propto r^{-1/2}$, so $k^{-1/2} \propto r^{1/4}$.

The phase is the one the free-fall picture predicts:

$$S(r) = \int^r k(r')\,{\rm d}r' \overset{(1)}{=} \mu\sqrt{r_h}\int^r \frac{{\rm d}r'}{\sqrt{r'}} \overset{(2)}{=} 2\mu\sqrt{r r_h},$$

(1) $k = \mu v_{\rm ff}$ with $v_{\rm ff} = \sqrt{r_h/r'}$.
(2) $\int r'^{-1/2}{\rm d}r' = 2r^{1/2}$.

and with $e^{-i\mu t}$ restored, $e^{-i(\mu t + S)}$ has constant phase along $S = -\mu t + \text{const}$: as t grows, r shrinks. The wave moves *inward*, which is the only choice allowed when the horizon absorbs everything and nothing comes back out. This is (T2.85): amplitude $r^{1/4}$, phase $2\mu\sqrt{r r_h}$. So the field is dark matter falling freely into the hole.

The density, and a check. $\rho \propto |\chi|^2/r^2 \propto r^{1/2}/r^2 = r^{-3/2}$. The amplitude condition $(A^2k)' = 0$ has a direct meaning: $A^2k \propto |\chi|^2 v_{\rm ff} \propto r^2\rho\, v_{\rm ff}$ is the mass crossing a sphere per unit time, divided by 4π. So the same exponent follows from steady inflow without any wave equation: the flux $4\pi r^2\rho\, v_{\rm ff}$ must be the same at every radius, and $v_{\rm ff} \propto r^{-1/2}$ forces $\rho \propto r^{-3/2}$ [93, Sec. 4]. Hancock and Witek find the same $r^{-3/2}$ for the vector field, for every mode [94, Sec. VI A].

Joining the pieces. At $r_{\rm sg}$ the infall profile must take over from the spike with the same density, $\rho_{\rm sp}(r_{\rm sp}/r_{\rm sg})^{7/3}$. Inside, it falls as $r^{-3/2}$:

$$\rho(r) = \rho_{\rm sp}\Big(\frac{r_{\rm sp}}{r_{\rm sg}}\Big)^{7/3}\Big(\frac{r_{\rm sg}}{r}\Big)^{3/2} \qquad (r < r_{\rm sg}).$$

The resulting profile is piecewise: infall $\rho \propto r^{-3/2}$ inside $r_{\rm sg}$, spike $r^{-7/3}$ out to $r_{\rm sp}$, NFW beyond. For $\mu \lesssim 6.681 \times 10^{-15}$ eV the WKB step fails near the hole and the field must be found

numerically. Its density then oscillates on the scale of the de Broglie wavelength, and Hancock and Witek smooth it over a few radial periods before matching [94, eq. (69)]. The smoothed profile is spread out near the hole instead of sharply peaked [94].

Figure T2.19 shows the whole construction. At r_{sg} the spike has reached $1.190\times10^{11}\,M_\odot\,\mathrm{pc}^{-3}$. On the EMRI's orbit four years before the ISCO, at $30.09\,r_h$, the density is $2.279\times10^{16}\,M_\odot\,\mathrm{pc}^{-3}$, about 2.279×10^{18} times the local value. That is the enhancement the opening estimate called for.

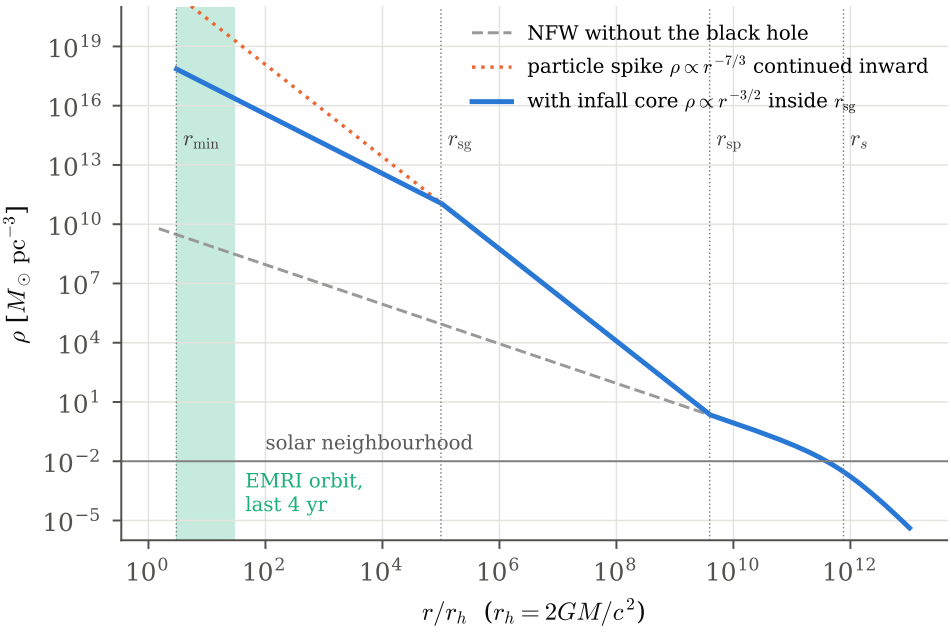

Figure T2.19: Dark matter around a $10^4\,M_\odot$ black hole in a $10^8\,M_\odot$ NFW halo. Without the hole the density would follow the grey dashed NFW profile. Slow growth of the hole turns the cusp inside r_{sp} into a $r^{-7/3}$ spike (dotted where continued inward). Inside the self-gravity radius $r_{sg}=10^5 r_h$ an ultralight field falls freely into the hole and the profile flattens to $r^{-3/2}$ (solid). The curves stop at $r_{min}=3r_h$: inside it nothing survives, the hole in the middle of the spike, and the density is zero. The green band is where the EMRI orbits during its last four years; the horizontal line is the density near the Sun.

Two further wave-dark-matter pictures. Kim et al. follow the adiabatic compression of a wave halo quantum mechanically [81]. Far from the hole the compressed wave halo looks like the particle spike, as expected when the wavelength is short. Close to it the picture changes, and the reason is the capture rule used above for particles. A wave component with angular-momentum quantum number l carries angular momentum $l\hbar$, that is $l\hbar/\mu$ per unit mass. A particle with less than $4GM/c$ per unit mass is swallowed, so the components with

$$l \lesssim l_{\mathrm{crit}} = \frac{4GM}{c}\cdot\frac{\mu}{\hbar} = \frac{2\mu c\, r_h}{\hbar}$$

fall into the hole, and over the age of the halo they are gone. A component of angular momentum l cannot come closer to the centre than the radius where its centrifugal barrier turns it back, a radius that grows with l. Once every component below l_{crit} has been absorbed, nothing is left to fill the region inside the turning radius of l_{crit}, and the density is cut off there [81, eq. (40)]. In the particle limit ($\mu r_h c/\hbar \gg 1$) l_{crit} is huge and the cutoff is the particle cutoff near 2–$3r_h$; for light bosons it moves out.

Chase et al. consider instead a virialised halo of ultralight *vector* dark matter made of many random waves [95]. The field oscillates at the frequency $\mu c^2/\hbar$, and its stress, which is quadratic in the field, oscillates at twice that, $\Omega = 2\mu c^2/\hbar$. Through Einstein's equations the stress makes the gravitational potential oscillate at Ω too. What the binary feels depends on the shape of that oscillation. For a scalar the oscillating stress is a pressure, the same in every direction; the oscillating pull on the companion is radial and the same at every point of a circular orbit, so it exerts no torque, and over many field oscillations its effect on the orbit averages to zero. A vector field points along a direction, its polarisation, so its stress is stronger along that axis. The oscillating tidal pull then depends on where the companion is on its orbit: a pattern with two maxima per turn, which exerts a torque proportional to $\sin 2(\omega t - \varphi_0)$ for orbital angular frequency ω and polarisation angle φ_0, and whose strength oscillates as $\cos \Omega t$. The product

$$\cos \Omega t \, \sin 2(\omega t - \varphi_0) = \tfrac{1}{2}\big[\sin\big((2\omega + \Omega)t - 2\varphi_0\big) + \sin\big((2\omega - \Omega)t - 2\varphi_0\big)\big]$$

averages to zero over many orbits unless $2\omega \approx \Omega$, when the second term stops oscillating. Away from that condition the pushes cancel; at it they add up, the way a swing responds only to pushes timed to its own period. This is the **resonance**, and the binary's phase changes mainly while its orbital frequency sweeps through it [95, Sec. V]. The effect is concentrated near one frequency, so, unlike friction and accretion (Section T2.10), it cannot be written as a single power of f.

T2.10 Environmental forces and the power law in the phase

Put the light companion of Section T2.4 (mass m_2, circling the heavy hole m_1, with $M = m_1 + m_2$) on its orbit inside the spike of Section T2.9. It moves at $v = \sqrt{GM/r}$, about $0.13c$ at $30r_h$, through dark matter of density $\rho(r)$. Three things happen. Its gravity focuses the dark matter it passes into a trailing wake, and the wake pulls it back: **dynamical friction**. It swallows the dark matter that comes close enough, and the swallowed matter has to be brought up to the companion's speed: **accretion**. And the dark matter inside the orbit adds to the central pull. The first two drain orbital energy on top of the gravitational waves, so the binary sweeps through frequency faster than in vacuum.

The question for the statistics is narrow: *for each effect, by how much does it speed up the sweep at frequency f, and what does that do to the Fourier phase $\Psi(f)$?* (Ψ is the phase of the stationary-phase signal of Section T2.5, $\tilde{h} = \mathcal{A} f^{-7/6} e^{-i\Psi}$.) The answer turns out to have the same form for all of them, a power of f added to the phase, and that is what makes a single, general forecast possible in Chapter 10.

T2.10.1 The forces

Dynamical friction. For a body of mass m_2 moving at speed v through collisionless matter of density ρ, Chandrasekhar's formula gives a drag

$$F_{\rm DF} = \frac{4\pi G^2 m_2^2 \, \rho \, \xi \ln \Lambda}{v^2} \tag{T2.87}$$

[96], [77, eq. (16)], [84, eq. (7)]. Every factor can be derived from one deflection.

One particle passing. Work in the companion's frame, where the dark matter streams past at speed v. Take first the simplest stream, every particle moving at exactly v. A particle of mass $m_{\rm dm} \ll m_2$ that would miss the companion by the **impact parameter** s (we write s, not the usual b, which is reserved for the ppE exponent below) is bent through an angle θ given by the Kepler hyperbola, $\tan(\theta/2) = Gm_2/(sv^2)$. Its speed far away is unchanged, only its direction

turns, so it loses forward momentum $m_{\rm dm} v(1-\cos\theta)$. That momentum goes to the companion and points along the stream, that is, against the companion's motion through the dark matter. The sideways kicks cancel between particles passing on opposite sides.

All the particles. Particles with impact parameter between s and $s+\mathrm{d}s$ arrive at the rate $(\rho/m_{\rm dm})\, v\, 2\pi s\, \mathrm{d}s$. With $s_{90} \equiv Gm_2/v^2$, the impact parameter that turns a particle through 90°,

$$F \overset{(1)}{=} \int \frac{\rho}{m_{\rm dm}}\, v\, 2\pi s\, \mathrm{d}s\; m_{\rm dm} v\,(1-\cos\theta) \overset{(2)}{=} 4\pi\rho v^2 s_{90}^2 \int_0^{s_{\rm max}} \frac{s\,\mathrm{d}s}{s^2+s_{90}^2}$$
$$\overset{(3)}{=} \frac{4\pi G^2 m_2^2 \rho}{v^2}\cdot\frac{1}{2}\ln\left(1+\frac{s_{\rm max}^2}{s_{90}^2}\right) \overset{(4)}{=} \frac{4\pi G^2 m_2^2\rho}{v^2}\,\ln\Lambda, \qquad \Lambda \equiv \frac{s_{\rm max}}{s_{90}}. \tag{T2.88}$$

(1) Momentum per particle times the rate of particles, summed over impact parameters. The mass $m_{\rm dm}$ cancels: only the density matters.
(2) $1-\cos\theta = 2\sin^2(\theta/2) = 2\tan^2(\theta/2)/[1+\tan^2(\theta/2)] = 2s_{90}^2/(s^2+s_{90}^2)$, using $\tan(\theta/2) = s_{90}/s$.
(3) $\int s\,\mathrm{d}s/(s^2+s_{90}^2) = \frac{1}{2}\ln(s^2+s_{90}^2)$; and $v^2 s_{90}^2 = G^2 m_2^2/v^2$.
(4) For $s_{\rm max} \gg s_{90}$, $\frac{1}{2}\ln(1+\Lambda^2) \approx \ln\Lambda$.

So each factor has a reason. One m_2 comes from the strength of each deflection and the other from the size s_{90} of the region where deflections are strong; the $1/v^2$ says a slow body has more time to bend each particle. The logarithm counts the e-folds of impact parameter between s_{90} and $s_{\rm max}$, each adding the same amount, so distant encounters matter as much as close ones and the integral must be cut off by hand. The lower end is $s_{\rm min} = s_{90}$, below which particles are turned right round and nothing more is gained; the upper end $s_{\rm max}$ is the size of the region in which the stream is a uniform flow, the orbit itself, $s_{\rm max} \sim r$.

Particles of all speeds. A real spike has particles with a spread of speeds. Chandrasekhar showed that for an isotropic distribution the particles faster than the body pull it, on average, equally forwards and backwards, and only those slower than v contribute. The factor ξ in (T2.87) is that fraction, $\xi = 4\pi\int_0^v f(u)u^2\,\mathrm{d}u$ for the distribution $f(u)$ of particle speeds. For the 7/3 spike, whose speeds are set by the hole's potential, it is about 0.58 [84]; papers that ignore the spread set it to one.

The size of the logarithm. On a circular orbit $v^2 = GM/r$, so $s_{90} = Gm_2/v^2 = r\,m_2/M$. With $s_{\rm max} = r$, $\Lambda \approx M/m_2 \approx m_1/m_2$. Coogan et al. take a more cautious $s_{\rm max} = \sqrt{r s_{90}}$, the geometric mean of the two ends, which halves the logarithm: $\ln\Lambda = \ln\sqrt{m_1/m_2}$ [84]. For the $10^3 + 1.4\,M_\odot$ IMRI that is 3.286 against 6.6; others take about 3 [77]. Only the logarithm enters, so this factor of two is the size of the uncertainty in the prescription. *Check at* $30r_h$. There $v^2/c^2 = r_h/(2r) = 1/60$, so $s_{90} = Gm_2/v^2 = \frac{1}{2}(2Gm_2/c^2)(c/v)^2 = 30$ Schwarzschild radii of the companion: the deflections that build the logarithm happen well outside the companion's own horizon, where the Newtonian hyperbola is a fair description. The power the friction removes is $P_{\rm DF} = F_{\rm DF}\, v$.

Friction on a wave. If the dark matter is a wave (Section T2.9), a wake smaller than its wavelength cannot form. The force keeps the form of (T2.87), with $\xi\ln\Lambda$ replaced by a function of kr, where $k = \mu v/\hbar$ is the dark matter's wavenumber [97, eq. (D14)], [81, eq. (42)]:

$$F_{\rm DF}^{\rm wave} = \frac{4\pi G^2 m_2^2 \rho\, C_w(kr)}{v^2}, \qquad C_w(kr) = \mathrm{Cin}(2kr) - 1 + \frac{\sin 2kr}{2kr}, \qquad \mathrm{Cin}(z) = \int_0^z \frac{1-\cos t}{t}\,\mathrm{d}t. \tag{T2.89}$$

Hui and Ostriker obtain it by solving the scattering of the wave by the companion and summing the momentum carried off by its partial waves. The integral shows why it is a softened Coulomb

logarithm. Its variable t measures distance in units of the reduced wavelength. Far beyond a wavelength, $\cos t$ oscillates and averages away, and the integrand is $1/t$, the integrand $\mathrm{d}s/s$ of $\ln\Lambda$. Within a wavelength the interference of the wave ($1-\cos t \approx t^2/2$) kills the integrand. So Cin is a Coulomb logarithm whose lower cutoff is the wavelength instead of s_{90}, and whose upper cutoff is the orbit, $z = 2kr$; the terms $-1+\sin z/z$ come from the finite size of the region.

Its two limits tell the story. For a short wavelength, $kr \gg 1$, split off the logarithm: $\mathrm{Cin}(z) = \gamma_E + \ln z - \mathrm{Ci}(z)$, where $\gamma_E = 0.577$ is Euler's constant and $\mathrm{Ci}(z) = -\int_z^\infty \cos t\,\mathrm{d}t/t$ is a decaying oscillation, of size $|\sin z|/z$ for large z. Both $\mathrm{Ci}(z)$ and $\sin z/z$ go to zero, so $C_w \to \ln(2kr) + \gamma_E - 1$: a Coulomb logarithm with $s_{\max} \sim r$ and $s_{\min} \sim 1/k$, the particle result. For a long wavelength, $z = 2kr \ll 1$,

$$C_w \overset{(1)}{=} \left(\frac{z^2}{4} - \frac{z^4}{96}\right) - 1 + \left(1 - \frac{z^2}{6} + \frac{z^4}{120}\right) + O(z^6) \overset{(2)}{=} \frac{z^2}{12} + O(z^4) = \frac{(kr)^2}{3} + O\big((kr)^4\big),$$

(1) Expand $1-\cos t = t^2/2 - t^4/24$, so $\mathrm{Cin}(z) = z^2/4 - z^4/96$; and $\sin z/z = 1 - z^2/6 + z^4/120$.
(2) The constants cancel and $\frac{1}{4} - \frac{1}{6} = \frac{1}{12}$; with $z = 2kr$, $z^2/12 = (kr)^2/3$.

so friction is suppressed as $(kr)^2$ when the wavelength exceeds the orbit. Figure T2.20 shows both limits; at $kr = 0.1$ the small-kr form is already accurate to 0.8254%. This suppression, together with the lower density near the hole, is why wave-like dark matter dephases the inspiral less than particle dark matter of the same mass density [81, Sec. III D].

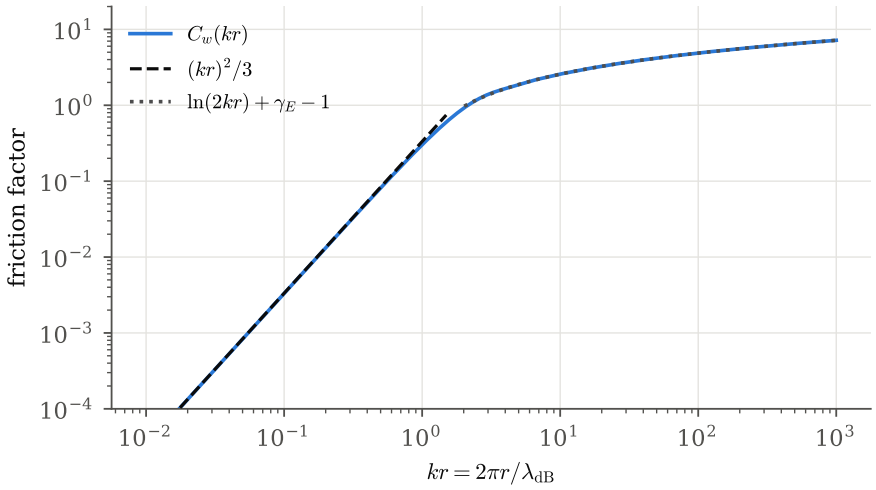

Figure T2.20: The friction factor of a wave-like medium as a function of $kr = 2\pi r/\lambda_{\mathrm{dB}}$. When the de Broglie wavelength is longer than the orbit ($kr \ll 1$) friction is suppressed as $(kr)^2/3$ (dashed); when it is shorter, the factor grows like the Coulomb logarithm of particle dark matter (dotted).

Accretion. How much dark matter does the companion swallow? In its own rest frame the dark matter streams in at speed v, each particle with angular momentum per unit mass $L = sv$ about the companion. General relativity supplies one fact: a particle arriving from far away with L below $L_{\mathrm{crit}} = 4Gm_2/c$ meets no centrifugal barrier and crosses the horizon (the same capture rule that cuts off the spike near the central hole, Section T2.9). Setting $sv = L_{\mathrm{crit}}$ gives the capture radius and the cross-section,

$$s_{\mathrm{cap}} = \frac{4Gm_2}{cv}, \qquad \sigma = \pi s_{\mathrm{cap}}^2 = \frac{16\pi G^2 m_2^2}{c^2 v^2}.$$

The mass swallowed per unit time is the mass flux through that area, $\dot{m} = \rho v \sigma = 16\pi G^2 m_2^2 \rho/(c^2 v)$. Now go back to the frame of the spike. There the dark matter is (on average) at rest, and after

capture it moves with the companion at speed v. The companion must supply that momentum, $\dot{m}\,v$ per unit time: a drag force $F_{\rm acc} = \dot{m}\,v$ and a power $P_{\rm acc} = \dot{m}v^2$. The ratio $s_{\rm cap}/s_{90} = 4v/c$ is about 0.5 at $30r_h$: the particles swallowed are a subset of those strongly deflected, which is why accretion comes out as a correction to friction. Compared with friction,

$$\frac{P_{\rm acc}}{P_{\rm DF}} = \frac{16\pi G^2 m_2^2 \rho\, v/c^2}{4\pi G^2 m_2^2 \rho \ln\Lambda/v} = \frac{4v^2}{c^2\ln\Lambda} = \frac{2r_h}{r\ln\Lambda}, \tag{T2.90}$$

using $v^2 = GM/r = c^2 r_h/(2r)$ and $\xi = 1$. With $\ln\Lambda = 3$ this is 0.02222 at $30r_h$ and 0.2222 at the ISCO. Accretion of collisionless dark matter is a relativistic correction to friction. Kim et al. check this for their binaries: over the last five years the companion's mass grows by only about one part in 10^4 [81, Sec. IV A]. For gas, which is collisional, the Bondi–Hoyle–Lyttleton rate $\dot{m} \propto \rho/v^3$ applies instead, and accretion then scales exactly like friction [87, Sec. X].

The gravitational pull. The dark matter inside the orbit adds to the central mass. For the spike $\rho = \rho_6(r_6/r)^\gamma$ (with $\gamma < 3$) it weighs

$$M_{\rm DM}(<r) = \int_0^r 4\pi r'^2 \rho_6 \Big(\frac{r_6}{r'}\Big)^\gamma \mathrm{d}r' = \frac{4\pi\rho_6 r_6^\gamma}{3-\gamma}\, r^{3-\gamma}.$$

By the shell theorem, a spherical mass inside the orbit pulls like a point mass at the centre, so Kepler's law holds with $M_{\rm tot} = M + M_{\rm DM}(<r)$ in place of M [83, eqs. (9)–(11)]. This removes no energy, but it changes the relation between the frequency and the orbit. How much does it change the chirp? Hold the gravitational-wave frequency f fixed, with $\omega = \pi f$, and treat $M_{\rm DM}$ as a constant addition to the central mass over the small range of radii near the current orbit. Each quantity in the chirp rate is a power of $M_{\rm tot}$:

$$r \overset{(1)}{=} \Big(\frac{GM_{\rm tot}}{\pi^2 f^2}\Big)^{1/3} \propto M_{\rm tot}^{1/3}, \qquad E \overset{(2)}{=} -\frac{GM_{\rm tot}\mu}{2r} = -\frac{\mu}{2}(\pi G M_{\rm tot} f)^{2/3} \propto M_{\rm tot}^{2/3},$$

$$P_{\rm GW} \overset{(3)}{=} \frac{32}{5}\frac{G}{c^5}\mu^2 r^4 \omega^6 \propto M_{\rm tot}^{4/3}, \qquad \frac{\dot{f}}{\dot{f}_{\rm V}} \overset{(4)}{=} \frac{P_{\rm GW}/|\mathrm{d}E/\mathrm{d}f|}{(\dots)_{M_{\rm tot}=M}} = \Big(1+\frac{M_{\rm DM}}{M}\Big)^{2/3} \approx 1 + \frac{2}{3}\frac{M_{\rm DM}(<r)}{M}.$$

(1) Kepler's law, $\omega^2 = GM_{\rm tot}/r^3$.
(2) The binding energy (T2.41) with $M \to M_{\rm tot}$; $\mathrm{d}E/\mathrm{d}f$ scales the same way.
(3) The quadrupole power at fixed ω depends on $M_{\rm tot}$ only through r^4.
(4) The chirp rate of (T2.43) is $P_{\rm GW}/|\mathrm{d}E/\mathrm{d}f| \propto M_{\rm tot}^{4/3-2/3}$; expand for $M_{\rm DM} \ll M$.

So the pull speeds up the chirp by the fraction

$$\epsilon_{\rm pull} = \frac{2}{3}\frac{M_{\rm DM}(<r)}{M} = \frac{8\pi\rho_6 r_6^\gamma}{3(3-\gamma)M}\, r^{3-\gamma} \propto f^{-2(3-\gamma)/3},$$

using $r \propto f^{-2/3}$. The coefficient $\frac{2}{3}$ is leading order only, because $M_{\rm DM}(<r)$ itself changes as the orbit shrinks; the exponent does not depend on that. Friction usually matters more [87, Sec. IX].

T2.10.2 From an extra power to a power law in the phase

The fractional extra power. Throughout, f is the gravitational-wave frequency, twice the orbital one, $f = \omega/\pi$ (T2.24). Friction drains energy slowly, so at each moment the orbit is still a circle obeying Kepler's law, and its energy at frequency f is the vacuum $E(f)$ of (T2.41); only the rate at which it moves through these energies changes. Energy balance now reads

$\mathrm{d}E/\mathrm{d}t = -(P_{\rm GW} + P_{\rm DF})$, with $P_{\rm GW}$ the quadrupole power of a circular binary (T2.27). As in (T2.43),

$$\dot f \overset{(1)}{=} -\frac{P_{\rm GW}+P_{\rm DF}}{\mathrm{d}E/\mathrm{d}f} \overset{(2)}{=} \frac{P_{\rm GW}}{|\mathrm{d}E/\mathrm{d}f|}\left(1+\frac{P_{\rm DF}}{P_{\rm GW}}\right) \overset{(3)}{=} \dot f_{\rm V}\left[1+\epsilon(f)\right], \qquad \epsilon \equiv \frac{P_{\rm DF}}{P_{\rm GW}}, \tag{T2.91}$$

(1) $\mathrm{d}E/\mathrm{d}t = (\mathrm{d}E/\mathrm{d}f)\,\dot f$, since E depends on time only through f.
(2) $\mathrm{d}E/\mathrm{d}f < 0$; factor out $P_{\rm GW}$.
(3) The first factor is the vacuum rate $\dot f_{\rm V}$ of (T2.43).

This is the energy balance of Kim et al. [81, eq. (36)]. For friction in a spike $\rho = \rho_6 (r_6/r)^\gamma$ (here and below γ is the spike slope $\gamma_{\rm sp}$ of Section T2.9, and ρ_6 the density at $r_6 = 10^{-6}$ pc),

$$\epsilon \overset{(1)}{=} \frac{4\pi G^2 m_2^2 \rho\, \xi \ln\Lambda/v}{\frac{32}{5}G^4 M (m_1 m_2)^2/(c^5 r^5)} \overset{(2)}{=} \frac{5\pi c^5 \xi \ln\Lambda}{8 G^{5/2} M^{3/2} m_1^2}\, \rho(r)\, r^{11/2} \overset{(3)}{=} c_f\, f^{-n}, \qquad n = \frac{11-2\gamma}{3}. \tag{T2.92}$$

(1) $P_{\rm DF} = F_{\rm DF} v$ from (T2.87); $P_{\rm GW} = \frac{32}{5}(G/c^5)\mu^2 r^4 \omega^6 = \frac{32}{5} G^4 M^3 \mu^2/(c^5 r^5)$ by Kepler, and $M^3\mu^2 = M(m_1 m_2)^2$ [84, eq. (6)].
(2) m_2^2 cancels, and $1/v = r^{1/2}(GM)^{-1/2}$. The result $\epsilon \propto \rho r^{11/2}$ is [83, eq. (16)].
(3) Insert $\rho = \rho_6 r_6^\gamma r^{-\gamma}$, so $\rho r^{11/2} = \rho_6 r_6^\gamma\, r^{11/2-\gamma}$, and trade the radius for the gravitational-wave frequency with Kepler's law, $r = (GM/\pi^2 f^2)^{1/3}$: $r^{11/2-\gamma} = (GM/\pi^2)^{(11/2-\gamma)/3} f^{-\frac{2}{3}(\frac{11}{2}-\gamma)}$, and $\frac{2}{3}(\frac{11}{2}-\gamma) = \frac{11-2\gamma}{3} = n$.

Collecting the constants of step (3),

$$c_f = \frac{5\pi c^5 \xi \ln\Lambda}{8 G^{5/2} M^{3/2} m_1^2}\, \rho_6 r_6^\gamma \left(\frac{GM}{\pi^2}\right)^{(11/2-\gamma)/3}, \tag{T2.93}$$

with units of Hz^n, so that $c_f f^{-n}$ is a pure number; the f in $c_f f^{-n}$ is the gravitational-wave frequency. Friction and radiation remove energy equally fast where $\epsilon = 1$, at $f_{\rm eq} \equiv c_f^{1/n}$. The same step works for any effect whose power, relative to the gravitational-wave power, varies as a power of the radius: $P_{\rm env}/P_{\rm GW} \propto r^p$ gives $\epsilon \propto f^{-2p/3}$. Since $P_{\rm GW} \propto r^{-5}$ falls so steeply with radius, nearly every environmental effect has $p > 0$: it matters most early in the inspiral, at low frequency.

The phase. Recall why the chirp rate controls the Fourier phase. The slope of the phase is the arrival time of each frequency, $\mathrm{d}\Psi/\mathrm{d}f = 2\pi t(f)$, and differentiating once more turns $\mathrm{d}t/\mathrm{d}f$ into $1/\dot f$: the curvature of the phase is $2\pi/\dot f$ (T2.53), derived with the stationary-phase approximation in Section T2.5. A binary that sweeps faster spends less time at each frequency, and the phase bends less. With (T2.91), and $\dot f_{\rm V} = K f^{11/3}$, $K = \frac{96}{5}\pi^{8/3}(G\mathcal{M}/c^3)^{5/3}$,

$$\begin{aligned}
\frac{\mathrm{d}^2\Psi}{\mathrm{d}f^2} &\overset{(1)}{=} \frac{2\pi}{\dot f_{\rm V}(1+\epsilon)} \overset{(2)}{=} \frac{2\pi}{\dot f_{\rm V}} - \frac{2\pi c_f}{K} f^{-11/3-n} + O(\epsilon^2), \\
\delta\Psi(f) &\overset{(3)}{=} -\frac{2\pi c_f}{K\,(n+\frac{8}{3})(n+\frac{5}{3})} f^{-5/3-n} + C_0 + C_1 f \overset{(4)}{=} \beta\, u^b, \qquad u \equiv \frac{\pi G\mathcal{M} f}{c^3}, \quad b = -\frac{5}{3} - n.
\end{aligned} \tag{T2.94}$$

(1) (T2.53) with (T2.91).
(2) $1/(1+\epsilon) = 1 - \epsilon + \ldots$ for $\epsilon \ll 1$; the first term gives the vacuum phase (T2.54), the second is the change, with $\epsilon/f^{11/3} = c_f f^{-11/3-n}$.

(3) Integrate twice: $f^{-11/3-n} \to f^{-8/3-n}/(-\frac{8}{3}-n) \to f^{-5/3-n}/[(\frac{8}{3}+n)(\frac{5}{3}+n)]$. The two integration constants $C_0 + C_1 f$ have the form of a shift of ϕ_c and of t_c in (T2.54), so they are absorbed there (Section T2.4.3).
(4) Rewrite $f = u\,c^3/(\pi G\mathcal{M})$, so $f^{-5/3-n} = u^b(\pi G\mathcal{M}/c^3)^{5/3+n}$; all constants go into β. u is the reduced frequency of (T2.58).

The amplitude, written out, is

$$\beta = -\frac{2\pi c_f}{K\,(n+\frac{8}{3})(n+\frac{5}{3})}\Big(\frac{\pi G\mathcal{M}}{c^3}\Big)^{5/3+n} = -\frac{5}{48}\,\frac{c_f\,(\pi G\mathcal{M}/c^3)^n}{(n+\frac{8}{3})(n+\frac{5}{3})},$$

using $2\pi(\pi G\mathcal{M}/c^3)^{5/3}/K = \frac{10\pi}{96}\pi^{5/3-8/3} = \frac{5}{48}$. It is proportional to c_f, hence to the density ρ_6 of the spike, and the combination $c_f(\pi G\mathcal{M}/c^3)^n$ is a pure number. A check: for $n = 0$ the environment speeds the chirp up by a constant fraction c_f, which by step (2) multiplies the Newtonian term $\frac{3}{128}u^{-5/3}$ of (T2.54) by $1 - c_f$; and indeed $-\frac{5}{48}c_f/(\frac{8}{3}\cdot\frac{5}{3}) = -\frac{3}{128}c_f$.

Key idea: Environments are power laws in the phase

If an environment adds a power $P_{\rm env}$ with $P_{\rm env}/P_{\rm GW} = c_f f^{-n} \ll 1$, the Fourier phase gains $\delta\Psi = \beta u^b$ with $u = \pi G\mathcal{M}f/c^3$ and $b = -5/3 - n$; the amplitude β carries the strength of the effect and the exponent b its physics. For dynamical friction in a spike $\rho \propto r^{-\gamma}$, $b = (2\gamma - 16)/3$; for $\gamma = 7/3$, $b = -34/9 \approx -3.78$.

This is the parametrised post-Einsteinian (ppE) phase term βu^b of (T2.70), now with a definite exponent: the general rule (T2.69) with $p = -3n$ gives the same $b = -\frac{5}{3} - n$. In the post-Newtonian counting of Section T2.6, a correction of relative size $(v/c)^{2k}$ is of order kPN, and on a circular orbit $(v/c)^2 = (\pi GMf/c^3)^{2/3} \propto f^{2/3}$. So $f^{-n} \propto [(v/c)^2]^{-3n/2}$, and $\epsilon \propto f^{-n}$ is a correction of order $-\frac{3}{2}n$ PN, so friction in a uniform medium ($\gamma = 0$, $n = 11/3$) is a -5.5PN effect. The dissipative effects, friction and accretion in any spike with $\gamma < 3$, have $b < -7/3$: they act more strongly at low frequency than the dipole radiation ($b = -7/3$) and the massive graviton ($b = -1$) of Section T2.6. In the Fisher matrix of Chapter 10 this is what separates them from the chirp mass, whose own phase term goes as $u^{-5/3}$: two terms with different powers of f are hard to mimic with one another.

The time-domain dephasing. Papers on environments usually plot a different phase: the number of radians the wave still has to go through before coalescence. Its phase advances at the rate $2\pi f$, so between frequency f and coalescence at f_c

$$\Phi(f) = 2\pi\int_t^{t_c} f(t')\,\mathrm{d}t' = 2\pi\int_f^{f_c}\frac{f'}{\dot f(f')}\,\mathrm{d}f',$$

changing the variable from time to frequency with $\mathrm{d}t' = \mathrm{d}f'/\dot f$. The **dephasing** is the vacuum phase still to come minus the phase still to come in the environment, $\Delta\Phi(f) = \Phi_{\rm V}(f) - \Phi(f)$ [81, eq. (49)]; $\Phi_{\rm V}$ is the Φ of Section T2.5 for the Newtonian chirp. A faster sweep leaves fewer cycles, so $\Delta\Phi > 0$.

Why two phases? $\Delta\Phi$ is the size that is easy to feel: it counts the radians of wave the environment removes, and once it reaches about a radian a vacuum template is visibly out of step with the signal. The Fisher matrix and the likelihood work in the frequency domain, with the phase Ψ of the template; there part of $\Delta\Phi$ is absorbed by adjusting the arrival time t_c and the phase ϕ_c, which are fitted anyway. So the two answer different questions, and we compute both.

With (T2.91) and $\dot f_{\rm V} = K f^{11/3}$,

$$\Delta\Phi(f) \overset{(1)}{=} 2\pi \int_f^\infty \frac{f'}{K f'^{11/3}}\Big(1 - \frac{1}{1 + c_f f'^{-n}}\Big)\mathrm{d}f' \overset{(2)}{=} \frac{2\pi c_f}{K}\int_f^\infty f'^{-8/3-n}\mathrm{d}f'$$
$$\overset{(3)}{=} \frac{2\pi c_f}{K}\,\frac{f^{-5/3-n}}{\frac{5}{3}+n} \overset{(4)}{=} \frac{5\,c_f f^{-n}}{2(8-\gamma)}\,\Phi_{\rm V}(f). \tag{T2.95}$$

(1) The difference of the two phase integrals, $1/\dot f_{\rm V} - 1/\dot f = \frac{1}{\dot f_{\rm V}}\big(1 - \frac{1}{1+\epsilon}\big)$, with the upper limit f_c sent to infinity (justified below).

(2) $1 - 1/(1+\epsilon) \approx \epsilon = c_f f'^{-n}$ for $\epsilon \ll 1$.

(3) $\int_f^\infty f'^{-8/3-n}\mathrm{d}f' = f^{-5/3-n}/(\frac{5}{3}+n)$.

(4) $\Phi_{\rm V} = \frac{2\pi}{K}\cdot\frac{3}{5}f^{-5/3}$, so the ratio is $\frac{5}{3}c_f f^{-n}/(\frac{5}{3}+n) = 5c_f f^{-n}/(5+3n)$, and $5+3n = 16-2\gamma$.

The upper limit. The integrand of $\Delta\Phi$ falls as $f'^{-8/3-n}$, so the part beyond f_c is a fraction $(f/f_c)^{5/3+n}$ of the whole. For the IMRI, with f_c the ISCO frequency of about 4.4 Hz and f the 21.7 mHz at which the four-year window opens, that fraction is about 2×10^{-9} for $\gamma = 7/3$, and smaller still for the other slopes. Integrating to infinity, as here, and stopping at the ISCO, as the script does, give the same numbers to that accuracy.

This is the high-frequency limit quoted by Coogan et al. [84, eq. (16)], and it has the same exponent $-5/3-n$ as $\delta\Psi$. The two coefficients compare in one line: from (T2.94) and (T2.95),

$$\frac{\delta\Psi}{\Delta\Phi} = \frac{-2\pi c_f/[K(n+\frac{8}{3})(n+\frac{5}{3})]}{2\pi c_f/[K(n+\frac{5}{3})]} = -\frac{1}{n+\frac{8}{3}} \qquad (f \gg f_{\rm eq}),$$

and for $n = 0$ (a constant fractional speed-up) this is the factor $\frac{3}{8}$ between the two kinds of phase found in Section T2.5. The sign only records that $\Delta\Phi$ is defined as vacuum minus environment.

Without the expansion. Step (2) needs $\epsilon \ll 1$, i.e. $f \gg f_{\rm eq}$. The integral can also be done exactly. Write the geometric series $1/(1+\epsilon) = \sum_k (-\epsilon)^k$ and integrate term by term:

$$\Phi(f) \overset{(1)}{=} \frac{2\pi}{K}\sum_{k=0}^{\infty}(-c_f)^k \int_f^\infty f'^{-8/3-kn}\mathrm{d}f'$$
$$\overset{(2)}{=} \Phi_{\rm V}(f)\sum_{k=0}^{\infty}\frac{a}{a+k}\big(-c_f f^{-n}\big)^k$$
$$\overset{(3)}{=} \Phi_{\rm V}(f)\;{}_2F_1\big(1, a; 1+a; -c_f f^{-n}\big), \qquad a \equiv \frac{5}{3n}. \tag{T2.96}$$

(1) $\Phi = 2\pi\int_f^\infty f'/\dot f\,\mathrm{d}f'$ with $\dot f = K f'^{11/3}(1 + c_f f'^{-n})$.

(2) $\int_f^\infty f'^{-8/3-kn}\mathrm{d}f' = f^{-5/3-kn}/(\frac{5}{3}+kn)$; factoring out the $k=0$ term, which is $\Phi_{\rm V}$, leaves $\frac{5/3}{5/3+kn} = \frac{a}{a+k}$.

(3) The **Pochhammer symbol** is the rising product $(x)_k = x(x+1)\cdots(x+k-1)$, with $(x)_0 = 1$. In $\frac{(a)_k}{(1+a)_k} = \frac{a(a+1)\cdots(a+k-1)}{(a+1)\cdots(a+k)}$ every factor but the first on top and the last below cancels, leaving $\frac{a}{a+k}$. The **hypergeometric function** is the series ${}_2F_1(\alpha,\beta;\gamma';z) = \sum_k \frac{(\alpha)_k(\beta)_k}{(\gamma')_k\,k!}z^k$; with $\alpha = 1$, $(1)_k = k!$ cancels the $k!$, and with $\beta = a$, $\gamma' = 1+a$ the series is $\sum_k \frac{a}{a+k}z^k$.

The geometric series converges only for $\epsilon < 1$, yet the phase at lower frequencies, where friction dominates, is a perfectly finite integral. The same substitution that turned the series into ${}_2F_1$

shows that nothing is lost. Put $t = (f/f')^n$ in the exact integral, with $z = -c_f f^{-n}$:

$$\frac{K}{2\pi}\Phi(f) \overset{(1)}{=} \int_f^\infty \frac{f'^{-8/3}\,\mathrm{d}f'}{1 + c_f f'^{-n}} \overset{(2)}{=} \frac{f^{-5/3}}{n}\int_0^1 \frac{t^{a-1}\,\mathrm{d}t}{1-zt} \overset{(3)}{=} \frac{3}{5} f^{-5/3}\, a\int_0^1 \frac{t^{a-1}\,\mathrm{d}t}{1-zt}.$$

(1) The definition with $\dot f = K f'^{11/3}(1 + c_f f'^{-n})$.

(2) $f' = f t^{-1/n}$, $\mathrm{d}f' = -(f/n)t^{-1/n-1}\mathrm{d}t$, and $c_f f'^{-n} = c_f f^{-n} t = -zt$; the powers of t combine to $t^{(8/3-1)/n-1} = t^{a-1}$, and f' from f to ∞ is t from 1 to 0.

(3) $1/n = \frac{3}{5}a$.

Expanding $1/(1-zt) = \sum_k (zt)^k$ and using $a\int_0^1 t^{a-1+k}\mathrm{d}t = a/(a+k)$ returns exactly the series of (T2.96), so the last integral *is* ${}_2F_1(1, a; 1+a; z)$ where the series converges. But the integral is finite and smooth for every $z \le 0$, since $1 - zt \ge 1$, so it defines the function at every frequency; this is Euler's integral for the hypergeometric function, the standard way of continuing it beyond $|z| < 1$. Hence (T2.96) holds at all frequencies [84, eq. (12)]. At low frequency, $f \to 0$, $z \to -\infty$ and the integral goes to zero: friction then sweeps the binary through each frequency so fast that it accumulates almost none of the vacuum phase, and $\Delta\Phi \to \Phi_{\mathrm{V}}$.

T2.10.3 The experiment: dephasing for several spike slopes

Their question

Coogan et al. asked whether LISA could tell an intermediate-mass-ratio inspiral wrapped in a dark-matter spike from the same binary in vacuum, and whether the signal would then measure the spike's density and slope [84]. Earlier estimates had used a fixed spike and found enormous dephasings. Their point was that the friction heats the spike it feeds on, so the honest question is what survives once the spike is allowed to respond. We reproduce the static part of their calculation, which is what the equations of this section describe, and use it to see where the static picture stops.

Their setup

The binary is a $10^3\,M_\odot$ black hole with a $1.4\,M_\odot$ companion, the IMRI of Section T2.4. Around the heavy hole sits a spike $\rho = \rho_6(r_6/r)^\gamma$ whose density at the pivot radius $r_6 = 10^{-6}$ pc is fixed to their benchmark value (Section T2.9 derived it from $\rho_{\mathrm{sp}} = 226\,M_\odot\,\mathrm{pc}^{-3}$). The companion feels Chandrasekhar's friction (T2.87), with the fraction ξ of slow particles appropriate for a 7/3 spike and their logarithm $\ln\sqrt{m_1/m_2}$. We keep ρ_6 fixed and vary the slope, to see how the dephasing depends on γ, and we look at the last four years before the ISCO, a nominal LISA mission.

quantity	meaning	value
m_1, m_2	central hole, companion	$10^3\,M_\odot$, $1.4\,M_\odot$
ρ_6	spike density at r_6	$5.45\times10^{15}\,M_\odot\,\mathrm{pc}^{-3}$
r_6	pivot radius	10^{-6} pc
ξ	fraction of slower particles	0.58
$\ln\Lambda$	Coulomb logarithm, $\ln\sqrt{m_1/m_2}$	3.286
γ	spike slope	1.5, 2, 7/3, 2.5
window	last four years before the ISCO	from 21.7 mHz

Their equations in ours

Everything needed has been derived above, and we kept their symbols wherever they had one: ρ_6, r_6, c_f and $f_{\rm eq}$ mean the same here as there, and f is in both cases the gravitational-wave frequency.

Coogan et al.	here	content
eq. (12)	(T2.96)	exact phase to coalescence in a static spike
eq. (15)	$f_{\rm eq} = c_f^{1/n}$, with (T2.93)	where friction and radiation are equal
eq. (16)	(T2.95)	high-frequency power law of the dephasing

The one convention to watch is which phase is quoted: their dephasing is the time-domain $\Delta\Phi$, not the Fourier $\delta\Psi$ of the Fisher matrix, and the two differ by the factor $-1/(n+\frac{8}{3})$ derived above.

What we compute

The script `05_dephasing.py` evaluates these formulas for the four slopes:

Listing T2.7: The friction-to-radiation ratio and the exact dephasing (`code/chT2/05_dephasing.py`)

```
36 def c_f(gam):
37     """eps(f) = P_DF/P_GW = c_f f^{-n} (SI evaluation of the text formula)."""
38     rho_SI = rho6 * MSUN / PC**3 * (r6 * PC) ** gam      # rho = rho_SI r^-gam (SI)
39     pref = 5*np.pi * c**5 * xi * lnL / (8 * G**2.5 * (M*MSUN)**1.5 * (m1*MSUN)**2)
40     n = (11 - 2 * gam) / 3
41     return pref * rho_SI * (G * M * MSUN / np.pi**2) ** ((11 - 2 * gam) / 6), n
42
43 def phi_vac(f):
44     """GW phase left to coalescence, Phi_V = (1/16) (pi G Mc f/c^3)^{-5/3}."""
45     return (np.pi * Mc * TSUN * f) ** (-5 / 3) / 16
46
47 def dphi_closed(f, gam):
48     """Phi_V - Phi_S, static dress: Phi_S = Phi_V 2F1(1,a;1+a;-c_f f^-n), a=5/3n."""
49     cf, n = c_f(gam)
50     b = 5 / (3 * n)
51     return phi_vac(f) * (1 - hyp2f1(1, b, 1 + b, -cf * f ** (-n)))
```

It makes four moves. First, lines 38–39 compute the constants of (T2.93): `rho_SI` is $\rho_6 r_6^\gamma$ in SI units, and `pref` is the prefactor of step (2) of (T2.92). Second, line 41 completes c_f by writing the radius through Kepler's law, the factor $(GM/\pi^2)^{(11-2\gamma)/6}$, so that $\epsilon = c_f f^{-n}$ is a function of the frequency alone. Third, lines 45 and 51 evaluate the vacuum phase $\Phi_{\rm V} = \frac{1}{16}(\pi G\mathcal{M} f/c^3)^{-5/3}$ and the exact dephasing $\Phi_{\rm V}(1-{}_2F_1)$ of (T2.96); the variable `b` on line 50 is the parameter $a = 5/(3n)$, and `dphi_closed` is $\Delta\Phi$. Fourth, the script integrates $2\pi f/\dot f$ directly, with no expansion and no hypergeometric function, and compares: the two agree to 1.343×10^{-13}. That check tests the algebra from ϵ to Φ, the series, the substitution and the code; it says nothing about whether the static-spike physics is right. The dephasing plotted is accumulated between f and the ISCO, as in [81, eq. (49)].

Reading the figure

Figure T2.21 has one idea: the dephasing is a broken power law, with the break at $f_{\rm eq}$. For $\gamma = 7/3$ friction and radiation balance at $f_{\rm eq} = 16.75\,$mHz. Below $f_{\rm eq}$ friction drives the inspiral, almost all of the vacuum phase is lost ($\Delta\Phi \to \Phi_{\rm V}$, as found above), and the local slope of $\Delta\Phi$

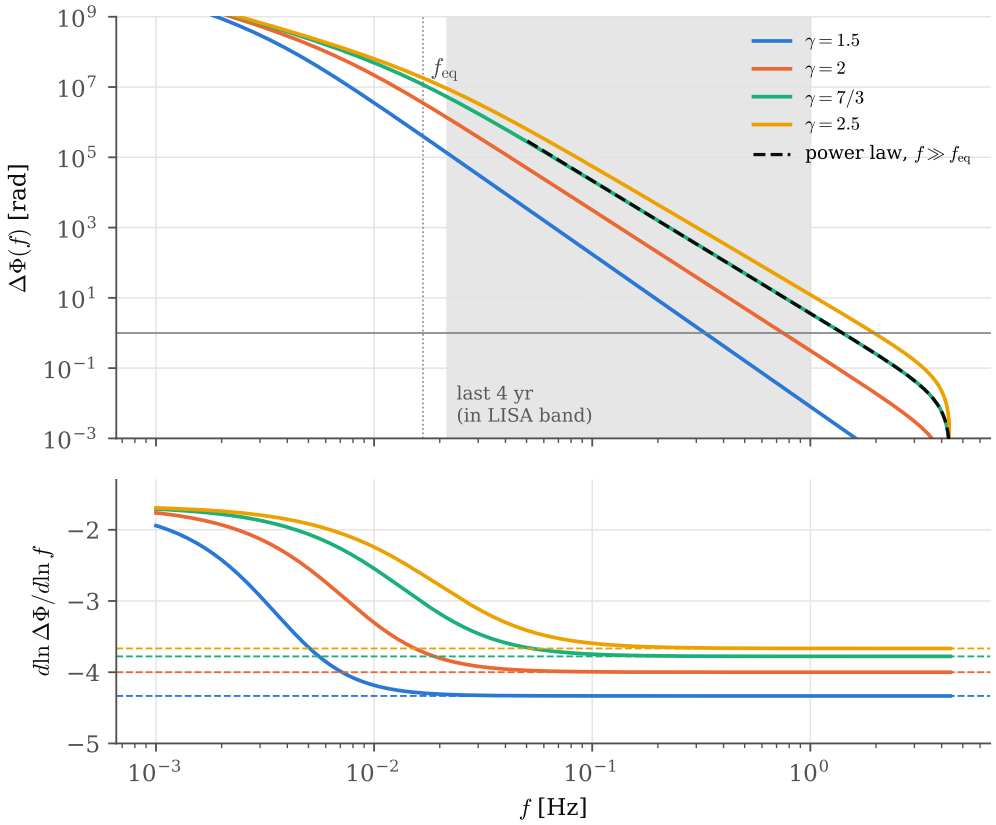

Figure T2.21: Dephasing of the $10^3 + 1.4\,M_\odot$ IMRI by friction in a static spike of slope γ, at fixed density ρ_6 at 10^{-6} pc. Top: phase lost between f and the ISCO; the dashed black line is the power law (T2.95) for $\gamma = 7/3$, drawn where $f > 3f_{\rm eq}$, and the grey band is the last four years. Bottom: the local slope $\mathrm{d}\ln\Delta\Phi/\mathrm{d}\ln f$ of the phase lost before coalescence. It moves from the vacuum value $-5/3$ at low frequency to the predicted $-5/3 - n$ (dashed, one per slope) above $f_{\rm eq}$.

is the vacuum $-5/3$. Above it each curve settles onto the predicted exponent $b = -5/3 - n$ of (T2.95): the measured local slopes are -4.333, -4, -3.778 and -3.667 for $\gamma = 1.5$, 2, 7/3, 2.5, against $-13/3$, -4, $-34/9$ and $-11/3$.

How large

The steeper the spike, the more phase it removes at fixed ρ_6: over the last four years before the ISCO (from 21.7 mHz), $\Delta\Phi = 1.302 \times 10^5$, 1.325×10^6, 5.191×10^6 and 8.937×10^6 rad for the four slopes. To give these a scale: a matched filter at signal-to-noise ratio ρ resolves a phase error of about $1/\rho$ radians, the weighted root-mean-square phase shift that the Fisher matrix can detect (Section 10.9.3), about a tenth of a radian for $\rho = 10$. So even the gentlest of these spikes would be glaringly visible in this idealised, static setting.

Paper and reproduction side by side

quantity ($\gamma = 7/3$)	Coogan et al.	ours (static)
$f_{\rm eq}$	$\approx 15\,$mHz [84, eq. (15)]	16.75 mHz
high-frequency slope of $\Delta\Phi$	$-34/9$ (static, eq. (16))	-3.778
exact vs. power law	eq. (12)	closed form = numerical to 1.343×10^{-13}
$\Delta\Phi$, last four years	much smaller, spike with feedback (Sec. IV)	5.191×10^{6} rad

Why they differ

The equality frequency. Ours is 12% above theirs. Since $f_{\rm eq} = c_f^{1/n}$ and $c_f \propto \xi \ln\Lambda\, \rho_6$, $f_{\rm eq} \propto (\xi \ln\Lambda\, \rho_6)^{1/n} = (\xi \ln\Lambda\, \rho_6)^{9/19}$ for $\gamma = 7/3$. A 12% shift in $f_{\rm eq}$ therefore corresponds to a $(1.12)^{19/9} - 1 \approx 26\%$ difference in the product $\xi \ln\Lambda\, \rho_6$. The prescriptions differ by more than that: setting $\xi = 1$ instead of 0.58 alone would move $f_{\rm eq}$ up by $(1/0.58)^{9/19} \approx 1.29$, and the two common choices of $\ln\Lambda$ differ by a factor of two. We have not pinned the remaining 12% on a single choice; it is the size expected from these conventions, and the exponents, which do not depend on them, agree.

Static against responding spike. This is the large difference. The energy friction removes from the orbit goes into the dark matter, and a rough count shows it is far more than the spike can absorb. Take the orbit at $f_{\rm eq}$, of radius $r = (GM/\pi^2 f_{\rm eq}^2)^{1/3} \approx 1.2 \times 10^{-8}\,$pc. The energy friction removes between $f_{\rm eq}$ and the ISCO is the friction share of the orbital energy lost,

$$E_{\rm DF} = \int_{f_{\rm eq}}^{f_c} \frac{\epsilon}{1+\epsilon} \left|\frac{{\rm d}E}{{\rm d}f}\right| {\rm d}f = \frac{\mu}{3}\left(\frac{\pi G M f_{\rm eq}}{c^3}\right)^{2/3} c^2 \int_1^{f_c/f_{\rm eq}} \frac{y^{-1/3}\,{\rm d}y}{1+y^n} \approx 1 \times 10^{-3}\, M_\odot c^2,$$

with $y = f/f_{\rm eq}$, $\epsilon = y^{-n}$, $|{\rm d}E/{\rm d}f|$ from (T2.41), and the last integral ≈ 0.51. The dark matter inside that orbit is $M_{\rm DM}(<r) = 4\pi\rho_6 r_6^\gamma r^{3-\gamma}/(3-\gamma) \approx 5 \times 10^{-3}\, M_\odot$, bound to the hole by roughly $GMM_{\rm DM}/r \approx 2 \times 10^{-5}\, M_\odot c^2$. The friction deposits some fifty times the binding energy of the dark matter it moves through. The spike near the orbit cannot stay as it was: it is heated and partly unbound, its density at a given radius falls during the inspiral, ϵ at fixed f falls with it, and the dephasing is smaller and its break moves. That is the qualitative result Coogan et al. find when they follow this feedback: a much smaller dephasing, still a broken power law, but with a different break frequency and exponents [84, Sec. IV]. Kim et al. mimic the same effect by capping the friction at the binding energy of a shell of halo [81, Sec. IV C].

The chirp itself. Our vacuum chirp is Newtonian and circular. Near the ISCO, where $v \approx 0.4c$, post-Newtonian corrections to $\dot f$ are large (Section T2.6), and relativistic corrections to the spike and to the friction push the other way from feedback, increasing the dephasing [83]. These change the numbers, not the exponents of (T2.94), which survive as the leading-order description of each effect.

What it taught us

The power law is not the whole story even before feedback. LISA's window is not far above $f_{\rm eq}$: at the start of the four-year window the power law misses the exact $\Delta\Phi$ for $\gamma = 7/3$ by 35.35%, and for $\gamma = 2.5$ the window starts *below* $f_{\rm eq} = 24.26\,$mHz, where no expansion in ϵ holds. A ppE forecast is reliable when the observed band lies well above $f_{\rm eq}$, that is, for weak

environments, which are exactly the ones whose detectability is in question; and a static spike strong enough to matter is one that the binary itself would destroy.

Taxonomy: Environmental effects as power laws in the phase

effect	$P_{\rm env}/P_{\rm GW} \propto$	n	$b = -\frac{5}{3} - n$	at $\gamma = \frac{7}{3}$
friction, spike $\rho \propto r^{-\gamma}$	$r^{11/2-\gamma}$	$\frac{11-2\gamma}{3}$	$\frac{2\gamma-16}{3}$	$-\frac{34}{9}$
friction, uniform density	$r^{11/2}$	$\frac{11}{3}$	$-\frac{16}{3}$ (−5.5PN)	—
accretion, collisionless	$r^{9/2-\gamma}$	$\frac{9-2\gamma}{3}$	$\frac{2\gamma-14}{3}$	$-\frac{28}{9}$
accretion, gas (BHL)	as friction			
pull of enclosed mass (no loss)	$r^{3-\gamma}$ (relative)	$\frac{2(3-\gamma)}{3}$	$\frac{2\gamma-11}{3}$	$-\frac{19}{9}$
dipole radiation (Brans–Dicke)	r	$\frac{2}{3}$	$-\frac{7}{3}$	—
vector ultralight DM	resonant: a step near one frequency, not a power law [95]			

The table also marks where the power-law picture stops. The oscillating potential of a vector dark-matter halo (Section T2.9) does nothing on average until the orbital frequency crosses a resonance with the field, and then shifts the phase within a narrow band [95, Sec. V]. A template βu^b cannot represent such a step; it needs its own model. The ppE parametrisation is a statement about smooth, monotonic effects, and its hidden assumption is that the environment changes slowly with radius.

Where each item is used. The waveform (T2.56) with phase (T2.54) and the correction (T2.94), together with the noise (T2.77), are the inputs of the gravitational-wave Fisher forecast in Chapter 10, which computes the error on β for a list of exponents b and checks it with the sampler of Chapter 9. The density profiles and the parametrisation by ρ_6 fix the physical meaning of β there. The likelihood $-\frac{1}{2}(d-h \mid d-h)$ with this S_n is the one derived in Chapter 0, and comparing a vacuum template with a dressed one is a Bayesian model comparison of the kind treated in Chapter 5.

Recap

- Energy balance with the quadrupole formula gives the chirp $\dot{f} = \frac{96}{5}\pi^{8/3}(G\mathcal{M}/c^3)^{5/3}f^{11/3}$; only the chirp mass enters at leading order, and LISA's benchmark inspirals complete millions of cycles in four years.
- The stationary-phase approximation gives $\tilde{h} = \mathcal{A}f^{-7/6}e^{-i\Psi(f)}$ with $\mathrm{d}^2\Psi/\mathrm{d}f^2 = 2\pi/\dot{f}$: anything that changes the sweep rate changes the phase.
- LISA's sensitivity $S_n(f)$ combines test-mass acceleration noise (low f), optical metrology noise and the arm response (high f), and the Galactic confusion foreground (around a millihertz); the signal-to-noise ratio is $\int (h_c/h_n)^2 \mathrm{d}\ln f$.
- Slow growth of a black hole compresses a cusp $r^{-\gamma_i}$ into a spike $r^{-(9-2\gamma_i)/(4-\gamma_i)}$, $r^{-7/3}$ for NFW, raising the density at the orbit by some eighteen orders of magnitude; ultralight dark matter falls freely inside the self-gravity radius, $\rho \propto r^{-3/2}$.
- An extra power $P_{\rm env} = c_f f^{-n} P_{\rm GW}$ shifts the phase by βu^b, $b = -5/3 - n$, valid for $f \gg f_{\rm eq}$; resonant effects are not power laws.

T2.11 Type Ia supernovae: candles that need a correction

A white dwarf is the burnt-out core of a star like the Sun, held up by the pressure of its degenerate electrons. If it gains mass from a companion, or merges with a second white dwarf, it can approach the Chandrasekhar limit of about $1.4\,M_\odot$, ignite carbon in its centre and blow itself apart. The explosion makes a few tenths of a solar mass of radioactive nickel-56, and the decay of that nickel powers the light we see for weeks. The fuel and the trigger are nearly the same every time, so the explosions are nearly the same every time. At its peak a type Ia supernova outshines its whole host galaxy, and it can be seen across half the observable universe.

"Nearly the same" is not good enough for cosmology. Raw peak magnitudes scatter by about 0.4 mag [98, p. 33], which is a 40% spread in luminosity and a 20% spread in the distance one would infer. Two observations rescue the method. Supernovae that are brighter at peak also fade more slowly, and supernovae that look redder are fainter. Both properties can be read off the light curve. A correction built from them shrinks the scatter to about 0.12 mag. Such an object is called a **standardisable candle** [its luminosity is not fixed, but it can be predicted from properties we measure on the same object].

The question. Given the light curve of one supernova in a few colour bands and the redshift of its host galaxy, what distance does it imply, how uncertain is that distance, and which statistical tools turn a few hundred such light curves into a measurement of the expansion history?

T2.11.1 What is measured, and the standardisation

A magnitude is a logarithm of a flux F: $m = -2.5\log_{10} F + \text{const}$, so 5 magnitudes is a factor of 100 in flux and a larger magnitude means a fainter object. The **distance modulus** of Chapter 3 links the apparent magnitude m to the absolute magnitude M (the magnitude at 10 pc) through the luminosity distance D_L of Chapter T1, the distance for which the flux is $L/4\pi D_L^2$:

$$\mu \equiv m - M = 5\log_{10}\frac{D_L}{10\,\text{pc}} = 5\log_{10}\frac{D_L}{\text{Mpc}} + 25. \tag{T2.97}$$

A light-curve fitter such as SALT [98, p. 39] compares the observed fluxes in each band, night after night, with a family of template light curves. It returns three numbers per supernova: the peak apparent magnitude m_B in the rest-frame B band, a **stretch** x_1 [how much wider than average the light curve is in time, zero for a typical one], and a **colour** c [how much redder than average the supernova is at peak, in magnitudes of $B - V$]. Figure T2.22 shows the chain from light curve to distance.

Working definition T2.4 (Tripp standardisation)

The observed distance modulus of a type Ia supernova is

$$\mu_{\text{obs}} = m_B - M + \alpha\, x_1 - \beta\, c, \tag{T2.98}$$

with M, α and β the same for every supernova. *Operationally:* fit the light curve to get (m_B, x_1, c); add αx_1 because broad supernovae are brighter than average (a smaller M); subtract βc because red ones are fainter. Typical values are $\alpha \approx 0.15$ and $\beta \approx 3$.

Why do the two corrections work? The amount of nickel-56 sets both the peak luminosity and the width. More nickel means a hotter, more opaque ejecta, so the light takes longer to diffuse out, and the curve is both brighter and broader [98, p. 33]. This is the Phillips relation. Colour

has two sources. Dust in the host galaxy absorbs blue light more than red, so it reddens and dims together. Milky-Way dust would give $\beta \approx R_B = R_V + 1 \approx 4.1$, with $R_V \equiv A_V/E(B-V) = 3.1$. Here A_B and A_V are the dimming by dust in the two bands, and the reddening is their difference, $E(B-V) = A_B - A_V$. The colour correction asks how much dimming in B comes with one magnitude of reddening, $R_B \equiv A_B/E(B-V) = (A_V + E(B-V))/E(B-V) = R_V + 1$. Fits to supernovae return a smaller β, as if R_V were 1.5–2.5 [98, p. 36]. Part of the colour spread is therefore intrinsic to the explosions and not dust at all. That is why β is fitted rather than taken from the physics of dust.

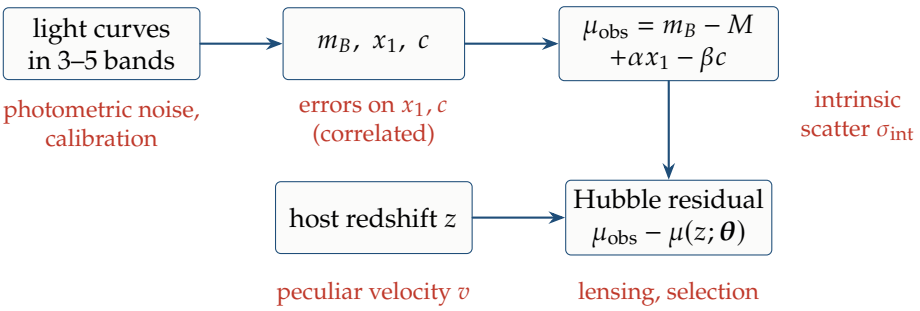

Figure T2.22: From light curves to a distance. Blue boxes are the steps of the analysis; red labels mark where noise enters. The fitted shape and colour turn the peak magnitude into a distance modulus, and the redshift of the host predicts that modulus in a cosmological model. Their difference, the Hubble residual, is the quantity whose sampling distribution every later fit needs.

T2.11.2 Where the noise lives

The datum that enters every fit is the **Hubble residual** $\Delta\mu = \mu_{\rm obs} - \mu(z;\boldsymbol{\theta})$, the difference between the standardised modulus and the one predicted at the host redshift by a model with parameters $\boldsymbol{\theta}$. Its scatter has four parts. The *intrinsic scatter* $\sigma_{\rm int} \approx 0.1$ mag is what the standardisation cannot remove. The *measurement errors* of m_B, x_1 and c enter through (T2.98), so an error σ_c in colour costs $\beta\sigma_c$ in μ. The *peculiar velocity* v of the host [its motion relative to the smooth expansion] shifts the redshift, and therefore the predicted modulus. And at high redshift, *gravitational lensing* by structure along the line of sight magnifies or demagnifies the supernova.

How big is the peculiar-velocity term? At low redshift $D_L \approx cz/H_0$, and (T2.97) turns a fractional error in distance into an additive error in magnitude:

$$\delta\mu \overset{(1)}{=} \frac{5}{\ln 10}\frac{\delta D_L}{D_L} \overset{(2)}{=} \frac{5}{\ln 10}\frac{\delta(cz)}{cz} \overset{(3)}{=} \frac{5}{\ln 10}\frac{v}{cz}, \qquad \sigma_{\mu,\rm pec} = 2.17\,\frac{\sigma_v}{cz}. \tag{T2.99}$$

(1) Differentiate $\mu = 5\log_{10} D_L + \text{const} = (5/\ln 10)\ln D_L + \text{const}$.
(2) $D_L \propto cz$ at low redshift, so the fractional changes are equal.
(3) A line-of-sight velocity v adds v to the measured cz. The number in front is $5/\ln 10 = 5/2.303 = 2.17$.

For $\sigma_v = 250$ km/s this is 0.030 mag at $z = 0.06$, but 0.18 mag at $z = 0.01$. That is why the low-redshift anchor of a supernova Hubble diagram starts at $z \approx 0.02$–0.03, the "sweet spot" where peculiar velocities are small but the distances still do not depend on the dark-energy parameters [98, p. 33].

Example: what one supernova is worth. Solve (T2.97) for D_L and take logarithms:

$$\ln D_L \overset{(1)}{=} \frac{\ln 10}{5}(\mu - 25), \qquad \sigma_{\ln D} \overset{(2)}{=} \frac{\ln 10}{5}\sigma_\mu = \frac{\sigma_\mu}{2\times 1.086} \overset{(3)}{=} \frac{0.12}{2.17} = 0.055. \tag{T2.100}$$

(1) $D_L/\mathrm{Mpc} = 10^{(\mu-25)/5}$ and $\ln 10^x = x \ln 10$.
(2) A constant factor passes through the standard deviation. Weinberg et al. write $\ln 10/5$ as $1/(2 \times 1.086)$: $1.086 = 2.5/\ln 10$ converts magnitudes to natural logarithms, and the 2 converts flux to distance, because flux goes as D_L^{-2}.
(3) The standardised scatter $\sigma_\mu \approx 0.12\,\mathrm{mag}$.

Each well-measured supernova gives its distance to about 6%. Averaging N independent supernovae in a redshift bin divides this by $\sqrt{N}$, which is Weinberg et al.'s eq. (51) [98, p. 34]. How many supernovae does a 1% distance in one bin need? Set the error of the mean equal to the target and solve for N:

$$\frac{0.055}{\sqrt{N}} = 0.01 \implies N = \left(\frac{0.055}{0.01}\right)^2 = 5.5^2 \approx 30, \qquad \frac{0.055}{\sqrt{N}} = 0.005 \implies N = 11^2 \approx 120,$$

as long as nothing systematic is left. The Pantheon+ compilation has 1550 spectroscopically confirmed supernovae from $z = 0.001$ to 2.26 [26]. Its statistical errors are already comparable to its systematic ones, which come from flux calibration across telescopes, the treatment of dust and colour, and a possible drift of the population with redshift, such as the 0.03 mag per decade of host stellar mass found in the residuals [98, pp. 39–41].

T2.11.3 Fitting α and β: least squares with noisy regressors

Write $y_i \equiv m_{B,i} - \mu(z_i)$ for a low-redshift sample with known cosmology. Then (T2.98) says $y_i = M - \alpha x_{1,i} + \beta c_i + \epsilon_i$. This is a linear model, and least squares (Chapter 3) seems to give M, α, β at once. There is a catch. The regressors x_1 and c are themselves measured with noise. Ordinary least squares assumes the regressors are exact. What does it do when they are not?

Take the colour term alone: $y = \beta c + \epsilon$, with the true colours spread with variance V_c and measured as $\hat{c} = c + e$, where e is independent noise of variance σ_c^2. For a large sample the least-squares slope tends to

$$\hat{\beta} \overset{(1)}{=} \frac{\mathrm{Cov}(y, \hat{c})}{\mathrm{Var}(\hat{c})} \overset{(2)}{=} \frac{\mathrm{Cov}(\beta c + \epsilon,\ c + e)}{\mathrm{Var}(c) + \mathrm{Var}(e)} \overset{(3)}{=} \frac{\beta V_c}{V_c + \sigma_c^2} \equiv \beta \lambda_c, \qquad \lambda_c = \frac{V_c}{V_c + \sigma_c^2}. \tag{T2.101}$$

(1) The least-squares slope of y on $\hat{c}$ is the sample covariance over the sample variance, and both converge to their expectations (the law of large numbers).
(2) Substitute the model and the measurement. c and e are independent, so their variances add.
(3) ϵ and e are independent of everything else, so only $\mathrm{Cov}(\beta c, c) = \beta V_c$ survives.

The fitted slope is pulled towards zero by the factor $\lambda_c < 1$. Statisticians call this **regression dilution**, and λ_c the reliability ratio. The scatter left after the correction follows from the same quantities:

$$\mathrm{Var}(y - \hat{\beta}\hat{c}) \overset{(1)}{=} \mathrm{Var}\left(\beta(1-\lambda_c)c - \beta\lambda_c e + \epsilon\right) \overset{(2)}{=} \beta^2\left[(1-\lambda_c)^2 V_c + \lambda_c^2 \sigma_c^2\right] + \sigma_\epsilon^2 \overset{(3)}{=} \beta^2 \lambda_c\, \sigma_c^2 + \sigma_\epsilon^2. \tag{T2.102}$$

(1) Substitute $y = \beta c + \epsilon$, $\hat{c} = c + e$ and $\hat{\beta} = \beta\lambda_c$.
(2) The three terms are independent, so their variances add.
(3) $1 - \lambda_c = \sigma_c^2/(V_c + \sigma_c^2)$, so $(1-\lambda_c)^2 V_c + \lambda_c^2 \sigma_c^2 = \dfrac{\sigma_c^4 V_c + V_c^2 \sigma_c^2}{(V_c + \sigma_c^2)^2} = \lambda_c \sigma_c^2$.

Here σ_ϵ^2 collects every other source: σ_{int}^2, the error on m_B and the peculiar velocities of (T2.99).

Watch out: A fitted slope is not the physical slope

With noisy regressors, least squares underestimates $|\beta|$ by the factor λ_c of (T2.101), however many supernovae are used. A diluted β is then applied to supernovae at high redshift, whose colours are noisier, so the bias does not cancel between the two ends of the Hubble diagram. Modern analyses treat the true x_1 and c of each supernova as unknown latent parameters with a population distribution, a hierarchical model of the kind built in Chapter 5.

The experiment. `06_sn_standardise.py` draws 400 supernovae at $0.02 < z < 0.1$ with $\alpha = 0.15$, $\beta = 3$, an intrinsic scatter of 0.1 mag, true colours of spread 0.1 measured with errors 0.03, and peculiar velocities of 250 km/s:

Listing T2.8: A mock low-redshift supernova sample and the least-squares standardisation (`code/chT2/06_sn_standardise.py`)

```

```

Line 46 is (T2.98) read backwards: the true absolute magnitude of each supernova. Line 47 moves the redshift by the peculiar velocity, and line 49 adds measurement noise to the regressors, which is what causes the dilution. The fit in lines 54–56 is ordinary least squares on the design matrix $[1, -x_1, c]$.

Figure T2.23 shows the result. Before any correction, the residual $m_B - \mu(z) - M$ carries the whole spread of the stretch and colour terms as well as the noise. Write V_x for the spread (variance) of the true stretches, as V_c is for the colours, and σ_m, $\sigma_{\rm pec}$ for the magnitude error and the peculiar-velocity term of (T2.99). All the terms are independent, so their variances add:

$$\sigma^2_{\rm raw} = \sigma^2_{\rm int} + \alpha^2 V_x + \beta^2 V_c + \sigma^2_m + \sigma^2_{\rm pec}.$$

The raw residuals scatter by 0.344 mag, against 0.353 from this sum. After standardisation they scatter by 0.142 mag, against the prediction 0.140 of (T2.102). Over 2000 mock samples the fitted β averages 2.754 ± 0.071, not 3: it agrees with the diluted value $\beta\lambda_c = 2.752$ ($\lambda_c = 0.917$). The stretch has its own reliability ratio, built as in (T2.101) from its spread and its measurement error σ_x, $\lambda_x = V_x/(V_x + \sigma_x^2)$. It is measured more precisely relative to its spread ($\lambda_x = 0.978$), and $\hat\alpha$ averages 0.1467 ± 0.0002, again $\alpha\lambda_x = 0.1467$ within its Monte Carlo error.

Where the statistics comes back in. The datum is the model's prediction plus one realisation of the noise, $\mu_{\rm obs} = \mu(z;\boldsymbol{\theta}) + \Delta\mu$ with $\Delta\mu \sim \mathcal{N}(0, \sigma^2)$. For a trial $\boldsymbol{\theta}$ the likelihood asks how plausible the particular noise realisation is that would turn that model's prediction into the magnitudes actually observed; a $\boldsymbol{\theta}$ that needs a large, improbable $\Delta\mu$ in every supernova

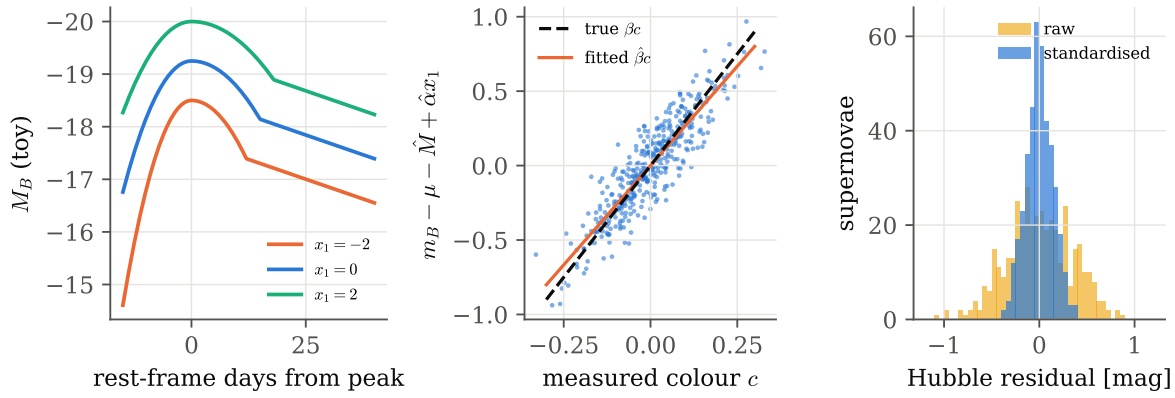

Figure T2.23: Standardising type Ia supernovae. Left: toy light curves; the broad one ($x_1 = 2$) is brighter, the narrow one fainter (the trend is exaggerated for visibility). Middle: after the stretch correction, the residual magnitude grows linearly with the measured colour; the fitted slope (orange) is shallower than the true one (dashed) because the colours are noisy. Right: Hubble residuals before (yellow) and after (blue) the correction.

is disfavoured. The residual $\Delta\mu$ is Gaussian in magnitudes, so the likelihood of Chapter 3 with the Hubble law, and the H_0 estimator built there, apply directly. Fitting α, β, M and the cosmology together is a linear-in-nuisance problem, solved by the least squares of Chapter 3 or marginalised in Chapter 5. Correlated systematics (a calibration offset shared by all supernovae from one telescope) enter as a full covariance matrix $\mathbf{C}$, whose use in the likelihood and in the Fisher matrix is the subject of Chapter 10. The hierarchical treatment of latent colours is sampled with the MCMC of Chapter 9.

T2.12 The distance ladder: why H_0 needs an anchor

The supernovae of Section T2.11 are excellent at *relative* distances: this one is 1.8 times farther than that one. They say nothing, on their own, about how far away either of them is in megaparsecs. The worked problem of Chapter 3 found the same thing in the language of likelihoods. In the Hubble law with supernova magnitudes, the absolute magnitude M and $5\log_{10} H_0$ enter only in the combination $M - 5\log_{10} H_0$, so the Fisher matrix of the two is singular. Brighter candles in a faster-expanding universe look exactly like fainter candles in a slower one. To measure H_0 someone has to tell us M, and the only way to do that is to find supernovae in galaxies whose distances are known by other means. Those distances in turn need calibrating, and the chain ends only at geometry. This chain is the **distance ladder**.

Where we have met H_0 before. In Section 3.17 we fitted mock surveys of 100 supernovae made with $H_0 = 70$ and an absolute magnitude $M = -19.25$ that we simply declared known, and the maximum-likelihood estimator, the weighted mean of $5\log_{10} H_0$, found H_0 to about 0.5 km/s/Mpc. Section 3.17.4 then freed M, saw the Fisher matrix of $(M, 5\log_{10} H_0)$ turn singular, and closed the gap by handing the fit one more number, $M_{\rm cal} \pm 0.03$ mag, from "the calibrators"; the calibration error then dominated, and the scatter of $\hat{H}_0$ grew to 1.1 km/s/Mpc. Here the parameter, the magnitude likelihood and the degeneracy are the same, and so is the estimator, now written as generalised least squares. What changes is where M comes from: instead of arriving as one number with an assumed error, it is produced by fitting the rungs below, so its error is assembled from parallaxes, Cepheids and calibrator supernovae, and we can ask which rung pays for most of it. The data are still mock, made with $H_0 = 73$ to sit near the published value, which is met in Section T2.12.3. The two error bars come out almost equal, 1.1 km/s/Mpc in both, because the ladder below delivers M to 0.03 mag, the precision the

worked problem assumed.

The question. Which measurements make up the ladder, what does each one measure and with what noise, and how do the errors of the rungs combine into the error on H_0?

T2.12.1 The rungs

Rung 1, geometry. The **parallax** p of a star is the half-angle through which it appears to move as the Earth goes round the Sun. Its distance is $d = 1\,\mathrm{AU}/\tan p$, that is $d = 1\,\mathrm{pc} \times (1''/p)$ for small angles [99, Sec. 8]. The Gaia satellite measures parallaxes to some 20 μas, so a Cepheid at 2 kpc ($p = 0.5$ mas) has its distance to 4%. Two other geometric anchors reach farther: detached eclipsing binaries in the Large Magellanic Cloud (the stars' sizes from the eclipse timing, their angular sizes from their surface brightness) and the water masers orbiting the black hole in NGC 4258 (a Keplerian disc whose velocity and proper motion give its physical and angular size). Both give distances to about 1–1.5% [24].

Rung 2, a stellar standard candle. **Cepheids** are pulsating giant stars whose brightness varies with periods of days to months. Brighter Cepheids pulsate more slowly. The **Leavitt law** [the period–luminosity relation of Cepheids, a straight line in $\log P$] says

$$m_W = \mu + M_W + b_W\,(\log_{10} P - 1), \tag{T2.103}$$

where m_W is a reddening-free combination of magnitudes in two bands (a "Wesenheit" magnitude), M_W the absolute magnitude of a 10-day Cepheid, and $b_W \approx -3.3$ the slope. The scatter about the line is about 0.25 mag per star, but a galaxy contains dozens of Cepheids, so its distance modulus μ is found to a few hundredths of a magnitude. The alternative second rung is the **tip of the red giant branch** (TRGB): the brightest red giants are those about to ignite helium in their cores, and the ignition happens at a fixed core mass, so the tip of the giant branch is a standard candle with $M_I \approx -4.05$. Both second rungs are reviewed in [100, Sec. IV.A].

Rung 3, supernovae in calibrator galaxies. A few dozen galaxies within ~ 40 Mpc have both Cepheids (or a measured TRGB) and a well-observed type Ia supernova. In each of them the Cepheids give μ, and the supernova gives m_B, so $M_B = m_B - \mu$. SH0ES uses 42 supernovae in 37 such hosts [24].

Rung 4, the Hubble flow. Supernovae at $0.023 < z < 0.15$ are far enough that peculiar velocities matter little ((T2.99)) and near enough that the distance depends on the cosmology only through the deceleration parameter q_0 [$q_0 = -\ddot{a}a/\dot{a}^2$ today, about -0.55 in ΛCDM]. What fixes that dependence? Expand the comoving distance $D_C = c\int_0^z \mathrm{d}z'/H(z')$ to second order with $H(z) \approx H_0[1 + (1 + q_0)z]$, and use $D_L = (1 + z)D_C$ for a flat universe [99, eqs. (15), (21)]:

$$\begin{aligned} D_L &\overset{(1)}{=} (1+z)\,\frac{c}{H_0}\int_0^z \left[1 - (1+q_0)z'\right]\mathrm{d}z' \\ &\overset{(2)}{=} (1+z)\,\frac{c}{H_0}\left[z - \frac{1+q_0}{2}z^2\right] \overset{(3)}{=} \frac{cz}{H_0}\left[1 + \frac{1-q_0}{2}z\right] + O(z^3). \end{aligned} \tag{T2.104}$$

(1) How fast does H change with redshift? Both H and z change with time, so divide their rates of change. The definition of q gives $\dot{H} = \ddot{a}/a - \dot{a}^2/a^2 = -H^2(1+q)$, and $1 + z = 1/a$ gives $\dot{z} = -\dot{a}/a^2 = -(1+z)H$. Then

$$\frac{\mathrm{d}H}{\mathrm{d}z} = \frac{\dot{H}}{\dot{z}} = \frac{-H^2(1+q)}{-(1+z)H} = \frac{H(1+q)}{1+z} \xrightarrow{z=0} (1+q_0)H_0,$$

so to first order $H(z) \approx H_0[1+(1+q_0)z]$, and $1/(1+\epsilon) \approx 1-\epsilon$ gives $1/H(z) \approx H_0^{-1}[1-(1+q_0)z]$.

(2) Integrate term by term.
(3) Multiply out: $(1+z)\big(z - \frac{1+q_0}{2}z^2\big) = z + z^2 - \frac{1+q_0}{2}z^2 + O(z^3)$.

What does a Hubble-flow supernova then tell us? Its apparent magnitude is its absolute magnitude plus its distance modulus (T2.97), and (T2.104) gives the distance. The logarithm of a product is a sum of logarithms, which splits the known part from the unknown one:

$$\begin{aligned} m_{B,i} &\overset{(1)}{=} M_B + 5\log_{10}\frac{D_L(z_i)}{\mathrm{Mpc}} + 25 \\ &\overset{(2)}{=} M_B + 5\log_{10}\left\{cz_i\left[1 + \frac{1-q_0}{2}z_i\right]\right\} + 25 - 5\log_{10}H_0 \overset{(3)}{=} M_B + x_i - a, \end{aligned} \tag{T2.105}$$

with $x_i \equiv 5\log_{10}\{cz_i[1+\frac{1}{2}(1-q_0)z_i]\} + 25$ and $a \equiv 5\log_{10}H_0$ (c in km/s and H_0 in km/s/Mpc, so that D_L is in Mpc).

(1) $m = M + \mu$, with μ from (T2.97).
(2) Substitute (T2.104) and use $\log(XY/H_0) = \log X + \log Y - \log H_0$.
(3) Name the pieces: x_i is computed from the measured redshift alone (with q_0 from the cosmology, a small correction at these redshifts); a is the one unknown that carries H_0.

Here the degeneracy of Chapter 3 is visible: only $M_B - a$ appears.

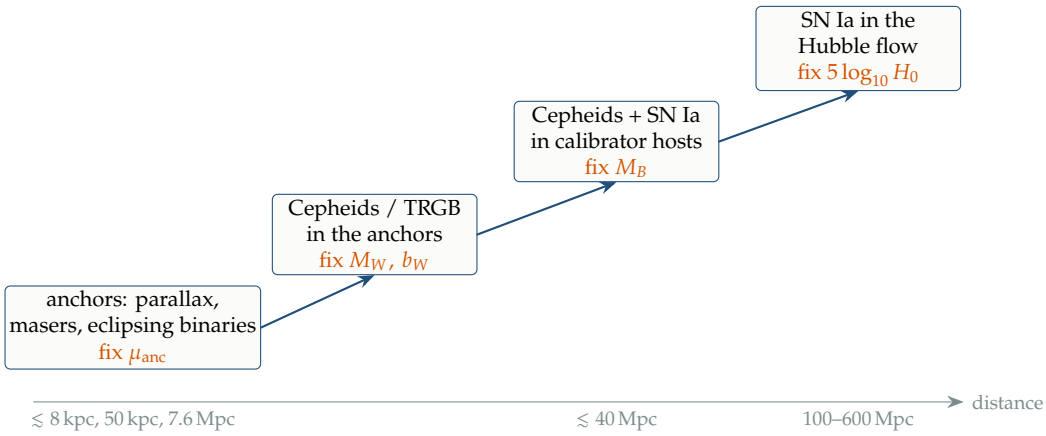

Figure T2.24: The distance ladder. Each rung measures distances to the objects of the next, and each pair of neighbouring rungs shares a parameter (orange): the anchor distances calibrate the Cepheid law, the Cepheids give the distances of the calibrator hosts and hence the supernova absolute magnitude M_B, and M_B turns Hubble-flow magnitudes into H_0. The grey scale gives the typical distances of each rung.

T2.12.2 One linear model for the whole ladder

Each measurement on every rung is a sum of unknowns plus noise. A geometric measurement says $\hat{\mu}_{\mathrm{anc}} = \mu_{\mathrm{anc}} + \text{noise}$. A Cepheid says (T2.103). A calibrator supernova says $m_B = \mu_{\mathrm{cal}} + M_B + \text{noise}$, and a Hubble-flow supernova says $m_B - x = M_B - a + \text{noise}$ by (T2.105). None of them multiplies two unknowns together, so the whole ladder is one linear model.

The smallest ladder first. Take two anchors, one calibrator host and one Hubble-flow supernova, with one Cepheid in each galaxy, and treat the Cepheid slope b_W as known, so that the term $b_W(\log_{10}P - 1)$ can be moved to the data side. The unknowns are the two anchor moduli, the calibrator modulus, the two absolute magnitudes and a, collected as $\boldsymbol{\theta} = (\mu_1, \mu_2, \mu_{\mathrm{cal}}, M_W, M_B, a)$. Write each measurement as one row: its coefficients on the

unknowns go into a row of the matrix A, and the measured number into $\boldsymbol{y}$,

$$\underbrace{\begin{pmatrix} \hat{\mu}_1 \\ \hat{\mu}_2 \\ m_{W,1} - b_W(\log_{10} P_1 - 1) \\ m_{W,2} - b_W(\log_{10} P_2 - 1) \\ m_{W,\mathrm{cal}} - b_W(\log_{10} P_{\mathrm{cal}} - 1) \\ m_{B,\mathrm{cal}} \\ m_{B,\mathrm{HF}} - x \end{pmatrix}}_{\boldsymbol{y}} = \underbrace{\begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 \end{pmatrix}}_{A} \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_{\mathrm{cal}} \\ M_W \\ M_B \\ a \end{pmatrix} + \boldsymbol{n}.$$

Read down a column to see how the rungs are tied. The column of M_W has a 1 in every Cepheid row, in the anchors and in the calibrator alike, so the anchors' geometry reaches the calibrator through it. The column of M_B has a 1 in both supernova rows, so the calibrator passes its information to the Hubble flow. The column of μ_{cal} joins the calibrator's Cepheid to its supernova. Only the last row involves a.

The real ladder is this pattern repeated: N_{anc} anchors and N_{cal} calibrator hosts, each with its own modulus column, dozens to hundreds of Cepheid rows per galaxy, one supernova row per calibrator, a row for each Hubble-flow supernova, and a seventh kind of column for b_W, whose entry in a Cepheid row is that star's $\log_{10} P - 1$. Stack all of them as $\boldsymbol{y} = A\boldsymbol{\theta} + \boldsymbol{n}$ with noise covariance $\mathbf{C}$. The generalised least-squares solution of Chapter 3 is

$$\hat{\boldsymbol{\theta}} = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}A^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{y}, \qquad \mathrm{Cov}(\hat{\boldsymbol{\theta}}) = (A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1} = \mathbf{F}^{-1}, \tag{T2.106}$$

and the matrix $A^{\mathsf{T}}\mathbf{C}^{-1}A$ is exactly the Fisher matrix $\mathbf{F}$ of this linear Gaussian model (Chapter 10). The ladder is "one big fit": the information flows up the rungs through the shared parameters, and so do the errors.

How the errors add up. It helps to see the answer rung by rung before letting the matrix do it. The ingredients, one at a time: there are N_{anc} anchors, each with a geometric error σ_{geo} (in magnitudes of distance modulus) and n_A Cepheids; there are N_{cal} calibrator hosts, each with n_C Cepheids and one supernova; a single Cepheid scatters about the Leavitt law by σ_{ceph}, a single calibrator supernova by σ_{SN}; and there are N_{HF} Hubble-flow supernovae, each of scatter σ_{HF}. Take the Cepheid slope b_W as known (it is fixed by thousands of Cepheids, so its error is small) and follow the estimate up the ladder, one rung at a time.

One anchor. Average its n_A Cepheids, after removing the known slope term, and subtract the geometric modulus. By (T2.103) what is left is M_W:

$$\hat{M}_W^{(j)} = \overline{\left[m_W - b_W(\log_{10} P - 1)\right]}_j - \hat{\mu}_{\mathrm{anc},j}, \qquad \mathrm{Var}\,\hat{M}_W^{(j)} = \frac{\sigma_{\mathrm{ceph}}^2}{n_A} + \sigma_{\mathrm{geo}}^2,$$

because the mean of n_A independent Cepheids has variance $\sigma_{\mathrm{ceph}}^2/n_A$, and the geometric error is independent of the Cepheids. *Then all anchors.* The N_{anc} anchors are independent of one another, so their average $\hat{M}_W$ has $1/N_{\mathrm{anc}}$ of this variance. That is line 1 of (T2.107) below.

One calibrator. Its Cepheids give its modulus as $\hat{\mu}_{\mathrm{cal},i} = \overline{\left[m_W - b_W(\log_{10} P - 1)\right]}_i - \hat{M}_W$, and its supernova then gives

$$\hat{M}_B^{(i)} = m_{B,i} - \hat{\mu}_{\mathrm{cal},i} = \underbrace{m_{B,i} - \overline{\left[m_W - b_W(\log_{10} P - 1)\right]}_i}_{\text{private to host } i} + \underbrace{\hat{M}_W}_{\text{common to all hosts}}.$$

The private part has variance $\sigma_{\rm SN}^2+\sigma_{\rm ceph}^2/n_C$ and is independent from host to host. The common part is the *same* number in every host: if $\hat{M}_W$ came out 0.02 mag too bright, every calibrator inherits the same 0.02 mag. *Average the $N_{\rm cal}$ hosts.* The private errors average down, to $1/N_{\rm cal}$ of their variance. The common error does not: the average of $N_{\rm cal}$ copies of the same offset is that offset. So

$$\operatorname{Var}\hat{M}_B=\operatorname{Var}\left(\overline{\text{private}}\right)+\operatorname{Var}(\hat{M}_W)=\frac{1}{N_{\rm cal}}\left(\sigma_{\rm SN}^2+\frac{\sigma_{\rm ceph}^2}{n_C}\right)+\operatorname{Var}(\hat{M}_W),$$

the two parts adding because the hosts' own errors are independent of the anchors'. That is line 2.

The Hubble flow, the same way. By (T2.105) each Hubble-flow supernova gives $\hat{a}^{(k)}=\hat{M}_B-(m_{B,k}-x_k)$. The term in brackets is private, with variance $\sigma_{\rm HF}^2$; $\hat{M}_B$ is common to all of them. Averaging $N_{\rm HF}$ supernovae shrinks only the private part. Collecting the three rungs,

$$\begin{aligned}
\operatorname{Var}(\hat{M}_W)&\overset{(1)}{=}\frac{1}{N_{\rm anc}}\left(\sigma_{\rm geo}^2+\frac{\sigma_{\rm ceph}^2}{n_A}\right),\\
\operatorname{Var}(\hat{M}_B)&\overset{(2)}{=}\operatorname{Var}(\hat{M}_W)+\frac{1}{N_{\rm cal}}\left(\sigma_{\rm SN}^2+\frac{\sigma_{\rm ceph}^2}{n_C}\right),\\
\operatorname{Var}(\hat{a})&\overset{(3)}{=}\operatorname{Var}(\hat{M}_B)+\frac{\sigma_{\rm HF}^2}{N_{\rm HF}},\qquad \frac{\sigma_{H_0}}{H_0}\overset{(4)}{=}\frac{\ln 10}{5}\sqrt{\operatorname{Var}(\hat{a})}.
\end{aligned}\tag{T2.107}$$

(1) One anchor gives $\sigma_{\rm geo}^2+\sigma_{\rm ceph}^2/n_A$; $N_{\rm anc}$ independent anchors divide it by $N_{\rm anc}$.

(2) The calibrators' private errors average down; the error of $\hat{M}_W$ is common to all of them and passes through whole.

(3) The same split one rung higher: the error of $\hat{M}_B$ is common to all Hubble-flow supernovae.

(4) $H_0=10^{a/5}=e^{(\ln 10/5)a}$, so $\delta H_0/H_0=\delta\ln H_0=(\ln 10/5)\,\delta a$.

Every rung adds its own variance, and the variance of a lower rung is never diluted by more objects on a higher one. A million Hubble-flow supernovae cannot fix a bad anchor.

Example: the error budget of a SH0ES-sized ladder. Take $N_{\rm anc}=3$ anchors with $\sigma_{\rm geo}=0.03$ mag and $n_A=100$ Cepheids each, $N_{\rm cal}=40$ calibrators with $n_C=30$ Cepheids each, $\sigma_{\rm ceph}=0.25$, $\sigma_{\rm SN}=0.13$, and $N_{\rm HF}=280$ Hubble-flow supernovae with $\sigma_{\rm HF}=0.14$. Substituting line 1 into line 2 and line 2 into line 3 of (T2.107) writes $\operatorname{Var}(\hat{a})$ as five separate terms, one per source of noise:

$$\begin{aligned}
\operatorname{Var}(\hat{a})&=\underbrace{\frac{\sigma_{\rm geo}^2}{N_{\rm anc}}}_{\text{anchor geometry}}+\underbrace{\frac{\sigma_{\rm ceph}^2}{N_{\rm anc}n_A}}_{\text{anchor Cepheids}}+\underbrace{\frac{\sigma_{\rm SN}^2}{N_{\rm cal}}}_{\text{calibrator SNe}}+\underbrace{\frac{\sigma_{\rm ceph}^2}{N_{\rm cal}n_C}}_{\text{calibrator Cepheids}}+\underbrace{\frac{\sigma_{\rm HF}^2}{N_{\rm HF}}}_{\text{Hubble flow}}\\
&=\underbrace{\frac{0.03^2}{3}}_{3.0\times10^{-4}}+\underbrace{\frac{0.25^2}{300}}_{2.1\times10^{-4}}+\underbrace{\frac{0.13^2}{40}}_{4.2\times10^{-4}}+\underbrace{\frac{0.25^2}{1200}}_{0.5\times10^{-4}}+\underbrace{\frac{0.14^2}{280}}_{0.7\times10^{-4}}=1.05\times10^{-3},
\end{aligned}$$

where $300=N_{\rm anc}n_A=3\times100$ and $1200=N_{\rm cal}n_C=40\times30$. So $\sigma_a=0.032$ mag and $\sigma_{H_0}/H_0=0.4605\times0.032=1.49\%$. The calibrator supernovae and the anchors dominate; the Hubble flow, with its 280 supernovae, contributes least. Doubling the number of calibrators is worth far more than doubling the Hubble-flow sample.

The experiment. `07_distance_ladder.py` builds the full matrix A for this ladder (47 parameters, one row per measurement) and solves (T2.106):

Listing T2.9: The ladder as one linear model, solved by generalised least squares (`code/chT2/07_distance_ladder.py`)

```
    # rung 1: geometric distance moduli of the anchors
    for i in range(Na):
        add([(i, 1)], mu_anc[i] + rng.normal(0, cfg["sig_geo"]), cfg["sig_geo"])
    # rung 2: Cepheids, m = mu + M_W + b_W (log P - 1)
    for i, (mu, n) in enumerate([(m, cfg["Nceph_anc"]) for m in mu_anc] +
                                [(m, cfg["Nceph_cal"]) for m in mu_cal]):
        lp = rng.uniform(0.6, 1.8, n) - 1.0
        m = mu + truth["MW"] + truth["bW"] * lp + rng.normal(0, cfg["sig_ceph"], n)
        for k in range(n):
            add([(i, 1), (iMW, 1), (ibW, lp[k])], m[k], cfg["sig_ceph"])
    # rung 3a: one supernova in each calibrator host, m = mu + M_B
    for i in range(Nc):
        add([(Na + i, 1), (iMB, 1)], mu_cal[i] + truth["MB"] + rng.normal(0,
    cfg["sig_sn"]), cfg["sig_sn"])
    # rung 3b: Hubble-flow supernovae, m = M_B + 5 log10(cz [1 + (1-q0) z/2]) + 25 - a
    z = rng.uniform(0.023, 0.15, cfg["Nhf"])
    x = 5 * np.log10(C_KMS * z * (1 + 0.5 * (1 - truth["q0"]) * z)) + 25
    a_true = 5 * np.log10(truth["H0"])
    m = truth["MB"] + x - a_true + rng.normal(0, cfg["sig_hf"], cfg["Nhf"])
    for k in range(cfg["Nhf"]):
        add([(iMB, 1), (ia, -1)], m[k] - x[k], cfg["sig_hf"])
    return np.array(y), np.array(rows), np.array(sig), ia

def gls(y, A, sig):
    W = 1 / sig**2
    F = A.T @ (A * W[:, None])                    # Fisher matrix A^T C^-1 A
    cov = np.linalg.inv(F)
    theta = cov @ (A.T @ (W * y))
    return theta, cov
```

Each call to `add` writes one row of A: its nonzero entries say which parameters that measurement involves. Lines 53, 56 and 63 are the three kinds of shared-parameter rows that tie the rungs together. One mock ladder gives $H_0 = 73.90 \pm 1.10$ (true value 73), a 1.49% measurement, the same as the rung-by-rung estimate. Over 400 independent mock ladders the estimates average 72.99 with standard deviation 1.10, while the quoted errors average 1.09, and the 1σ interval covers the truth in 70% of them: the inverse Fisher matrix is the true covariance here, as it must be for a linear Gaussian model. Figure T2.25 shows the budget as the number of calibrators grows: the error falls from 3.05% with 5 calibrators to 1.22% with 160, and then flattens on the anchor floor of 0.80%.

T2.12.3 The real ladder and the Hubble tension

Where we have met H_0 before. Every H_0 so far was made up by us: the 70 of the mock supernovae of Section 3.17, where M was known, and the 73 of the mock ladder just built, recovered as 73.90 ± 1.10. In both the truth was known, and the only question was whether the estimator found it and whether its error bar covered it. Here the numbers are published measurements, the truth is not known, and the question becomes whether two of them can be measurements of the same constant. The ladder side is the same construction as above, the Hubble-flow fit of Section 3.17.4 with M supplied by the rungs, and its published error, 1.04, is close to our mock 1.10 because the mock was built to be SH0ES-sized. The other side is calibrated by something else entirely: no candle, but the sound horizon at recombination, whose angle on the sky fixes

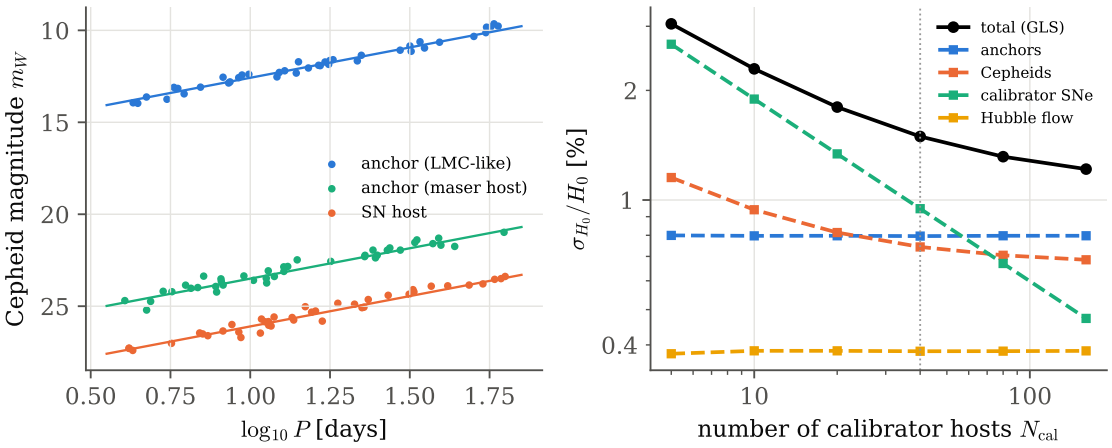

Figure T2.25: Left: mock Cepheids in two anchors and one supernova host follow parallel Leavitt laws; their vertical offsets are the differences of distance modulus. Right: the fractional error on H_0 from the full fit (black) and the contribution of each rung (computed by making that rung noiseless and subtracting in quadrature), against the number of calibrator hosts. The dotted line marks the default ladder.

H_0 as a parameter derived from the CMB fit (Section 10.6.3). The degeneracy of Section 3.17.4 reappears as the way to read the disagreement: since supernovae fix only $M - 5\log_{10} H_0$, a gap in H_0 is a gap in the luminosity of the candle. Section 9.23.1 later adds the ladder value to a CMB chain by reweighting, and Section 11.20 sets all the routes side by side.

Two kinds of measurement give H_0, and they answer different questions. The SH0ES team asks: *how fast are galaxies around us receding now, per megaparsec of distance, with distances from geometry alone?* Their ladder is the one built above, and the only physics it assumes is in the rungs themselves (parallax, the Leavitt law, standardised supernovae); no cosmological model enters except the small q_0 term of (T2.104). The Planck team asks a different question: *which ΛCDM universe produces the pattern of hot and cold spots we see in the CMB, emitted at $z \approx 1100$?* H_0 is one of the outputs of that fit. It is not measured locally but predicted forward, by running the fitted model from $z \approx 1100$ to today. So the two numbers are not two measurements of the same quantity by two instruments; one is a local measurement, the other a prediction of ΛCDM. If they disagree, either a rung of the ladder is wrong or the model that carries the CMB to today is.

method	H_0 [km/s/Mpc]	what it assumes
SH0ES, Cepheid ladder	73.04 ± 1.04	local geometry and the physics of each rung
Planck, CMB	67.36 ± 0.54	flat ΛCDM from $z \approx 1100$ to today
CCHP TRGB ladder	69.8 ± 1.7	local geometry, red giants in place of Cepheids

The values are from [24], [25, Table 2] (TT,TE,EE+lowE+lensing) and [100, Sec. IV.A], which quotes the TRGB value of the Carnegie–Chicago Hubble Program (CCHP) of Freedman et al. The TRGB ladder lands between the other two.

How many standard deviations apart? The two measurements are independent, so the variance of their difference is the sum of their variances (Chapter 4), and

$$\frac{73.04 - 67.36}{\sqrt{1.04^2 + 0.54^2}} = \frac{5.68}{1.17} = 4.8,$$

the "about 5σ" of [100, Sec. IV.A].

The same gap in magnitudes. By (T2.105) the Hubble-flow supernovae fix only $M_B - a = M_B - 5\log_{10} H_0$. Hold that combination fixed and raise H_0 by a factor r: a grows by $5\log_{10} r$, so M_B must grow by the same amount. A larger M_B means intrinsically fainter supernovae, which for the same apparent magnitude must be nearer, and nearer galaxies with the same redshifts mean a faster expansion. For the two values,

$$\Delta M_B = 5\log_{10}\frac{73.04}{67.36} = 5\times 0.035 = 0.18\ \text{mag}:$$

the whole tension is equivalent to a disagreement of 0.18 mag about how bright type Ia supernovae are, with the ladder's supernovae the fainter ones. That is why it is cleanest to carry the ladder into a cosmological fit not as a value of H_0 but as a Gaussian prior on M_B [100, Sec. IV.E, eq. (1)]: the ladder calibrates M_B, and H_0 then follows from the supernovae together with whatever cosmological model is being tested.

Example: can a local void explain it? Suppose we live inside a sphere whose mean density is below the cosmic mean, with δ the mean density contrast inside the sphere ($\delta < 0$ for a void). Why would the local expansion be faster? The denser surroundings pull the matter at the edge of the sphere outwards, and the sphere has less mass inside to hold it back, so matter streams out of the void. On top of the Hubble flow there is an outflow, and someone inside who measures recession velocities sees them grow faster with distance than the global H_0: the local rate is $H_0 + \delta H$ with $\delta H > 0$. How much faster? Linear continuity, $\dot\delta = -\nabla\cdot\boldsymbol{v}$ for the peculiar velocity $\boldsymbol{v}$ (derived in Section T2.14, (T2.118)), and the growth rate $\dot\delta = fH\delta$ with $f \approx \Omega_m^{0.55} \approx 0.53$ give

$$\frac{\delta H_0}{H_0} \overset{(1)}{=} \frac{\nabla\cdot\boldsymbol{v}}{3H_0} \overset{(2)}{=} -\frac{\dot\delta}{3H_0} \overset{(3)}{=} -\frac{f}{3}\,\delta, \tag{T2.108}$$

(1) The extra outflow grows in proportion to distance, $\boldsymbol{v} = \delta H\,\boldsymbol{r}$, which is what a change δH of the local Hubble rate means. Its divergence is $\nabla\cdot\boldsymbol{v} = \partial_x v_x + \partial_y v_y + \partial_z v_z = 3\,\delta H$.

(2) Continuity: matter flowing out of the sphere lowers its density, $\dot\delta = -\nabla\cdot\boldsymbol{v}$.

(3) Linear growth, $\delta \propto D(t)$, so $\dot\delta = (\mathrm{d}\ln D/\mathrm{d}\ln a)(\dot a/a)\,\delta = fH\delta$, with $H = H_0$ today.

which is Abdalla et al.'s eq. (2) [100, Sec. IV.F]. The sign is as expected: $\delta < 0$ gives $\delta H_0 > 0$. How empty would the void have to be? The gap between the ladder and the CMB is $(73.04 - 67.36)/67.36 = 8.4\%$, about 8%, so

$$0.08 = \frac{0.53}{3}\,|\delta| \quad\Longrightarrow\quad |\delta| = \frac{3\times 0.08}{0.53} = 0.45,$$

a region almost half empty, over the whole volume probed by the Hubble-flow supernovae, out to $z = 0.15$ or some 600 Mpc. Density fluctuations on such scales are at the percent level, and theory and simulations put the expected scatter of the local H_0 at 0.5–1% [100, Sec. IV.F], an order of magnitude too small.

Where the statistics comes back in. The ladder is generalised least squares (Chapter 3), and its covariance is the inverse Fisher matrix (Chapter 10). Testing whether two measurements of H_0 agree is a hypothesis test on their difference (Chapter 4). Using the ladder as a prior on M_B is Bayesian combination of independent data (Chapter 5). Peculiar velocities and the local Hubble flow are taken up again as data in their own right in Section 11.16, and the local cosmic variance of H_0, the careful version of the void estimate above, in Section 11.17.

T2.13 Selection effects: what a flux limit does to a sample

Every survey has a faintest object it can detect. Close to that limit the survey does not see a fair sample of what is there: it sees the objects that happened to be brighter than average, because their fainter siblings at the same distance were lost. Treat the survivors as typical, and their distances come out too small. At high redshift, where most of the cosmological information sits, the supernovae look brighter than the model predicts, and the fit moves the cosmological parameters to make them so.

The plain claim is that "the mean absolute magnitude of type Ia supernovae is M_0". The everyday question is: *if I average the absolute magnitudes of the supernovae in my catalogue, do I get M_0?* The question hides a sampling rule. "The mean" of the luminosity function is an average over supernovae drawn uniformly *per unit volume*. A catalogue is drawn by a different rule: a supernova enters it if its apparent magnitude is below the limit. Change the sampling rule and the distribution changes, exactly as the distribution of an oscillator's position changes when we sample it uniformly in position rather than in time. The physics of the explosions is the same in both cases; what differs is how the objects were selected.

Selection is conditioning, and conditioning has a picture (Figure 1.11, Section 5.2). Draw every supernova that went off in the survey volume as a point in a rectangle: that rectangle is the full sample space, and the luminosity function describes how the points are spread over it. Detection draws a line through the rectangle: on one side are the supernovae brighter than the limit, $m < m_{\lim}$, on the other the ones we never see. Once we know a supernova is in the catalogue, everything on the far side of the line is discarded. The surviving region becomes the new sample space, and every probability is measured again as a fraction of its area. If the survivors are a fraction $P(\text{detected})$ of the whole, every probability of the full population is divided by that fraction. The mean of the survivors, and the likelihood of what they show us, are both computed in the shrunken space. Nothing about an individual explosion has changed; only the region against which it is measured has.

The question. For candles with a Gaussian spread of absolute magnitudes, (1) what is the mean absolute magnitude of the ones a flux-limited survey detects, (2) how biased are the Hubble residuals near the limit, and (3) what likelihood removes the bias?

T2.13.1 The classical Malmquist bias

The inputs are three.

1. *Physical:* the candles are spread uniformly through a static Euclidean space, with number density n.
2. *Physical:* their absolute magnitudes follow a Gaussian **luminosity function** [the distribution of absolute magnitudes among the candles] $\varphi(M) = \mathcal{N}(M_0, \sigma^2)$, the same everywhere and independent of position.
3. *Selection:* we look at the objects whose apparent magnitude lies in a narrow interval $[m, m + \mathrm{d}m]$.

What we observed is an object of apparent magnitude m. *What could have produced it?* Any absolute magnitude M, placed at the distance modulus $\mu = m - M$ that makes it appear at m. *How likely is each candidate?* It is the probability of drawing that M from the luminosity function, times the number of places at that distance where the object could be. The number of objects in

a shell of radius r and thickness $\mathrm{d}r$ is $n\,4\pi r^2\mathrm{d}r$, and r is tied to μ by $r = 10^{\mu/5+1}$ pc. So

$$\mathrm{d}N(M,\mu) \overset{(1)}{=} n\,\varphi(M)\,\mathrm{d}M\,4\pi r^2\,\frac{\mathrm{d}r}{\mathrm{d}\mu}\,\mathrm{d}\mu \overset{(2)}{=} n\,\varphi(M)\,\mathrm{d}M\,4\pi\frac{\ln 10}{5}\,r^3\,\mathrm{d}\mu \;\propto\; \varphi(M)\,10^{0.6\mu}\,\mathrm{d}M\,\mathrm{d}\mu,$$

$$p(M\mid m) \overset{(3)}{=} \frac{\varphi(M)\,10^{0.6(m-M)}}{\int \varphi(M')\,10^{0.6(m-M')}\mathrm{d}M'} \overset{(4)}{=} \mathcal{N}\big(M_0 - 0.6\ln 10\,\sigma^2,\ \sigma^2\big). \tag{T2.109}$$

(1) Independence of luminosity and position (inputs 1 and 2): the joint density is the product. Change variable from r to μ.
(2) $r \propto 10^{\mu/5}$, so $\mathrm{d}r/\mathrm{d}\mu = (\ln 10/5)\,r$, and $r^3 \propto 10^{3\mu/5}$.
(3) Fix m (input 3): $\mu = m - M$, and $\mathrm{d}\mu = \mathrm{d}m$ does not depend on M. Normalise over M.
(4) $10^{-0.6M} = e^{-0.6\ln 10\,M}$. Multiply it into the Gaussian and complete the square: $-\frac{(M-M_0)^2}{2\sigma^2} - kM = -\frac{(M-M_0+k\sigma^2)^2}{2\sigma^2} + \text{const}$ with $k = 0.6\ln 10$.

Key idea: Malmquist bias

In a flux-limited sample of candles spread uniformly in Euclidean space, the detected objects are on average brighter than the luminosity function by

$$\langle M\rangle_{\mathrm{det}} - M_0 = -0.6\ln 10\;\sigma^2 = -1.382\,\sigma^2,$$

at every apparent magnitude. The reason is volume: there is more space at large distances, so an object at a given m is more likely to be a bright one far away than a faint one nearby.

The shift does not depend on m or on where the limit is, so the whole flux-limited sample shares it. The size matters. For raw supernovae, $\sigma = 0.4$ mag, the shift is

$$\langle M\rangle_{\mathrm{det}} - M_0 = -1.382\times 0.4^2 = -0.22\ \text{mag}.$$

Which way does that move a distance? We infer the distance modulus as $\mu_{\mathrm{inf}} = m - M_0$. The detected supernovae really have, on average, $M = M_0 - 0.22$, so their true modulus is $\mu = m - M_0 + 0.22$, and the inferred one is too small by 0.22: a candle that is brighter than we assume looks closer than it is. Since $D_L \propto 10^{\mu/5}$ by (T2.97),

$$\frac{D_{\mathrm{inf}}}{D_{\mathrm{true}}} = 10^{-0.22/5} = 10^{-0.044} = 0.90,$$

so distances come out 10% too small. After standardisation, $\sigma = 0.12$ mag, the shift is $1.382\times 0.12^2 = 0.020$ mag and $10^{-0.020/5} = 0.99$, a 1% distance error, which is still as large as the statistical error of a modern survey. The key idea depends on its inputs. In an expanding universe the volume does not grow as r^3; if the spread σ itself depends on distance, or the luminosity function has a non-Gaussian tail, the number changes. The mechanism, a luminosity function reweighted by the volume where each luminosity can be seen, does not.

T2.13.2 Near the limit: a truncated Gaussian

Now the version that matters for a supernova Hubble diagram. At redshift z, the model predicts a mean apparent magnitude $\bar m(z;\boldsymbol\theta) = M_B + \mu(z;\boldsymbol\theta)$, and the observed magnitudes scatter about it, $m = \bar m + \epsilon$ with $\epsilon \sim \mathcal{N}(0,\sigma^2)$. The survey keeps a supernova only if $m < m_{\mathrm{lim}}$. *What is the mean residual of the supernovae it keeps?* With $t \equiv (m_{\mathrm{lim}} - \bar m)/\sigma$ the distance of the limit from the mean in units of σ, and ϕ, Φ the standard normal density and distribution function,

$$\mathbb{E}[\epsilon\mid \epsilon < t\sigma] \overset{(1)}{=} \frac{\int_{-\infty}^{t\sigma} \epsilon\,\frac{1}{\sigma}\phi(\epsilon/\sigma)\,\mathrm{d}\epsilon}{\Phi(t)} \overset{(2)}{=} \frac{-\sigma\big[\phi(\epsilon/\sigma)\big]_{-\infty}^{t\sigma}}{\Phi(t)} \overset{(3)}{=} -\sigma\,\frac{\phi(t)}{\Phi(t)}. \tag{T2.110}$$

(1) Conditional expectation: integrate over the kept region and divide by its probability $\mathrm{P}(\epsilon < t\sigma) = \Phi(t)$. The division is the renormalisation of the shrunken sample space: the kept region has total probability $\Phi(t)$, and dividing by it makes the probabilities inside it add up to one again.
(2) $\frac{\mathrm{d}}{\mathrm{d}\epsilon}\phi(\epsilon/\sigma) = -\frac{\epsilon}{\sigma^2}\phi(\epsilon/\sigma)$, so $\epsilon\,\phi(\epsilon/\sigma)/\sigma$ is $-\sigma$ times the derivative of $\phi(\epsilon/\sigma)$.
(3) ϕ vanishes at $-\infty$.

Two cases give the result a size. Far from the limit ($t \gg 1$), $\Phi(t) \to 1$ (almost nothing is cut) and $\phi(t) \to 0$ (the Gaussian has no weight there), so the bias vanishes. Where half the supernovae are lost ($t = 0$), $\phi(0) = 1/\sqrt{2\pi}$ and $\Phi(0) = 1/2$, so the bias is $-\sigma \cdot 2/\sqrt{2\pi} = -\sigma\sqrt{2/\pi} = -0.80\,\sigma$. Beyond that ($t < 0$) it grows without bound. Figure T2.26 shows the mechanism at three distances.

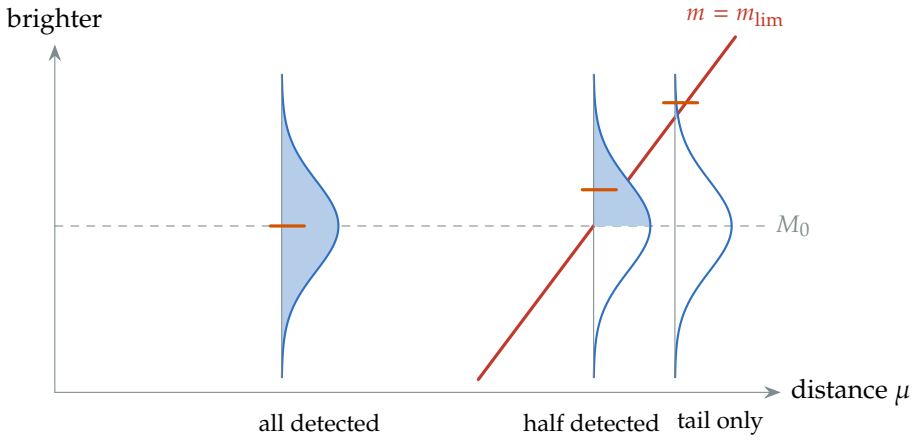

Figure T2.26: The luminosity function of the candles (blue bell, brighter upwards) at three distances, with the flux limit (red). Only the shaded part, brighter than the limit, is detected. The orange tick marks the mean brightness of the detected objects: at the true M_0 nearby, 0.8σ brighter where the limit cuts the bell in half, and about 2.7σ brighter where only the bright tail survives.

The fix: write the likelihood of what was selected. The likelihood asks how probable the observed magnitudes are under each model. For a catalogue, the honest version of that question is: how probable are they *among the supernovae that could have entered the catalogue*? That is the shrunken sample space again, now for a density instead of a mean:

$$p(m \mid z, \boldsymbol{\theta}, \text{detected}) \overset{(1)}{=} \frac{p(m, \text{detected} \mid z, \boldsymbol{\theta})}{\mathrm{P}(\text{detected} \mid z, \boldsymbol{\theta})} \overset{(2)}{=} \frac{\mathcal{N}\big(m; \bar{m}(z;\boldsymbol{\theta}), \sigma^2\big)}{\Phi\big(t(z;\boldsymbol{\theta})\big)} \qquad (m < m_{\mathrm{lim}}),$$

$$-\ln \mathcal{L} \overset{(3)}{=} \sum_i \left[\frac{(m_i - \bar{m}_i)^2}{2\sigma^2} + \ln\sigma + \tfrac{1}{2}\ln 2\pi + \ln\Phi(t_i)\right]$$

$$\overset{(4)}{=} \sum_i \left[\frac{(m_i - \bar{m}_i)^2}{2\sigma^2} + \ln\Phi(t_i)\right] + \text{const.} \tag{T2.111}$$

(1) The definition of conditional probability: the joint density divided by the probability of the condition.

(2) For $m < m_{\rm lim}$ "detected" is automatically true, so the joint density is just the Gaussian. The probability of detection is $\mathrm{P}(m < m_{\rm lim}) = \Phi(t)$, the same $\Phi(t)$ that renormalised the mean in (T2.110).

(3) The supernovae are independent, so the likelihood is a product and $-\ln\mathcal{L}$ a sum. Write out $-\ln$ of the Gaussian density $\frac{1}{\sqrt{2\pi}\sigma}e^{-(m-\bar m)^2/2\sigma^2}$, and note that $-\ln(1/\Phi) = +\ln\Phi$.

(4) σ is known and the same for every model, so $\ln\sigma + \frac{1}{2}\ln 2\pi$ is a constant that does not move the fit.

The first term is the naive $\chi^2/2$. The second is new, and it depends on $\boldsymbol{\theta}$ through $t_i = (m_{\rm lim} - \bar m_i)/\sigma$. Since $\Phi \le 1$, $\ln\Phi(t) \le 0$: the term *lowers* $-\ln\mathcal{L}$, most strongly for a model whose mean $\bar m$ lies near or beyond the limit, where $\Phi(t)$ is small. *What is that credit for?* Take one supernova detected at $m = m_{\rm lim} - 0.5\sigma$ and two models. Model A puts the mean exactly there, $\bar m = m_{\rm lim} - 0.5\sigma$, so $t = 0.5$. Model B puts the mean fainter than the limit, $\bar m = m_{\rm lim} + \sigma$, so $t = -1$ and the supernova sits 1.5σ out in the bright tail.

model	$\chi^2/2$	$\ln\Phi(t)$	$-\ln\mathcal{L}$ (no constant)
A, $t = 0.5$	0	$\ln 0.69 = -0.37$	-0.37
B, $t = -1$	$1.5^2/2 = 1.13$	$\ln 0.16 = -1.84$	-0.72

The naive fit prefers A by a factor $e^{1.13} \approx 3$, because under B this supernova is a 1.5σ excursion. But under B, *every* supernova we can see is an excursion into the bright tail: the selection guarantees it. Being in the tail is not evidence against B; it is what B predicts for the supernovae that got into the catalogue. The $\ln\Phi$ term returns exactly that credit, and with it B is, if anything, slightly preferred (by $e^{0.35} \approx 1.4$), because under B the detected supernovae pile up just inside the limit, which is where this one is. With many supernovae the balance is set by how they are spread inside the limit, which is what the full sum in (T2.111) weighs. (The number of detected supernovae is not used here. A likelihood that also used the count would add a term that does penalise a model for predicting too few detections.) The result is the likelihood of Chapter 3, written for the data *as they were collected*: a density for what could have been observed, given the rule that decided what got into the sample. Real surveys have no sharp limit. The detection probability $\eta(m)$ rises smoothly from 0 to 1 and depends on the observing conditions, so it is measured by injecting fake supernovae into the real images, and $\Phi(t)$ in (T2.111) becomes $\int \eta(m)\mathcal{N}(m;\bar m,\sigma^2)\,\mathrm{d}m$. Pantheon+ corrects each supernova by a bias computed from large simulations of the whole survey [26].

The experiment. `08_malmquist.py` does both calculations.

The Euclidean test. It places 4×10^5 candles uniformly in a ball and keeps those brighter than a limit. The mean M of the detected ones is shifted by -0.0138, -0.1280 and -0.348 mag for $\sigma = 0.1$, 0.3 and 0.5, against $-1.382\sigma^2 = -0.0138$, -0.1243 and -0.345 from the key idea.

The survey. Then it simulates supernova surveys in an expanding universe, with two samples:

sample	redshifts	selection
low redshift	$0.02 < z < 0.1$	complete: every supernova is kept
deep	$0.1 < z < 1.2$	kept only if $m < m_{\rm lim} = 24$
both	flat ΛCDM with $\Omega_{m0} = 0.3$; scatter $\sigma = 0.15$ mag about $\bar m(z)$	

Each fit has two free numbers, Ω_{m0} and an overall magnitude offset (the combination $M_B - 5\log_{10}H_0$ of Section T2.12), which the complete low-redshift sample pins down. The two fits differ by one line:

Listing T2.10: The naive and the selection-aware negative log-likelihood (code/chT2/08_malmquist.py)

```
68 def nll(p, z, m, lim, corrected):
69     om, off = p
70     if not 0.02 < om < 0.98:
71         return 1e10
72     mod = mu_model(z, om) + off
73     t = (m - mod) / SIG
74     out = 0.5 * np.sum(t**2)
75     if corrected:
76         fin = np.isfinite(lim)
77         out += np.sum(norm.logcdf((lim[fin] - mod[fin]) / SIG))
78     return out
```

Line 74 is the $\chi^2/2$ of a standard fit. Line 77 adds $\sum \ln \Phi(t_i)$, the second term of (T2.111), for the supernovae of the deep sample.

The result. Figure T2.27 shows it. Half the supernovae are lost at $z \approx 0.73$, and in the last redshift bin that still contains supernovae ($z \approx 0.75$) the mean residual is -0.140 mag. Over 200 mock surveys the naive χ^2 returns $\Omega_{m0} = 0.353 \pm 0.019$, too high. The chain that leads there has three links. The selected high-redshift supernovae are brighter than the model mean, so they look nearer than they are. The offset is fixed by the complete low-redshift sample, so the only way the naive fit can bring the model to them is to shorten the model's distances at high redshift. In flat ΛCDM at fixed H_0, a shorter $D_L = (1+z)\,c\int_0^z \mathrm{d}z'/H(z')$ at high redshift needs a larger $H(z')$ in the past, so the expansion must have slowed down more since then: more deceleration, which needs more matter. The selection-aware likelihood returns 0.301 ± 0.018, unbiased, with the same scatter. The naive bias is almost three times its own error bar, and it would not shrink with more supernovae.

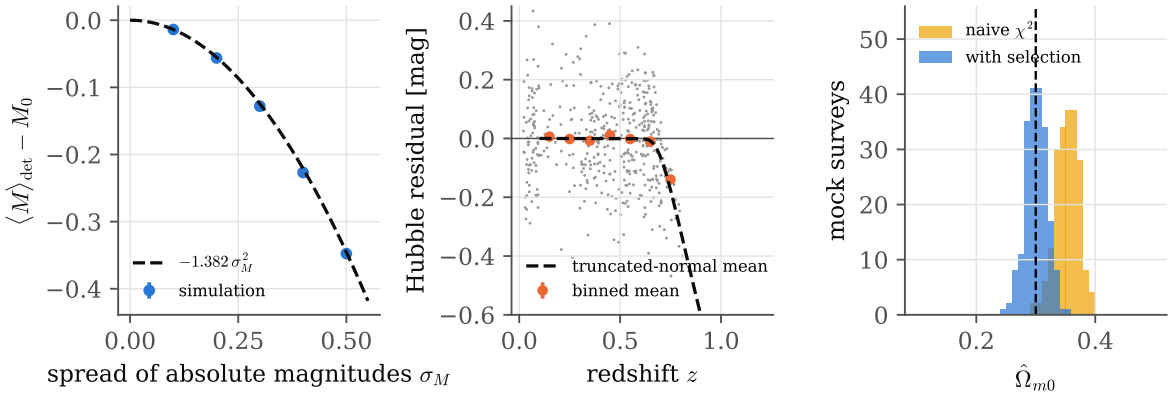

Figure T2.27: Left: the classical Malmquist shift measured in simulation against $-1.382\sigma^2$. Middle: Hubble residuals of a magnitude-limited survey; the binned means (orange) follow the truncated-normal mean $-\sigma\phi(t)/\Phi(t)$ (dashed) and plunge as the limit cuts into the population. Right: Ω_{m0} from many mock surveys; the naive fit is biased, the likelihood with the selection term is not.

A relative: Eddington bias. A related effect acts on counts rather than on luminosities. If the number of objects rises steeply towards faint fluxes, measurement noise scatters more objects up across a threshold than down, so the objects just above the threshold are, on average, fainter than they were measured. Both biases have the same cure: model the selection, and write the likelihood of the data that were actually kept.

Where the statistics comes back in. The conditional density (T2.109) is Bayes' theorem of Chapter 5, with the luminosity function as prior and the volume factor as likelihood. The truncated likelihood is the likelihood of Chapter 3 written for the data actually collected. Selection functions that are known only from simulations are a Monte Carlo problem (Chapter 6), and when they are folded into a hierarchical supernova model the posterior is explored by MCMC (Chapter 9).

T2.14 Galaxies as biased tracers in redshift space

A redshift survey records, for each galaxy, two angles on the sky and a redshift. The Dark Energy Spectroscopic Instrument (DESI) did this for more than six million galaxies and quasars in its first year: bright galaxies at $0.1 < z < 0.4$, luminous red galaxies at $0.4 < z < 1.1$, star-forming emission-line galaxies at $0.8 < z < 1.6$, quasars at $0.8 < z < 2.1$, and the absorption of quasar light by intergalactic hydrogen (the Lyman-α forest) out to $z \approx 4$ [101, Sec. 2.2, Table 1]. A fiducial cosmology turns each redshift into a distance and the survey into a three-dimensional map of points. The counts in cells of that map define the galaxy overdensity $\delta_g(\boldsymbol{x}) = n(\boldsymbol{x})/\bar{n} - 1$, and its two-point statistics, the correlation function $\xi_g(r)$ and the power spectrum $P_g(k)$ of Chapter 7, are what the statistics chapters work with.

The map is not the matter field. Three things stand between them. Galaxies form only where matter has collapsed into haloes, so they are *biased*: their density contrast is larger than that of the matter. Galaxies are discrete points, so their map carries *shot noise*. And the redshift contains the galaxy's peculiar velocity as well as its distance, so the map is *distorted* along the line of sight.

The question. How is the galaxy power spectrum related to the matter power spectrum on large scales, and what is the noise of a measured P_g?

T2.14.1 Why galaxies cluster more strongly than matter

The inputs are two. *Physical:* a galaxy forms where the local density, smoothed on the scale of a halo, exceeds a threshold. *Mathematical:* the initial density field is Gaussian. Write the local density at $\boldsymbol{x}$ as $u(\boldsymbol{x})$, with variance σ^2, and say a galaxy forms where $u > \nu\sigma$; the number ν measures how rare the galaxies are. The local density is a sum of two parts, $u = u_{\text{long}} + u_{\text{short}}$: a long-wavelength part, shared with the surroundings over tens of megaparsecs, and a short-wavelength part that varies from halo to halo and decides locally whether the threshold is crossed. Only the first can link a galaxy to matter far away.

What we know is that a galaxy formed at $\boldsymbol{x}$. *What does that tell us about the matter at* $\boldsymbol{y}$*, a distance* r *away?* The galaxy is a sign that $u(\boldsymbol{x})$ was high. Because $u(\boldsymbol{x})$ and $\delta(\boldsymbol{y})$ are correlated, the matter at $\boldsymbol{y}$ is denser than average too. The cross-correlation of galaxies and matter is exactly that expected density:

$$\xi_{gm}(r) \overset{(1)}{=} \frac{\mathbb{E}[I(\boldsymbol{x})\,\delta(\boldsymbol{y})]}{\mathbb{E}[I]} \overset{(2)}{=} \mathbb{E}\left[\delta(\boldsymbol{y}) \,|\, u(\boldsymbol{x}) > \nu\sigma\right] \overset{(3)}{=} \mathbb{E}\left[\frac{\xi(r)}{\sigma^2}\, u \,\middle|\, u > \nu\sigma\right] \overset{(4)}{=} \frac{\xi(r)}{\sigma}\,\frac{\phi(\nu)}{1-\Phi(\nu)} \equiv b_L\,\xi(r). \tag{T2.112}$$

(1) $I(\boldsymbol{x})$ is 1 where a galaxy forms and 0 elsewhere, so $\delta_g = I/\mathbb{E}[I] - 1$; the -1 drops out because $\mathbb{E}[\delta] = 0$.

(2) Dividing by $\mathbb{E}[I] = \mathrm{P}(u > \nu\sigma)$ turns the average into a conditional expectation.

(3) For two jointly Gaussian variables the conditional mean is linear: $\mathbb{E}[\delta(\boldsymbol{y}) \,|\, u] = \frac{\mathrm{Cov}(\delta(\boldsymbol{y}),u(\boldsymbol{x}))}{\mathrm{Var}\,u}\,u$ (derived in Eq. (7.7) and Section 2.12.4). Which part of $u(\boldsymbol{x})$ is correlated with matter a

distance r away? Split $u = u_{\text{long}} + u_{\text{short}}$ as above. The short-wavelength part varies over the size of a halo and has no memory of what happens tens of megaparsecs away, so $\operatorname{Cov}(\delta(\boldsymbol{y}), u_{\text{short}}(\boldsymbol{x})) = 0$. The long-wavelength part is the matter field itself, smoothed over a region much smaller than r, so $\operatorname{Cov}(\delta(\boldsymbol{y}), u_{\text{long}}(\boldsymbol{x})) = \xi(r)$, the matter correlation. Hence $\operatorname{Cov}(\delta(\boldsymbol{y}), u(\boldsymbol{x})) = \xi(r)$, while $\operatorname{Var} u = \sigma^2$ counts both parts.

(4) The mean of a Gaussian above $\nu\sigma$ is $\sigma\phi(\nu)/[1-\Phi(\nu)]$, the upper-tail version of (T2.110).

For rare galaxies, $\nu \gg 1$, the ratio $\phi(\nu)/[1-\Phi(\nu)] \to \nu$, and $b_L \to \nu/\sigma$: the rarest objects are the most strongly clustered. This is Kaiser's explanation of why rich galaxy clusters cluster more strongly than galaxies.

From galaxy–matter to galaxy–galaxy. Equation (T2.112) conditions on one galaxy and looks at the matter. The galaxy map has a galaxy at both ends of each pair, so both points are now conditioned. Write $x_1 = u(\boldsymbol{x})/\sigma$ and $x_2 = u(\boldsymbol{y})/\sigma$ for the two local densities in units of σ. They are jointly Gaussian with unit variances and a small correlation $\rho = \xi(r)/\sigma^2$ (the long-wavelength parts carry it, as in item 3). Then

$$1+\xi_{gg}(r) \overset{(1)}{=} \frac{\mathbb{E}[I(\boldsymbol{x})I(\boldsymbol{y})]}{\mathbb{E}[I]^2} \overset{(2)}{=} \frac{1}{\mathbb{E}[I]^2}\int_\nu^\infty\!\!\int_\nu^\infty \phi(x_1)\phi(x_2)\big(1+\rho\, x_1x_2\big)\,\mathrm{d}x_1\mathrm{d}x_2$$
$$\overset{(3)}{=} 1+\rho\left[\frac{\int_\nu^\infty x\,\phi(x)\,\mathrm{d}x}{1-\Phi(\nu)}\right]^2 \overset{(4)}{=} 1+\frac{\xi(r)}{\sigma^2}\left[\frac{\phi(\nu)}{1-\Phi(\nu)}\right]^2 = 1+b_L^2\,\xi(r). \tag{T2.113}$$

(1) $\delta_g = I/\mathbb{E}[I]-1$, so $\mathbb{E}[(1+\delta_g(\boldsymbol{x}))(1+\delta_g(\boldsymbol{y}))] = 1+\xi_{gg}$.

(2) The bivariate Gaussian density with correlation ρ is $\frac{1}{2\pi\sqrt{1-\rho^2}}\exp\big[-\frac{x_1^2-2\rho x_1x_2+x_2^2}{2(1-\rho^2)}\big]$. To first order in ρ the prefactor and the $1-\rho^2$ are unchanged, and the exponent gains $+\rho x_1x_2$, so the density is $\phi(x_1)\phi(x_2)e^{\rho x_1x_2} \approx \phi(x_1)\phi(x_2)(1+\rho x_1x_2)$.

(3) The 1 integrates to $[1-\Phi(\nu)]^2 = \mathbb{E}[I]^2$. The ρx_1x_2 term factorises into two identical one-dimensional integrals.

(4) $\int_\nu^\infty x\phi(x)\mathrm{d}x = [-\phi(x)]_\nu^\infty = \phi(\nu)$, as in (T2.110). Compare with (T2.112): $b_L = \phi(\nu)/\{\sigma[1-\Phi(\nu)]\}$.

Each conditioned point contributes one factor b_L: a galaxy at $\boldsymbol{x}$ raises the expected density near $\boldsymbol{y}$ by $b_L\xi$ (that is (T2.112)), and the threshold at $\boldsymbol{y}$ turns that raised density into b_L times as many extra galaxies. So $\xi_{gg} = b_L^2\,\xi$, and since the power spectrum is the Fourier transform of the correlation function, $P_{gg} = b_L^2 P$.

This bias is "Lagrangian": it describes where the galaxies formed. Afterwards they move with the matter, and the motion adds the matter's own contrast. *Label each bit of matter by where it started.* Call the starting (Lagrangian) position $\boldsymbol{q}$. Write $\delta_L(\boldsymbol{q})$ for the linear matter contrast there, grown to the time we observe with the linear growth factor, so that $b_L\delta_L$ is the galaxies' contrast of (T2.112) at their birth place. At the start the matter is uniform to first order, while the galaxies already carry their contrast $\delta_g^L = b_L\delta_L$. *Move everything.* Each bit of matter, and any galaxy riding in it, moves to its present (Eulerian) position $\boldsymbol{x} = \boldsymbol{q} + \boldsymbol{\psi}(\boldsymbol{q})$, with $\boldsymbol{\psi}$ the displacement. A small volume d^3q becomes $\mathrm{d}^3x = J\,\mathrm{d}^3q$, with $J = |\det(\partial x_i/\partial q_j)|$ the Jacobian of the map. *Count.* No galaxy and no matter is created or lost on the way, so the number in the small volume is the same before and after:

$$\bar n_g\big(1+\delta_g(\boldsymbol{x})\big)\,\mathrm{d}^3x \overset{(1)}{=} \bar n_g\big(1+b_L\delta_L(\boldsymbol{q})\big)\,\mathrm{d}^3q \quad\Longrightarrow\quad 1+\delta_g \overset{(2)}{=} \frac{1+b_L\delta_L}{J}, \qquad 1+\delta \overset{(3)}{=} \frac{1}{J},$$
$$1+\delta_g \overset{(4)}{=} \big(1+b_L\delta_L\big)\big(1+\delta\big) \overset{(5)}{=} 1+b_L\delta+\delta+O(\delta^2). \tag{T2.114}$$

(1) Number conservation for the galaxies; $\bar n_g$, the mean density, is the same before and after because the total volume and number do not change.

(2) Divide by $\bar{n}_g\,\mathrm{d}^3x = \bar{n}_g J\,\mathrm{d}^3q$.
(3) The same count for the matter, which started uniform.
(4) Eliminate J between the two.
(5) Multiply out and keep first-order terms. To first order the evolved contrast and the linear one are the same field, $\delta = \delta_L$, and $\boldsymbol{x}$ and $\boldsymbol{q}$ differ only by the small displacement, so $\delta_L(\boldsymbol{q}) = \delta(\boldsymbol{x})$ to this order.

So, to first order,

$$\delta_g = (1 + b_L)\,\delta \equiv b\,\delta, \qquad P_g(k) = b^2 P(k), \tag{T2.115}$$

the "continuity" derivation that Cooray and Sheth mention for the large-scale bias of haloes [102, Sec. 3.3].

The halo-model version of the same idea gives each halo mass its bias, quoted in a different variable. A halo of mass m forms where the linear density smoothed on the scale of that mass, of rms $\sigma(m)$, exceeds the spherical-collapse threshold $\delta_{\rm sc} \approx 1.69$. In our language the threshold in units of σ is $\nu = \delta_{\rm sc}/\sigma(m)$. Cooray and Sheth use instead its square, which we write $\nu_h \equiv \delta_{\rm sc}^2/\sigma^2(m) = \nu^2$ to keep the two apart, and quote $b_1(m) = 1 + (\nu_h - 1)/\delta_{\rm sc}$ for spherical collapse, with an improved form fitted to simulations [102, eqs. (53), (68)–(70)]. *How does this compare with ours?* The "1+" is the step from Lagrangian to Eulerian just derived. For the Lagrangian part, our high-threshold limit gives

$$b_L \to \frac{\nu}{\sigma} = \frac{\delta_{\rm sc}}{\sigma^2} = \frac{\nu_h}{\delta_{\rm sc}},$$

so the halo formula differs from ours only by the -1. It comes from what is being counted. Our b_L belongs to the fraction of space above a threshold, a Gaussian tail. The halo model counts haloes in a narrow mass range, which is the rate at which that tail changes with mass, and for spherical collapse this abundance goes as $\nu_h^{1/2} e^{-\nu_h/2}$ instead of a tail probability. A long-wavelength contrast $\delta_{\rm long}$ lowers the barrier to $\delta_{\rm sc} - \delta_{\rm long}$, so $\nu_h \to (\delta_{\rm sc} - \delta_{\rm long})^2/\sigma^2$ and $\mathrm{d}\nu_h/\mathrm{d}\delta_{\rm long} = -2\nu_h/\delta_{\rm sc}$. The fractional change of the abundance is then

$$\frac{\mathrm{d}}{\mathrm{d}\delta_{\rm long}}\Big[\tfrac{1}{2}\ln\nu_h - \tfrac{1}{2}\nu_h\Big] = \Big(\frac{1}{2\nu_h} - \frac{1}{2}\Big)\Big(-\frac{2\nu_h}{\delta_{\rm sc}}\Big) = \frac{\nu_h - 1}{\delta_{\rm sc}},$$

the Lagrangian bias of the halo formula. The ν_h is our threshold effect, and the -1 comes from the prefactor $\nu_h^{1/2}$. For rare haloes, $\nu_h \gg 1$, the two agree. A galaxy population then has the occupation-weighted average bias $b_{\rm gal} = \int \mathrm{d}m\, n(m)\, b_1(m) \langle N_{\rm gal} \,|\, m\rangle/\bar{n}_{\rm gal}$, and $P_{\rm gal} \approx b_{\rm gal}^2 P_{\rm lin}$ on large scales [102, eqs. (130)–(131)]. Since $b_1(m)$ grows with ν_h, and so with mass, luminous red galaxies, which live in massive haloes, are more strongly biased than emission-line galaxies, which live in smaller ones.

Key idea: Linear bias

On scales much larger than a halo, the galaxy density contrast is proportional to the matter density contrast, $\delta_g = b\,\delta$, so $P_g(k) = b^2 P(k)$ and $\xi_g(r) = b^2 \xi(r)$. The shape of the clustering is the matter's; only its amplitude belongs to the galaxies. The bias is a nuisance parameter in every fit of galaxy clustering.

T2.14.2 Shot noise

Galaxies are a discrete sample of a continuous field: given the field, the number of galaxies in a small cell is Poisson-distributed with mean $\bar{n}(1 + \delta_g)\,\mathrm{d}V$ (Section 2.5.1). What does that do to the measured power? Put $N = \bar{n}V$ galaxies at positions $\boldsymbol{x}_i$ in a box of volume V. The density is

a sum of spikes, $n(\boldsymbol{x}) = \sum_i \delta_D(\boldsymbol{x} - \boldsymbol{x}_i)$, and its Fourier transform at any $\boldsymbol{k} \neq 0$ is a sum of phases, so with the convention $\mathbb{E}[\delta_{\boldsymbol{k}} \delta^*_{\boldsymbol{k}}] = V P(k)$ of Section 11.1.3,

$$\hat{P}_g(k) = \frac{|\delta_{g,\boldsymbol{k}}|^2}{V} \overset{(1)}{=} \frac{1}{V\bar{n}^2} \sum_i \sum_j e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}_i - \boldsymbol{x}_j)} \overset{(2)}{=} \frac{1}{V\bar{n}^2}\Big[N + \sum_{i \neq j} e^{-i\boldsymbol{k}\cdot(\boldsymbol{x}_i - \boldsymbol{x}_j)}\Big],$$
$$\langle \hat{P}_g(k) \rangle \overset{(3)}{=} \frac{N}{V\bar{n}^2} + b^2 P(k) \overset{(4)}{=} b^2 P(k) + \frac{1}{\bar{n}}. \tag{T2.116}$$

(1) $\delta_g = n/\bar{n} - 1$, and the -1 only touches $\boldsymbol{k} = 0$, so $\delta_{g,\boldsymbol{k}} = \bar{n}^{-1} \sum_i e^{-i\boldsymbol{k}\cdot\boldsymbol{x}_i}$; the modulus squared is a double sum.
(2) Split off the $i = j$ terms: each is $e^0 = 1$, and there are N of them.
(3) The pairs of different galaxies are the clustering: averaged over realisations, their phases add up to $V\bar{n}^2\, b^2 P(k)$, the power of the field the galaxies trace.
(4) $N = \bar{n}V$.

The self-pairs, each galaxy paired with itself, add a constant $1/\bar{n}$ at every k: a white-noise floor, the **shot noise** (derived in full in Section 11.1.3).

How noisy is the measured $\hat{P}_g$? The Gaussian-field result of Chapter 7 answers it in two steps. *Count the modes.* In a box of volume V the allowed wavevectors sit on a grid, one per $(2\pi)^3/V$ of $\boldsymbol{k}$-space. A shell of radius k and width Δk has volume $4\pi k^2 \Delta k$, so it holds $N_k = 4\pi k^2 \Delta k\, V/(2\pi)^3 = V k^2 \Delta k/(2\pi^2)$ grid points. The field is real, so $\delta_{-\boldsymbol{k}} = \delta^*_{\boldsymbol{k}}$ and only $N_k/2$ of them are independent. *The error of one shell.* One independent mode gives $|\delta_{\boldsymbol{k}}|^2/V$, whose standard deviation equals its mean (it is $\frac{1}{2}\chi^2_2$ times the mean, (7.26)), and the mean is now the total power $b^2P + 1/\bar{n}$. Averaging $N_k/2$ independent modes divides the variance by $N_k/2$ ((7.27)), so $\sigma_P = \sqrt{2/N_k}\,(b^2P + 1/\bar{n})$. Divide by the signal b^2P:

$$\frac{\sigma_P}{b^2 P} = \sqrt{\frac{2}{N_k}}\Big(1 + \frac{1}{\bar{n} b^2 P}\Big). \tag{T2.117}$$

Two terms limit a survey. Cosmic variance, the $\sqrt{2/N_k}$, falls only with volume. Shot noise is negligible once $\bar{n}b^2P \gtrsim 1$. A survey designer therefore covers as much volume as possible with just enough galaxies to reach $\bar{n}P \approx 1$ on the scales of interest, around $k = 0.1\,h\,\mathrm{Mpc}^{-1}$ [98, Sec. 4.4.5]. DESI's "effective volume" $V_{\mathrm{eff}} = \int [\bar{n}P/(1 + \bar{n}P)]^2 \mathrm{d}V$ is this trade-off in one number [101, Table 1].

If several galaxies share one halo, their pairs add a second constant on large scales, the one-halo term $\int \mathrm{d}m\, n(m) \langle N(N-1) \,|\, m \rangle / \bar{n}^2$ [102, eq. (128)]. It behaves like extra shot noise.

T2.14.3 Redshift-space distortions

The redshift of a galaxy measures its distance plus its peculiar velocity along the line of sight. In comoving coordinates the map position is $\boldsymbol{s} = \boldsymbol{x} + u_z \hat{\boldsymbol{z}}$, with $\hat{\boldsymbol{z}}$ the line of sight and $u_z = v_z/(aH)$ the velocity expressed as a distance. Galaxies falling towards an overdensity from in front are pushed back, those behind are pulled forward, and the structure looks squashed along the line of sight (Figure T2.28).

How strong is the squashing? The inputs are: linear theory ($|\delta| \ll 1$); a distant observer, so the line of sight is the same direction $\hat{\boldsymbol{z}}$ for every galaxy; and velocities set by the growth of structure. That last input needs a short derivation, because the velocity is what moves the galaxies in the map.

The velocities from the growth of structure. Matter that flows out of a region lowers its density. In comoving coordinates, with $\boldsymbol{v}$ the peculiar velocity, mass conservation to first order in δ and

$\boldsymbol{v}$ reads

$$\frac{\partial\delta}{\partial t} \overset{(1)}{=} -\frac{1}{a}\,\nabla\cdot\boldsymbol{v}, \qquad \frac{\partial\delta}{\partial t} \overset{(2)}{=} fH\,\delta \quad\Longrightarrow\quad \nabla\cdot\boldsymbol{v} \overset{(3)}{=} -afH\,\delta, \qquad \nabla\cdot\boldsymbol{u} \overset{(4)}{=} -f\,\delta. \tag{T2.118}$$

(1) The continuity equation: the outflow rate through the surface of a small comoving volume, per unit volume, is $\nabla\cdot\boldsymbol{v}$ in physical units, and a comoving gradient is a times a physical one, hence the $1/a$.
(2) Linear growth: $\delta(\boldsymbol{x},t) = \delta(\boldsymbol{x},t_0)D(t)$, with D the linear growth factor, so $\partial\delta/\partial t = (\dot D/D)\delta = (\mathrm{d}\ln D/\mathrm{d}\ln a)(\dot a/a)\delta = fH\delta$, which defines the growth rate $f = \mathrm{d}\ln D/\mathrm{d}\ln a \approx \Omega_m(z)^{0.55}$.
(3) Equate the two and multiply by $-a$.
(4) Divide by aH: $\boldsymbol{u} = \boldsymbol{v}/(aH)$ is the velocity expressed as a comoving distance.

In physical coordinates, with $\boldsymbol{r} = a\boldsymbol{x}$, the first relation is $\dot\delta = -\nabla_{\boldsymbol{r}}\cdot\boldsymbol{v}$, the form used for the local void in Section T2.12. The divergence fixes only part of $\boldsymbol{u}$. In linear theory any rotation of the flow decays as the universe expands, so the flow is a gradient, $\boldsymbol{u} = \nabla\Phi_u$, and in Fourier space $\boldsymbol{u}_{\boldsymbol{k}} = i\boldsymbol{k}\,\Phi_{u,\boldsymbol{k}}$ points along $\boldsymbol{k}$. Its divergence is $i\boldsymbol{k}\cdot\boldsymbol{u}_{\boldsymbol{k}} = -k^2\Phi_{u,\boldsymbol{k}}$, and setting this equal to $-f\,\delta_{\boldsymbol{k}}$ gives $\Phi_{u,\boldsymbol{k}} = f\,\delta_{\boldsymbol{k}}/k^2$, so

$$\boldsymbol{u}_{\boldsymbol{k}} = \frac{i\boldsymbol{k}\,f\,\delta_{\boldsymbol{k}}}{k^2}.$$

Now the map. Galaxies are conserved by the mapping from real to redshift space, $(1+\delta_s)\,\mathrm{d}^3s = (1+\delta_g)\,\mathrm{d}^3x$. So

$$\delta_s \overset{(1)}{=} \delta_g - \frac{\partial u_z}{\partial z} \xrightarrow{\text{Fourier}} \delta_{s,\boldsymbol{k}} \overset{(2)}{=} b\,\delta_{\boldsymbol{k}} - ik_z\,\frac{ik_z f}{k^2}\,\delta_{\boldsymbol{k}} \overset{(3)}{=} \left(b + f\mu^2\right)\delta_{\boldsymbol{k}},$$
$$P_s(k,\mu) \overset{(4)}{=} b^2\left(1+\beta\mu^2\right)^2 P(k), \qquad \beta \equiv \frac{f}{b}, \qquad \mu \equiv \frac{k_z}{k}. \tag{T2.119}$$

(1) $\mathrm{d}^3s = (1+\partial u_z/\partial z)\,\mathrm{d}^3x$, because only the z coordinate is moved; expand to first order.
(2) $\delta_g = b\delta$, and $\partial/\partial z \to ik_z$.
(3) $-i\cdot i = 1$ and $k_z^2/k^2 = \mu^2$, the squared cosine of the angle between $\boldsymbol{k}$ and the line of sight.
(4) Square the modulus and average over realisations.

This is the **Kaiser formula** [103]. Waves across the line of sight ($\mu = 0$) are untouched; waves along it are enhanced by $(1+\beta)^2$. Averaging over all directions gives the **monopole**. Directions are spread uniformly in μ between -1 and 1, and the factor is even in μ, so the average is $\int_0^1 \mathrm{d}\mu$. Expand the square and integrate term by term, with $\int_0^1 \mu^2\mathrm{d}\mu = \frac{1}{3}$ and $\int_0^1 \mu^4\mathrm{d}\mu = \frac{1}{5}$:

$$\int_0^1 \left(1+\beta\mu^2\right)^2\mathrm{d}\mu = \int_0^1 \left(1+2\beta\mu^2+\beta^2\mu^4\right)\mathrm{d}\mu = 1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2.$$

Why this separates growth from bias. The amplitude of P is usually written through σ_8 [the rms matter contrast in spheres of $8\,h^{-1}$Mpc], so that $P(k)/\sigma_8^2$ is a fixed shape. Write (T2.119) in that form, using $b(1+\beta\mu^2) = b + f\mu^2$:

$$P_s(k,\mu) = \left(b\sigma_8 + f\sigma_8\,\mu^2\right)^2\,\frac{P(k)}{\sigma_8^2}.$$

The part of the amplitude that does not depend on direction is $b\sigma_8$; the part that grows as μ^2 is $f\sigma_8$. Fitting how the power changes with μ gives the two separately: the angular dependence of the galaxy power spectrum measures the growth rate of structure, independently of the unknown bias. On small scales the random velocities inside haloes do the opposite and stretch groups into "fingers" pointing at the observer; that regime needs models beyond linear theory.

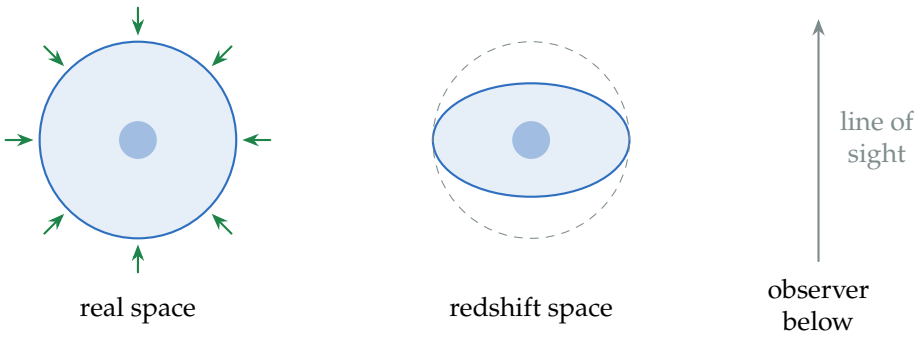

Figure T2.28: The Kaiser effect. Left: a spherical shell of galaxies around an overdensity, falling inwards (green arrows). Right: the same shell placed at the distances inferred from redshifts. Galaxies on the near side move away from us and appear farther; those on the far side move towards us and appear nearer. The shell is flattened along the line of sight; across it nothing changes (the dashed circle is the true shell).

T2.14.4 The experiment: thresholds, bias and squashing in a box

`09_tracers_rsd.py` tests (T2.112), (T2.115) and (T2.119) on a simulated universe. The ingredients:

ingredient	value	what it stands for
box side, grid	$1000\,h^{-1}$Mpc, 128^3 cells	a survey volume, periodic
matter field	Gaussian, linear CAMB $P(k)$ at $z=1$	the initial density, grown linearly
smoothing scale R	$10\,h^{-1}$Mpc, $\sigma_R = 0.229$	the size of a halo: $u_{\rm long}$
small-scale part	independent, rms 1.5	unresolved physics inside haloes: $u_{\rm short}$
total rms σ	1.516	$\sigma^2 = \sigma_R^2 + 1.5^2$
threshold	cells with $u > \nu\sigma$	where galaxies form
growth rate	$f = 0.876$ at $z=1$	sets the velocities

One sentence per ingredient. The box cannot resolve haloes, so the local density that decides where galaxies form is built by hand from the two parts of u: the field smoothed on the scale of a halo is $u_{\rm long}$, the part that correlates with distant matter; the independent small-scale part is $u_{\rm short}$, which by construction correlates with nothing. Cells above the threshold host galaxies. Then every particle and every galaxy is moved by its Zel'dovich displacement $\boldsymbol{\psi}_{\boldsymbol{k}} = i\boldsymbol{k}\delta_{\boldsymbol{k}}/k^2$, the first-order displacement of (T2.114) (it has $-\nabla\cdot\boldsymbol{\psi} = \delta$, so $1/J = 1+\delta$ to first order), and in redshift space by an extra $f\psi_z\hat{\boldsymbol{z}}$, which is the u_z of (T2.118).

Measuring b without cosmic variance. The box has only about a thousand independent modes at $k < 0.05\,h\,\mathrm{Mpc}^{-1}$, and in each of them the auto spectrum $|\delta_{g,\boldsymbol{k}}|^2$ scatters as much as its mean ((7.26)). But the box also holds the matter field that made it, and for each mode $\delta_{g,\boldsymbol{k}} = b\,\delta_{\boldsymbol{k}} + \text{noise}$. Then

$$\frac{\mathrm{Re}\big(\delta_{g,\boldsymbol{k}}\delta^*_{\boldsymbol{k}}\big)}{|\delta_{\boldsymbol{k}}|^2} = b + \frac{\mathrm{Re}(\text{noise}\cdot\delta^*_{\boldsymbol{k}})}{|\delta_{\boldsymbol{k}}|^2},$$

and the random amplitude $|\delta_{\boldsymbol{k}}|^2$ of the particular mode cancels in the first term. The ratio is b in every mode, whatever the realisation drew. The script averages it over $k < 0.05\,h\,\mathrm{Mpc}^{-1}$.

Figure T2.29 shows what came out. Before the move, the measured bias follows b_L of (T2.112): 1.06 ± 0.03 against 1.01 at $\nu = 1$, and 1.71 ± 0.09 against 1.57 at $\nu = 2$. The high-ν limit ν/σ (1.32 at $\nu = 2$) is still poor at these thresholds. After the move the bias is 2.62 ± 0.08 at $\nu = 2$, against $1 + b_L = 2.57$: the matter's own clustering has been added, as (T2.115) says.

A galaxy sample with $\nu = 1.5$ and $\bar{n} = 3\times10^{-4}\,h^3\mathrm{Mpc}^{-3}$ (299091 galaxies) has $b = 2.24 \pm 0.06$ from the cross spectrum (2.28 predicted). Its auto spectrum shows the noise terms of (T2.116).

Subtracting only the Poisson term $1/\bar{n} = 3343\,h^{-3}\mathrm{Mpc}^3$ gives an apparent bias of 2.42, too high. *What is missing?* Galaxies are placed in the selected cells as a Poisson number N with mean $\lambda = 2.13$ per cell, so a cell often holds two or more, and its galaxies pair with one another. Those pairs are at zero separation, like the self-pairs of (T2.116), so they too add a constant to the power. Counting them is one line. A Poisson number has $\mathbb{E}\,N = \mathrm{Var}\,N = \lambda$, so $\mathbb{E}[N(N-1)] = \mathbb{E}\,N^2 - \mathbb{E}\,N = (\lambda + \lambda^2) - \lambda = \lambda^2$. There are $N_{\mathrm{sel}} = \bar{n}V/\lambda$ selected cells, so the number of within-cell pairs is $N_{\mathrm{sel}}\lambda^2 = \bar{n}V\lambda$, and in the same normalisation as the $N/(V\bar{n}^2)$ of (T2.116),

$$\text{one-halo constant} = \frac{N_{\mathrm{sel}}\;\mathbb{E}[N(N-1)]}{V\bar{n}^2} = \frac{\bar{n}V\lambda}{V\bar{n}^2} = \frac{\lambda}{\bar{n}} = 2.13 \times 3343 \approx 7114\,h^{-3}\mathrm{Mpc}^3,$$

the cell version of the one-halo term above. Subtracting it too gives 2.19, in agreement with the cross spectrum. In redshift space the ratio $P_s(k,\mu)/P_r(k)$ rises with μ as $(1+\beta\mu^2)^2$ with $\beta = f/b = 0.391$; the monopole ratio is 1.314 against $1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2 = 1.292$. The highest-$\mu$ bin, which holds the fewest modes, scatters most. For the matter ($b = 1$) one box is not enough to read that bin, so the script repeats the matter part on fresh boxes. Averaged over 11 boxes, the enhancement at $\mu \approx 0.95$ is 3.08 ± 0.01 against 3.21: the Zel'dovich motions have begun to smear the largest line-of-sight displacements, the first sign of the non-linear regime.

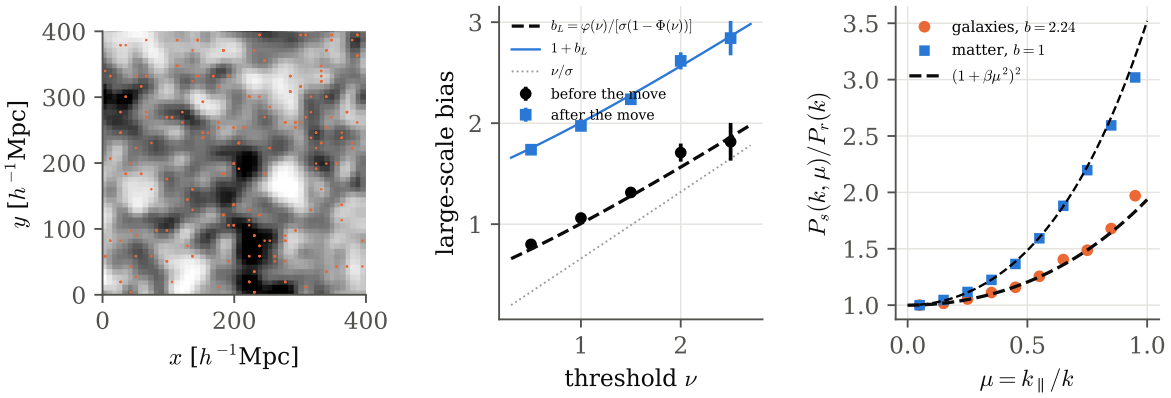

Figure T2.29: Left: a slice of the smoothed density field with the galaxies of one thin slab (orange); the galaxies sit in the dense regions. Middle: the large-scale bias against the threshold ν; before the move it follows b_L (dashed), after it $1 + b_L$ (blue line); the dotted line is the high-threshold limit ν/σ. Right: redshift-space power divided by real-space power, against μ; galaxies (orange) and matter (blue) follow the Kaiser factor with $\beta = f/b$ and $\beta = f$ respectively.

Nerfed, honestly. The box is a single Gaussian realisation of $(1\,h^{-1}\mathrm{Gpc})^3$ with $7.8\,h^{-1}\mathrm{Mpc}$ cells, run in seconds, and the haloes are replaced by a threshold on a field with a white-noise small-scale part. Research analyses use N-body simulations with 10^{10} particles, find haloes in them, populate the haloes with galaxies by an occupation model fitted to the small-scale clustering, and build hundreds to thousands of approximate mock catalogues to estimate the covariance of $\hat{P}_g$.

Where the statistics comes back in. The galaxy power spectrum and correlation function, their estimators and their Gaussian covariance, are the random-field statistics of Chapter 7. Shot noise is the Poisson process of Chapter 2. Bias, the shot-noise amplitude and $f\sigma_8$ are the parameters of a clustering likelihood whose forecast is a Fisher calculation (Chapter 10) and whose posterior is sampled with MCMC (Chapter 9). Galaxy clustering, redshift-space distortions and peculiar velocities as cosmological data are the subject of Chapter 11.

T2.15 Baryon acoustic oscillations: a standard ruler

Before recombination, photons and baryons were held together by Thomson scattering into a single hot fluid. Every small overdensity in that fluid launched a spherical sound wave, which ran outwards until the baryons were released from the photons and then stopped. How fast did it run? *The pressure comes from the photons, the inertia from both.* Radiation has pressure $p = \rho_\gamma c^2/3$; the baryons add mass but, being cold, no pressure. A sound wave squeezes photons and baryons together, so both number densities rise by the same fraction. For photons $\rho_\gamma \propto T^4$ and $n_\gamma \propto T^3$, so $\delta\rho_\gamma/\rho_\gamma = \frac{4}{3}\,\delta n/n$; for baryons $\delta\rho_b/\rho_b = \delta n/n$. Hence $\delta\rho_b = \frac{3}{4}(\rho_b/\rho_\gamma)\,\delta\rho_\gamma$, and

$$c_s^2 = \frac{\delta p}{\delta\rho} = \frac{c^2\,\delta\rho_\gamma/3}{\delta\rho_\gamma + \delta\rho_b} = \frac{c^2}{3(1+R)}, \qquad R \equiv \frac{3\rho_b}{4\rho_\gamma}.$$

Without baryons this is $c/\sqrt{3}$; the baryons' inertia slows the wave a little. *How far did it get?* In a time $\mathrm{d}t$ the wave covers a physical distance $c_s\mathrm{d}t$, which is a comoving distance $c_s\mathrm{d}t/a$. With $a = 1/(1+z)$ and $\mathrm{d}z/\mathrm{d}t = -(1+z)H$, this is $c_s\mathrm{d}t/a = -c_s\,\mathrm{d}z/H$. Summing from the beginning ($z = \infty$) to the moment the baryons stop feeling the photons' push, the **drag epoch** $z_d \approx 1060$ (slightly after recombination, because photons outnumber baryons by about a billion to one and keep dragging them a little longer), each initial peak was left with a thin shell of extra baryons at the comoving distance sound had travelled,

$$r_d = \int_{z_d}^{\infty} \frac{c_s(z)}{H(z)}\,\mathrm{d}z \approx 147\ \mathrm{Mpc} \tag{T2.120}$$

[101, eqs. (2.3)–(2.4)]. Dark matter fell into both the central peak and the shell, and galaxies later formed in both. So each overdensity is surrounded by a shell at r_d, and pairs of galaxies separated by r_d, one in a peak and one in its shell, are slightly more common than chance. Counting pairs by separation, that excess shows up as a bump in the correlation function at $r \approx r_d$, the feature computed in Chapter T1. The integral (T2.120) depends only on the physical matter and baryon densities $\omega_m = \Omega_m h^2$ and $\omega_b = \Omega_b h^2$ (through H and R) and the number of relativistic species $N_{\rm eff}$ (through H). A fit to its numerical value, quoted by DESI, is $r_d \approx 147.05\,(\omega_m/0.1432)^{-0.23}(N_{\rm eff}/3.04)^{-0.1}(\omega_b/0.02236)^{-0.13}$ Mpc [101, eq. (2.5)]; the exponents are fitted numbers, not derived ones. The CMB measures it to 0.2%: $r_d = 147.09 \pm 0.26$ Mpc [25, Table 2]. A feature of known length, seen at many redshifts, is a **standard ruler**.

The question. What exactly does the position of the bump measure, how is it extracted from a noisy correlation function, how precisely, and what did DESI find?

T2.15.1 What the ruler measures

The survey measures angles and redshifts, not lengths. A pair of galaxies at redshift z separated by r_d *across* the line of sight subtends an angle

$$\Delta\theta = \frac{r_d}{D_M(z)}, \qquad D_M(z) = \int_0^z \frac{c\,\mathrm{d}z'}{H(z')}\ \ \text{(flat)},$$

where D_M is the transverse comoving distance [99, eq. (16)]. A pair separated by r_d *along* the line of sight differs in redshift by Δz, and since the comoving distance changes by $\mathrm{d}\chi = c\,\mathrm{d}z/H(z)$,

$$\Delta z = \frac{r_d}{D_H(z)}, \qquad D_H(z) \equiv \frac{c}{H(z)}.$$

So the bump measures D_M/r_d from its angular size and D_H/r_d from its depth in redshift [101, Sec. 2.1]. Figure T2.30 draws both.

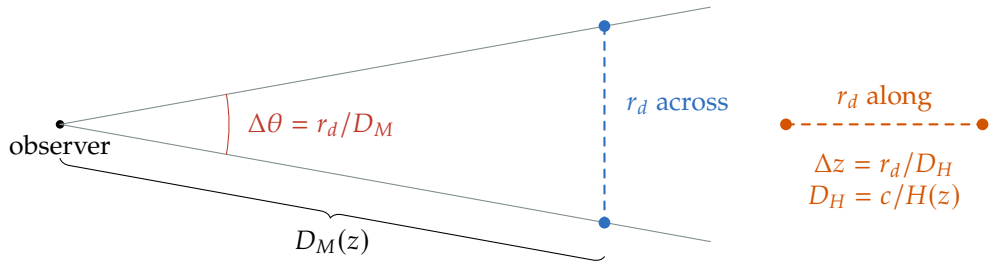

Figure T2.30: What a standard ruler measures. Left: two galaxies separated by r_d across the line of sight appear an angle $\Delta\theta = r_d/D_M$ apart. Right: two galaxies separated by r_d along the line of sight differ in redshift by $\Delta z = r_d/D_H$. The first gives the distance, the second the expansion rate, both in units of r_d.

The map is drawn with an assumed cosmology. To place galaxies in space at all, the survey assumes a fiducial cosmology, with distances $D_M^{\rm fid}$ and $D_H^{\rm fid}$ and a sound horizon $r_d^{\rm fid}$. The question, in words: *if the true distances differ from the assumed ones, where in the fiducial map does the true ring of radius r_d end up, and how do we read the true distances off its position?*

Across the line of sight first. The survey turns a measured angle into a length with the assumed distance, and the angle is set by the true one:

$$r_\perp^{\rm app} \overset{(1)}{=} D_M^{\rm fid}\,\Delta\theta \overset{(2)}{=} r_d\,\frac{D_M^{\rm fid}}{D_M} \overset{(3)}{=} \frac{r_d^{\rm fid}}{\alpha_\perp}, \qquad \alpha_\perp \equiv \frac{D_M/r_d}{D_M^{\rm fid}/r_d^{\rm fid}}. \tag{T2.121}$$

(1) The map converts angle to transverse length with the fiducial distance.
(2) The true pair at separation r_d subtends $\Delta\theta = r_d/D_M$, with the true D_M.
(3) Name the ratio of the apparent ring to the ring the template expects, $r_\perp^{\rm app}/r_d^{\rm fid} = 1/\alpha_\perp$.

Along the line of sight, the same way. A redshift difference becomes a length through the fiducial D_H, and the true one sets $\Delta z = r_d/D_H$: $r_\parallel^{\rm app} = D_H^{\rm fid}\Delta z = r_d D_H^{\rm fid}/D_H = r_d^{\rm fid}/\alpha_\parallel$. Together,

$$\alpha_\perp = \frac{D_M/r_d}{D_M^{\rm fid}/r_d^{\rm fid}}, \qquad \alpha_\parallel = \frac{D_H/r_d}{D_H^{\rm fid}/r_d^{\rm fid}}. \tag{T2.122}$$

So a sphere of radius r_d in the true universe appears in the fiducial map as an ellipsoid with semi-axes $r_d^{\rm fid}/\alpha_\perp$ across the line of sight and $r_d^{\rm fid}/\alpha_\parallel$ along it. Read the direction carefully: $\alpha > 1$ means the true distance (in units of r_d) is larger than assumed, the ring looks *smaller* than the template, and the feature appears at smaller r.

From the ring to the template fit. The template correlation function $\xi_{\rm fid}(r)$ of the fiducial cosmology has its bump at $r = r_d^{\rm fid}$. The data have it at $r^{\rm app} = r_d^{\rm fid}/\alpha$. The dilated template $\xi_{\rm fid}(\alpha r)$ has its bump where $\alpha r = r_d^{\rm fid}$, that is at $r = r_d^{\rm fid}/\alpha$, exactly where the data put it. So fitting the data with $\xi_{\rm fid}(\alpha r)$ and finding the best α measures the ratio of true to fiducial distance in (T2.122). DESI reports the same information in the form D_M/r_d and D_H/r_d [101, Sec. 2.1], which is our $\alpha_\perp$ and $\alpha_\parallel$ multiplied by the fiducial $D_M^{\rm fid}/r_d^{\rm fid}$ and $D_H^{\rm fid}/r_d^{\rm fid}$.

Why D_V, and why the factor z. When the data are too noisy to separate the two directions, one fits the angle-averaged correlation function with a single dilation α. The single scale that preserves the volume of the ellipsoid, which is what an angle average responds to at first order, is the geometric mean of its three axes:

$$\alpha_{\rm iso} \overset{(1)}{=} \left(\alpha_\perp^2\,\alpha_\parallel\right)^{1/3} \overset{(2)}{=} \frac{\left(D_M^2 D_H\right)^{1/3}/r_d}{\left(D_M^{\rm fid\,2} D_H^{\rm fid}\right)^{1/3}/r_d^{\rm fid}} \overset{(3)}{=} \frac{D_V/r_d}{D_V^{\rm fid}/r_d^{\rm fid}}, \qquad D_V \equiv \left(z\,D_M^2\,D_H\right)^{1/3}. \tag{T2.123}$$

(1) Two transverse axes and one radial axis: the volume scales as $\alpha_\perp^2 \alpha_\parallel$.
(2) Substitute (T2.122).
(3) Multiply numerator and denominator by $z^{1/3}$, which cancels.

The factor z is a convention, and it is there so that D_V is a distance with a familiar limit: at low redshift $D_M \approx cz/H_0$ and $D_H \approx c/H_0$, so $D_V \approx \left(z \cdot (cz/H_0)^2 \cdot c/H_0\right)^{1/3} = cz/H_0$, the Hubble-law distance. This is Eisenstein et al.'s eq. (2), $D_V = [D_M^2\, cz/H(z)]^{1/3}$ [42, Sec. 4], and DESI's eq. (2.6) [101].

Watch out: Which "angular diameter distance"?

Three conventions meet here. Hogg's $D_A = D_M/(1+z)$ is the physical angular diameter distance [99, eq. (18)], and so is the D_A of Chapter T1. Weinberg et al. write D_A for the *comoving* angular diameter distance, which is D_M [98, p. 46]. Eisenstein et al. and DESI write D_M. A factor $(1+z)$ in a BAO formula is usually this.

T2.15.2 Measuring the dilation, and how well

A correlation function is measured in bins of separation r_i. How noisy is each bin, and how are neighbouring bins tied together? For a Gaussian field the answer follows from the power spectrum. The correlation function is the Fourier transform of the power, so the estimate in bin i is a weighted sum of the power measured in thin k-shells, $\hat{\xi}(r_i) = \sum_{\text{shells}} \frac{k^2\Delta k}{2\pi^2} \hat{P}(k)\, \bar{j}_0(kr_i)$, where $\bar{j}_0$ is the spherical Bessel function $\sin x/x$ averaged over the width of the bin (Section 7.3.2). Different shells are independent, and each has $\mathrm{Var}\,\hat{P} = 2P_{\text{tot}}^2/N_k$ with $P_{\text{tot}} = b^2P + 1/\bar{n}$ and $N_k = Vk^2\Delta k/(2\pi^2)$ modes ((T2.117)). So

$$\mathrm{Cov}\left[\hat{\xi}(r_i), \hat{\xi}(r_j)\right] \overset{(1)}{=} \sum_{\text{shells}} \left(\frac{k^2\Delta k}{2\pi^2}\right)^2 \bar{j}_0(kr_i)\, \bar{j}_0(kr_j)\, \frac{2P_{\text{tot}}^2}{Vk^2\Delta k/(2\pi^2)}$$
$$\overset{(2)}{=} \frac{2}{V} \int \frac{k^2 \mathrm{d}k}{2\pi^2} \left[b^2P(k) + \frac{1}{\bar{n}}\right]^2 \bar{j}_0(kr_i)\, \bar{j}_0(kr_j). \tag{T2.124}$$

(1) The covariance of two weighted sums of independent terms is the sum of weight times weight times variance.
(2) Cancel one factor $k^2\Delta k/(2\pi^2)$ and let the shells become thin.

Each piece now has a meaning. The $1/V$ is the averaging over independent modes: a bigger survey has more of them. The square is there because a variance of a power is the square of the power (one mode's $|\delta_k|^2$ scatters as much as its mean). The $1/\bar{n}$ inside it is the shot noise of (T2.116). And since every bin draws on the same shells, neighbouring bins share their errors.

The model is the fiducial template, dilated, plus a smooth curve that absorbs everything the BAO feature does not determine [101, p. 9]:

$$\xi_{\text{model}}(r) = B^2\, \xi_{\text{fid}}(\alpha r) + a_0 + \frac{a_1}{r} + \frac{a_2}{r^2}. \tag{T2.125}$$

Each term has one job. α is the dilation of (T2.122), the only number we want. B^2 absorbs the amplitude: the galaxy bias b^2 of Section T2.14 relative to the template's, and the redshift-space boost. a_0, a_1/r and a_2/r^2 absorb the broadband shape, whatever smooth errors the template has from non-linear growth or a bias that changes slowly with scale. None of them can make a narrow bump, so the bump's position, and with it α, is left to the data.

Solving for the nuisance terms. For a fixed trial α the model is a fixed matrix X (its four columns are $\xi_{\text{fid}}(\alpha r_i)$, 1, $1/r_i$, $1/r_i^2$) times the vector $\boldsymbol{\beta} = (B^2, a_0, a_1, a_2)$. So $\chi^2(\boldsymbol{\beta}) = (\hat{\boldsymbol{\xi}} - X\boldsymbol{\beta})^{\mathsf{T}} \mathbf{C}^{-1} (\hat{\boldsymbol{\xi}} - X\boldsymbol{\beta})$

is quadratic in $\boldsymbol{\beta}$, and a quadratic has one minimum, found exactly by generalised least squares (Chapter 3), $\hat{\boldsymbol{\beta}} = (X^{\mathsf{T}}\mathbf{C}^{-1}X)^{-1}X^{\mathsf{T}}\mathbf{C}^{-1}\hat{\boldsymbol{\xi}}$. Marginalising $\boldsymbol{\beta}$ with flat priors instead (Chapter 5) integrates $e^{-\chi^2/2}$ over a Gaussian in $\boldsymbol{\beta}$, which gives $e^{-\chi^2_{\min}/2}$ times $\det(X^{\mathsf{T}}\mathbf{C}^{-1}X)^{-1/2}$, the same structure as the amplitude integral of (T2.128); that factor changes only slowly with α, so the two routes agree closely. What is left is a profile $\chi^2(\alpha)$.

Is the bump really there? The **BAO detection significance** compares the profile with the best fit of a template with the wiggles removed: $\Delta\chi^2 = \chi^2_{\text{no wiggle}} - \chi^2_{\text{BAO}}$. The null hypothesis is the smooth, wiggle-free correlation function, and the test asks: if there were no bump, would a $\Delta\chi^2$ this large, or larger, be something we would reasonably expect from noise? Think of the BAO model as the no-wiggle model plus the wiggles with a free amplitude; the null sets that one amplitude to zero. Then Wilks' theorem (Section 4.7, (4.30)) says that under the null $\Delta\chi^2$ is a χ^2 with one degree of freedom, which is the square of one unit Gaussian Z. So

$$\mathrm{P}\left(\Delta\chi^2 > n^2 \,|\, \text{no bump}\right) = \mathrm{P}(|Z| > n) = 2\big[1 - \Phi(n)\big],$$

the probability of a Gaussian fluctuation beyond n standard deviations. A measured $\Delta\chi^2$ therefore corresponds to a detection at $n = \sqrt{\Delta\chi^2}$ standard deviations. (The amplitude being one extra parameter is an approximation: α too is free only in the BAO model, which makes the real tail a little heavier.)

Example: the first detection. *Their question.* In 2005 the acoustic bump had been predicted for decades but never seen in galaxies. Eisenstein et al. asked: is there a bump near $100\,h^{-1}$Mpc in the correlation function of galaxies, and if so, what distance does its position give?

Their setup. They used luminous red galaxies (LRGs) from SDSS: 46,748 of them at $0.16 < z < 0.47$ over 3816 square degrees. LRGs are rare and bright, so they can be seen far away and fill a large volume, which beats down the cosmic variance of (T2.117); and they live in massive haloes, so their bias is high and the bump in $\xi_g = b^2\xi$ stands out against the shot noise. The covariance of $\hat{\xi}$ came from 1278 mock catalogues, which play the role of our (T2.124) with the survey's real shape and selection built in.

Their key equation. With galaxies at a range of redshifts and a correlation function averaged over directions, the bump measures the single dilation α_{iso} of (T2.123), that is D_V/r_d at the effective redshift $z = 0.35$. Their eq. (2), $D_V = [D_M^2\, cz/H(z)]^{1/3}$, is our $D_V = (zD_M^2 D_H)^{1/3}$ with $D_H = c/H$.

Their result, through our recipe. The best BAO model had $\chi^2 = 16.1$ for 17 degrees of freedom; the best model without the acoustic peak had 27.8. The significance recipe above gives

$$\Delta\chi^2 = 27.8 - 16.1 = 11.7, \qquad n = \sqrt{11.7} = 3.4,$$

a 3.4σ detection. The peak position gave $D_V(0.35) = 1370 \pm 64$ Mpc, so $64/1370 = 4.7\%$ [42, Sec. 4, Fig. 6]. Our mock survey below, with a somewhat larger volume and a denser sample, finds a median detection of 3.8σ and a scatter of 0.0272 in α, about 3%: the same order, a little better, as it should be for more volume and more galaxies.

The experiment. `10_bao_ruler.py` needs two templates and a survey.

Why the bump is smeared. Between the drag epoch and today each galaxy has moved from where it formed, by some $8\,h^{-1}$Mpc in each direction, pulled by the large-scale flows. Treat that displacement $\boldsymbol{\psi}$ as a random Gaussian vector with variance Σ^2_{nl} per direction. A wave $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$ sampled at the displaced positions is multiplied, on average, by $\mathbb{E}[e^{i\boldsymbol{k}\cdot\boldsymbol{\psi}}] = e^{-k^2\Sigma^2_{\text{nl}}/2}$, the characteristic function of a Gaussian. The acoustic wiggles live at $k \gtrsim 0.05\,h\,\text{Mpc}^{-1}$, where this

factor bites, so they fade; in $\xi(r)$ the narrow bump is smoothed into a broader one. The value $\Sigma_{\rm nl} = 8\,h^{-1}$Mpc is the one before reconstruction (the step that real surveys use to move galaxies back towards where they started).

What "no wiggle" means. The comparison template is a power spectrum with the same broadband shape as the real one but without the oscillations. Eisenstein and Hu give a smooth transfer function for that [104, eqs. (26), (28)–(31)]. Calling the CAMB linear spectrum $P_{\rm lin}$ and the smooth one $P_{\rm nw}$, the difference $P_{\rm lin} - P_{\rm nw}$ is the BAO signal alone, and the template damps only that part: $P_{\rm w} = P_{\rm nw} + (P_{\rm lin} - P_{\rm nw})\, e^{-k^2\Sigma_{\rm nl}^2/2}$.

The survey, about one DESI redshift bin:

quantity	value	enters through
volume V	$1\,(h^{-1}\text{Gpc})^3$	the $1/V$ of (T2.124)
number density $\bar{n}$	$3\times10^{-4}\,h^3\text{Mpc}^{-3}$	the shot noise $1/\bar{n}$
bias b	2	the signal b^2P
separation bins	20, from 50 to 150 h^{-1}Mpc	the data vector $\hat{\boldsymbol{\xi}}$
mock surveys	10000	draws from $\mathcal{N}(\xi_{\rm true}, \mathbf{C})$

It draws the mock $\hat{\xi}$ vectors with $\mathbf{C}$ from (T2.124), and fits each one:

Listing T2.11: The profile $\chi^2(\alpha)$ with the linear nuisance parameters solved at each α (`code/chT2/10_bao_ruler.py`)

```
80 alphas = np.linspace(0.8, 1.2, 401)
81 # design matrices: [xi_fid(alpha r), 1, 1/r, 1/r^2]; the linear parameters are solved
       exactly at each alpha
82 basis = lambda a, wig: np.column_stack([template(rc, a, wig), np.ones_like(rc), 1 / rc, 1 /
       rc**2])
83 PROJ = {}
84 for wig in (True, False):
85     PROJ[wig] = []
86     for a in alphas:
87         X = basis(a, wig)
88         F = X.T @ CINV @ X
89         PROJ[wig].append((X, np.linalg.solve(F, X.T @ CINV)))
90
91
92 def chi2_curve(d, wig=True):
93     out = np.empty(alphas.size)
94     for i, (X, P) in enumerate(PROJ[wig]):
95         res = d - X @ (P @ d)
96         out[i] = res @ CINV @ res
97     return out
98
99
100 def fit_alpha(d):
101     cw, cn = chi2_curve(d, True), chi2_curve(d, False)
102     i = np.argmin(cw)
103     inside = alphas[cw <= cw[i] + 1]
104     return alphas[i], 0.5 * (inside.max() - inside.min()), cw.min(), cn.min(), cw, cn
```

Lines 83–89 compute, for every trial α, the design matrix X and the matrix that turns data into the best nuisance values,

$$P_\alpha = (X^{\mathsf T}\mathbf{C}^{-1}X)^{-1}X^{\mathsf T}\mathbf{C}^{-1}, \qquad \hat{\boldsymbol{\beta}} = P_\alpha\hat{\boldsymbol{\xi}}.$$

The residual is then $\hat{\boldsymbol{\xi}} - X\hat{\boldsymbol{\beta}} = (1 - XP_\alpha)\,\hat{\boldsymbol{\xi}}$, and

$$\chi^2(\alpha) = \hat{\boldsymbol{\xi}}^{\mathsf T}(1 - XP_\alpha)^{\mathsf T}\,\mathbf{C}^{-1}\,(1 - XP_\alpha)\,\hat{\boldsymbol{\xi}}.$$

The data enter only at the two ends; everything in between depends on α through X and on nothing else. So these projection matrices are computed once per trial α and reused for all 10000 mocks, and each fit is a matrix product (line 95). Line 103 reads the $\Delta\chi^2 = 1$ interval off the profile.

Figure T2.31 shows one mock: $\hat{\alpha} = 1.030 \pm 0.026$, $\chi^2_{\rm min} = 11.8$ for 15 degrees of freedom, and a no-wiggle penalty $\Delta\chi^2 = 13.7$. Over all mocks the median detection is 3.8σ (16–84% range 2.7–4.8σ), comparable to the first SDSS detection. The estimates $\hat{\alpha}$ average 0.9997: the ruler is unbiased. Their scatter, 0.0272, is larger than both the Fisher error 0.0207 (the width predicted from the curvature of the profile $\chi^2(\alpha)$ of noise-free data at its minimum, Chapter 10) and the average $\Delta\chi^2 = 1$ half-width 0.0218, and the $\Delta\chi^2 = 1$ interval covers the truth in 66% of the mocks (±0.5%, the binomial error) instead of 68%.

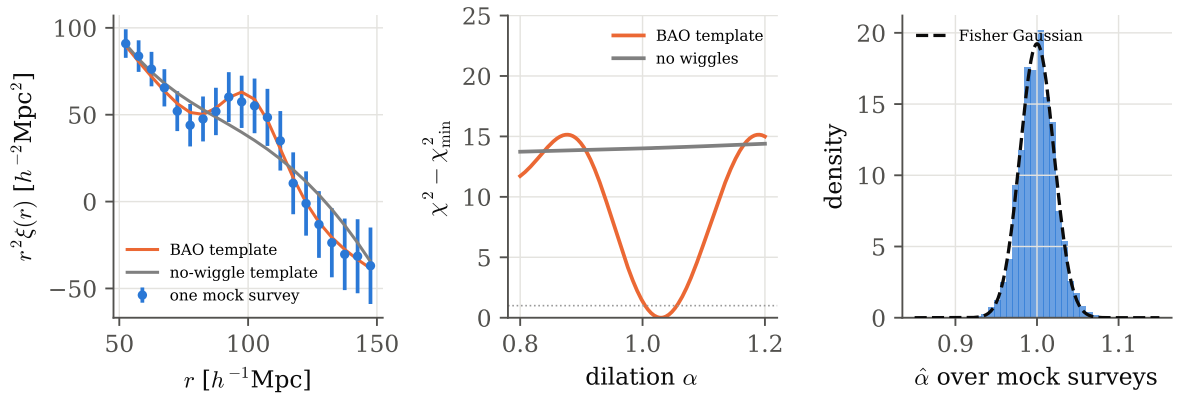

Figure T2.31: Fitting the BAO dilation. Left: one mock correlation function (times r^2, with the diagonal errors) and the best fits of the BAO template and of the no-wiggle template. Middle: the profile $\chi^2(\alpha)$ for both; the BAO template has a clear minimum near $\alpha = 1$, the no-wiggle one is flat and higher. Right: the distribution of $\hat{\alpha}$ over the mock surveys and the Gaussian of the Fisher error; the tails are heavier than the Gaussian.

Why the heavier tails? In a mock where noise happens to weaken the bump, $\chi^2(\alpha)$ is shallow and can have a second minimum where a noise wiggle lines up with the template. The likelihood is then far from Gaussian in α, and the curvature at the minimum underestimates the real spread. At a 4σ detection this happens often; at the 10–20σ of a DESI bin it does not, and DESI finds its posteriors "well approximated by Gaussian distributions" [101, Sec. 2.3.2].

How this is used in real research: Verification versus research

Here the mocks *verify* the analysis: we know $\alpha = 1$, and we check that the estimator is unbiased and that its error bar covers the truth at the stated rate. In research the same machinery is the *instrument*. DESI estimates the covariance of $\hat{\xi}$ from large sets of mock catalogues and analytic models, because the real survey has a mask, varying completeness and non-linear clustering that (T2.124) ignores; it calibrates the reconstruction and the theoretical systematics (below 0.1–0.2%) on simulations; and it blinds the data, shifting the BAO position in the catalogues until the pipeline is frozen [101, Sec. 2.3.1]. A full analysis uses thousands of mocks; ours uses 10000 Gaussian draws from an analytic covariance and no reconstruction.

T2.15.3 What DESI's distances say

Their question. DESI measured the ruler at seven redshifts in its first year. The question we reproduce is: *do the BAO distances alone, with no CMB and no supernovae, fix the matter density* Ω_m

and the expansion scale $H_0 r_d$ in flat ΛCDM, and do they agree with the ΛCDM that fits the CMB? It matters because the ruler is calibrated by early-universe physics and read at $z < 2.5$, a test of the model across most of cosmic time.

Their data. Each bin gives D_M/r_d and D_H/r_d with their correlation coefficient where the signal is strong, and D_V/r_d alone for the bright galaxies (BGS) and the quasars (QSO), where it is weak [101, Table 1]:

tracer	$z_{\rm eff}$	D_M/r_d	D_H/r_d	D_V/r_d	correlation
BGS	0.295	–	–	7.93 ± 0.15	–
LRG	0.510	13.62 ± 0.25	20.98 ± 0.61	–	−0.445
LRG	0.706	16.85 ± 0.32	20.08 ± 0.60	–	−0.420
LRG+ELG	0.930	21.71 ± 0.28	17.88 ± 0.35	–	−0.389
ELG	1.317	27.79 ± 0.69	13.82 ± 0.42	–	−0.444
QSO	1.491	–	–	26.07 ± 0.67	–
Lyα	2.330	39.71 ± 0.94	8.52 ± 0.17	–	−0.477

Five bins with two numbers and two bins with one make $5\times2+2 = 12$ numbers. The correlation is negative because the data pin down the overall size of the ring better than its shape: a fit that stretches the ring across the line of sight compensates by shrinking it along the line of sight.

The model, derived. In flat ΛCDM at these redshifts (radiation is 0.1% of H^2 even at $z = 2.3$) the predictions are

$$\frac{D_H}{r_d}(z) = \frac{c}{H_0 r_d}\frac{1}{E(z)}, \qquad \frac{D_M}{r_d}(z) = \frac{c}{H_0 r_d}\int_0^z \frac{\mathrm{d}z'}{E(z')}, \qquad E(z) = \sqrt{\Omega_m(1+z)^3 + 1 - \Omega_m}. \tag{T2.126}$$

Only two numbers appear: Ω_m, which sets how the distances change with redshift, and the product $H_0 r_d$, which sets their overall scale. BAO alone therefore cannot separate H_0 from r_d.

Where we have met H_0 before. The mock supernovae of Section 3.17, made with $H_0 = 70$, fixed only $M - 5\log_{10} H_0$, and H_0 came out only once M was supplied from outside. The ladder of Section T2.12 supplied it from parallaxes and Cepheids, and the real ladder gave 73.04 ± 1.04, 4.8σ above the CMB's 67.36 ± 0.54 (Section T2.12.3). The same degeneracy is back here with a ruler in place of the candle: the distances fix only the product $H_0 r_d$, as the magnitudes fixed only $M - 5\log_{10} H_0$, and the ruler's length plays the role of the candle's luminosity. Three things differ. The data are real DESI distances at $0.3 < z < 2.3$, far beyond the $z < 0.15$ of the Hubble-flow supernovae, so Ω_m must be fitted alongside the scale rather than entering as the small q_0 correction. The calculation is a Bayesian posterior on a grid rather than a least-squares fit. And the calibration comes from the early Universe: r_d is set by the sound waves before recombination, the same physics that fixes the CMB value of H_0 (Section 10.6.3), not by geometry nearby. That is why the H_0 found below lands near the CMB value and not near the ladder's.

What we compute. Each bin is a measurement $\boldsymbol{d}_b$ (two numbers or one) with Gaussian noise, and the model $\boldsymbol{m}_b(\Omega_m, h r_d)$ is (T2.126) evaluated at $z_{\rm eff}$ (with $D_V = (z D_M^2 D_H)^{1/3}$ of (T2.123) for the one-number bins). The bins are independent, so the χ^2 is a sum over bins,

$$\chi^2(\Omega_m, h r_d) = \sum_{b=1}^{7} \big(\boldsymbol{d}_b - \boldsymbol{m}_b\big)^{\mathsf{T}} C_b^{-1} \big(\boldsymbol{d}_b - \boldsymbol{m}_b\big), \qquad C_b = \begin{pmatrix} \sigma_M^2 & \rho\,\sigma_M\sigma_H \\ \rho\,\sigma_M\sigma_H & \sigma_H^2 \end{pmatrix}, \tag{T2.127}$$

where σ_M and σ_H are the quoted errors of D_M/r_d and D_H/r_d and ρ is their correlation; for a D_V bin C_b is just σ_V^2. The posterior with flat priors on a grid of (Ω_m, hr_d) is Bayes' theorem (Chapter 5) with a constant prior:

$$p(\Omega_m, hr_d \mid \boldsymbol{d}) = \frac{e^{-\chi^2(\Omega_m, hr_d)/2}}{\sum_{\text{grid}} e^{-\chi^2/2}},$$

and the means, standard deviations and correlation are sums over the grid weighted by it.

DESI and ours, side by side. Figure T2.32 shows the distances and the posterior; the numbers are

	DESI [101, eqs. (4.1), (4.3)]	ours
Ω_m	0.295 ± 0.015	0.296 ± 0.015
hr_d [Mpc]	101.8 ± 1.3	101.8 ± 1.3
H_0 [km/s/Mpc], with the CMB r_d	69.29 ± 0.87	69.2 ± 0.9

with correlation -0.92 between our Ω_m and hr_d. The best fit has $\chi^2 = 12.8$ for $12 - 2$ degrees of freedom, an ordinary value.

Why they differ, and by how much. They barely do: the largest difference, 0.001 in Ω_m, is a fifteenth of the error bar. Three things could cause differences of that size. Our grid has steps of 0.001 in Ω_m and 0.1 Mpc in hr_d, where DESI samples its posterior with MCMC. Our Gaussian is built from the errors and correlations as quoted in the table, rounded to two or three digits. And we neglect radiation, which changes H^2 by at most 0.1% at the highest redshift, the Lyα bin, so D_H by at most 0.05%, far below its 2% error. For H_0, DESI also propagates the 0.2% error of r_d, which we leave out; it is small next to the 1.3% from hr_d.

Is Planck's ΛCDM consistent with it? The Planck best fit ($hr_d = 99.1$ Mpc) has $\chi^2 = 21.1$ against our minimum 12.8, so $\Delta\chi^2 = 21.1 - 12.8 = 8.3$. Under the hypothesis that the Planck point is the truth, $\Delta\chi^2$ between it and the best fit is a χ^2 with two degrees of freedom, one per fitted parameter (Wilks' theorem, Section 4.7). Its tail is $\mathrm{P}(\chi^2_2 > v) = e^{-v/2}$ ((10.61)), so $p = e^{-8.3/2} = 0.016$. Converted to the two-sided Gaussian language of the detection test, $2[1 - \Phi(n)] = 0.016$ gives $n = 2.4\sigma$. That treats the Planck point as exact. DESI, including the errors of the CMB values, which spread the Planck point into its own small ellipse, quantifies the difference as a 1.9σ discrepancy (1.6σ without CMB lensing) [101, eq. (4.2)]: a mild tension, not a contradiction.

The lesson. Twelve published numbers and a two-parameter grid are enough to recover DESI's headline constraint; what the grid cannot do on its own is separate H_0 from r_d, which is the subject of the next example.

Example: the inverse distance ladder. Take $r_d = 147.09$ Mpc from the CMB. Then $h = (hr_d)/r_d$, and the posterior above gives $H_0 = 69.2 \pm 0.9$ km/s/Mpc; DESI, propagating the small error of r_d too, finds 69.29 ± 0.87, and 68.53 ± 0.80 with r_d computed from a big-bang-nucleosynthesis value of ω_b instead of the CMB [101, eqs. (4.3)–(4.4)]. This is a distance ladder run backwards, anchored at $z \approx 1060$ by the physics of sound waves rather than at $z \approx 0$ by parallaxes. It lands near the CMB value and well below the 73.04 ± 1.04 of the Cepheid ladder of Section T2.12: the Hubble tension appears again when a ruler replaces a candle.

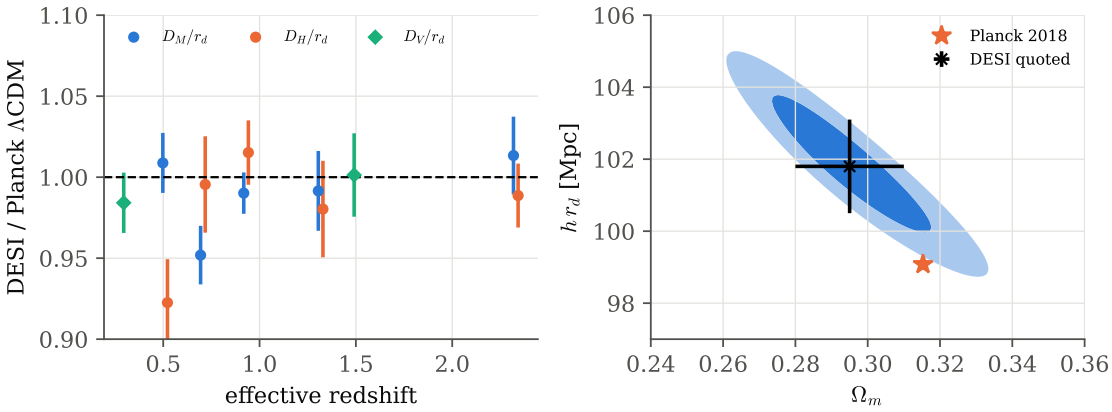

Figure T2.32: Left: DESI DR1 BAO distances divided by the Planck ΛCDM prediction. Right: the 68% and 95% regions in (Ω_m, hr_d) from the twelve DESI numbers, computed on a grid, with DESI's quoted result (cross) and the Planck best fit (star). The long, tilted contour is the degeneracy of (T2.126): a higher Ω_m can be traded for a lower hr_d.

Where the statistics comes back in. The estimator and covariance of $\hat{\xi}$ and $\hat{P}$ are Chapter 7. The template fit is least squares with linear nuisances (Chapter 3), the detection is a likelihood-ratio test (Chapter 4), and the posterior on (Ω_m, hr_d) is the Bayesian grid of Chapter 5, replaced by MCMC (Chapter 9) when more parameters are free. The forecast precision of a BAO survey is a Fisher calculation (Chapter 10), and galaxy clustering as cosmological data is Chapter 11.

T2.16 Photometric redshifts and their error distributions

A spectrum gives a redshift to a part in ten thousand, but it costs a fibre and many minutes of a large telescope for each galaxy. Imaging surveys such as the ones used for weak lensing (Chapter T1) detect a billion galaxies, far too many and mostly too faint for spectra. What they have is the flux of each galaxy in five or six broad filters. That is enough for a rough redshift, because galaxy spectra have sharp features. The strongest in the optical is the break near 4000 Å, where old stars and metal absorption make the light drop by a factor of two or three to the blue. At high redshift the Lyman series of intergalactic hydrogen removes the light blueward of 1216 Å. As a galaxy is moved to higher redshift its spectrum slides to the red, and the break passes from one filter into the next (Figure T2.33). The ratio of fluxes in neighbouring filters, a **colour**, therefore encodes the redshift. An estimate made this way is a **photometric redshift** (photo-z).

The question. How is a redshift computed from a few fluxes, what is the distribution of its error, and how does that error propagate into the redshift distribution $n(z)$ of a sample, which is what cosmology actually uses?

T2.16.1 Template fitting as a likelihood

What we observed is a vector of fluxes F_b in bands $b = 1, \dots, 6$, each with a Gaussian error σ_b. *What could have produced it?* A galaxy of some spectral type T, at some redshift z, with some overall brightness A, predicting fluxes $A\,T_b(z)$, where $T_b(z)$ is the template spectrum redshifted to z and integrated through filter b. *How likely are the observed fluxes under each* (z, T)*?* The brightness is not of interest, so we integrate it out with a flat prior. The χ^2 is quadratic in A,

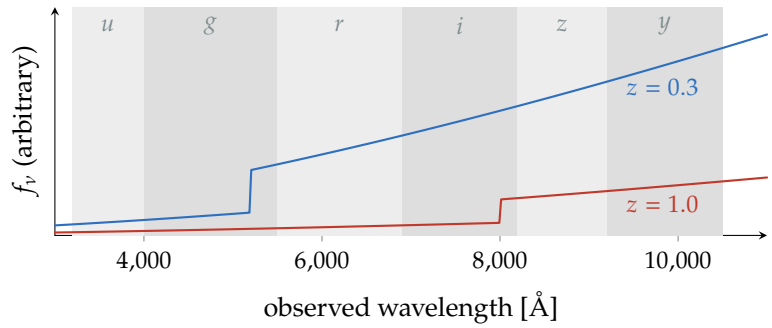

Figure T2.33: The same red-galaxy spectrum at two redshifts, seen through six broad filters (grey bands). At $z = 0.3$ the 4000 Å break lands at 5200 Å, inside the g band; at $z = 1.0$ it has moved to 8000 Å, inside the i band. Which filter holds the break, and how deep the drop is, is what a photometric redshift reads.

$\chi^2(A) = \chi^2_{\min} + (A - \hat{A})^2 S$ with $S = \sum_b T_b^2/\sigma_b^2$, so

$$\mathcal{L}(z,T) \overset{(1)}{=} \int \mathrm{d}A \, \exp\Big[-\frac{1}{2}\sum_b \frac{(F_b - AT_b)^2}{\sigma_b^2}\Big] \overset{(2)}{=} e^{-\chi^2_{\min}/2} \int \mathrm{d}A \, e^{-S(A-\hat{A})^2/2} \overset{(3)}{=} \sqrt{\frac{2\pi}{S}}\, e^{-\chi^2_{\min}(z,T)/2},$$

$$\chi^2_{\min} \overset{(4)}{=} \sum_b \frac{F_b^2}{\sigma_b^2} - \frac{\big(\sum_b F_b T_b/\sigma_b^2\big)^2}{S}, \qquad p(z \mid \boldsymbol{F}) \propto n(z) \sum_T \mathcal{L}(z,T). \tag{T2.128}$$

(1) Independent Gaussian errors in each band; marginalise the nuisance amplitude (Chapter 5).
(2) Expand the square in A and complete it; $\hat{A} = \sum_b F_b T_b \sigma_b^{-2}/S$ is the least-squares amplitude.
(3) The Gaussian integral $\int e^{-Sx^2/2}\mathrm{d}x = \sqrt{2\pi/S}$.
(4) Substitute $\hat{A}$ into χ^2.

The last expression is Bayes' theorem with the redshift distribution $n(z)$ of the population as the prior and the type summed over. The sum gives every template the same weight: it is a flat prior over the types, even though the population the experiment below draws from is 35% red and 65% blue. A type prior would multiply each $\mathcal{L}(z,T)$ by the fraction of galaxies of type T. The photo-z is then usually the peak of $p(z \mid \boldsymbol{F})$, but the whole posterior is the honest answer.

T2.16.2 The error distribution

The error $z_{\text{phot}} - z$ is not a Gaussian. It has a Gaussian-looking core whose width grows with redshift as $\sigma_z \propto 1 + z$. Why? A feature at rest wavelength λ_{rest} is observed at $\lambda_{\text{obs}} = (1+z)\lambda_{\text{rest}}$, so $\delta(1+z)/(1+z) = \delta\lambda_{\text{obs}}/\lambda_{\text{obs}}$. Broad filters locate the break only to a fixed fraction of the wavelength (a filter's width is roughly proportional to its central wavelength), so $\delta\lambda_{\text{obs}}/\lambda_{\text{obs}}$ is about constant, and then $\sigma_z = \delta z$ is a constant times $1+z$. Good surveys reach $\sigma_z/(1+z) \approx 0.02$–$0.05$. And it has **catastrophic outliers** with $|z_{\text{phot}} - z| \sim 1$. The main cause is a degeneracy: a sharp drop observed at a wavelength λ_{obs} may be the 4000 Å break of a nearby galaxy or the Lyman-α edge of a distant one, $(1 + z_{\text{low}})\,4000\,\text{Å} = (1 + z_{\text{high}})\,1216\,\text{Å}$. For $z_{\text{low}} = 0.16$,

$$1 + z_{\text{high}} = 1.16 \times \frac{4000}{1216} = 3.82, \qquad z_{\text{high}} = 2.8,$$

so a galaxy at $z_{\text{high}} = 2.8$ can be mistaken for one at $z_{\text{low}} = 0.16$ [98, p. 96]. Filters on both sides of both features, from u to the near infrared, break the degeneracy.

Weinberg et al. describe the error by the joint distribution $P(z_p, z)$ of photo-z and true redshift, and summarise it by the conditional bias and scatter $\delta z(z_p) = z_p - \langle z \rangle_{z_p}$ and $\sigma_z(z_p)$

[98, p. 94, eq. (100)]. They then make a point that is pure Bayes: $P(z \mid z_p) = P(z)\,P(z_p \mid z)/P(z_p)$ [98, eq. (101)], so a photo-z that is unbiased in the sense $\langle z_p \rangle_z = z$ can still have $\delta z(z_p) \neq 0$.

A picture makes the reason plain (Section 5.3). Think of each true redshift z as an urn, and of the photo-z as a ball drawn from it: the urn at z gives out balls spread around z, with $P(z_p \mid z)$ saying how readily it gives the ball labelled z_p. The population $n(z)$ says how many urns of each kind there are. We are handed one ball, labelled z_p, and asked which urn it came from. Two things decide: how readily each kind of urn gives this ball, and how many urns of that kind there are. Where urns are plentiful, even a modest chance per urn adds up to many balls labelled z_p, so the answer is pulled towards the crowded side. The ball tells us about its urn; it does not change the urns. This is the shrinking sample space once more: knowing the label z_p discards every draw with a different label, and what survives is weighted by the number of urns that produced it (Section 5.2). It is the same structure as the Malmquist calculation of Section T2.13, where the urns were absolute magnitudes and their number was set by the volume. How large is the difference? Take a Gaussian error, $P(z_p \mid z) = \mathcal{N}(z_p; z, \sigma^2)$, and a population whose number rises locally as $P(z) \propto e^{sz}$. Then

$$P(z \mid z_p) \overset{(1)}{=\!\propto} e^{sz} \exp\left[-\frac{(z - z_p)^2}{2\sigma^2}\right] \overset{(2)}{=\!\propto} \exp\left[-\frac{(z - z_p - s\sigma^2)^2}{2\sigma^2}\right], \qquad \langle z \rangle_{z_p} \overset{(3)}{=} z_p + s\sigma^2. \quad \text{(T2.129)}$$

(1) Bayes' theorem; $P(z_p)$ does not depend on z.
(2) Complete the square, exactly as in the Malmquist calculation (T2.109).
(3) The mean of the Gaussian.

Where $n(z)$ rises, galaxies observed at z_p are more likely to have scattered *up* from below, since there were more of them below; where it falls, the opposite. It is the Malmquist bias of Section T2.13 with redshift in place of magnitude: the population we draw from reweights the measurement.

Why the mean of $n(z)$ is the number that matters. A weak-lensing analysis bins galaxies by photo-z and needs the true $n(z)$ of each bin. The lensing signal depends mostly on its mean redshift. A lens bends the light of a source more the farther the source lies behind it (the lensing efficiency grows with the source distance, Chapter T1). So a bin whose mean is estimated too high predicts too much lensing for a given clustering amplitude; to match the observed shear, the fit lowers the amplitude, and S_8 comes out low [S_8 is the clustering amplitude that weak lensing constrains best]. Stage-III surveys need the mean redshift of each bin to about 0.01, and Euclid and LSST need it 5–10 times better [100, Sec. V.B.2]. Outliers matter in proportion to their number. Suppose a fraction f of a high-redshift bin are really foreground galaxies, in front of the lenses and so not lensed by them. The mean shear of the bin is then $(1 - f)$ times the true one, and the shear power spectrum, which is quadratic in the shear, is $(1 - f)^2 \approx 1 - 2f$ times. For $f = 1\%$ that is 1% and 2% [98, p. 94]. Photometric redshifts can also be used for BAO, but only the transverse measurement survives, and only if $\sigma_z/(1 + z) \lesssim 4\%$ [98, pp. 62–63]. The line-of-sight measurement is lost much earlier. A redshift error equivalent to a velocity σ_v, that is $\sigma_z = (1 + z)\sigma_v/c$, smears positions along the line of sight by $c\sigma_z/H(z) = (1 + z)\sigma_v/H(z)$. For $\sigma_v = 1000\,\mathrm{km/s}$ at $z = 1$, with $H(1) \approx 120\,\mathrm{km/s/Mpc}$, that is $2 \times 1000/120 \approx 17\,\mathrm{Mpc}$, comparable to or larger than the width of the acoustic bump, so its radial position, and with it $H(z)$, is erased [98, pp. 62–63]. The distribution $P(z \mid z_p)$ is calibrated with spectroscopic subsamples (10^5 spectra for Stage IV) or with the angular cross-correlation of photometric galaxies with a spectroscopic survey. Why does the cross-correlation measure $P(z \mid z_p)$? Both samples trace the same matter, $\delta_{\mathrm{spec}} = b_{\mathrm{spec}}\delta$ and $\delta_{\mathrm{phot}} = b_{\mathrm{phot}}\delta$ (Section T2.14). Galaxies at different true redshifts are too far apart to be correlated, so the photometric galaxies selected by z_p correlate with a thin spectroscopic slice at z only through the fraction of them that really sit

at z. Their cross-correlation is therefore $b_{\rm spec}\, b_{\rm phot}\, P(z \mid z_p)$ times the matter correlation at z [98, p. 97]: the bias of Section T2.14 returns as a nuisance.

The experiment. `11_photoz.py` builds a mock imaging survey:

ingredient	choice	why
galaxies	20000, from $n(z) \propto z^2 e^{-(z/0.55)^{1.5}}$	a typical deep-imaging redshift distribution
types	35% red, 65% blue	two templates, strong and weak 4000 Å break
spectra	power law, 4000 Å break, Lyman absorption	the features a photo-z reads
mismatch	each galaxy's slope and break differ a little	templates are never exactly right
filters	six top-hats, u to y (Figure T2.33)	broad bands
depths	5σ limits 24.0–25.4 mag	realistic noise
redshift grid	800 values, $0 < z < 4$	where (T2.128) is evaluated

It computes the six fluxes, adds noise, and evaluates (T2.128) on the grid:

Listing T2.12: The template likelihood, with the amplitude and the type marginalised, and the two posteriors (`code/chT2/11_photoz.py`)

```

```

Line 73 is $\chi^2_{\rm min}$ of (T2.128), line 74 the width $\sqrt{1/S}$ of the amplitude integral, and line 76 the sum over types. Line 83 multiplies by the prior $n(z)$.

Two summary numbers describe the errors, both measured on $\Delta z \equiv (z_p - z)/(1+z)$, the error in the units in which it is roughly constant. A galaxy is an **outlier** if $|\Delta z| > 0.15$, that is $|z_p - z| > 0.15(1+z)$: an error far too large for the Gaussian core, typically a degeneracy. The width of the core is measured on the remaining galaxies by the **normalised median absolute deviation**, $\mathrm{NMAD} = 1.48 \times \mathrm{median}\,\big|\Delta z - \mathrm{median}(\Delta z)\big|$. The median is used instead of the mean

so that a few large errors cannot inflate it, and the factor 1.48 makes it equal to σ for a Gaussian (the median of $|x|$ for a unit Gaussian is $0.674 = 1/1.48$).

With a flat prior the core width is NMAD = 0.018, and 9.8% of the galaxies are outliers.

With the $n(z)$ prior, the cause first. A degenerate galaxy has a likelihood with two peaks, one at low and one at high redshift. The prior multiplies each peak by the number of galaxies at that redshift, and $n(z)$ is far larger at $z \lesssim 1$ than at $z \approx 3$; so the peak on the poorly populated side is down-weighted, and when it was a spurious peak the error is removed. Then the size: the core barely changes (0.019), but the outliers drop from 9.8% to 4.3%. The price is paid by the rare galaxies that really sit on the poorly populated side: the high-redshift galaxy of Figure T2.34 ($z = 2.00$) has a bimodal likelihood whose higher peak is right, and the prior moves it to the wrong, low-redshift peak, because the prior is doing exactly what it should for the typical galaxy with that colour, and this one is not typical.

The mean of a bin. For the bin $0.8 < z_p < 1.2$ (6199 galaxies) the true mean redshift is 0.965 and the mean photo-z is 0.975, an error of 0.01, at the Stage-III requirement. Stacking the posteriors instead of the point estimates gives 0.975, no better. Why no better? A posterior accounts for the photometric noise, but every posterior here is computed with the same two templates, and every real galaxy differs from its template in the same kind of way. That template mismatch shifts all the posteriors together, and averaging many of them cannot remove an error they share. The asymmetry of (T2.129) is visible where $n(z)$ is steep: at $z = 0.5$, on the rising side, $\langle z_p \rangle_z = 0.531$ but $\langle z \rangle_{z_p} = 0.500$; at $z = 1.5$, on the falling side, 1.449 against 1.407.

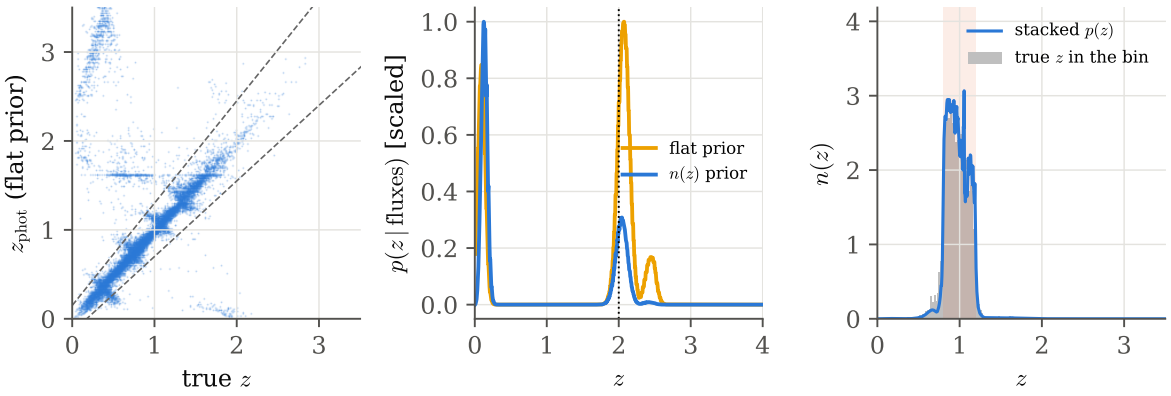

Figure T2.34: Left: photo-z against true redshift (flat prior); the dashed lines bound the core $|z_p - z| < 0.15(1+z)$, and the clumps outside are the degeneracies. Middle: the redshift posterior of one galaxy at $z = 2.0$ (dotted line) with a flat prior and with the $n(z)$ prior. Right: the true redshifts of the galaxies selected by $0.8 < z_p < 1.2$ (grey) and the sum of their posteriors (blue).

Nerfed, honestly. Two toy templates, top-hat filters and a population independent of magnitude make the experiment run in a second. Real pipelines use hundreds of templates or machine-learning estimators trained on spectroscopic samples, fold in magnitude-dependent priors, and calibrate $n(z)$ per bin with spectroscopic subsamples, clustering redshifts and self-organising maps of colour space; the residual uncertainty of each bin's mean is then carried as a nuisance parameter.

Where the statistics comes back in. The photo-z posterior is Bayes' theorem with a nuisance amplitude marginalised (Chapter 5). The core-plus-outliers error distribution is a mixture model, fitted with the likelihood methods of Chapter 3. The shift of the mean of each bin is the nuisance parameter that weak-lensing likelihoods marginalise (Chapter T1), sampled with

MCMC (Chapter 9), and its required accuracy is set by a Fisher forecast (Chapter 10).

Where each item is used. The standardised supernova distance (T2.98) with the noise budget (T2.99) is the datum of the H_0 problem of Chapter 3 and of every supernova likelihood after it. The ladder (T2.106) is a worked generalised least-squares fit whose covariance is the inverse Fisher matrix of Chapter 10. The selection-aware likelihood (T2.111) is the template for any analysis of a selected sample. The bias, shot noise and Kaiser factor (T2.112)–(T2.119) turn the matter $P(k)$ of Chapter 7 into the galaxy $P_g(k,\mu)$ that Chapter 11 fits. The BAO distances (T2.123) and (T2.126) are a compact, nearly Gaussian likelihood used with the samplers of Chapter 9. And the photo-z posterior (T2.128) and its mean-redshift bias are the redshift nuisances of the weak-lensing likelihoods of Chapter T1.

Recap

- Type Ia supernovae are standardisable: $\mu = m_B - M + \alpha x_1 - \beta c$ reduces a 0.4 mag scatter to ≈ 0.12 mag, a 6% distance per supernova; noisy colours dilute the fitted β by $V_c/(V_c+\sigma_c^2)$, and peculiar velocities add $2.17\,\sigma_v/cz$ mag.
- Supernovae measure only $M_B - 5\log_{10} H_0$. The ladder (geometry $\to$ Cepheids or TRGB $\to$ calibrator supernovae $\to$ Hubble flow) is one linear model; each rung adds its variance, and lower-rung errors never average down.
- A flux limit biases a sample: $\langle M\rangle_{\rm det} = M_0 - 1.382\sigma^2$ in Euclidean space, $-\sigma\phi(t)/\Phi(t)$ near the limit; the cure is the likelihood of the selected data, $\mathcal{N}/\Phi(t)$.
- Galaxies trace matter with a bias, $\delta_g = b\delta$, $b = 1 + b_L$ with $b_L = \phi(\nu)/[\sigma(1-\Phi(\nu))]$ for threshold tracers; their power has shot noise $1/\bar{n}$; in redshift space $P_s = b^2(1+\beta\mu^2)^2P$, $\beta = f/b$.
- The BAO bump at $r_d \approx 147$ Mpc measures D_M/r_d and D_H/r_d, or D_V/r_d; in flat ΛCDM DESI's distances fix $\Omega_m = 0.295 \pm 0.015$ and $hr_d = 101.8 \pm 1.3$ Mpc, and with the CMB r_d an inverse ladder gives $H_0 \approx 69$.
- Photometric redshifts have a core of width $\sim 0.02(1+z)$ and catastrophic outliers from the Lyman/4000 Å degeneracy; $\langle z\rangle_{z_p} \neq z_p$ even when $\langle z_p\rangle_z = z$, and a bin's mean redshift must be known to $\lesssim 0.01$.

Chapter summary

Each astrophysical object of the chapter enters the statistics the same way: what is measured, where its noise lives, and which tool turns the measurement into physics.

Compact binaries and gravitational waves

concept	operational meaning	used later in
chirp, chirp mass	$\dot{f} = \frac{96}{5}\pi^{8/3}(G\mathcal{M}/c^3)^{5/3}f^{11/3}$ from energy balance; only $\mathcal{M} = (m_1 m_2)^{3/5}/M^{1/5}$ at leading order	Chapter 10
stationary-phase waveform	$\tilde{h} = \mathcal{A}f^{-7/6}e^{-i\Psi(f)}$, $\mathrm{d}^2\Psi/\mathrm{d}f^2 = 2\pi/\dot{f}$: the signal model of the likelihood	Chapters 0, 5 and 10
LISA noise $S_n(f)$	acceleration noise at low f, metrology and arm response at high f, Galactic foreground near a mHz; the covariance of Gaussian detector noise	Chapters 0 and 10
signal-to-noise ratio	$\rho^2 = 4\int \lvert\tilde{h}\rvert^2/S_n\,\mathrm{d}f$; phase resolution $\sim 1/\rho$ rad	Chapter 10
dark-matter spike	$\rho \propto r^{-(9-2\gamma_i)/(4-\gamma_i)}$ around a growing black hole; fixes the physical meaning of the environmental parameter	Chapter 10
power-law dephasing	extra power $\propto f^{-n}P_{\mathrm{GW}}$ gives $\delta\Psi = \beta u^b$, $b = -5/3 - n$; one Fisher calculation per exponent	Chapters 9 and 10

Standard candles, distances and galaxy surveys

concept	operational meaning	used later in
Tripp standardisation	$\mu = m_B - M + \alpha x_1 - \beta c$; Hubble residual Gaussian in magnitude, $\sigma \approx 0.12$ mag	Chapters 3 and 5
regression dilution	least squares with noisy regressors shrinks a slope by $V/(V+\sigma^2)$; cure: latent variables in a hierarchical model	Chapters 3, 5 and 9
distance ladder	one linear model through shared parameters M_W, M_B; covariance $(A^{\mathsf{T}}\mathbf{C}^{-1}A)^{-1}$; the H_0–M_B degeneracy broken by geometry	Chapters 3, 4 and 10
Malmquist bias	detected candles brighter by $1.382\sigma^2$; near a limit $-\sigma\phi(t)/\Phi(t)$; likelihood of the selected data divides by $\Phi(t)$	Chapters 3, 5 and 6
linear bias	$\delta_g = b\delta$, $P_g = b^2P$ on large scales; threshold and halo-model values; a nuisance in every clustering fit	Chapters 7 and 11
shot noise	$1/\bar{n}$ added to P_g; error $\sqrt{2/N_k}(1 + 1/\bar{n}P)$ per band; one-halo constant	Chapters 2, 7 and 10
Kaiser formula	$P_s(k,\mu) = b^2(1+\beta\mu^2)^2P$; monopole $1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2$; measures $f\sigma_8$	Chapter 11
BAO ruler	$\Delta\theta = r_d/D_M$, $\Delta z = r_d/D_H$, $D_V = (zD_M^2D_H)^{1/3}$; dilation α from a template fit with broadband nuisances	Chapters 4, 7, 9 and 11
DESI BAO likelihood	Gaussian in $(D_M/r_d, D_H/r_d)$ per bin; depends on Ω_m and $H_0 r_d$ only; inverse ladder with r_d	Chapters 5 and 9
photometric redshift	template likelihood with amplitude marginalised, times an $n(z)$ prior; core $\propto 1+z$ plus outliers; $P(z \mid z_p)$ by Bayes	Chapters T1 and 5
mean-redshift nuisance	shift of each bin's $\langle z\rangle$, required to $\lesssim 0.01$; marginalised in lensing likelihoods	Chapters T1, 9 and 10

Reading the literature

Chapter T3

CMB Morphology and Topology

Where this chapter is going

Look at a map of the microwave sky and the first thing you see is not a number but a pattern: hot blobs and cold blobs, some isolated, some joined into long ridges, a few large cold lakes with hot islands inside them. The angular power spectrum C_ℓ of Chapter 7 turns that map into one number per multipole, the mean squared amplitude of the fluctuation on that angular scale. It does not record how the blobs are joined to each other. For a Gaussian, statistically isotropic sky nothing is lost by that (Section 7.13): the phases are random and the spectrum is the whole story. For any other sky, the way the blobs connect carries information the spectrum has thrown away, and the question becomes physical. What does inflation predict for the shapes? What would a small primordial skewness, measured by $f_{\rm NL}$, do to them? What does gravitational lensing, which shifts every point of the image by a couple of arcminutes, do to them? And which shape statistics are left untouched by those shifts, so that they can be trusted when the shifts are a nuisance? That last question is the general one behind everything below. An experiment gives one imperfect realization of a field, and smoothing, noise and propagation effects change its detailed values; what we want are summaries of shape and structure that survive the transformations we regard as nuisance.

The polarization of the microwave background adds a second pattern. At every point the polarization is a short stick with a direction but no arrowhead. Where the polarized intensity drops to zero the stick has no direction at all, and around such a point the sticks turn by half a revolution. These points are the polarization singularities. They can be counted, their number per square degree follows from the spectrum, and a smooth remapping such as lensing moves them but cannot create or destroy them one at a time.

The ideas connect as in Figure T3.1. The shapes of a temperature map are read through its *excursion sets*, the regions hotter than a chosen threshold, and through three numbers for each set: its area, the length of its boundary and its Euler characteristic, which counts hot regions minus holes (Section T3.1). For a Gaussian sky all three are known in closed form, and they depend on C_ℓ through just two numbers, the variance of the map and the variance of its gradient. A non-Gaussian sky moves the curves, but part of the move is only a relabelling of the threshold, and only what survives the relabelling is information about non-local physics; lensing, by contrast, leaves the one-point distribution of the map exactly as it was (Section T3.2). The polarization singularities have a half-integer index, and their density follows from the spectrum by a counting argument (Section T3.3). Lensing remaps the sky smoothly and invertibly, which preserves both the topology of every excursion set and every singularity with its index; what breaks the protection is anything applied after the remapping, such as the beam (Section T3.4). *Planck* used exactly these statistics, together with the bispectrum, to test whether the sky is Gaussian and isotropic, and found it consistent with both apart from a handful of

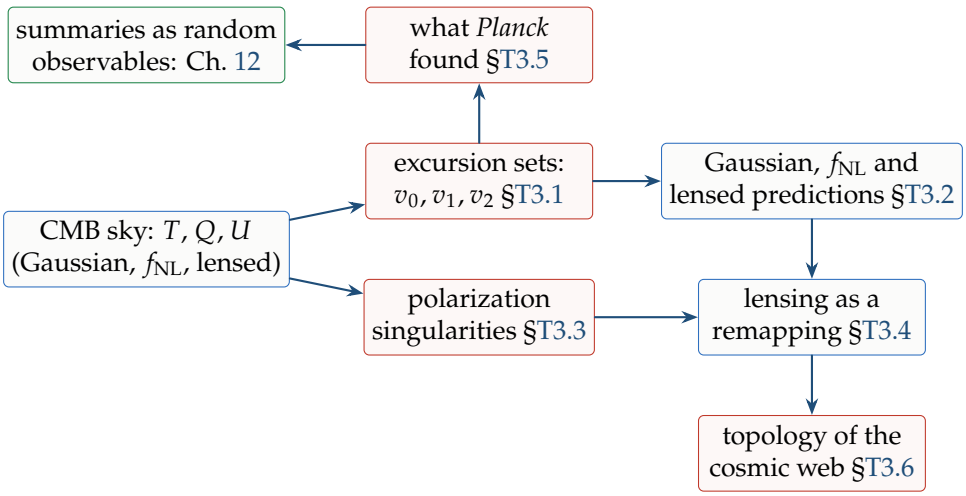

Figure T3.1: How the ideas of the chapter connect. Blue boxes are physics: the sky, what a Gaussian, a non-Gaussian or a lensed sky predicts for its shapes, and what lensing does geometrically. Red boxes are the things one measures on a map: the three Minkowski functionals of the excursion sets, the polarization singularities, the published *Planck* tests, and the same tools applied to the three-dimensional matter distribution. The green box is the statistics: Chapter 12 treats every one of these summaries as a random variable with a sampling distribution, and tests and fits with it.

large-angle anomalies (Section T3.5). The same counting, applied in three dimensions to the matter distribution, describes the cosmic web (Section T3.6).

In the language of the book's pipeline (Chapter 0): the physical model is the primordial field plus everything that happens to the photons on the way to us. The data set is the map. What we choose to keep is the connectivity of its hot and cold regions and the zeros of its polarization. Each such summary has a sampling distribution, known in closed form for a Gaussian sky and obtained by simulation otherwise, and Chapter 12 uses those distributions to infer physics. The cosmology that produces each spectrum is in the cosmology notes.

T3.1 The shape of a temperature map

Take a temperature map of a patch of sky, like the left panel of Figure T3.2, and paint every pixel hotter than one standard deviation. What is left is a scatter of islands: 73 more separate hot pieces than holes in this patch. Lower the threshold to one standard deviation *below* the mean and paint again. Now almost everything is painted, and the unpainted pixels form cold lakes inside one connected hot continent: the count of pieces minus holes has become -84. Somewhere in between, at the mean, the painted and unpainted regions are two interlocked networks, neither of which is a sea around the other. This change of connectivity with the threshold is the morphology of the map. Two maps with the same C_ℓ can have different morphologies (the phase-scrambling experiment of Section 7.13 built one), so a statistic of connectivity is a probe that the spectrum does not replace.

The question. If we colour every point of the sky hotter than ν standard deviations, how much of the sky is coloured, how long is the coastline of the coloured region, and how many separate pieces does it have once its holes are subtracted? And for a Gaussian sky with a given C_ℓ, what should each of those three numbers be at each ν?

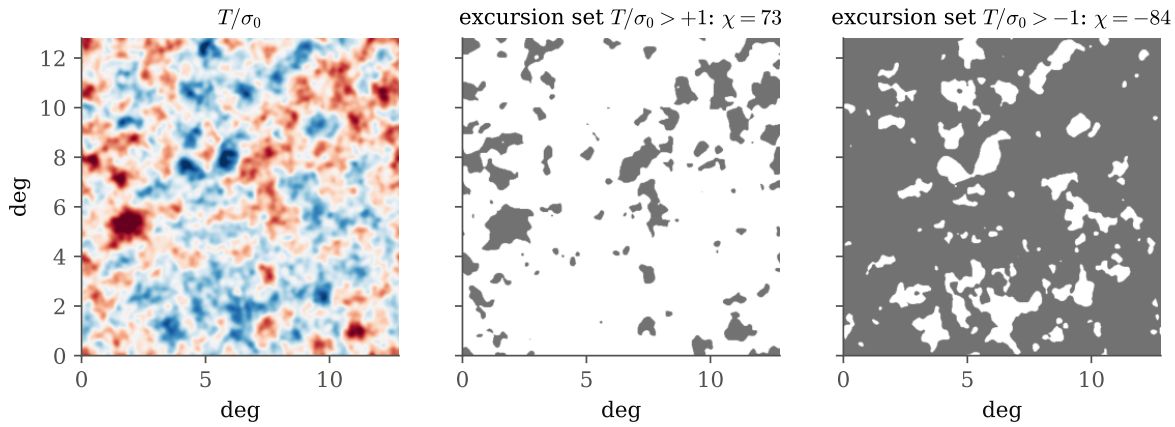

Figure T3.2: Left: a simulated $12.8° \times 12.8°$ patch of the CMB temperature, smoothed by a 10′ beam, in units of its standard deviation σ_0. Middle: the pixels hotter than $+1\sigma_0$ form separate islands, with very few holes. Right: the pixels hotter than $-1\sigma_0$ form one connected region pierced by cold lakes, so holes outnumber pieces and the Euler characteristic is negative.

T3.1.1 Excursion sets and their three numbers

Write the temperature fluctuation in direction $\hat{\boldsymbol{n}}$ as $T(\hat{\boldsymbol{n}})$, measured from the mean, and its standard deviation over the sky as σ_0 (the subscript says it is the variance of the field itself, with no derivatives). The region of the sky where the field exceeds ν standard deviations is the **excursion set** at threshold ν,

$$Q_\nu = \{\hat{\boldsymbol{n}} \,:\, T(\hat{\boldsymbol{n}}) > \nu\,\sigma_0\}. \tag{T3.1}$$

Figure T3.2 shows two of them. In two dimensions a classical theorem of integral geometry (Hadwiger's) says that any summary of the shape of a region that adds up over disjoint pieces and does not care where the region sits or how it is turned is a combination of just three numbers [105]: the area, the length of the boundary, and the Euler characteristic. These are the three **Minkowski functionals**.

Working definition T3.1 (the Minkowski functionals of a map)

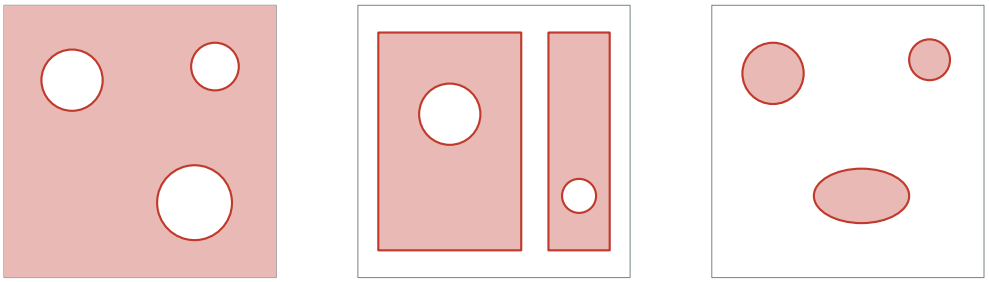
For a map T on a patch of area A and a threshold ν, divide by the area to get densities:

- $v_0(\nu)$, the *area fraction* [the fraction of pixels with $T > \nu\sigma_0$];
- $v_1(\nu) = \frac{1}{4A}\times$ the total length of the boundary of Q_ν [the factor $\frac{1}{4}$ is a convention of integral geometry];
- $v_2(\nu) = \frac{1}{A} \times \chi(Q_\nu)$, where the *Euler characteristic* χ is the number of separate pieces of Q_ν minus the number of holes in them [a hole is a cold region completely surrounded by hot sky].

Operational: v_0 is a pixel count. v_1 is the average of $|\nabla T|\,\delta(T - \nu\sigma_0)$ over the map, with the delta replaced by a narrow bin. χ is counted on the pixel grid as vertices minus edges plus faces of the union of the hot pixels (see the topology notes for why this alternating count gives pieces minus holes).

Why these three and not others? Each answers a physical question about the coloured region. The area fraction says how much of the sky is hotter than the threshold. The boundary length says how wiggly the coastline is, which is a statement about how fast the field changes in space. The Euler characteristic is the one number that does not change when the region is stretched or bent without tearing: it sees only connectivity. Its value is the same whether the

island is round or elongated, so it is the most robust of the three to anything that distorts the map smoothly, a point that returns in Section T3.4. On the full sky there is one more fact, from the Gauss–Bonnet theorem: a region that grows until it covers the whole sphere ends with $\chi = 2$ (the Euler characteristic of a sphere), not 0, so the full-sky count contains a small term proportional to the area, $\chi = V_2 + V_0/(2\pi R^2)$ in the notation of [105] (their eq. 7), where V_0 is the area, V_2 the integrated boundary curvature divided by 2π and R the radius of the sphere.



$\nu = -1$: one continent, three lakes
$\chi = 1 - 3 = -2$

$\nu = 0$: two pieces, two holes
$\chi = 2 - 2 = 0$

$\nu = +1$: three islands
$\chi = 3 - 0 = 3$

Figure T3.3: Cartoon of excursion sets at three thresholds (shaded: hotter than the threshold). At a low threshold the hot region is one piece with cold lakes in it; at a high threshold it is a set of separate islands. The Euler characteristic, pieces minus holes, runs from negative to positive as the threshold rises.

T3.1.2 What a Gaussian sky predicts

The area first. The area fraction is the share of the sky where $T > \nu\sigma_0$. On a statistically homogeneous sky the average of a quantity over the sky equals its average over the ensemble of possible skies (ergodicity, Section 7.5). So the expected area fraction is the probability that the field at one point exceeds the threshold. For a Gaussian field of mean zero and variance σ_0^2,

$$\mathbb{E}[v_0(\nu)] \overset{(1)}{=} \mathrm{P}\left(T(\hat{\boldsymbol{n}}) > \nu\sigma_0\right) \overset{(2)}{=} \int_{\nu\sigma_0}^{\infty} \frac{e^{-t^2/2\sigma_0^2}}{\sqrt{2\pi}\,\sigma_0}\,\mathrm{d}t \overset{(3)}{=} \int_{\nu/\sqrt{2}}^{\infty} \frac{e^{-s^2}}{\sqrt{\pi}}\,\mathrm{d}s \overset{(4)}{=} \tfrac{1}{2}\,\mathrm{erfc}\big(\nu/\sqrt{2}\big). \tag{T3.2}$$

(1) The sky average of the indicator of Q_ν equals its ensemble average at one point (ergodicity), and the average of an indicator is a probability.
(2) The one-point density of a Gaussian field.
(3) Substitute $s = t/(\sqrt{2}\sigma_0)$, so $\mathrm{d}t = \sqrt{2}\sigma_0\,\mathrm{d}s$.
(4) The definition $\mathrm{erfc}(x) = \frac{2}{\sqrt{\pi}}\int_x^\infty e^{-s^2}\mathrm{d}s$.

Example: the area above one standard deviation. At $\nu = 1$, (T3.2) gives $\frac{1}{2}\,\mathrm{erfc}(0.7071) = 0.1587$: about one sky pixel in six. The 300 simulated patches of Figure T3.4 give 0.1585. Notice what v_0 does *not* depend on: the spectrum. Only the one-point distribution enters, so v_0 is a test of the shape of the histogram of pixel values and nothing else.

Two numbers from the spectrum. The boundary length and the Euler characteristic do depend on the spectrum, but only through two of its moments: the variance of the field, $\sigma_0^2 = \langle T^2\rangle$, and the variance of its gradient, $\sigma_1^2 = \langle|\nabla T|^2\rangle$ [105, 106]. Both follow from C_ℓ. Write $T = \sum_{\ell m} a_{\ell m} Y_{\ell m}$

with $\langle a_{\ell m} a^*_{\ell' m'} \rangle = C_\ell \, \delta_{\ell\ell'} \delta_{mm'}$ (Eq. (7.62)). Then

$$\sigma_0^2 = \langle T(\hat{\boldsymbol{n}})^2 \rangle \overset{(1)}{=} \sum_{\ell m} C_\ell \, |Y_{\ell m}(\hat{\boldsymbol{n}})|^2 \overset{(2)}{=} \sum_\ell \frac{2\ell+1}{4\pi} \, C_\ell , \tag{T3.3}$$

$$\begin{aligned} \sigma_1^2 = \langle |\nabla T|^2 \rangle &\overset{(3)}{=} \left\langle \frac{1}{4\pi} \int |\nabla T|^2 \, \mathrm{d}\Omega \right\rangle \overset{(4)}{=} -\left\langle \frac{1}{4\pi} \int T \, \nabla^2 T \, \mathrm{d}\Omega \right\rangle \\ &\overset{(5)}{=} \frac{1}{4\pi} \sum_{\ell m} \ell(\ell+1) \langle |a_{\ell m}|^2 \rangle = \sum_\ell \frac{2\ell+1}{4\pi} \, \ell(\ell+1) \, C_\ell . \end{aligned} \tag{T3.4}$$

(1) Expand both factors of $T^2 = T\,T^*$ (the field is real) and average; only $\ell = \ell'$, $m = m'$ survives.
(2) Addition theorem (7.63) at coincident points, $\sum_m |Y_{\ell m}|^2 = (2\ell+1)/4\pi$.
(3) On an isotropic sky the expectation at one point equals the expectation of the sky average.
(4) Integrate by parts on the sphere; there is no boundary term because the sphere has no edge.
(5) $\nabla^2 Y_{\ell m} = -\ell(\ell+1) Y_{\ell m}$ and orthonormality of the $Y_{\ell m}$.

A beam of window b_ℓ multiplies C_ℓ by b_ℓ^2 in both sums. The ratio has the dimension of an inverse angle squared, so it defines a correlation angle

$$\theta_c \equiv \sigma_0 / \sigma_1 , \tag{T3.5}$$

the typical distance over which the field changes by one standard deviation. In flat-sky language, $\ell(\ell+1) \to |\boldsymbol{\ell}|^2$ and the sums become integrals over the plane of wave vectors.

Example: the correlation angle of a 10′ map. For the fiducial *Planck* spectrum smoothed by a 10′ beam, the full-sky sums give $\sigma_0 = 104.2\,\mu$K and $\theta_c = 13.4'$. On a 12.8° patch the multipoles below $\ell \approx 2\pi/12.8° \approx 28$ do not fit, so σ_0 drops to 93.8 μK and θ_c to 12.0′. The lowest multipoles carry a large share of the variance but almost none of the gradient: they are the gentle, sky-wide tilts.

The boundary length: counting crossings. The boundary of Q_ν is the set of points where $T = \nu\sigma_0$ exactly. Its length per unit area is the sky average of $|\nabla T| \, \delta(T - \nu\sigma_0)$: the delta function selects the points on the contour, and the factor $|\nabla T|$ converts "a thin slab of threshold values of width $\mathrm{d}T$" into the length of contour it contains, since a steeper field crosses the slab in a narrower strip. By ergodicity the sky average is an ensemble average at one point, and at one point the value and the gradient of a homogeneous field are independent, because $\langle T \, \partial_i T \rangle = \frac{1}{2} \partial_i \langle T^2 \rangle = 0$ and both are Gaussian. So the average factorises. On an isotropic sky the total gradient variance σ_1^2 splits equally between the two directions, so each component of ∇T has variance $s^2 = \sigma_1^2/2$. The length $r = |\nabla T|$ of such a two-dimensional Gaussian vector has the Rayleigh density $(r/s^2) e^{-r^2/2s^2}$, with mean $\int_0^\infty (r^2/s^2) e^{-r^2/2s^2} \mathrm{d}r = s\sqrt{\pi/2}$. Hence

$$\begin{aligned} \mathbb{E}[v_1(\nu)] &\overset{(1)}{=} \frac{1}{4} \, \mathbb{E}\left[|\nabla T| \, \delta(T - \nu\sigma_0) \right] \overset{(2)}{=} \frac{1}{4} \, \frac{e^{-\nu^2/2}}{\sqrt{2\pi}\,\sigma_0} \, \mathbb{E}\,|\nabla T| \\ &\overset{(3)}{=} \frac{1}{4} \, \frac{e^{-\nu^2/2}}{\sqrt{2\pi}\,\sigma_0} \, \frac{\sigma_1}{\sqrt{2}} \sqrt{\frac{\pi}{2}} \overset{(4)}{=} \frac{1}{8\sqrt{2}\,\theta_c} \, e^{-\nu^2/2} . \end{aligned} \tag{T3.6}$$

(1) The definition of v_1 (a quarter of the length per unit area) and the crossing-counting argument above.
(2) Independence of T and ∇T at a point; the average of $\delta(T - \nu\sigma_0)$ is the one-point density of T at $\nu\sigma_0$.

(3) The Rayleigh mean with $s = \sigma_1/\sqrt{2}$.
(4) $\frac{1}{\sqrt{2\pi}} \cdot \frac{1}{\sqrt{2}}\sqrt{\frac{\pi}{2}} = \frac{1}{2\sqrt{2}}$, and $\sigma_1/\sigma_0 = 1/\theta_c$.

The Euler characteristic, stated. The same reasoning applied to the number of hot regions minus holes needs the second derivatives of the field as well, and its derivation is in Chapter 12. The result is

$$\mathbb{E}[v_2(\nu)] = \frac{1}{(2\pi)^{3/2}} \frac{1}{2\theta_c^2}\, \nu\, e^{-\nu^2/2}, \tag{T3.7}$$

and (T3.6) with (T3.7) are the two curves referred to below as the Gaussian functionals. Here we read off what each factor means. The factor $e^{-\nu^2/2}$ is the reason a coastline exists at all: a boundary needs the field to be exactly at the threshold, and the probability density of that is proportional to $e^{-\nu^2/2}$. So boundaries and islands are rare at large $|\nu|$. The factor $1/\theta_c$ in v_1 turns "crossings per unit of threshold" into "length per unit area": a field that changes faster has more coastline. The factor $1/\theta_c^2$ in v_2 is one island per correlation area. Finally the factor ν makes v_2 odd. That follows from the symmetry of a Gaussian under $T \to -T$: the complement of the set $\{T > -\nu\sigma_0\}$ is the set $\{-T \geq \nu\sigma_0\}$, which has the same statistics as Q_ν, and on a closed patch (a torus, or the plane far from edges) the Euler characteristic of a region and of its complement are opposite, because the pieces of one are the holes of the other. So $v_2(-\nu) = -v_2(\nu)$, and $v_2(0) = 0$.

Example: how many hot spots above 2σ? At $\nu = 2$ holes inside hot spots are rare, so χ counts the hot spots. On the full sky the Gaussian kinematic formula adds the sphere's own Euler characteristic times the area fraction to 4π times the density (T3.7) [105]:

$$\begin{aligned}\mathbb{E}[\chi_{\rm sky}(2)] &\overset{(1)}{=} 4\pi\, \frac{1}{(2\pi)^{3/2}} \frac{1}{2\theta_c^2}\, 2e^{-2} + 2\cdot\tfrac{1}{2}\,\mathrm{erfc}(\sqrt{2}) \\ &\overset{(2)}{=} 4\pi \times 0.0635 \times \frac{1}{2\,(3.90\times10^{-3})^2} \times 0.271 + 2\times 0.0228 \;\approx\; 7.1\times10^3.\end{aligned}$$

(1) The density (T3.7) at $\nu = 2$ times the area 4π of the sphere, plus $\chi(S^2) = 2$ times $\mathbb{E}[v_0(2)]$ from (T3.2).
(2) $(2\pi)^{-3/2} = 0.0635$, $\theta_c = 13.4' = 3.90\times10^{-3}$ rad, $2e^{-2} = 0.271$. The second term is negligible.

The unrounded evaluation in `01_excursion_mfs.py` gives 7157. A 10′ map of the whole sky has several thousand hot spots above two standard deviations; a sky with a hundred more or a hundred fewer would be a statement about physics.

T3.1.3 Checking the formulas on simulated skies

To see the formulas at work we simulate 300 flat patches of $12.8^\circ \times 12.8^\circ$, with 1.5′ pixels and the fiducial lensed spectrum smoothed by a 10′ beam, and measure all three functionals at 41 thresholds. The area fraction is a pixel count, the boundary length uses the binned-delta average of $|\nabla T|$, and the Euler characteristic is counted on the pixel grid:

Listing T3.1: Counting pieces minus holes on the pixel grid (`code/chT3/lib_t3.py`)

```
def euler_torus(mask):
    """Euler characteristic of the union of closed pixel squares in ‘mask‘, on the periodic
    grid.

    F = pixels in the set; an edge belongs to the complex if either pixel sharing it is in
    the set;
    a vertex belongs if any of the four pixels around it is in the set.  chi = V - E + F.
    (Closed squares touching at a corner are connected: 8-connectivity for the set.)
```

```
    """
    m = np.asarray(mask, bool)
    F = m.sum(axis=(-2, -1))
    r = lambda a, s, ax: np.roll(a, s, axis=ax)
    Eh = (m | r(m, 1, -2)).sum(axis=(-2, -1))      # edges between vertical neighbours
    Ev = (m | r(m, 1, -1)).sum(axis=(-2, -1))      # edges between horizontal neighbours
    V = (m | r(m, 1, -2) | r(m, 1, -1) | r(r(m, 1, -2), 1, -1)).sum(axis=(-2, -1))
    return V - (Eh + Ev) + F
```

Each pixel above the threshold is a closed square. The function counts the squares (F), the pixel edges that belong to at least one of them (E), and the pixel corners that belong to at least one of them (V); the alternating sum $V - E + F$ is the Euler characteristic of their union. The rolls make the patch periodic, so the patch is a torus and has no edge to correct for. On one map the count agrees exactly with `skimage.measure.euler_number` (89 and 89), the library routine the research literature uses.

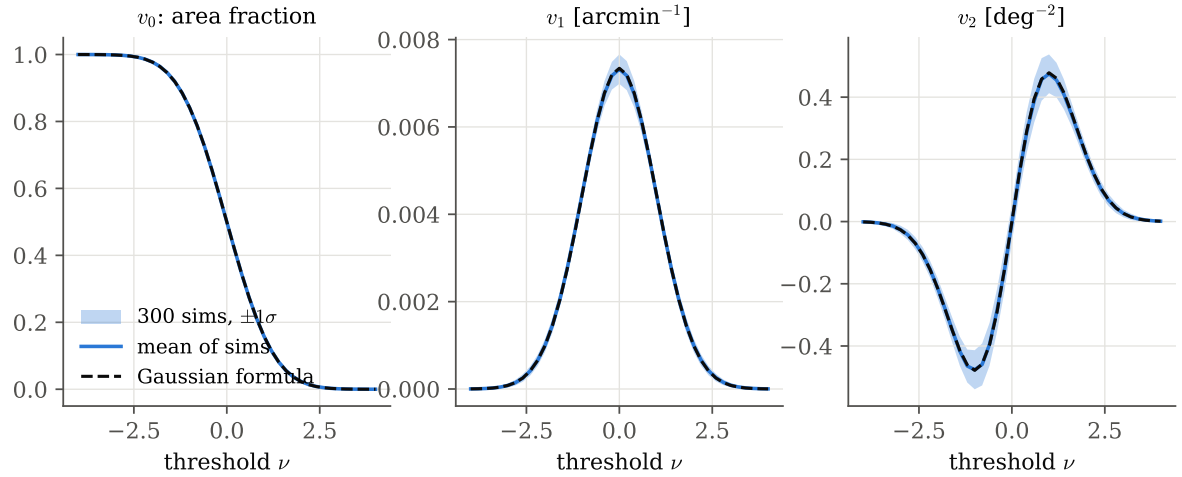


Figure T3.4: The three Minkowski functionals of simulated Gaussian CMB patches (10′ beam) against the threshold. The band is the spread of single patches, the solid line their mean, and the dashed line the Gaussian formulas (T3.2) and (T3.6), (T3.7) with σ_0 and σ_1 computed from the spectrum. The Euler characteristic changes sign at $\nu = 0$: islands above, lakes below.

Figure T3.4 shows the result. The mean of the simulations lies on the Gaussian curves; the largest departure of the mean Euler characteristic from the formula is 1.4% of its peak, against a Monte Carlo error of 0.8% on the mean. The bands are wide: a single 164-square-degree patch has a peak Euler characteristic near 78, and the patch-to-patch scatter is many times larger than the error on the mean. That scatter is the sampling distribution of the statistic, and it is what Chapter 12 estimates by Monte Carlo to turn a measured curve into a test.

Watch out: Thresholds in units of which σ_0?

The formulas use the true σ_0 of the ensemble. A map only gives its own sample standard deviation, which differs from patch to patch (a 164 deg^2 patch misses all the variance at $\ell \lesssim 28$). Normalising each map by its own standard deviation removes most of the scatter in the *amplitude* of the curves and leaves their shape, which is why *Planck* does it (Section T3.5). Whichever choice is made, the simulations must make the same one.

Real maps are not Gaussian random fields drawn on a computer, and the functionals are just as easy to compute on any surface. [105] show them for the Earth's topography binned onto a sky map: the curves change sharply at the depth of the ocean floor and at sea level, the Euler characteristic dips where the mid-ocean ridges emerge as long connected ranges, and

nothing about them looks like (T3.6), (T3.7). A strongly non-Gaussian surface announces itself immediately. The cosmological question is the opposite one: how small a departure from the Gaussian curves can be detected, and what would cause it.

T3.2 What a skewed sky and a lensed sky change

The simplest inflationary models make the primordial fluctuations almost exactly Gaussian. Models with more than one field can leave a small quadratic piece. The standard way of writing it, used by *Planck*, is the **local model** [107]

$$\Phi(\boldsymbol{x}) = \phi(\boldsymbol{x}) + f_{\mathrm{NL}}\big[\phi^2(\boldsymbol{x}) - \langle\phi^2\rangle\big], \tag{T3.8}$$

where ϕ is a Gaussian field, Φ is the primordial potential (Bardeen's potential, $\Phi = \frac{3}{5}\zeta$ on super-horizon scales, with ζ the comoving curvature perturbation; see the cosmology notes), and f_{NL} is a number that measures how much of the square is mixed in. Subtracting $\langle\phi^2\rangle$ keeps the mean of Φ zero. Because $\phi \sim 10^{-5}$, even $f_{\mathrm{NL}} \sim 10$ makes the quadratic term a part in 10^4 of the linear one. The question is what such a term does to the three curves of Figure T3.4. A second question runs alongside it. Every CMB photon has been deflected by a couple of arcminutes on its way to us; does that change the curves?

The question. If the sky is slightly skewed, which of the three Minkowski functionals move, by how much, and how much of the move tells us about the physics that produced the skewness rather than about the histogram of pixel values? And what does lensing do to the same three numbers?

T3.2.1 The first correction to the Gaussian curves

A mildly non-Gaussian field is described, to first order, by its three-point averages. For the Minkowski functionals in two dimensions only three such averages matter [108] (his eqs. 2.61–2.63 with $d = 2$). Measured in units of σ_0, and with $\theta_c = \sigma_0/\sigma_1$ the correlation angle of (T3.5), they are

$$S^{(0)}\sigma_0 = \frac{\langle T^3\rangle}{\sigma_0^3}, \qquad S^{(1)}\sigma_0 = -\frac{3}{4}\,\frac{\langle T^2\,\nabla^2 T\rangle}{\sigma_0\,\sigma_1^2}, \qquad S^{(2)}\sigma_0 = -3\,\frac{\langle |\nabla T|^2\,\nabla^2 T\rangle\,\sigma_0}{\sigma_1^4}. \tag{T3.9}$$

The first is the ordinary skewness of the histogram of pixel values: positive when the hot tail is longer than the cold one. The other two, the **skewness parameters** of the derivatives, say whether hot regions differ from cold ones in how steep and how curved they are. All three vanish for a Gaussian field. To first order in them, Matsubara's result (his eq. 3.48, $d = 2$) reads

$$\begin{aligned}
\mathbb{E}[v_0(\nu)] &= \tfrac{1}{2}\,\mathrm{erfc}\big(\nu/\sqrt{2}\big) + \frac{e^{-\nu^2/2}}{\sqrt{2\pi}}\,\frac{S^{(0)}\sigma_0}{6}\,H_2(\nu),\\
\mathbb{E}[v_1(\nu)] &= \frac{1}{8\sqrt{2}\,\theta_c}\,e^{-\nu^2/2}\Big\{1 + \Big[\frac{S^{(0)}}{6}H_3(\nu) + \frac{S^{(1)}}{3}H_1(\nu)\Big]\sigma_0\Big\},\\
\mathbb{E}[v_2(\nu)] &= \frac{1}{(2\pi)^{3/2}}\,\frac{1}{2\theta_c^2}\,e^{-\nu^2/2}\Big\{H_1(\nu) + \Big[\frac{S^{(0)}}{6}H_4(\nu) + \frac{2S^{(1)}}{3}H_2(\nu) + \frac{S^{(2)}}{3}\Big]\sigma_0\Big\},
\end{aligned} \tag{T3.10}$$

with the Hermite polynomials $H_n(\nu) = e^{\nu^2/2}(-\mathrm{d}/\mathrm{d}\nu)^n e^{-\nu^2/2}$, that is $H_1 = \nu$, $H_2 = \nu^2 - 1$, $H_3 = \nu^3 - 3\nu$, $H_4 = \nu^4 - 6\nu^2 + 3$. Setting the $S^{(a)}$ to zero gives back (T3.2) and (T3.6), (T3.7). The derivation is the Gaussian one of Chapter 12 with the joint density of the field and its derivatives expanded one order beyond the Gaussian (an Edgeworth expansion).

T3.2.2 A pointwise distortion only relabels the threshold

The claim in words. Suppose the observed map is a fixed increasing function of a Gaussian map, $T = g(u)$, applied pixel by pixel. Then the region where T exceeds t is exactly the region where u exceeds $g^{-1}(t)$. The two maps have the same excursion sets; only the labels on the thresholds differ. So every functional of T at threshold t is the Gaussian functional of u at threshold $g^{-1}(t)$, and the whole non-Gaussian correction is a sideways shift of the curves.

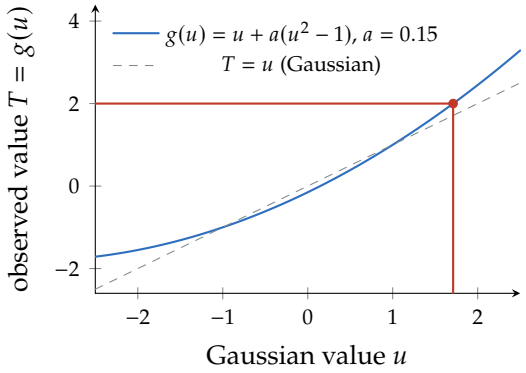

Figure T3.5: A pointwise, increasing distortion of the values. The threshold $T = 2$ on the observed map (horizontal red line) picks out exactly the pixels with $u > g^{-1}(2) \approx 1.71$ on the Gaussian map (vertical red line). The excursion set is the same set of pixels; only the number attached to the threshold has changed.

Example: the relabelling reproduces Matsubara's correction. Take $T = u + a(u^2 - 1)$ with u Gaussian of unit variance and a small (Figure T3.5). Its skewness is

$$\langle T^3 \rangle \overset{(1)}{=} \langle u^3 \rangle + 3a \, \langle u^2(u^2 - 1) \rangle + O(a^2) \overset{(2)}{=} 0 + 3a \, (3 - 1) = 6a,$$

(1) Expand the cube and keep terms of first order in a.
(2) Odd Gaussian moments vanish, $\langle u^4 \rangle = 3$ and $\langle u^2 \rangle = 1$.

so $S^{(0)}\sigma_0 = 6a$, and a calculation of the same kind (or the simulation below) gives $S^{(1)}\sigma_0 = S^{(2)}\sigma_0 = 6a$ as well. Now do it the other way. The threshold ν on T corresponds to $u_\nu = g^{-1}(\nu) = \nu - a(\nu^2 - 1) + O(a^2)$, so

$$v_2^T(\nu) = v_2^G(u_\nu) \overset{(1)}{=} v_2^G(\nu) - a(\nu^2 - 1) \frac{\mathrm{d}v_2^G}{\mathrm{d}\nu} \overset{(2)}{=} v_2^G(\nu) + \frac{1}{(2\pi)^{3/2}} \frac{1}{2\theta_c^2} \, e^{-\nu^2/2} \, a \, (\nu^2 - 1)^2$$
$$\overset{(3)}{=} v_2^G(\nu) + \frac{1}{(2\pi)^{3/2}} \frac{1}{2\theta_c^2} \, e^{-\nu^2/2} \left[\frac{6a}{6} H_4 + \frac{2 \cdot 6a}{3} H_2 + \frac{6a}{3} \right].$$

(1) Taylor expansion to first order in the shift $-a(\nu^2 - 1)$.
(2) $\frac{\mathrm{d}}{\mathrm{d}\nu}(\nu e^{-\nu^2/2}) = (1 - \nu^2)e^{-\nu^2/2}$, so the product of the two minus signs is $+a(\nu^2 - 1)^2$.
(3) $H_4 + 4H_2 + 2 = \nu^4 - 6\nu^2 + 3 + 4\nu^2 - 4 + 2 = (\nu^2 - 1)^2$.

The last line is (T3.10) with all three skewness parameters equal to $6a$. For a pointwise distortion the perturbative formula is nothing but the relabelling.

Removing the relabelling. The relabelling can be undone without knowing g. Instead of the threshold ν, label each excursion set by the area it covers: define the **area threshold** ν_A by $\frac{1}{2}\,\mathrm{erfc}(\nu_A/\sqrt{2})$ = the measured area fraction. A pointwise increasing distortion keeps the order of the pixel values, so the set covering a given fraction of the sky is the same set before and after

it. At fixed ν_A the three functionals of $T = g(u)$ are therefore exactly those of u. In Matsubara's expansion this shows up as follows: rewritten in terms of ν_A, the corrections contain only the differences $S^{(1)} - S^{(0)}$ and $S^{(2)} - S^{(0)}$ [108] (his eq. 3.54), which vanish when the three are equal. What is left at fixed area fraction is information about how the skewness is shared between the field and its slopes and curvatures, and that information can only come from physics that couples neighbouring points.

T3.2.3 Testing it on two skewed skies

`02_nongaussian_mfs.py` builds two kinds of skewed patch, both with the smoothed CMB spectrum shape of Section T3.1.3, and with amplitudes exaggerated so that the effect stands out in 300 patches. The *local* sky is $T = u + a(u^2 - 1)$ with $a = 0.05$; the code measures $S^{(0)}\sigma_0, S^{(1)}\sigma_0, S^{(2)}\sigma_0 = 0.298, 0.300, 0.299$, against $6a = 0.30$. The *non-local* sky applies the same quadratic term, with coefficient 0.1, to a scale-invariant field ϕ (equal power per logarithmic interval of ℓ, like the primordial potential) and then filters the result with the transfer function that turns ϕ's spectrum into the CMB one. The filter mixes neighbouring points, as the physics between the end of inflation and last scattering does, and the measured parameters are no longer equal: 0.493, 0.443, 0.470.

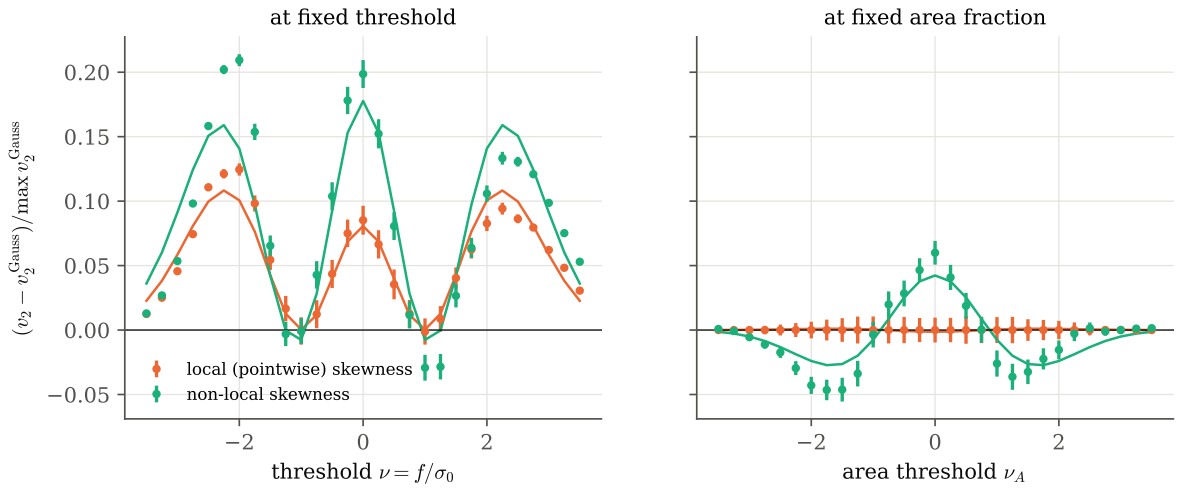

Figure T3.6: Change of the Euler characteristic density of two skewed skies from the Gaussian one, in units of the peak of the Gaussian curve. Points: 300 simulated patches; lines: Matsubara's first-order formula with the measured skewness parameters. Left, at fixed threshold ν: the local sky moves by up to about a tenth of the peak, the non-local one by up to about a fifth. Right, at fixed area fraction: the pointwise (local) distortion disappears exactly, the non-local one does not.

Figure T3.6 shows the result. At fixed threshold the local sky shifts by up to 12% of the peak, with the shape $(\nu^2 - 1)^2$ predicted above. At fixed area fraction the shift is 0.0%: the same pixels, the same sets, the same counts, realisation by realisation. The non-local sky keeps a shift of up to 6.0% of the peak at fixed area fraction, against a Monte Carlo error of 1.0% (the non-local and Gaussian patches are independent draws, so both errors enter), and the first-order formula follows it roughly. Near $\nu_A = -2$ the points and the formula differ by -1.9% of the peak, 2.8 times that error, too few for 300 patches to pin down. A difference there would be no surprise: $S^{(0)}\sigma_0 \approx 0.5$ is not small, and the formula keeps only the first order.

Example: what the real $f_{\rm NL}$ does on large scales. On the largest angular scales the temperature is set by the potential at last scattering alone, $\Delta T/T = -\Phi/3$ (the Sachs–Wolfe limit; see the cosmology notes). Insert the local model (T3.8) and write the Gaussian part of the temperature

as $t = -\phi/3$, so that $\phi = -3t$:

$$\frac{\Delta T}{T} = -\frac{\Phi}{3} \overset{(1)}{=} -\frac{\phi}{3} - \frac{f_{\rm NL}}{3}\left(\phi^2 - \langle\phi^2\rangle\right) \overset{(2)}{=} t - 3f_{\rm NL}\left(t^2 - \langle t^2\rangle\right) \overset{(3)}{=} \sigma_t\Big[u - 3f_{\rm NL}\sigma_t\,(u^2-1)\Big].$$

(1) Substitute (T3.8).
(2) $\phi = -3t$, so $\phi^2 = 9t^2$ and $-\frac{f_{\rm NL}}{3}\cdot 9 = -3f_{\rm NL}$.
(3) Write $t = \sigma_t u$ with u of unit variance.

This is the local toy with $a = -3f_{\rm NL}\sigma_t$. Two conclusions follow. First, the sign: a positive $f_{\rm NL}$ gives a negative skewness $6a$, so the cold spots of the Sachs–Wolfe sky are the more extreme ones. Second, the size: the large-angle temperature has $\sigma_t \approx 2\times10^{-5}$, so $f_{\rm NL} = 5$ gives $|6a| \approx 18\times5\times2\times10^{-5} \approx 2\times10^{-3}$, a shift of the Euler characteristic of order 0.1–0.2% of its peak, and at fixed area fraction none at all. On scales where the temperature is a pointwise function of the potential, the Minkowski functionals at fixed area fraction are blind to local $f_{\rm NL}$; the signal that survives comes from the acoustic scales, where the transfer is non-local, and it is small there too. This is why *Planck* measures $f_{\rm NL}$ with the bispectrum, the optimal statistic for a known three-point shape, and uses the Minkowski functionals as a model-independent check (Section T3.5).

T3.2.4 Lensing leaves the one-point distribution alone

Lensing moves the photons arriving in direction $\hat{\boldsymbol{n}}$ so that we see the last-scattering surface at a neighbouring point, $\tilde{T}(\hat{\boldsymbol{n}}) = T(\hat{\boldsymbol{n}} + \boldsymbol{\alpha})$, with a deflection $\boldsymbol{\alpha}$ of a couple of arcminutes that is coherent over a couple of degrees [47] (their §1.2). It does not change the photons' energies, so it conserves surface brightness: every temperature we see in the lensed sky is a temperature that existed on the unlensed one, seen in a slightly different direction. For a statistically homogeneous sky the lensed one-point distribution is therefore the unlensed one, and in particular the variance is unchanged, $\tilde{\sigma}_0 = \sigma_0$ (their eq. 4.30). By (T3.2) the area functional $v_0(\nu)$ is untouched. The gradient variance is not: lensing shears and magnifies the image, moving power to smaller scales, so $\tilde{\sigma}_1 > \sigma_1$. Plugged into (T3.6), (T3.7), that would predict more coastline and more islands. Whether there really are more islands is a question about topology, and Section T3.4 answers it: a smooth remapping cannot change how many islands there are.

Example: lensing that looks like $f_{\rm NL}$. The deflection is produced by the same large-scale structure that, through the integrated Sachs–Wolfe effect, adds a little to the large-angle temperature. The two are correlated, and the correlation produces a three-point signal in the observed temperature whose shape resembles the local one. *Planck*'s temperature-only estimate of local $f_{\rm NL}$ is 6.7 ± 5.6 before subtracting the expected lensing contribution and -0.5 ± 5.6 after it [107] (their Table 5, KSW estimator, `SMICA`). A lensed sky is, for three-point statistics, a slightly non-Gaussian sky with a known shape, and an analysis that forgets it reports a spurious $f_{\rm NL}$ of about one standard deviation.

T3.3 Polarization patterns and their singularities

The CMB is linearly polarized at the level of a few per cent of its anisotropy. At each point of the sky the polarization is described by two Stokes parameters, Q and U, measured with respect to a pair of axes drawn on the sky at that point. Draw a short stick at each point, along the direction of the polarization. The stick has a direction but no arrowhead: turning it by 180° gives the same stick, because a polarization direction is the orientation of an oscillating electric

field, not the direction of a vector. In the language of [1], the sky is covered with headless rods, like the molecules of a thin film of nematic liquid crystal, and such patterns have point defects. Wherever Q and U both vanish, the stick has no direction at all. Walk around such a point and the sticks turn steadily, by half a turn in one sense or the other. These points are the **polarization singularities**.

The question. Where does the polarization vanish? What does the pattern of sticks look like around such a point, and why only half a turn? How many such points does a Gaussian polarization map with given C_ℓ^{EE} and C_ℓ^{BB} have per square degree, and does their arrangement carry information that the spectra do not?

T3.3.1 Headless sticks and a half-integer index

From Q and U to a stick. The polarization at a point is a symmetric, trace-free 2×2 matrix [1] (their eq. 1),

$$\mathsf{P} = \begin{pmatrix} Q & U \\ U & -Q \end{pmatrix}, \qquad \frac{\mathsf{P}}{2P} = \hat{\boldsymbol{m}}\hat{\boldsymbol{m}}^{\mathsf{T}} - \tfrac{1}{2}\mathbb{1}, \qquad P = \sqrt{Q^2+U^2}, \tag{T3.11}$$

with $\hat{\boldsymbol{m}} = (\cos\alpha, \sin\alpha)$ the unit vector along the stick. Multiplying out $\hat{\boldsymbol{m}}\hat{\boldsymbol{m}}^{\mathsf{T}} - \frac{1}{2}\mathbb{1}$ gives the matrix with entries $\frac{1}{2}\cos 2\alpha$ and $\frac{1}{2}\sin 2\alpha$, so $Q = P\cos 2\alpha$ and $U = P\sin 2\alpha$ [2] (their eq. 2). The vector $\hat{\boldsymbol{m}}$ enters twice, so $\hat{\boldsymbol{m}}$ and $-\hat{\boldsymbol{m}}$ give the same matrix: that is the missing arrowhead. In complex notation,

$$Q + iU = P\, e^{2i\alpha}, \qquad \alpha = \tfrac{1}{2}\arg(Q+iU), \tag{T3.12}$$

and rotating the reference axes by an angle ψ changes α by $-\psi$ and the pair (Q,U) by -2ψ. That factor two is what is meant by calling the polarization a spin-2 quantity.

Working definition T3.2 (polarization singularity and its index)

A *polarization singularity* is a point where $Q = U = 0$ [the polarized intensity P vanishes, so the stick direction α is undefined]. Its *index* is the number of turns the stick makes along a small loop Γ around it,

$$W_\Gamma = \frac{1}{2\pi}\oint_\Gamma \mathrm{d}\alpha,$$

with $\mathrm{d}\alpha$ the change of the stick angle along the loop [1] (their eq. 5). *Operational:* on a pixel grid, add the changes of $\arg(Q+iU)$ around each 2×2 block of pixels, each change taken the short way round the circle; the total is $2\pi n$, and the index is $n/2$.

Why the index is a half-integer. Go once around the loop. The complex number $Q+iU$ comes back to its starting value, so its phase 2α has changed by a whole number of turns, $2\pi n$. The stick angle α has therefore changed by πn, and $W_\Gamma = n/2$. A stick that has turned by π looks exactly as it did at the start, so half-integers are allowed, which they would not be for arrows. *Why $\pm\frac{1}{2}$ is the usual value.* Near a generic zero both Q and U vanish linearly. The simplest such patterns are $Q+iU = x+iy$ and $Q+iU = x-iy$, with (x,y) measured from the zero. In polar coordinates $x+iy = re^{i\theta}$, the first gives $\alpha = \theta/2$: the stick turns half a turn in the same sense as the loop, index $+\frac{1}{2}$. The second gives $\alpha = -\theta/2$: half a turn against it, index $-\frac{1}{2}$. These two patterns, drawn in Figure T3.7, are the fundamental singularities; a general linear zero, $Q+iU = c_1(x+iy)+c_2(x-iy)$, has the index of whichever coefficient is larger in modulus. The index ± 1 patterns often drawn in the CMB literature (radial and circular patterns, and saddles) are pairs of fundamental singularities sitting on top of each other [1, 2], which a random field produces only by accident.

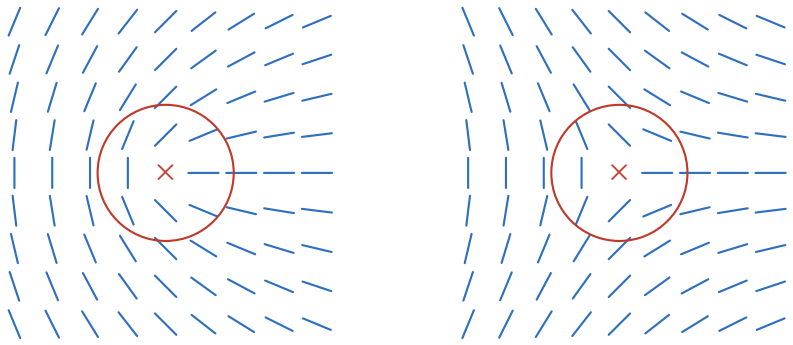

Figure T3.7: The two fundamental polarization singularities. Each stick is drawn along $\alpha = \pm\frac{1}{2}\arg(x + iy)$ at its grid point, and the cross marks the zero. Following the sticks once around the red loop, they turn half a turn with the loop (left) or half a turn against it (right).

The total index. On a closed surface the indices of all singularities of a line field add up to the Euler characteristic of the surface (the Poincaré–Hopf theorem; see the topology notes). The sky is a sphere, so the indices of all the singularities on the full sky add up to +2 [1]: it is impossible to comb the polarization smoothly over the whole sky. With thousands of singularities of each sign this excess of four half-charges is negligible [2]. On a periodic flat patch, a torus, the total is exactly 0.

T3.3.2 How many singularities a Gaussian sky has

The counting idea. Look at a tiny square of sky of area $\mathrm{d}A$. The map $(x, y) \mapsto (Q, U)$ sends it to a tiny parallelogram in the (Q, U) plane of area $|\det J|\,\mathrm{d}A$, where J is the Jacobian matrix with rows ∇Q and ∇U. The square contains a zero exactly when that parallelogram contains the origin of the (Q, U) plane. So the expected number of zeros per unit area is the probability density of (Q, U) at the origin, times the average area factor:

$$n \overset{(1)}{=} p_{Q,U}(0,0)\ \mathbb{E}\,|\det J| \overset{(2)}{=} \frac{1}{2\pi\sigma_0^2}\ \mathbb{E}\,|\det J| \overset{(3)}{=} \frac{1}{2\pi\sigma_0^2}\cdot\frac{\sigma_1^2}{2} = \frac{\sigma_1^2}{4\pi\sigma_0^2}, \tag{T3.13}$$

(1) For a statistically homogeneous Gaussian field the value and the gradient at the same point are uncorrelated, hence independent: $\langle Q\,\partial_x Q\rangle = \frac{1}{2}\partial_x\langle Q^2\rangle = 0$, and similarly for the other pairs.

(2) For isotropic polarization Q and U are uncorrelated at a point with equal variances σ_0^2, so their joint density at the origin is $1/(2\pi\sigma_0^2)$.

(3) Shown just below, with $\sigma_1^2 = \langle|\nabla Q|^2\rangle = \langle|\nabla U|^2\rangle$.

The average area factor. Write $\det J = |\nabla Q|\,|\nabla U|\,\sin\theta$, with θ the angle between the two gradients. For isotropic polarization the four derivatives are independent Gaussians of equal variance $s^2 = \sigma_1^2/2$ (a direction-averaged statement checked by `03_polarization.py`). Each gradient is then a two-dimensional Gaussian vector, whose length has the Rayleigh mean $s\sqrt{\pi/2}$ (the integral done for (T3.6)), and whose direction is uniform and independent of the other. So $\mathbb{E}\,|\det J| = (s\sqrt{\pi/2})^2 \cdot \mathbb{E}\,|\sin\theta| = s^2\frac{\pi}{2}\cdot\frac{2}{\pi} = s^2 = \sigma_1^2/2$.

Both variances come from the spectra exactly as in (T3.3) and (T3.4), now with $C_\ell^P = C_\ell^{EE} + C_\ell^{BB}$ in place of C_ℓ (Q and U each carry half of the total E plus B power, and the half cancels in the ratio). The ratio is an average of $\ell(\ell+1)$ weighted by the polarization power, so the expected

number of singularities on the full sky is

$$N_{\rm sky} = 4\pi n = \frac{\sum_\ell (2\ell+1)\,\ell(\ell+1)\,C_\ell^P}{\sum_\ell (2\ell+1)\,C_\ell^P} \equiv \big\langle \ell(\ell+1) \big\rangle_P . \tag{T3.14}$$

In words: one singularity per patch of area $4\pi\theta_P^2$, where $\theta_P = \sigma_0/\sigma_1$ is the correlation angle of the polarization. (On the sphere the spin-2 nature of $Q + iU$ changes $\ell(\ell+1)$ to $\ell(\ell+1) - 4$ at the lowest multipoles, which does not matter for the counts below.)

Example: a 10′ polarization map. For the fiducial $C_\ell^{EE} + C_\ell^{BB}$ smoothed by a 10′ beam, (T3.13) predicts 1510 singularities in a $12.8° \times 12.8°$ patch, about 9.2 per square degree. The 200 simulated patches of Figure T3.9 have 1501 on average, off the prediction by −0.6%, which is 3.0 standard errors of the mean but tiny next to the spread from patch to patch. That spread is 39 ± 2, close to the Poisson value $\sqrt{N} = 39$. The net index of every patch is exactly zero, as Poincaré–Hopf requires on a torus.

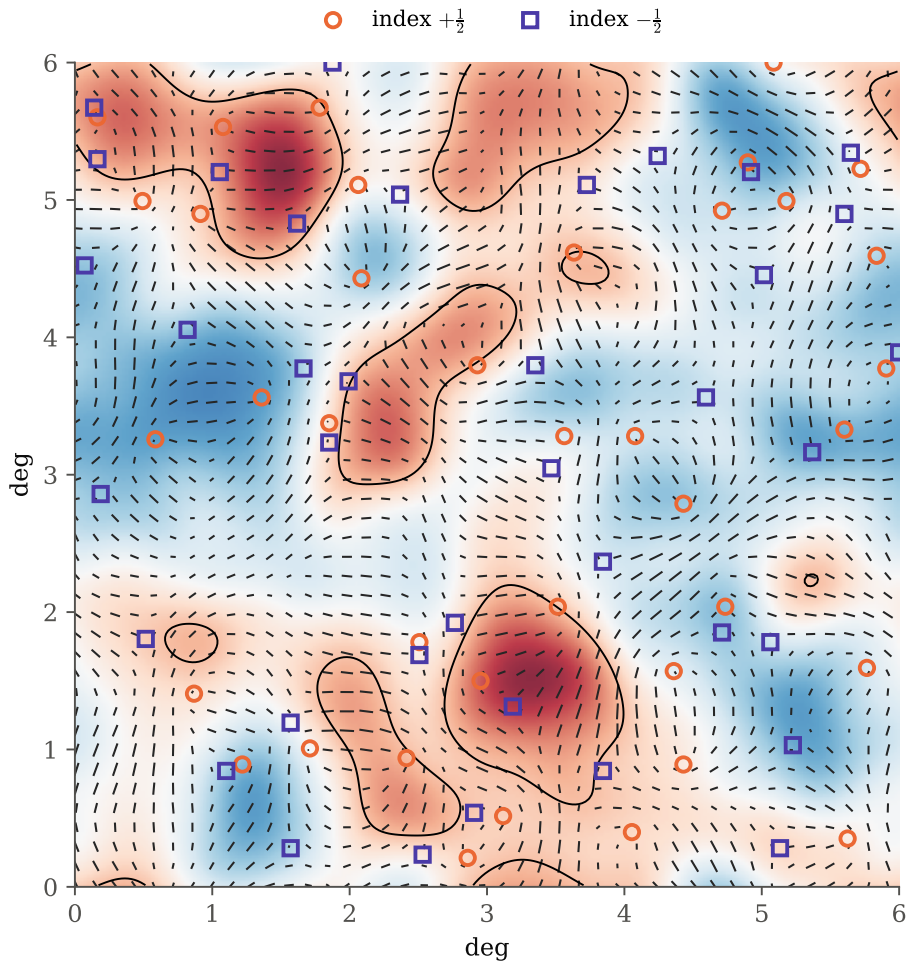

Figure T3.8: A simulated $6° \times 6°$ patch of the CMB with a 30′ beam: temperature in colour (units of its standard deviation), the boundary of the excursion set $T > +1\sigma_0$ as black contours, the polarization as headless sticks whose length grows with P, and the polarization singularities, $+\frac{1}{2}$ as circles and $-\frac{1}{2}$ as squares. The patch holds 76 singularities, 38 of each index. Near every marker the sticks are short, and they turn by half a turn around it.

In Figure T3.8 the colour and the black contours are the temperature and its excursion set of Section T3.1; the sticks and markers are the polarization. The singularities sit where the sticks

are shortest, they come in comparable numbers of each index, and they are scattered fairly evenly, with a tendency for a circle and a square to sit close together. The finder is a few lines:

Listing T3.2: Finding polarization singularities by the winding of $Q + iU$ (`code/chT3/lib_t3.py`)

```
def singularities(Q, U):
    """Zeros of P = Q + iU on the periodic grid, one per plaquette, with their index.

    Around each plaquette (i,j)->(i+1,j)->(i+1,j+1)->(i,j+1)->(i,j) add the changes of
    arg(Q + iU), each wrapped into (-pi, pi]. The total is 2 pi n with n an integer; the
    polarization angle alpha = arg/2 turns by n pi, so the index is n/2.
    Returns (i, j, index) arrays; positions are plaquette centres (i + 1/2, j + 1/2).
    """
    a = np.angle(Q + 1j * U)
    def d(x, y):
        return np.angle(np.exp(1j * (y - x)))
    a10 = np.roll(a, -1, 0)
    a11 = np.roll(a10, -1, 1)
    a01 = np.roll(a, -1, 1)
    w = d(a, a10) + d(a10, a11) + d(a11, a01) + d(a01, a)
    n = np.rint(w / (2 * np.pi)).astype(int)
    i, j = np.nonzero(n)
    return i, j, n[i, j] / 2
```

`np.angle` gives $\arg(Q + iU)$ at every pixel. The helper `d` takes the change of phase between two neighbours the short way round, wrapping it into $(-\pi, \pi]$, which is the pixelized version of following the stick continuously [2] (their Appendix A, there written for α with jumps wrapped into $\pm\pi/2$). Summing the four changes around a 2×2 block gives $2\pi n$, and the block holds a singularity of index $n/2$ when $n \neq 0$.

T3.3.3 Reproducing the Huterer–Vachaspati counts

Their question. When Huterer and Vachaspati wrote, polarization maps were about to arrive, and they asked what the singularities of a ΛCDM polarization map should look like: how many, how they cluster, and how robust those statistics are to changes in the model [2]. *Their setup.* They computed spectra for a flat ΛCDM model ($\Omega_m = 0.3$, $\Omega_m h^2 = 0.127$, $\Omega_b h^2 = 0.021$, $n_s = 1$, no tensors), drew Gaussian E and B coefficients on the full sky with power up to a cutoff $\ell_{\max}$, made HEALPix maps at $N_{\rm side} = 256$, and counted singularities with the winding rule. They report about 6000 singularities for $\ell_{\max} = 100$ and about 150 000 for $\ell_{\max} = 500$, growing roughly as $\ell_{\max}^2$. *Their key equation, here.* The count is (T3.14): for a spectrum cut sharply at $\ell_{\max}$ and rising with ℓ, as C_ℓ^{EE} does below $\ell \approx 1000$, the average of $\ell(\ell+1)$ is a fixed fraction of $\ell_{\max}^2$, which is the scaling they found. *What we compute.* The fiducial *Planck* spectra of this book, cut at the same two values, in (T3.14), and a direct count on 20° flat patches cut at $\ell_{\max} = 500$, scaled to the full sky.

$\ell_{\max}$	H&V 2005 (their maps)	(T3.14), our spectra	our flat patches, scaled
100	≈ 6000	5310	–
500	$\approx 150\,000$	133315	133453

Why they differ. The formula and our direct count agree to a fraction of a per cent. The published counts are about 12% higher, and their spectrum accounts for the direction: with $n_s = 1$ instead of 0.965 their model has relatively more power at high ℓ, which raises the power-weighted average of $\ell(\ell+1)$; their numbers are also quoted as round figures, and a pixel of 14′ at $N_{\rm side} = 256$ resolves the $\ell_{\max} = 500$ pattern only coarsely. *The lesson.* The *number* of

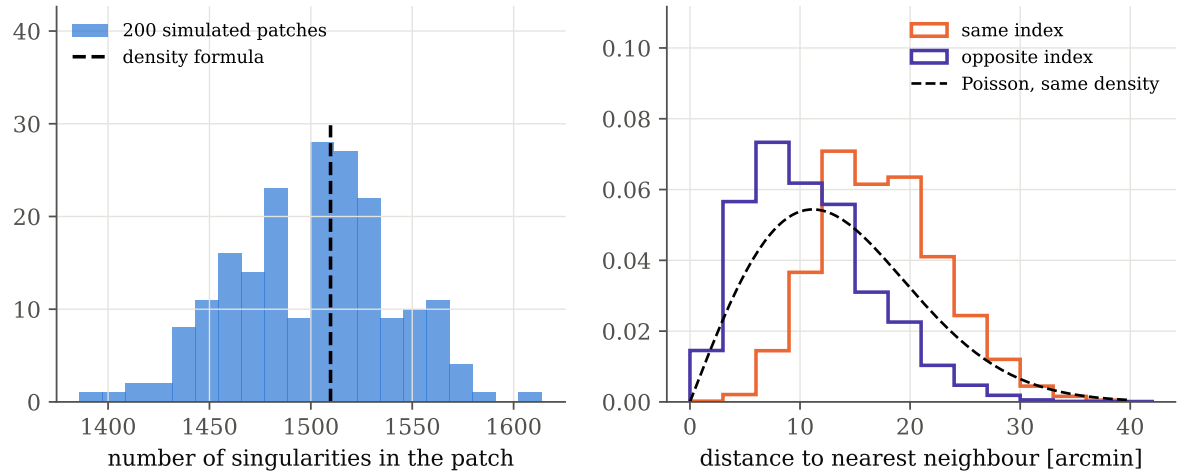

Figure T3.9: Left: number of polarization singularities in 200 simulated 10′-beam patches; the dashed line is the density formula (T3.13). Right: distance from each singularity to its nearest neighbour of the same index and of the opposite index, against the distribution for points scattered at random with the density of one index. Opposite indices sit closer than random points would; equal indices keep apart.

singularities is one moment of the polarization spectrum; it carries nothing that C_ℓ^{EE} and C_ℓ^{BB} do not. Whatever new information the singularities hold must be in their *arrangement*.

What the arrangement shows. Huterer and Vachaspati measured three things. The net index inside a closed loop of length L fluctuates with a root-mean-square value growing as L^β with $\beta \approx 0.5$ (between 0.54 for $\ell_{\max} = 100$ and 0.45 for 500): the index enclosed is a sum of roughly L/ξ independent contributions from the stretches of the loop, one per correlation length ξ, and a sum of that many random terms grows as their square root [1]. Singularities of the same index repel and those of opposite index attract: for $\ell_{\max} = 100$ the mean distance to the nearest neighbour of the same index is 3.24° and of the opposite index 2.69°. Beyond about 10° the singularities are uncorrelated. The right panel of Figure T3.9 shows the same attraction and repulsion at 10′ resolution: mean nearest-neighbour distances of 17.3′ for the same index and 10.6′ for the opposite one, against 14.0′ for random points. Physically, a $+\frac{1}{2}$ and a $-\frac{1}{2}$ are the two ends of a short region where the field passes close to zero; they are born together.

Huterer and Vachaspati also found these statistics remarkably robust. Tensor modes, strongly tilted spectra and even strongly non-Gaussian, exponentially distributed E and B coefficients left the scaling exponent, the correlation function and the nearest-neighbour distances unchanged; only skies with grossly broken isotropy moved them. That robustness cuts both ways: the singularity distribution is a poor probe of primordial non-Gaussianity, but any departure from it in real data would point to something that happened to the photons after last scattering, and lensing is the obvious candidate [2]. Section T3.4 shows what lensing actually does.

T3.4 Lensing moves the pattern but keeps its topology

Between last scattering and us, every CMB photon passes a few dozen potential wells and hills of the large-scale structure, each of which bends its path by about 10^{-4} radians. The bends add up like a random walk to a deflection of about 2.7′, coherent over a couple of degrees, because the potentials that matter are a few hundred megaparsecs across [47] (their §1.2). The image of the last-scattering surface is therefore not blurred but remapped: each patch is shifted, slightly

stretched and slightly sheared. A degree-sized hot spot appears a few per cent larger or smaller than it was. For the shapes of the previous sections this is a nuisance. The question is which of them it can change.

The question. If the observed sky is the unlensed sky seen through a smooth, slightly distorted window, which morphological numbers come through unchanged, and what could change them anyway?

T3.4.1 The remapping, for temperature and for polarization

For the temperature the remapping is the one already used in Section T3.2.4: the lensed field in direction $\hat{\boldsymbol{n}}$ is the unlensed field at the displaced point, $\tilde{T}(\hat{\boldsymbol{n}}) = T(\hat{\boldsymbol{n}} + \boldsymbol{\alpha})$, where the deflection is the gradient of a lensing potential, $\boldsymbol{\alpha} = \nabla\psi$ [3] (their eq. 1). On the sphere "the displaced point" means: walk a distance $|\boldsymbol{\alpha}|$ along the great circle that leaves $\hat{\boldsymbol{n}}$ in the direction of $\boldsymbol{\alpha}$.

For polarization there is one more step, and it is the point of [3]. The Stokes parameters are components of the matrix (T3.11) in a pair of axes at each point, usually the local north and east directions. Copying the numbers Q and U from the displaced point to $\hat{\boldsymbol{n}}$ would compare components in two different sets of axes, and on a curved sky those axes are rotated relative to each other by an angle that depends on the coordinates. The physical statement is that the polarization *matrix* at the displaced point is carried back to $\hat{\boldsymbol{n}}$ by parallel transport along the great circle, and only then read in the local axes (their eq. 4). The naive copy differs from the transported one by a factor $e^{-2i\chi}$ in $Q + iU$, with χ a rotation angle of the order of the deflection times a coordinate factor that grows towards the poles (their eqs. 7–8); in the flat-sky limit it vanishes, and in any case the residual rotation of the polarization basis is of order an arcminute and negligible [47] (their §3). The upshot for us is simple: the lensed polarization at $\hat{\boldsymbol{n}}$ is the unlensed polarization at $\hat{\boldsymbol{n}} + \boldsymbol{\alpha}$, the same headless stick carried along.

T3.4.2 Why the topology survives

The excursion sets. The lensed hot region is $\{\hat{\boldsymbol{n}} : T(\hat{\boldsymbol{n}} + \boldsymbol{\alpha}) > \nu\sigma_0\}$. Call the remapping $f(\hat{\boldsymbol{n}}) = \hat{\boldsymbol{n}} + \boldsymbol{\alpha}(\hat{\boldsymbol{n}})$. The lensed excursion set is exactly the set of points that f sends into the unlensed excursion set, $\tilde{Q}_\nu = f^{-1}(Q_\nu)$, with the same threshold, because lensing does not change σ_0 (Section T3.2.4). If f is smooth and has a smooth inverse, it neither tears regions apart nor glues them together, so $\tilde{Q}_\nu$ has as many pieces and as many holes as Q_ν. The Euler characteristic at every threshold is unchanged, realisation by realisation. The area and the boundary length are not protected in the same way: they change wherever the image is magnified or sheared, although on the full sky the first-order changes average out because the convergence integrates to zero.

The singularities. A lensed singularity sits wherever the unlensed polarization at $f(\hat{\boldsymbol{n}})$ vanishes, so the lensed zeros are the images under f^{-1} of the unlensed ones, one for one. Their indices are unchanged too. A small loop around a lensed zero is mapped by f to a small loop around its parent, and the stick along one loop is the stick along the other; if f keeps the orientation of the sky, the two loops are traversed in the same sense and the number of half-turns is the same. In general a continuous change can only move a singularity, or create or destroy a $+\frac{1}{2}$ and $-\frac{1}{2}$ together, since the total index inside any fixed large loop is an integer multiple of $\frac{1}{2}$ that cannot jump [1].

When is the remapping invertible? Locally, f stretches a small patch by the magnification matrix $\mathsf{A} = \mathbb{1} + \partial\boldsymbol{\alpha}$, with entries $\delta_{ij} + \partial_i\alpha_j$ [47] (their eq. 1.4). As long as $\det\mathsf{A} > 0$ everywhere, f is a local diffeomorphism that keeps orientation; it fails only where $\det\mathsf{A}$ passes through zero,

on the caustics of strong lensing. With a convergence $\kappa = -\frac{1}{2}\nabla \cdot \boldsymbol{\alpha}$ whose rms is below 0.1 even on arcminute scales, CMB lensing is nowhere near that.

Example: how far from a caustic? In the 20 simulated 10° patches of Section T3.4.4 the deflection has an rms of 1.81′ (lower than the full-sky 2.7′, because the patch cannot hold the degree-scale modes that carry most of the deflection, and a uniform shift of the whole patch would not matter anyway), the convergence has an rms of 0.071, and the smallest value of $\det \mathsf{A}$ anywhere in any patch is 0.38. It never comes close to zero.

T3.4.3 What breaks the protection

The protection is exact for the remapping alone. Each of the following steps falls outside it.

- *Anything applied after lensing.* The telescope beam convolves the *lensed* sky. Smoothing then lensing is a pure remapping; lensing then smoothing is not, because lensing has already moved power to small scales that the beam partly removes. Two singularities of opposite index closer than the beam can be merged and annihilate; a thin hot bridge can be smoothed away. Instrumental noise, added last, creates and destroys features at the noise scale.
- *A finite patch, and local densities.* On a patch with an edge, features cross the edge as they move. Magnification also changes the number of features per unit *observed* area, even though the total is fixed, which is how lensing could leave the small-scale imprint on the singularity distribution that [2] anticipated.
- *Splitting into E and B.* Lensing turns part of the E pattern into B. The singularities of the full (Q, U) field are protected; those of an E-only or B-only map, built non-locally from it, are not.
- *The Gaussian formula itself.* The lensed C_ℓ has a larger $\tilde{\sigma}_1$, so plugging it into (T3.6), (T3.7) predicts more islands. The prediction is wrong for the remapped sky, which is no longer Gaussian: its islands are the old ones, deformed.

T3.4.4 Testing it: lensing simulated patches

`04_lensing_remap.py` draws 20 unlensed $10° \times 10°$ patches of T, Q and U (pixels of 0.59′) from CAMB's unlensed spectra, a lensing potential ψ from its spectrum $C_\ell^{\psi\psi}$ (CAMB's $C_\ell^{\phi\phi}$), and the deflection $\boldsymbol{\alpha} = \nabla\psi$; the lensed maps are the unlensed ones evaluated at $\boldsymbol{x} + \boldsymbol{\alpha}(\boldsymbol{x})$ by cubic-spline interpolation. Case A smooths with a 5′ beam and then lenses: a pure remapping of a smooth sky. Case B lenses the raw sky and then applies the beam, which is the order in which a real telescope sees it. For every lensed singularity in case A, the code follows the deflection back to $\boldsymbol{x} + \boldsymbol{\alpha}(\boldsymbol{x})$ and asks whether an unlensed singularity of the same index is there.

Figure T3.10 shows the outcome. In case A, 99.8% of the lensed singularities (never fewer than 99.6% in any patch) sit within a pixel and a half of the point the deflection points back to, on a parent of the same index; the rest are pixel-scale ambiguities in where a zero sits inside its 2×2 block. The Euler characteristic at every threshold and the singularity count change by at most 0.16% of their size, which is the accuracy of counting on a grid. In case B the singularity count changes by $-0.21 \pm 0.19\%$ and the Euler characteristic by up to $0.66 \pm 0.69\%$ of its peak, where each error is the patch-to-patch scatter of the change divided by $\sqrt{20}$. (In case A the same errors are at most 0.19%.) Lensing followed by the beam is no longer a pure remapping, so nothing protects the counts. But at a 5′ resolution the change is small: a few tenths of a per cent, no more than two or three times its error, so 20 patches cannot pin it down. The Gaussian formula with the lensed gradient variance predicts a change of +1.0%, which these patches can

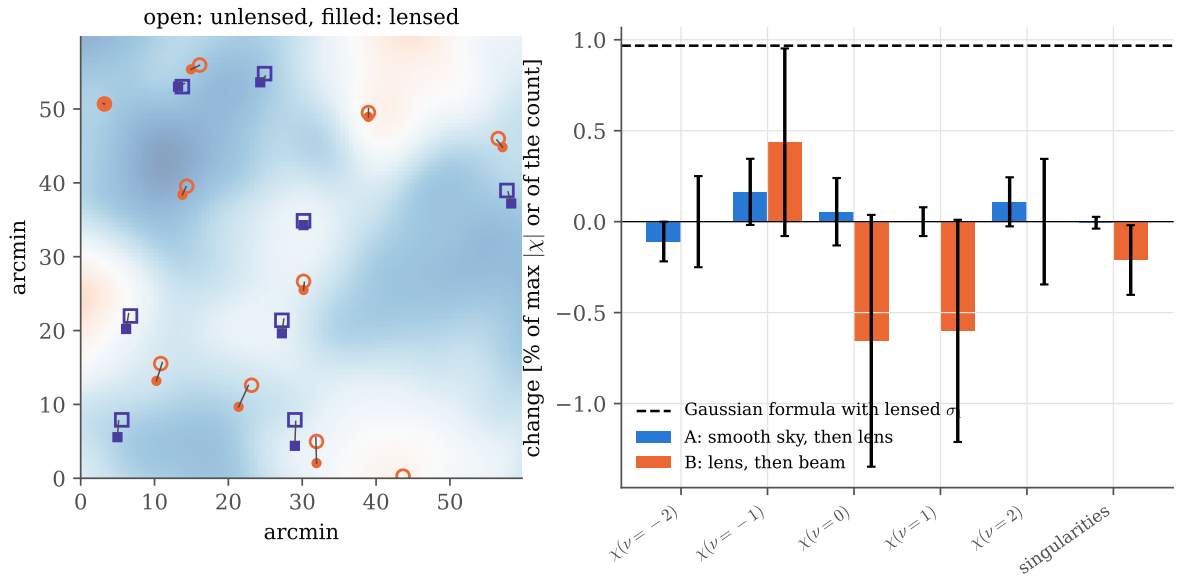

Figure T3.10: Left: a $1^\circ \times 1^\circ$ corner of one patch; open markers are unlensed singularities, filled markers the lensed ones (circles $+\frac{1}{2}$, squares $-\frac{1}{2}$), and each grey line joins a lensed singularity to the point its deflection traces back to. Every one lands on a parent of the same index, an arcminute or two away. Right: change of the Euler characteristic at five thresholds and of the singularity count. Case A (pure remapping) changes nothing beyond pixel-level effects; case B (beam after lensing) changes them by less than one per cent. Error bars: the patch-to-patch scatter of each change divided by $\sqrt{20}$. The dashed line is what the Gaussian formula with the lensed σ_1 would predict for the Euler characteristic.

neither confirm nor rule out; and the formula has no right to be used here anyway, because the lensed sky is not a new Gaussian sky.

What this bought us. For the analysis of real maps the lesson is practical. A topological count (the Euler characteristic, the number of singularities and their indices) is insensitive to lensing to the extent that lensing acts as a remapping, and the residual comes from the instrument's smoothing and noise, which simulations of the instrument capture. The nuisance operator $\mathcal{N}$ of Chapter 12 here is "lens, then smooth, then add noise"; the first factor is harmless for topology, the last two are not, and that is where the Monte Carlo of Chapter 12 has to be careful. The full research version would lens full-sky HEALPix maps at $N_{\mathrm{side}} \geq 2048$ with the curved-sky remapping and parallel transport of [3], include noise, and use thousands of realisations; the flat 10° patches here miss the degree-scale deflection modes, which only shift a patch as a whole, and probe the effect at a single 5′ resolution.

T3.5 What *Planck* found

By 2018 the *Planck* temperature maps were limited by cosmic variance over most of the sky and most angular scales: a better instrument would see the same sky. The final release asked, in two papers, the question that the shapes of the previous sections make sharp. Is the CMB a Gaussian, statistically isotropic field, as the simplest inflationary models predict [109]? And if a primordial three-point signal is there, how large can f_{NL} be [107]?

The question. Measured against simulations of the full *Planck* pipeline, do the shapes of the real maps look like the shapes of Gaussian, isotropic skies? If not, where do they differ, and how surprised should we be?

T3.5.1 The Minkowski-functional test

Planck computes the three functionals of Section T3.1.1 on masked maps at resolutions from $N_{\rm side} = 16$ to 2048: the area fraction as a pixel count, the boundary length from the contour lengths of all hot and cold spots, and the Euler characteristic as $(N_{\rm hot} - N_{\rm cold})/(2\pi A_{\rm tot})$, the number of compact hot spots minus compact cold spots per area, which is the count of pieces minus holes in another guise [109] (their eqs. 13–15). Two choices are worth noticing, because Chapter 12 has to make them too. First, each functional is divided by its Gaussian amplitude, the factor A_k that carries all the dependence on σ_0 and σ_1, so that a Gaussian sky would give exactly $v_k(\nu) = e^{-\nu^2/2} H_{k-1}(\nu)$ (their eqs. 16–19, our (T3.2)–(T3.7) rearranged); the thresholds are in units of the map's own standard deviation, as in the pitfall of Section T3.1.3. This removes the large cosmic-variance fluctuation of the overall amplitude and keeps the shape. Second, polarization is tested through maps of the scalar E mode, because the functionals of Q and U depend on the orientation of the axes once a mask breaks the symmetry of the sky.

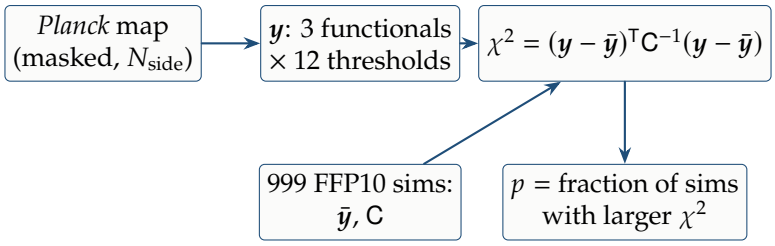

Figure T3.11: The *Planck* Minkowski-functional test. The data vector stacks the three normalised functionals at twelve thresholds between $-3\sigma_0$ and $3\sigma_0$. Its mean and covariance come from end-to-end simulations of Gaussian, isotropic skies processed exactly like the data, and the simulations also supply the distribution of χ^2 under that hypothesis.

The data vector $\boldsymbol{y}$ stacks v_0, v_1, v_2 at twelve thresholds from -3 to 3: 36 numbers per map (Figure T3.11). Its mean $\bar{\boldsymbol{y}}$ and covariance C are estimated from 999 FFP10 simulations, which contain the lensed Gaussian CMB, the instrument's noise, beams and scanning, and the component-separation pipeline. The statistic is $\chi^2 = (\boldsymbol{y} - \bar{\boldsymbol{y}})^{\mathsf{T}} \mathsf{C}^{-1} (\boldsymbol{y} - \bar{\boldsymbol{y}})$ (their eqs. 20–22), and the reported number is the fraction of simulations with a larger χ^2 than the data. This is a hypothesis test in exactly the sense of Chapter 4: the null hypothesis is the one whose sampling distribution we can generate, and the question is whether a χ^2 as large as the observed one, or larger, would be unremarkable if it were true.

Example: the scale of a χ^2 with 36 components. If $\boldsymbol{y}$ were exactly Gaussian with the estimated mean and covariance, χ^2 would follow a χ^2 distribution with 36 degrees of freedom: mean 36, standard deviation $\sqrt{2 \times 36} \approx 8.5$. A value of 53 would then sit at the 97th percentile. *Planck* does not rely on that shortcut: the simulations give the distribution directly, which also absorbs the noise in C estimated from a finite number of simulations (Chapter 12).

The result. For temperature, across four component-separation methods and eight resolutions, the probabilities of a larger χ^2 range from about 24% to 99.8%: no map is unusual (their Table 5). For E-mode polarization most values are similarly unremarkable; a few low ones (down to 1% for one method at $N_{\rm side} = 16$) appear for one method and not for the others, which points to residual systematics and noise in the polarization data rather than to the sky. Measured scale by scale, on needlet-filtered maps, the temperature functionals on the largest scales ($\ell \lesssim 32$)

give probabilities of a few per cent (their Table 6), a mild echo of the large-angle anomalies below. Together with one-point moments, N-point correlation functions, peak statistics and the stacking of hot and cold spots, the verdict is: no significant departure from Gaussianity on intermediate and small scales [109].

T3.5.2 $f_{\rm NL}$ from the bispectrum

For a specific three-point shape the bispectrum is the optimal statistic, and *Planck* uses it for the local model (T3.8) and for two shapes typical of single-field models with unusual kinetic terms, the equilateral and orthogonal templates. The temperature-plus-E results, after subtracting the expected lensing contribution, are [107]

$$f_{\rm NL}^{\rm local} = -0.9 \pm 5.1, \qquad f_{\rm NL}^{\rm equil} = -26 \pm 47, \qquad f_{\rm NL}^{\rm ortho} = -38 \pm 24 \qquad (68\%). \tag{T3.15}$$

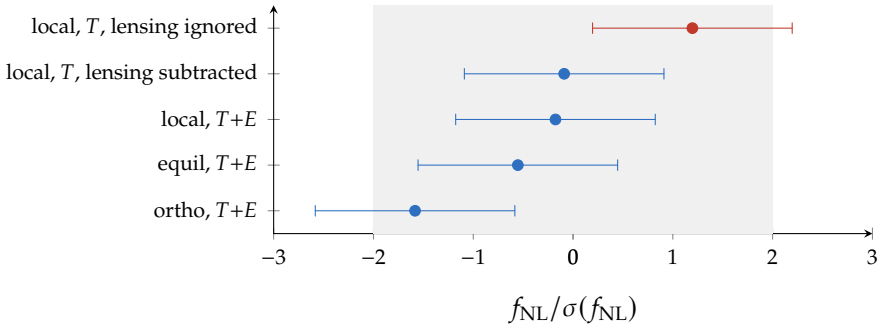

Figure T3.12: *Planck* 2018 $f_{\rm NL}$ estimates in units of their own standard deviations, with $\pm1\sigma$ bars; the shaded band is $\pm2\sigma$. All are consistent with zero. The red point is the temperature-only local estimate before the lensing contribution is subtracted: lensing alone moves it by more than one standard deviation.

Example: what ±5.1 means for the map. By the Sachs–Wolfe estimate of Section T3.2.3, $f_{\rm NL} = 5$ skews the large-angle temperature by $|6a| \approx 2 \times 10^{-3}$. The bispectrum detects a three-point signal of this size because it adds up the contributions of millions of triangles of multipoles, each weighted by how well it matches the template; the three Minkowski functionals compress the same map into 36 numbers that are not tuned to any one shape. That is the division of labour: the bispectrum to measure a known shape, the functionals to look for anything unexpected.

T3.5.3 The anomalies

A handful of large-angle features, first seen by WMAP, are confirmed in the *Planck* temperature maps [109] (their §§6–7). The variance of the map at low resolution is low: about 1% of the simulations have a variance as small. The angular correlation function $C(\theta)$ is almost zero beyond 60°: the statistic $S_{1/2} = \int_{-1}^{1/2} [C(\theta)]^2 \, {\rm d}\cos\theta$ is smaller in the data than in all but about 1% of the simulations, and partly because the quadrupole is low (removing it lowers the significance from about 99% to 86% of simulations having a larger value). One half of the sky has more power than the other, a dipolar modulation of the fluctuation amplitude. Odd multipoles carry more power than even ones at the lowest ℓ, a preference for odd point-parity. And there is the Cold Spot, an unusually deep and wide cold region in the southern hemisphere.

Each of these is a deviation at roughly the 2–3σ level, and each was noticed *before* a statistic was designed to measure it. That makes the quoted significances hard to interpret: among

the many statistics one could have computed, some are bound to look unusual by chance (the look-elsewhere effect). Since the temperature on these scales is cosmic-variance limited, more temperature data cannot settle it. Polarization can, because it is generated by different modes. The 2018 polarization maps show no corresponding anomaly (no lack of large-angle correlation, no hemispherical asymmetry, no point-parity violation, no polarization signature of the Cold Spot), but their signal-to-noise on these scales is low, and the absence is not yet strong evidence either way [109].

How this is used in real research: verification and research with the same machinery

The Gaussian checks of Sections T3.1.3 and T3.3.2 *verify* known formulas: the simulations had to reproduce (T3.6), (T3.7) and (T3.13), and they did. In the *Planck* test the same machinery is the *research instrument*: for a masked sky with anisotropic noise, component-separation residuals and lensing, no formula gives the mean, the covariance or the χ^2 distribution of the functionals, and a thousand end-to-end simulations are the only way to get them. Chapter 12 builds that test on simulated skies; Chapter 13 applies the summary statistics to real *Planck* maps.

T3.6 The topology of the cosmic web

The same questions can be asked one dimension up. Galaxy surveys and simulations show the matter of the late universe arranged in a web: dense clusters at the nodes, filaments joining them, thin walls, and large empty voids. In 1986, before the web had a name, Hamilton, Gott and Weinberg asked whether its connectivity looked like that of a Gaussian field: were the dense regions isolated clumps in an empty background (a "meatball" topology), isolated voids in a dense background ("Swiss cheese"), or two interpenetrating networks, like a sponge in which both the material and the holes are connected [110]?

The question. If we take the density contrast δ of a three-dimensional field, smoothed on some scale, and keep the region with $\delta > \nu\sigma$, how connected is it at each ν, and does a Gaussian field predict a sponge at the median density?

T3.6.1 The genus of a Gaussian field

In three dimensions the boundary of the excursion set is a surface, and its connectivity is measured by its **genus**: roughly, the number of tunnels through the set minus the number of separate pieces of the surface. A doughnut contributes +1 more than a ball. Per unit volume the convenient definition is $g = -\chi/V$, with χ the Euler characteristic of the set itself [5]: every tunnel adds +1 to g, while every isolated clump and every isolated void adds −1. For a Gaussian field the expectation is [108, 110]

$$g(\nu) = \frac{1}{4\pi^2}\left(\frac{\langle k^2\rangle}{3}\right)^{3/2}(1-\nu^2)\,e^{-\nu^2/2}, \qquad \langle k^2\rangle = \frac{\langle|\nabla\delta|^2\rangle}{\langle\delta^2\rangle}, \tag{T3.16}$$

the three-dimensional counterpart of (T3.6), (T3.7): again the spectrum enters only through the ratio of the gradient variance to the field variance, and the shape in ν is a Hermite polynomial times the Gaussian, now $-H_2(\nu) = 1-\nu^2$. Read it from the middle outwards. Near $\nu = 0$ the genus is positive: many tunnels, a sponge. For $|\nu| > 1$ it is negative: at high thresholds isolated clusters (meatballs), at low thresholds isolated voids (Swiss cheese). A Gaussian field is symmetric between the two, so the curve is even in ν. Gravitational evolution breaks that

symmetry, shifting the curve towards a meatball topology, and measuring that shift, at fixed volume fraction as in Section T3.2.2, is the classic use of the genus statistic [108].

Example: a simulated box. `05_web_genus.py` draws 50 periodic boxes of 128^3 cells of side $2\,h^{-1}$Mpc, with a power spectrum $P(k) \propto k^{-1.5}$ smoothed on $6\,h^{-1}$Mpc, and counts the Euler characteristic of the excursion sets as vertices minus edges plus faces minus cubes of the union of voxels, the three-dimensional version of the counter of Section T3.1.3 (on one box it agrees with scikit-image: 128 and 128). At the median density a box has a genus of 259, against 260 from (T3.16); over all thresholds the mean of the boxes stays within 1.6% of the peak of the formula, with a Monte Carlo error of 1.3% (Figure T3.13). A Gaussian field is a sponge.

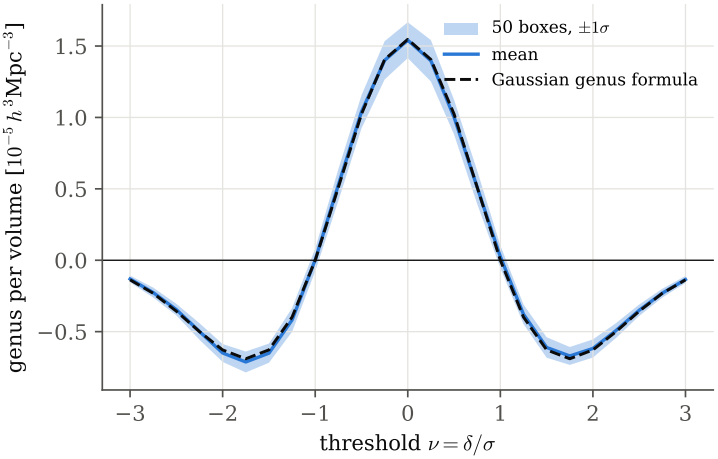

Figure T3.13: Genus per unit volume of the excursion sets of simulated three-dimensional Gaussian fields against the threshold. Band: box-to-box scatter; solid: mean of 50 boxes; dashed: the Gaussian formula (T3.16). Positive genus near the median density means many tunnels (a sponge); negative genus at $|\nu| > 1$ means isolated clumps or isolated voids.

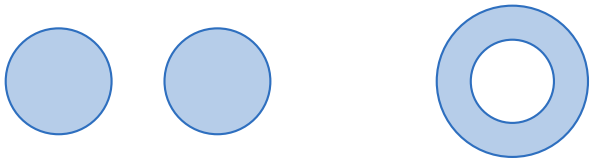
T3.6.2 Betti numbers and persistence

The Euler characteristic is an alternating sum, $\chi = \beta_0 - \beta_1 + \beta_2$, of three counts, the **Betti numbers** [5]: β_0 counts separate pieces (clusters), β_1 independent tunnels or loops (the loops formed by filaments), and β_2 enclosed cavities (voids sealed inside the set); see the topology notes for why they are well defined. A sum with alternating signs can hide its terms: two isolated clusters and one hollow shell around a void both have $\chi = 2$ (Figure T3.14). Pranav and collaborators showed that the Betti numbers separately, as functions of the threshold, distinguish web-like models that the genus alone does not, and they introduced *persistence*: follow each feature as the threshold is lowered, record the level at which it appears and the level at which it merges or fills in, and plot the pairs [5]. A feature that persists over a wide range of thresholds is a robust structure; one that lives only briefly is noise. Chapter 12 builds these tools from scratch.

Three later studies show what this buys in practice. In ΛCDM simulations, the persistence diagrams of clusters, filament loops and voids have sharp apexes, and the apex for clusters sits at the density at which matter typically detaches from the Hubble expansion and begins to collapse; persistence diagrams track the hierarchical build-up of the web more informatively than the Euler characteristic or the Betti numbers alone [4]. In halo catalogues from N-body simulations, persistent homology detects a local primordial non-Gaussianity of $f_{\rm NL}^{\rm loc} = 10$ at 97.5% confidence in about 85% of 40 $(h^{-1}\text{Gpc})^3$ volumes, using information at $\sim 10\,h^{-1}$Mpc that



two solid clusters
$\beta_0 = 2,\ \beta_1 = 0,\ \beta_2 = 0$
$\chi = 2$

one shell around a void
$\beta_0 = 1,\ \beta_1 = 0,\ \beta_2 = 1$
$\chi = 2$

Figure T3.14: Cross-sections of two three-dimensional sets with the same Euler characteristic. Left: two separate solid balls. Right: a single hollow ball, whose interior cavity is a sealed void. The Euler characteristic cannot tell them apart; the Betti numbers can.

is complementary to the scale-dependent bias of the power spectrum [111]. And in weak-lensing mass maps, persistent Betti numbers fed to an emulator and an MCMC give constraints on $S_8 = \sigma_8\sqrt{\Omega_m/0.3}$ that are 5% tighter than peak counts for a KiDS-like survey and, for a 100 deg^2 Euclid-like mock, 18% tighter on S_8 and 10% on Ω_m [56]. In each case the topological summary is an ordinary random observable, with a mean and a covariance taken from simulations and a likelihood built on them, which is the machinery of Chapters 9, 10 and 12.

The full research version of the experiment above would replace the Gaussian boxes by N-body simulations or galaxy catalogues of a few $h^{-3}\mathrm{Gpc}^3$, add redshift-space distortions and a survey mask, and compute Betti curves and persistence diagrams; the 128^3 Gaussian boxes here only verify the Gaussian baseline that those analyses measure departures from.

Chapter summary

The microwave sky carries information in its pattern, not only in its amplitudes. Its temperature map is cut at thresholds into excursion sets whose area, coastline and connectivity are three numbers per threshold; a Gaussian sky fixes all three through σ_0 and σ_1, a pointwise skewness merely relabels the threshold, and what survives at fixed area fraction is non-local physics. Its polarization has half-integer singularities whose number is a moment of the spectrum and whose arrangement is robust. Lensing remaps both patterns smoothly, which leaves their topology intact until the instrument smooths and adds noise. *Planck* found the sky consistent with Gaussianity and isotropy apart from a few large-angle anomalies of debated significance, and f_{NL} consistent with zero. Table T3.1 collects the pieces.

Reading the literature

Recap

- The Minkowski functionals of the excursion sets (area fraction, boundary length, Euler characteristic) are the complete set of additive, motion-invariant shape numbers in two dimensions.
- For a Gaussian sky: $v_0 = \frac{1}{2}\,\mathrm{erfc}(\nu/\sqrt{2})$ needs no spectrum; $v_1 \propto e^{-\nu^2/2}/\theta_c$ and $v_2 \propto \nu e^{-\nu^2/2}/\theta_c^2$ need only $\theta_c = \sigma_0/\sigma_1$.
- A pointwise increasing distortion only relabels thresholds; at fixed area fraction it vanishes exactly. Local f_{NL} is such a distortion on Sachs–Wolfe scales.
- Polarization singularities have index $\pm\frac{1}{2}$; their density is $\sigma_1^2/4\pi\sigma_0^2$, about $\langle \ell(\ell+1)\rangle_P$ on the full sky; opposite indices attract, equal ones repel.
- Lensing is a smooth invertible remapping: it moves singularities and islands but keeps their number and index; the beam and noise applied afterwards break the protection slightly.
- *Planck*: Gaussian and isotropic within errors on intermediate and small scales; a few large-angle anomalies at the 2–3σ level; $f_{\mathrm{NL}}^{\mathrm{local}} = -0.9 \pm 5.1$.
- In three dimensions the genus curve of a Gaussian field is a sponge at the median density; Betti numbers and persistence separate what the genus adds together.

Chapter T4

Particle Physics for the Data Analyst

Where this chapter is going

Two beams of protons circle the Large Hadron Collider in opposite directions and cross each other forty million times a second. At every crossing a few dozen pairs of protons collide. Almost all of these collisions are ordinary: the protons break up into sprays of light particles that the theory has described for decades. Roughly once in a billion and a half collisions something rarer happens, and a Higgs boson is made. It lives for about 10^{-22} s, far too short to travel a measurable distance, and in about two decays out of a thousand it turns into two photons. The detector never sees the Higgs boson. It sees two photons, measures their energies and their directions, and writes these numbers to disk together with everything else that happened in that crossing.

From the two photons of an event one number can be computed that does not care how fast the Higgs boson was moving: the *invariant mass* of the pair. For a Higgs decay it is always 125 GeV, up to the blurring of the measurement. For the many ordinary events that also contain two photons it is spread over a smooth, falling range. So a histogram of this one number, made from millions of events, shows a smooth background with a small bump on it. That histogram is the data of the Higgs discovery of 2012, and of the capstone of Chapter 13, where we analyse the real collision data that the ATLAS experiment has released to the public.

The statistics of the search, worked out in Chapter 4, needs one thing from physics: the *expected* number of events in each bin of that histogram, as a function of a few parameters. Each piece of that expectation is a physical quantity. How often the process happens is a cross section σ. How many collisions were recorded is the integrated luminosity L. What fraction of the produced events the detector keeps are the acceptance A and the efficiency ε. Where the kept events land on the mass axis is a template, made by simulating the detector. How much of the predicted signal is really there is the signal strength μ. How well all of these are known is described by a handful of nuisance parameters $\boldsymbol{\theta}$, each pinned down by a calibration. Figure T4.1 shows how they connect.

A collider produces collisions at a known rate, and the expected number of events of any kind is its cross section times the integrated luminosity, $N = \sigma L$; the formula follows from the overlap of two bunches of protons, and the number actually recorded is a Poisson count (Section T4.2). What is counted is a recorded event: a list of reconstructed particles, each with a transverse momentum p_T, a pseudorapidity η and an azimuth ϕ (Section T4.1). From two of these particles comes the invariant mass, which is the same in every decay of a given particle; its spread comes from the lifetime of the particle and from the resolution of the detector, and both shapes can be derived (Section T4.3). Simulated events and the side regions of the data give the expected shapes of signal and background, the templates, and the signal strength μ scales the predicted signal (Section T4.4). Every input is known only to some precision; each imprecision

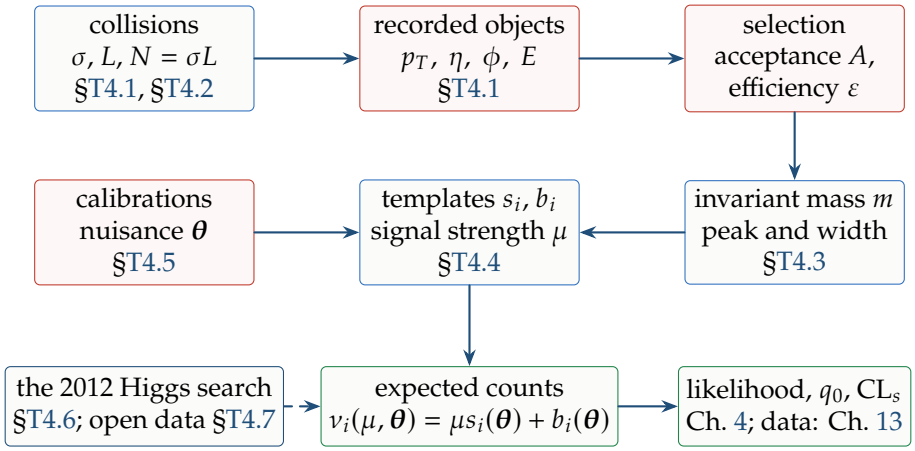

Figure T4.1: The path from collisions to the numbers the statistics uses. Blue boxes are physics that theory and simulation predict: how often a process happens, and where its events land on the mass axis. Red boxes are what the detector and the analysis do to the events: record them, keep some of them, and get calibrated. The two green boxes are where the statistics of Chapter 4 takes over: every arrow above ends in the expected count ν_i of one histogram bin, and the likelihood compares those expectations with the observed counts.

becomes a nuisance parameter with its own calibration measurement (Section T4.5). All of these were at work in the two searches that found the Higgs boson in 2012 (Section T4.6), and every one has a column, or a combination of columns, in the open-data files that Chapter 13 analyses (Section T4.7). Table T4.3 lists each symbol with its typical size and the place in the book where it is used.

The likelihood of a histogram, the treatment of nuisance parameters, the discovery statistic q_0, the look-elsewhere effect and the CL_s limits are built on these expected counts in Chapter 4 (Sections 4.14 to 4.16); undoing the detector's blurring is Section 6.14. In the language of the book's pipeline (Chapter 0), the collider case reads as follows. The physical model is the Standard Model with or without the Higgs signal. The data set is the list of recorded events. What matters in it is the invariant mass of the photon pair, and the summary is a histogram of that mass. The sampling distribution of each bin is Poisson, with a mean that physics supplies. Inference then asks the question of Chapter 5 in its collider form: which signal strengths, and which values of the calibration constants, could have produced the histogram we recorded?

T4.1 What a collider does, and what an event is

A proton is not a hard ball. It is a bound state of quarks and gluons, together called **partons**, which share its momentum among themselves in a way that changes from one moment to the next. When two bunches of protons cross at the LHC, most protons pass each other untouched. A few pairs come close enough for one parton of each to collide hard. Those two partons, not the whole protons, make the interesting new particles. Each parton carries an unknown fraction of its proton's momentum, so the collision we care about happens in a frame that moves along the beam line at a speed we do not know. Everything else in the two protons sprays out as low-energy debris, mostly close to the beam.

Around the collision point sits the detector, a set of nested cylinders, each built to measure one kind of particle. A crossing of two bunches lasts a fraction of a nanosecond, and the next one comes 25 ns later. Only a few hundred crossings per second can be written to disk, so fast electronics, the **trigger**, decide within microseconds whether a crossing looks interesting enough to keep, for example because two large deposits of electromagnetic energy appeared

in the calorimeter [112]. What is kept is the raw response of millions of detector channels. Reconstruction programs then turn these responses into a short list of particles with measured momenta. That list is what an analyst works with.

The questions in words.

1. What does the detector record, and how does a photon look different from an electron, a muon, a jet or a neutrino?
2. Which numbers describe a recorded particle, and why does a hadron collider describe directions by a pseudorapidity η instead of the polar angle θ?
3. What is the energy of a photon in terms of those numbers?

T4.1.1 The detector, layer by layer

The ATLAS detector used for the Higgs search has four layers [113, Sec. 2], [112]. Going outwards from the beam:

- The **inner detector**: layers of silicon sensors and straw tubes inside a 2 T magnetic field. A charged particle leaves a trail of hits, and the curvature of the trail in the field gives its momentum. Neutral particles leave nothing here.
- The **electromagnetic calorimeter**: liquid argon between lead plates. Photons and electrons dump all their energy in it, in a narrow shower. Its first layer is finely segmented in angle, so that a single photon can be told apart from the two nearby photons of a decaying neutral pion.
- The **hadronic calorimeter**: iron and scintillating tiles. Protons, pions and the other strongly interacting particles shower here.
- The **muon spectrometer**: tracking chambers in a toroidal magnetic field outside everything else. Muons are the only charged particles that cross the calorimeters.

Each kind of particle leaves a different pattern across the layers, and the pattern is its identity. Figure T4.2 draws the five patterns that matter.

Working definition T4.1 (event and reconstructed object)

An **event** is everything recorded in one bunch crossing that the trigger kept. A **reconstructed object** is one particle candidate built from it, a photon, electron, muon, jet or hadronic tau decay, with four measured numbers: its transverse momentum p_T, pseudorapidity η, azimuth ϕ and energy E, plus quality flags. *Operationally:* an event in the files of Section T4.7 is one row of a table; each kind of object fills a set of columns that hold one entry per object of that kind [a row with three photons has three numbers in the photon-p_T column].

Two of the identity rules need a word more. A photon can convert into an electron–positron pair in the material in front of the calorimeter; it then leaves one or two tracks that start in the middle of the inner detector instead of at the collision point, and is recognised as a *converted* photon. In the open data, about a third of the selected photons are converted (34.66%). And a jet is not one particle but the collimated spray of hadrons that a quark or gluon becomes; its energy is the sum of everything in a cone around its axis.

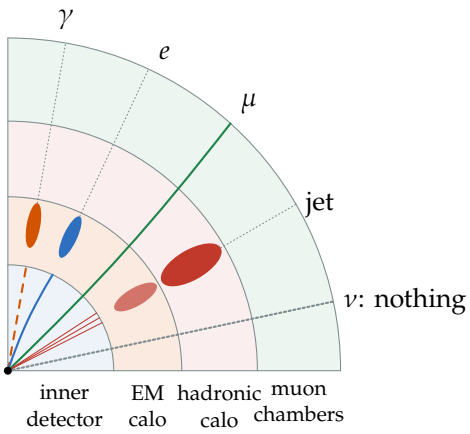

Figure T4.2: A quarter of the detector seen along the beam, with the beam at the lower left corner, and the five signatures. A photon leaves no track and a narrow shower in the electromagnetic calorimeter. An electron leaves a track and the same narrow shower. A muon crosses everything. A jet, the spray of hadrons from a quark or gluon, leaves several tracks and showers in both calorimeters. A neutrino leaves nothing at all; it shows up only as an imbalance of the momenta of everything else.

T4.1.2 Coordinates: why the transverse plane

ATLAS uses a right-handed frame with the origin at the collision point and the z axis along the beam [113, footnote 2]. The polar angle θ is measured from the z axis, and the azimuth ϕ around it, in the plane perpendicular to the beam called the **transverse plane**. A particle's momentum splits into a part along the beam, $p_z = |\boldsymbol{p}| \cos\theta$, and a part in the transverse plane, of size

$$p_T = \sqrt{p_x^2 + p_y^2} = |\boldsymbol{p}| \sin\theta. \tag{T4.1}$$

Why the transverse part is special. Before the collision, the two partons move along the beam. Their momenta along z are $x_1 E_\mathrm{b}$ and $-x_2 E_\mathrm{b}$, where E_b is the beam energy and x_1, x_2 are the momentum fractions the two partons happened to carry. Neither fraction is measured, so the total z momentum of the hard collision, $(x_1 - x_2)E_\mathrm{b}$, is unknown in every event. Their transverse momenta, on the other hand, are close to zero. Momentum conservation then says that the transverse momenta of everything produced add up to zero, while it says nothing useful about the z momenta. Two consequences follow. A particle that escapes unseen, like a neutrino, shows up as an imbalance of the transverse momenta of the visible particles, the **missing transverse momentum** $-\sum_i \boldsymbol{p}_{T,i}$ [114, (49.49)]; and the description of a particle should use quantities that do not change when the whole event is boosted along z by an unknown amount.

A variable that adds under boosts. The **rapidity** of a particle is [114, (49.40)]

$$y = \frac{1}{2} \ln \frac{E + p_z}{E - p_z}. \tag{T4.2}$$

What happens to it under a boost along z with velocity β (in units of $c = 1$) and $\gamma = (1-\beta^2)^{-1/2}$? The Lorentz transformation of [114, (49.1)] gives $E' = \gamma(E - \beta p_z)$ and $p_z' = \gamma(p_z - \beta E)$. Then

$$\begin{aligned} y' &\overset{(1)}{=} \frac{1}{2} \ln \frac{\gamma(E - \beta p_z) + \gamma(p_z - \beta E)}{\gamma(E - \beta p_z) - \gamma(p_z - \beta E)} \overset{(2)}{=} \frac{1}{2} \ln \frac{(1-\beta)(E + p_z)}{(1+\beta)(E - p_z)} \\ &\overset{(3)}{=} y + \frac{1}{2} \ln \frac{1-\beta}{1+\beta} \overset{(4)}{=} y - \tanh^{-1}\beta. \end{aligned} \tag{T4.3}$$

(1) Insert the boosted energy and momentum into (T4.2).
(2) Collect terms: the numerator is $\gamma(E + p_z)(1 - \beta)$ and the denominator $\gamma(E - p_z)(1 + \beta)$; the γ's cancel.
(3) The logarithm of a product is the sum of the logarithms.
(4) $\tanh^{-1}\beta = \frac{1}{2}\ln\frac{1+\beta}{1-\beta}$, the inverse of $\tanh u = (e^u - e^{-u})/(e^u + e^{-u})$.

A boost along the beam shifts every rapidity in the event by the same amount. The *difference* of two rapidities is therefore the same in every frame, and so is the shape of a distribution of rapidities [114, §49.5.2]. The unknown motion of the parton pair along the beam drops out of every rapidity difference.

From rapidity to an angle. Rapidity needs the energy and p_z, and so the mass. For a massless particle, or any particle with $|\boldsymbol{p}| \gg m$, $E = |\boldsymbol{p}|$ and $p_z = |\boldsymbol{p}|\cos\theta$, and the rapidity becomes a function of the angle alone:

$$y \overset{(1)}{=} \frac{1}{2}\ln\frac{1+\cos\theta}{1-\cos\theta} \overset{(2)}{=} \frac{1}{2}\ln\frac{2\cos^2(\theta/2)}{2\sin^2(\theta/2)} \overset{(3)}{=} -\ln\tan\frac{\theta}{2} \;\equiv\; \eta. \tag{T4.4}$$

(1) Divide numerator and denominator of (T4.2) by $|\boldsymbol{p}| = E$.
(2) The half-angle identities $1 + \cos\theta = 2\cos^2(\theta/2)$ and $1 - \cos\theta = 2\sin^2(\theta/2)$.
(3) $\frac{1}{2}\ln(\cot^2 u) = \ln\cot u = -\ln\tan u$.

This is the **pseudorapidity** [114, (49.47)]. It is defined for every particle as $-\ln\tan(\theta/2)$, whatever its mass, because the angle is always measured; for photons it is exactly the rapidity, and for light particles at high momentum it is very nearly so.

Working definition T4.2 (pseudorapidity)

The **pseudorapidity** of a particle at polar angle θ from the beam is $\eta = -\ln\tan(\theta/2)$, and inversely $\theta = 2\arctan e^{-\eta}$. It is 0 perpendicular to the beam and grows without bound towards the beam. *Operationally:* $\eta = \sinh^{-1}(p_z/p_T)$ from the measured momentum components [a form that follows from $\sinh\eta = \cot\theta$, derived below]. For a massless particle, differences of η do not change under boosts along the beam.

Energy and momentum from (p_T, η, ϕ). Write $t = \tan(\theta/2)$, so $e^\eta = 1/t$ by (T4.4). Then

$$\sinh\eta \overset{(1)}{=} \frac{1}{2}\left(\frac{1}{t} - t\right) \overset{(2)}{=} \frac{1-t^2}{2t} \overset{(3)}{=} \cot\theta, \qquad \cosh\eta \overset{(1)}{=} \frac{1}{2}\left(\frac{1}{t} + t\right) \overset{(2)}{=} \frac{1+t^2}{2t} \overset{(3)}{=} \frac{1}{\sin\theta}. \tag{T4.5}$$

(1) The definitions $\sinh\eta = (e^\eta - e^{-\eta})/2$ and $\cosh\eta = (e^\eta + e^{-\eta})/2$, with $e^\eta = 1/t$.
(2) Put both terms over the common denominator $2t$.
(3) The double-angle formulas in terms of $t = \tan(\theta/2)$: $\tan\theta = 2t/(1 - t^2)$ and $\sin\theta = 2t/(1 + t^2)$.

Combining these with (T4.1), a particle's momentum components and, for a massless particle, its energy are

$$p_x = p_T\cos\phi, \qquad p_y = p_T\sin\phi, \qquad p_z = p_T\sinh\eta, \qquad E = |\boldsymbol{p}| = \frac{p_T}{\sin\theta} = p_T\cosh\eta. \tag{T4.6}$$

The first two are the definition of the azimuth; the third is $p_z = |\boldsymbol{p}|\cos\theta = p_T\cot\theta$ with $\cot\theta = \sinh\eta$; the last uses $\cosh\eta = 1/\sin\theta$. These four numbers are all that the invariant mass of Section T4.3 needs.

Example: angles and pseudorapidities. At $\theta = 90°$, $\tan 45° = 1$ and $\eta = 0$. At $\theta = 45°$, $\tan 22.5° = 0.4142$ and $\eta = -\ln 0.4142 = 0.881$. At $\theta = 10°$, $\tan 5° = 0.08749$ and $\eta = 2.436$. The

pseudorapidity grows slowly over most of the detector and fast near the beam: the last 10° next to the beam cover more than $\eta = 2.4$ onwards. Going the other way, the ATLAS photon acceptance ends at $|\eta| = 2.37$, which is $\theta = 2\arctan e^{-2.37} = 2\arctan 0.0935 = 10.7°$ from the beam, and the gap between the barrel and the end-cap calorimeters, $1.37 < |\eta| < 1.52$, is the thin cone between $\theta = 24.7°$ and 28.5° (on each side), where cables and services pass and photons are poorly measured [113, Sec. 5.1]. Figure T4.3 draws these directions.

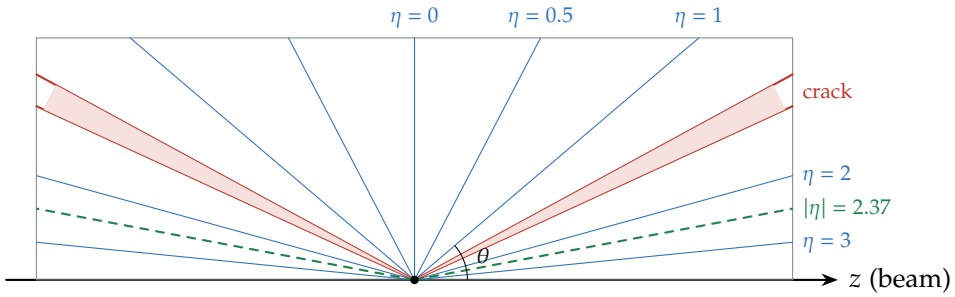

Figure T4.3: Directions of constant pseudorapidity in the plane containing the beam, drawn at their true angles $\theta = 2\arctan e^{-\eta}$. Equal steps in η crowd towards the beam. The shaded red wedges are the barrel/end-cap gap $1.37 < |\eta| < 1.52$, and the green dashed lines mark the edge $|\eta| = 2.37$ of the region where photons are accepted.

Example: a photon's energy from its three numbers. A photon is recorded with $p_T = 50\,\text{GeV}$ and $\eta = 1.2$. Then $\sinh 1.2 = 1.5095$ and $\cosh 1.2 = 1.8107$, so by (T4.6) $p_z = 75.5\,\text{GeV}$ and $E = 90.5\,\text{GeV}$. As a check, $p_T^2 + p_z^2 = 2500 + 5697 = 8197\,\text{GeV}^2 = E^2$, as it must be for a massless particle. A photon going straight up, at $\eta = 0$, would have $E = p_T$; the same p_T further forward carries more energy, because most of its momentum then points along the beam.

Example: why the beam direction is lost. Suppose the two partons carry $x_1 = 0.02$ and $x_2 = 0.005$ of their protons' momenta at $E_\text{b} = 6.5\,\text{TeV}$. The parton pair then has energy $(x_1 + x_2)E_\text{b} = 162.5\,\text{GeV}$ and momentum $(x_1 - x_2)E_\text{b} = 97.5\,\text{GeV}$ along $+z$, so it moves with $\beta = 97.5/162.5 = 0.6$ and every particle it makes has its rapidity shifted by $\tanh^{-1} 0.6 = \frac{1}{2}\ln 4 = 0.693$, by (T4.3) read backwards. In the next event the fractions are different and so is the shift. A search that looked at η itself would see the decay products smeared by this random shift; one that looks at p_T, at differences of η, or at the invariant mass, does not. The collision energy available to make new particles is $\sqrt{x_1 x_2}\,\sqrt{s} = \sqrt{10^{-4}} \times 13\,\text{TeV} = 130\,\text{GeV}$ in this example, which is why a 125 GeV Higgs boson needs only a small slice of the 13 TeV of the protons.

Watch out: Pseudorapidity is an angle, rapidity is a boost

Only rapidity differences are exactly unchanged by a boost along the beam. For a massive particle, such as a heavy jet or a slow proton, η and y differ, and η differences do change under the boost. For photons and electrons at the energies of this chapter the two are equal to better than one part in 10^6, and the distinction never matters.

Where this is used. The photon columns of the open data (Section T4.7) are exactly p_T, η, ϕ and E. The acceptance cuts $|\eta| < 2.37$ outside 1.37–1.52 appear in every diphoton selection of the book, from the toy of Section T4.2 to the capstone of Chapter 13. The identity $E = p_T \cosh\eta$ is checked on a real event in Section T4.7.

T4.2 Cross section, luminosity and the expected number of events

Before a search can ask whether the Higgs boson is in the data, it has to say how many Higgs bosons the data *should* contain if the Standard Model is right. That prediction has two factors that come from two different communities. Theorists compute how likely the process is when two protons collide, a number with the dimension of an area called the cross section. The accelerator physicists know how many chances the beams gave for that process to happen, a number with the dimension of an inverse area called the integrated luminosity. Their product is a pure number of events. A third factor comes from the experiment itself: of the events produced, only some land in the detector where photons can be measured, and only some of those survive the selection.

The questions in words.

1. What is a cross section, as a physical picture we could draw?
2. How many collisions do two crossing bunches of protons give, and how does that turn into the luminosity?
3. Of the events produced, what fraction is kept, and why is the number kept a Poisson count with mean $\sigma L \varepsilon A$?

T4.2.1 A cross section is an area

Shoot one small projectile through a thin slab of material of thickness $\mathrm{d}x$ containing n target particles per unit volume. Suppose each target behaves like a small disc of area σ facing the projectile: if the projectile's path crosses the disc, the reaction happens; otherwise nothing happens. *What is the probability of a reaction?* Look at a patch of the slab of area S as seen by the projectile. It holds $nS\,\mathrm{d}x$ targets, whose discs cover the area $nS\,\mathrm{d}x\,\sigma$, and for a thin enough slab the discs do not overlap. The projectile arrives at a random point of the patch, so the probability that it hits a disc is the covered fraction,

$$\mathrm{P}(\text{reaction in } \mathrm{d}x) = \frac{nS\,\mathrm{d}x\,\sigma}{S} = n\sigma\,\mathrm{d}x. \tag{T4.7}$$

This is the operational meaning of the **cross section** σ: the effective area a target presents for one particular reaction. It has nothing to do with the geometric size of the proton. A process with a small quantum-mechanical amplitude has a small σ, even though the protons are the same. The unit is the **barn**, $1\,\mathrm{b} = 10^{-24}\,\mathrm{cm}^2$, with $1\,\mathrm{mb} = 10^{-3}\,\mathrm{b}$, $1\,\mathrm{pb} = 10^{-12}\,\mathrm{b}$ and $1\,\mathrm{fb} = 10^{-15}\,\mathrm{b}$. In natural units, $(\hbar c)^2 = 0.3894\,\mathrm{GeV}^2\,\mathrm{mb}$ converts a cross section computed in GeV^{-2} into millibarn [114, §49].

Two cross sections set the scale of the whole chapter. At $\sqrt{s} = 13\,\mathrm{TeV}$, the probability that two crossing protons interact at all corresponds to the **inelastic cross section** $\sigma_{\mathrm{inel}} = 78.1 \pm 2.9\,\mathrm{mb}$ [115]. The probability that they make a Higgs boson by gluon fusion that then decays to two photons corresponds to $\sigma \cdot B(H \to \gamma\gamma) = 0.102\,\mathrm{pb}$, the number stored in the simulated signal files of Section T4.7 [116]. Their ratio is $0.102 \times 10^{-12}/78.1 \times 10^{-3} = 1.3 \times 10^{-12}$: one Higgs-to-diphoton decay for every 7.7×10^{11} collisions.

T4.2.2 Two bunches crossing: the luminosity

At a collider the targets are not at rest in a slab; they are the protons of the other bunch. *How many reactions happen when one bunch crosses another?* Describe each bunch by its number of

protons, N_1 and N_2, and by how they are spread over the plane transverse to the beam: $\rho_1(x,y)$ and $\rho_2(x,y)$, each normalised to $\int \rho \,\mathrm{d}x\,\mathrm{d}y = 1$. The length of the bunches along the beam does not matter, because every proton of one bunch passes through the whole of the other.

Take one proton of bunch 1 at transverse position (x,y). As it crosses bunch 2 it meets an areal density of targets $N_2\rho_2(x,y)$ (protons per unit transverse area). Bunch 2 is then a thin slab whose targets cover the fraction $\sigma N_2\rho_2(x,y)$ of the area, so by the same argument as (T4.7) this proton reacts with probability $\sigma N_2\rho_2(x,y)$. Bunch 1 has $N_1\rho_1(x,y)\,\mathrm{d}x\,\mathrm{d}y$ protons in a small patch around (x,y). Adding up over the patches, the expected number of reactions in one crossing is

$$\bar{n}_{\text{crossing}} = \sigma\, N_1 N_2 \int \rho_1(x,y)\,\rho_2(x,y)\,\mathrm{d}x\,\mathrm{d}y. \tag{T4.8}$$

Everything except σ is a property of the beams. With n_b pairs of bunches, each pair crossing f times per second (once per turn of the ring), the reaction rate is σ times the **instantaneous luminosity**

$$L_{\text{inst}} = n_b f\, N_1 N_2 \int \rho_1\rho_2\,\mathrm{d}x\,\mathrm{d}y \qquad [\mathrm{cm}^{-2}\,\mathrm{s}^{-1}]. \tag{T4.9}$$

Gaussian bunches. The transverse profile of a bunch is close to Gaussian, $\rho(x,y) = g(x;\sigma_x)\,g(y;\sigma_y)$ with $g(x;s) = e^{-x^2/2s^2}/(\sqrt{2\pi}\,s)$. Let the two beams have the same sizes and let their centres be separated by Δ along x. The x part of the overlap integral is

$$\begin{aligned}\int_{-\infty}^{\infty} g(x;\sigma_x)\,g(x-\Delta;\sigma_x)\,\mathrm{d}x &\overset{(1)}{=} \frac{1}{2\pi\sigma_x^2}\int \exp\!\Big[-\frac{x^2+(x-\Delta)^2}{2\sigma_x^2}\Big]\mathrm{d}x \\ &\overset{(2)}{=} \frac{e^{-\Delta^2/4\sigma_x^2}}{2\pi\sigma_x^2}\int \exp\!\Big[-\frac{(x-\Delta/2)^2}{\sigma_x^2}\Big]\mathrm{d}x \overset{(3)}{=} \frac{e^{-\Delta^2/4\sigma_x^2}}{2\sqrt{\pi}\,\sigma_x}.\end{aligned} \tag{T4.10}$$

(1) Write out the two Gaussians and multiply them.
(2) Complete the square: $x^2+(x-\Delta)^2 = 2(x-\Delta/2)^2 + \Delta^2/2$, so the exponent splits into a part that depends on x and the constant $-\Delta^2/4\sigma_x^2$.
(3) The Gaussian integral $\int e^{-u^2/a^2}\mathrm{d}u = \sqrt{\pi}\,a$ with $a = \sigma_x$.

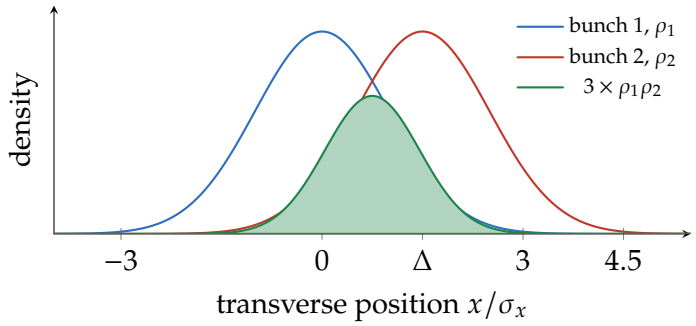

Figure T4.4: The overlap that sets the luminosity, in one transverse direction, for two bunches of equal width whose centres are $\Delta = 1.5\,\sigma_x$ apart. The shaded curve is the product of the two profiles (magnified three times); its area is the integral (T4.10). It is centred half-way between the bunches, and its area falls as $e^{-\Delta^2/4\sigma_x^2}$ when they are pulled apart, here to 57% of its head-on value.

The y part is the same with $\Delta = 0$, that is $1/(2\sqrt{\pi}\,\sigma_y)$. Multiplying the two parts and inserting into (T4.9),

$$L_{\text{inst}} = \frac{n_b f\, N_1 N_2}{4\pi\,\sigma_x\sigma_y}\, e^{-\Delta^2/4\sigma_x^2}\, F. \tag{T4.11}$$

At $\Delta = 0$ this is the formula of the PDG review [114, (31.3)], where a factor F of order one, written in here as well, corrects for the small crossing angle of the beams and for the finite length of the bunches. The Gaussian dependence on the separation will be the basis of the luminosity calibration in Section T4.5.

Working definition T4.3 (cross section and luminosity)

The **cross section** σ of a process is the reaction rate it produces divided by the instantaneous luminosity; for a target at rest it is the effective area per target, (T4.7). The **instantaneous luminosity** L_{inst} [collision opportunities per unit area per second] is a property of the beams alone, (T4.11). The **integrated luminosity** is $L = \int L_{\text{inst}}\,\mathrm{d}t$, quoted in inverse femtobarn, $1\,\text{fb}^{-1} = 10^{39}\,\text{cm}^{-2}$. *Operationally:* the expected number of events of a process in a data set is $N = \sigma L$ [114, (31.2)].

The relation $N = \sigma L$ follows by integrating the rate $\sigma L_{\text{inst}}(t)$ over the running time. It is the reason cross sections are quoted in barns and luminosities in inverse barns: their product needs no conversion factor, as long as the prefixes are matched ($1\,\text{pb} \times 1\,\text{fb}^{-1} = 10^3$).

Example: the LHC design luminosity, and how many collisions share one crossing. The LHC was designed for $N_1 = N_2 = 1.15 \times 10^{11}$ protons per bunch, $n_b = 2808$ bunches per beam, a revolution frequency $f = 11\,245\,\text{Hz}$, beams of r.m.s. size $\sigma_x = \sigma_y = 16.7\,\mu\text{m}$ at the collision point, and $F = 0.836$ [117]. Then (T4.11) with $\Delta = 0$ gives

$$L_{\text{inst}} \overset{(1)}{=} \frac{2808 \times 11\,245\,\text{s}^{-1} \times (1.15 \times 10^{11})^2}{4\pi \times (16.7 \times 10^{-4}\,\text{cm})^2} \times 0.836$$
$$\overset{(2)}{=} 1.192 \times 10^{34}\,\text{cm}^{-2}\text{s}^{-1} \times 0.836 = 9.961 \times 10^{33}\,\text{cm}^{-2}\text{s}^{-1}, \tag{T4.12}$$

(1) Insert the design values; $16.7\,\mu\text{m} = 16.7 \times 10^{-4}\,\text{cm}$.
(2) Numerator $4.18 \times 10^{29}\,\text{s}^{-1}$, denominator $3.50 \times 10^{-5}\,\text{cm}^2$.

the famous $10^{34}\,\text{cm}^{-2}\text{s}^{-1}$. The rate of inelastic collisions is $\sigma_{\text{inel}} L_{\text{inst}} = 7.780 \times 10^8$ per second, spread over $n_b f = 3.16 \times 10^7$ bunch crossings per second, so each crossing contains on average

$$\bar{n}_{\text{pu}} = \frac{\sigma_{\text{inel}} L_{\text{inst}}}{n_b f} = 24.64 \tag{T4.13}$$

simultaneous collisions. One of them may be interesting; the others, called **pile-up**, add soft particles everywhere in the detector. The 8 TeV data of 2012 had about 20 such collisions per crossing [113, Sec. 1], and the PDG quotes up to 50 for recent runs [114, §31.4.1]. Pile-up is why the analyses ask for photons with little energy around them (Section T4.7) and why the efficiency of that requirement is itself a calibrated quantity (Section T4.5).

Example: how many Higgs bosons in the open data. The 2016 data released by ATLAS correspond to $L = 10\,\text{fb}^{-1}$ [118]. The expected number of Higgs bosons made by gluon fusion and decaying to two photons is

$$N = \sigma B\, L \overset{(1)}{=} 0.102\,\text{pb} \times 10\,\text{fb}^{-1} \overset{(2)}{=} 0.102 \times 10^3\,\text{fb} \times 10\,\text{fb}^{-1} = 1020. \tag{T4.14}$$

(1) The cross section times branching fraction stored in the simulation files, and the luminosity of the release.
(2) $1\,\text{pb} = 10^3\,\text{fb}$, so the femtobarns cancel.

In the same $10\,\text{fb}^{-1}$ the number of inelastic collisions is $\sigma_{\text{inel}} L = 78.1 \times 10^{12}\,\text{fb} \times 10\,\text{fb}^{-1} = 7.8 \times 10^{14}$. Almost none of them were recorded: the trigger kept 7 798 424 events with two energetic photon candidates in the released diphoton stream (Section T4.7).

T4.2.3 The events we keep: acceptance and efficiency

Not every Higgs boson produced becomes an event in our histogram. Its photons may fly too close to the beam, outside the calorimeter. They may hit the gap between barrel and end-cap. One of them may be too soft to pass the trigger, may fail the identification, or may have too much energy around it. The fraction of produced events that survive is split, by convention, into two factors [Cowan §11.1]. The **acceptance** A is the fraction that is geometrically and kinematically inside the region the analysis looks at (here: both photons at $|\eta| < 2.37$ outside the crack, with large enough p_T). The **efficiency** ε is the fraction of those that the detector and the selection actually record as two good photons. Cowan uses "efficiency" for the product; the split matters only because the two factors are calibrated in different ways. The expected number of selected events is then [Cowan (2.12)], [29, (15)]

$$\boxed{\nu = \sigma \, L \, \varepsilon \, A} \tag{T4.15}$$

Cranmer writes the same relation as "rate = flux × cross section × efficiency × acceptance", and calls the product $\sigma\varepsilon A$ an effective cross section [29, (16)].

Example: the acceptance of a diphoton selection, by simulation. We generate 200 000 Higgs decays with a short script (`01_mass_lineshape.py`), isotropic in the rest frame of the boson, and give each boson a random transverse momentum (exponential, mean 25 GeV) and a random rapidity (Gaussian, width 1.5) to mimic production by gluon fusion. Requiring both photons inside $|\eta| < 2.37$ and outside the crack keeps a fraction 0.631 of the decays; adding $p_T > 40$ and 30 GeV for the two photons leaves $A = 0.551 \pm 0.001$. Almost half of the Higgs bosons are lost before the detector has done anything wrong, simply because the photons go where the detector cannot measure them. (The production model is a toy; the number is meant to show the size of the effect, not to replace the full simulation used below.)

Example: the cut flow of the open-data signal. For the real simulation of gluon fusion in the 2016 detector, the script `02_open_data.py` applies a selection modelled on the 2012 analysis and follows the expected number of events step by step; Figure T4.5 shows the result next to the number of recorded data events that survive the same steps. The files contain only events that passed a loose two-photon preselection, which already removes almost half of the produced signal. Requiring both photons to pass the *tight identification* [a shower shape like that of one photon, not of two photons from a neutral pion] removes another fifth. The acceptance cuts in η cost almost nothing more, because the preselection had already applied them; the p_T cuts and the isolation requirement [at most 4 GeV of energy in a cone around each photon] cost a few per cent each. In the end $\varepsilon A = 0.3872$ and $\nu = 395$ selected signal events are expected. The data lose far more at the same steps (from 7 798 424 to 151 767 events): most recorded photon pairs are fakes from jets, and identification and isolation are designed to remove exactly those.

T4.2.4 Why the number of selected events is a Poisson count

The claim is plain: *the number of selected signal events in a data set is a Poisson random variable with mean* $\nu = \sigma L \varepsilon A$. The everyday question behind it is "if the LHC had delivered the same data set again, how many would we have got?" That question hides an assumption, namely what is held fixed when the data set is "delivered again". The answer is: the integrated luminosity. Not the running time, which depends on how the beams behaved, and not the total number of recorded events. With that fixed, we can derive the Poisson law from three physical inputs, as we derived it for photons from a star in Section 2.5.1.

The inputs (all physical).

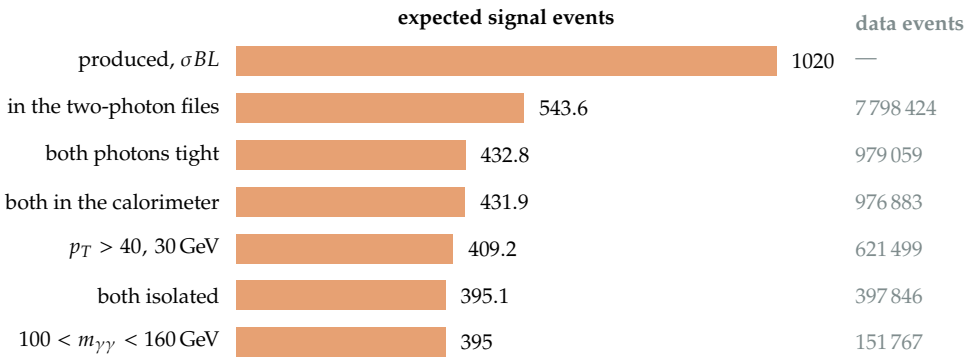

Figure T4.5: Where the Higgs bosons go. Bars: the expected number of gluon-fusion $H \to \gamma\gamma$ events in $10\,\text{fb}^{-1}$ after each step of the selection, from the weighted simulation. Grey column: the number of recorded data events left after the same steps. Signal survives the identification and isolation steps far better than the data, which are dominated by jets faking photons; the final ratio of the two columns is what the mass histogram has to overcome.

(C1) *Crossings are independent.* What happens in one bunch crossing does not change the probabilities in another.

(C2) *The process is rare in each crossing.* In crossing k the probability of producing the process is $\sigma\,\ell_k$, where $\ell_k = N_1 N_2 \int \rho_1 \rho_2$ is that crossing's luminosity, (T4.8); it is tiny, a few times 10^{-11} for the Higgs signal, and the chance of two such events in one crossing is negligible.

(C3) *Each produced event is kept independently.* It is selected with probability εA, independently of everything else.

The luminosity of a crossing may vary freely from one crossing to the next, as it does during a fill when the beams lose protons. Nothing is assumed about it.

What is the probability of the total count? The count in crossing k is 1 with probability $q_k = \sigma \ell_k \varepsilon A$ and 0 otherwise (inputs C2, C3: produced and kept). By C1 the total is a sum of independent Bernoulli variables with different probabilities. Its probability generating function $G(z) = \mathbb{E}\, z^N$ is the product of the individual ones, $1 - q_k + q_k z$, so

$$\ln G(z) \overset{(1)}{=} \sum_k \ln\bigl[1 + q_k(z-1)\bigr] \overset{(2)}{=} \sum_k q_k(z-1) + O\Bigl(\sum_k q_k^2\Bigr)$$
$$\overset{(3)}{=} (z-1)\,\sigma\varepsilon A \sum_k \ell_k \overset{(4)}{=} (z-1)\,\sigma L \varepsilon A = (z-1)\,\nu. \tag{T4.16}$$

(1) Independent factors: the generating function of a sum is the product of the generating functions, and the logarithm of a product is a sum.
(2) $\ln(1+u) = u + O(u^2)$, with $u = q_k(z-1)$ small because every q_k is tiny.
(3) Insert $q_k = \sigma \ell_k \varepsilon A$; the neglected term is at most $(\max_k q_k)\,\nu$, some $10^{-11}\nu$.
(4) The integrated luminosity is the sum of the luminosities of all crossings, $L = \sum_k \ell_k$.

So $G(z) = e^{\nu(z-1)}$, which is the generating function of the Poisson distribution with mean ν (with $z = e^t$ it is (2.13)). The count is Poisson, $\mathrm{P}(N = n) = e^{-\nu}\nu^n/n!$, with $\nu = \sigma L \varepsilon A$. This is the Poisson limit of the binomial of Section 2.4, generalised to trials with unequal probabilities; and the factor εA is the thinning of a Poisson stream from Section 2.5.

The clock of a collider. In Section 2.5.1 a constant rate (input P2) was needed so that the mean count in a window depended only on its length. Here no constant rate is needed. The mean depends only on the sum of the crossing luminosities, so the integrated luminosity plays

the role that elapsed time played for the star: it is the collider's clock, and a fill in which the luminosity decays is just a clock that ticks unevenly.

A counterexample: change what is held fixed. Suppose instead the experiment had decided to stop after recording exactly M selected diphoton events, signal and background together. Then the number of signal events among them is no longer Poisson. Each of the M events is signal with probability $\nu_S/(\nu_S + \nu_B)$, and the count is binomial with M trials, bounded by M and with a smaller variance than a Poisson count of the same mean. The same physics gives a different distribution because the sampling rule changed. The general version of this, a Poisson total split into bins, is the multinomial-to-Poisson step of Section 4.15.1.

Key idea: Counts at a collider

With the integrated luminosity held fixed, the number of selected events of a process is Poisson with mean $\nu = \sigma L \varepsilon A$: cross section from theory, luminosity from the machine, acceptance and efficiency from the detector. Independent processes add their means, and the counts in different bins of a histogram are independent Poisson variables.

What would break it. Input C1 fails if the selection in one crossing depends on the previous one, for example through detector dead time after a large deposit; this is small and corrected for in the luminosity. C3 fails if a whole batch of events is lost together, for example a run with a faulty calorimeter section; such runs are removed from the data before the luminosity is computed, so that L refers only to the data actually used [118]. And ν itself is uncertain, because L, ε and A are measured: that is the subject of Section T4.5.

Where this is used. The expected count in bin i of a histogram, $\nu_i = \mu s_i + b_i$, is (T4.15) applied to signal and background separately and shared among the bins (Section T4.4); its Poisson probability is the building block of the search likelihood in Section 4.15.1. The number 395 is the starting point of the capstone in Chapter 13.

T4.3 Invariant mass: why a decaying particle makes a peak

A Higgs boson is made with some momentum that we do not control and do not measure: a sideways kick from the gluons that made it, and a motion along the beam inherited from the unequal momentum fractions of the two partons (Section T4.1.2). When it decays, its two photons share its energy in a way that depends on that motion and on the direction of the decay. In one event they may carry 40 and 90 GeV, in the next 300 and 35 GeV. A histogram of photon energies would show no trace of the Higgs boson. Yet one combination of the two photons' energies and momenta comes out the same in every decay, and that combination turns a rare particle into a narrow peak.

The questions in words.

1. Which combination of the photons' energies and momenta is the same in every decay, and why?

2. How is it computed from the recorded p_T, η and ϕ?

3. Why is the peak not infinitely sharp? What shape does the finite lifetime of the particle give it, what shape does the detector give it, and which of the two wins for the Z boson and for the Higgs boson?

T4.3.1 The invariant mass of a pair

The energy E and momentum $\boldsymbol{p}$ of a particle form a four-vector $p = (E, \boldsymbol{p})$. The combination $p^2 \equiv E^2 - |\boldsymbol{p}|^2$ is the same in every inertial frame, and equals the square of the particle's mass, $p^2 = m^2$ [114, §49.1]. More generally the product $p \cdot q = E_p E_q - \boldsymbol{p} \cdot \boldsymbol{q}$ of any two four-vectors is frame independent. That is the only fact of special relativity we need.

The event. A particle of mass M decays into two particles with four-momenta p_1 and p_2, and the detector measures both. *What do p_1 and p_2 know about M?* Energy and momentum are conserved in the decay, so the parent's four-momentum is $P = p_1 + p_2$, in every event and in every frame. Squaring,

$$M^2 \overset{(1)}{=} P^2 \overset{(2)}{=} (p_1 + p_2)^2 \overset{(3)}{=} p_1^2 + p_2^2 + 2\, p_1 \cdot p_2 \overset{(4)}{=} m_1^2 + m_2^2 + 2\big(E_1 E_2 - \boldsymbol{p}_1 \cdot \boldsymbol{p}_2\big). \tag{T4.17}$$

(1) The parent's own mass: $P^2 = M^2$ for the parent's four-momentum, in any frame.
(2) Four-momentum conservation in the decay.
(3) Expand the square of a sum; the product is symmetric, $p_1 \cdot p_2 = p_2 \cdot p_1$.
(4) $p_j^2 = m_j^2$ for each daughter, and the definition of the four-product.

The right-hand side is built from measured quantities only. Its square root is the **invariant mass** of the pair, m_{12}, and (T4.17) says that it equals the parent's mass in every decay, however fast and in whichever direction the parent was moving [114, (49.2)]. The parent's motion changes E_1, E_2 and the angle between the daughters, but only in the combination that leaves m_{12} unchanged.

Two photons. Photons are massless, $m_1 = m_2 = 0$ and $|\boldsymbol{p}_j| = E_j$, so with θ_{12} the opening angle between them,

$$m_{\gamma\gamma}^2 = 2E_1 E_2\,(1 - \cos\theta_{12}). \tag{T4.18}$$

In the variables the detector records. Insert the components (T4.6), $E_j = p_{Tj}\cosh\eta_j$ and $\boldsymbol{p}_j = (p_{Tj}\cos\phi_j,\ p_{Tj}\sin\phi_j,\ p_{Tj}\sinh\eta_j)$:

$$\begin{aligned} E_1E_2 - \boldsymbol{p}_1\cdot\boldsymbol{p}_2 &\overset{(1)}{=} p_{T1}p_{T2}\big[\cosh\eta_1\cosh\eta_2 - \cos\phi_1\cos\phi_2 - \sin\phi_1\sin\phi_2 - \sinh\eta_1\sinh\eta_2\big] \\ &\overset{(2)}{=} p_{T1}p_{T2}\big[\cosh(\eta_1-\eta_2) - \cos(\phi_1-\phi_2)\big], \\ m_{\gamma\gamma}^2 &\overset{(3)}{=} 2\,p_{T1}p_{T2}\big[\cosh\Delta\eta - \cos\Delta\phi\big]. \end{aligned} \tag{T4.19}$$

(1) Multiply the energies and take the scalar product of the momenta; every term carries $p_{T1}p_{T2}$.
(2) Two addition formulas: $\cosh a\cosh b - \sinh a\sinh b = \cosh(a-b)$ and $\cos a\cos b + \sin a\sin b = \cos(a-b)$.
(3) Insert into (T4.17) with $m_1 = m_2 = 0$; $\Delta\eta = \eta_1 - \eta_2$, $\Delta\phi = \phi_1 - \phi_2$.

This is the PDG's (49.45) for massless particles [114], and it is the formula every diphoton analysis in the book uses. Only the differences $\Delta\eta$ and $\Delta\phi$ appear: a rotation about the beam adds the same angle to both ϕ_j, and a boost along the beam adds the same amount to both η_j (Section T4.1.2), so neither can change the mass.

Working definition T4.4 (invariant mass)

The **invariant mass** of a set of particles is $m = \sqrt{(\sum_j E_j)^2 - |\sum_j \boldsymbol{p}_j|^2}$, the mass of a single particle that would have their total energy and momentum [114, (49.26)]. *Operationally*, for two photons: $m_{\gamma\gamma} = \sqrt{2p_{T1}p_{T2}(\cosh\Delta\eta - \cos\Delta\phi)}$ from the recorded columns. If the

pair came from the decay of one particle, m is that particle's mass in every event, up to measurement errors.

Example: the Higgs boson at rest, and moving. At rest, the two photons share the energy equally, $E_1 = E_2 = M/2 = 62.5\,\text{GeV}$, and fly back to back, $\theta_{12} = \pi$, so (T4.18) gives $m^2 = 2 \times 62.5^2 \times 2 = 125^2\,\text{GeV}^2$. Now let the boson move with momentum $p_H = 100\,\text{GeV}$, so $E_H = \sqrt{125^2 + 100^2} = 160.1\,\text{GeV}$, and let it decay with the photons along its line of flight, one forwards and one backwards. In the rest frame each has energy $M/2$; boosting with $\gamma = E_H/M$ and $\beta = p_H/E_H$ gives the forward photon $\gamma\frac{M}{2}(1+\beta) = \frac{1}{2}(E_H + p_H) = 130.0\,\text{GeV}$ and the backward one $\frac{1}{2}(E_H - p_H) = 30.0\,\text{GeV}$. They are still back to back, so

$$m^2 \overset{(1)}{=} 2 \cdot \tfrac{1}{2}(E_H + p_H) \cdot \tfrac{1}{2}(E_H - p_H) \cdot 2 \overset{(2)}{=} E_H^2 - p_H^2 \overset{(3)}{=} M^2. \tag{T4.20}$$

(1) (T4.18) with $1 - \cos\pi = 2$.
(2) $(a+b)(a-b) = a^2 - b^2$.
(3) The boson's own mass-shell relation.

Energies of 130 and 30 GeV instead of 62.5 and 62.5, and the same mass. Figure T4.6 draws a decay at an angle, where the opening angle changes too.

Figure T4.6: The same decay in two frames, with arrow lengths proportional to momentum. In the rest frame of the Higgs boson the photons are back to back with 62.5 GeV each. In the lab, where the boson moves to the right, the forward photon gains energy, the backward one loses it, and the opening angle closes to $\theta_{12} = 114°$. Both pictures give $2E_1E_2(1 - \cos\theta_{12}) = 125^2\,\text{GeV}^2$.

Example: two hundred thousand decays in a computer. The script `01_mass_lineshape.py` makes the same check on 200 000 simulated decays with random directions and random boosts. The lines that matter are these:

Listing T4.1: Boost the rest-frame photons and recompute the mass from (p_T, η, ϕ) (`code/chT4/01_mass_lineshape.py`)

```
def boost(p, P, M):
    """Lorentz-boost four-vectors p (given in the rest frame of P) into the frame where P
    is measured."""
    gamma = P[:, 0] / M
    bvec = P[:, 1:] / P[:, :1]                                  # velocity of the
    parent
    b2 = np.sum(bvec**2, axis=1)
    bp = np.sum(bvec * p[:, 1:], axis=1)
    E = gamma * (p[:, 0] + bp)
    coef = np.where(b2 > 0, (gamma - 1) * bp / np.where(b2 > 0, b2, 1), 0.0) + gamma * p[:,
    0]
    return np.column_stack([E, p[:, 1:] + coef[:, None] * bvec])

```

```
60
61 p1, p2 = boost(p1_rest, PH, MH), boost(p2_rest, PH, MH)
62
63
64 def pt_eta_phi(p):
65     pt = np.hypot(p[:, 1], p[:, 2])
66     eta = np.arcsinh(p[:, 3] / pt)                                    # eta =
       asinh(pz/pT), massless
67     return pt, eta, np.arctan2(p[:, 2], p[:, 1])
68
69
70 pt1, eta1, phi1 = pt_eta_phi(p1)
71 pt2, eta2, phi2 = pt_eta_phi(p2)
72 m_lab = np.sqrt(2 * pt1 * pt2 * (np.cosh(eta1 - eta2) - np.cos(phi1 - phi2)))   # PDG
       (49.45), massless
```

The function `boost` applies the Lorentz transformation for a general velocity $\boldsymbol{\beta} = \boldsymbol{P}/E_P$ of the parent: $E' = \gamma(E + \boldsymbol{\beta}\cdot\boldsymbol{p})$ and $\boldsymbol{p}' = \boldsymbol{p} + \left[(\gamma-1)\boldsymbol{\beta}\cdot\boldsymbol{p}/\beta^2 + \gamma E\right]\boldsymbol{\beta}$, the vector form of [114, (49.1)]. Lines 64–67 convert each photon to the detector variables, with $\eta = \sinh^{-1}(p_z/p_T)$ from (T4.5), and line 72 is (T4.19). The photon energies spread from 36.4 to 660.5 GeV (5th to 95th percentile), while the largest deviation of $m_{\gamma\gamma}$ from 125 GeV in all the decays is 2.211×10^{-11} GeV, the rounding error of double precision. Panel (a) of Figure T4.7 shows the two histograms side by side.

T4.3.2 The natural width: a Breit–Wigner from a finite lifetime

The Breit–Wigner shape has been with us since Chapter 2. In Section 2.10.5 it was the line shape of the Z boson, with mass $M = 91.1876$ GeV and width $\Gamma = 2.4952$ GeV, and its lack of a mean defeated a running average. In Section 2.16.2 it was smeared with a Gaussian detector error of 2.0 GeV, and the tails of the resulting Voigt profile stayed those of the Breit–Wigner. In Section 3.3.4 the average of N draws from it was shown to be no better than one draw. In all three places the shape was taken as given, with the detector ignored or modelled crudely. What is new here is where the shape comes from, what the width means physically, and how it competes with a realistic detector resolution.

The question. If the parent's mass is exactly M, (T4.17) gives a spike, not a peak. *What spreads the invariant mass of real decays?* A particle that decays does not have a sharp energy. It exists only for a time of order its lifetime τ, and a state that lasts a time τ can only have its energy defined to about $\hbar/\tau$. We can make this exact in three short steps, with $\hbar = c = 1$.

The decaying state as a damped oscillation. In its rest frame, a stable particle's quantum amplitude oscillates as e^{-iMt}. An unstable one survives to time t with probability $e^{-\Gamma t}$, with $\Gamma = 1/\tau$ [114, (49.14)]. The probability is the squared modulus of the amplitude, so the amplitude must also decay, at half the rate:

$$\psi(t) = e^{-iMt}\, e^{-\Gamma t/2} \qquad (t \geq 0), \qquad |\psi(t)|^2 = e^{-\Gamma t}. \tag{T4.21}$$

Which energies does it contain? The amplitude for energy E is the Fourier component of ψ at E:

$$\tilde{\psi}(E) \overset{(1)}{=} \int_0^\infty e^{iEt}\,\psi(t)\,\mathrm{d}t \overset{(2)}{=} \int_0^\infty e^{[\,i(E-M)-\Gamma/2\,]t}\,\mathrm{d}t \overset{(3)}{=} \frac{1}{\Gamma/2 - i(E-M)},$$
$$|\tilde{\psi}(E)|^2 \overset{(4)}{=} \frac{1}{(E-M)^2 + \Gamma^2/4}. \tag{T4.22}$$

(1) Fourier analysis of a signal that starts at $t = 0$: the weight of the frequency E in $\psi(t)$.
(2) Insert (T4.21) and combine the exponentials.

(3) $\int_0^\infty e^{-at}\,\mathrm{d}t = 1/a$ for $\mathrm{Re}\,a > 0$; here $a = \Gamma/2 - i(E - M)$, whose real part $\Gamma/2$ is positive, so the integrand vanishes at infinity.

(4) The squared modulus of $1/(x - iy)$ is $1/(x^2 + y^2)$.

Normalise it. With $u = 2(E - M)/\Gamma$, $\int \mathrm{d}E/[(E - M)^2 + \Gamma^2/4] = (2/\Gamma)\int \mathrm{d}u/(1 + u^2) = 2\pi/\Gamma$. Dividing by this,

$$p(E \mid M, \Gamma) = \frac{1}{\pi}\,\frac{\Gamma/2}{(E - M)^2 + \Gamma^2/4}, \tag{T4.23}$$

which is exactly the Breit–Wigner (2.58) of Chapter 2, and the bracket of the PDG's resonance cross section [114, (51.1)]. The density falls to half its peak value where $(E - M)^2 = \Gamma^2/4$, so the full width at half maximum is Γ: the **width** of a particle is its decay rate, $\Gamma = \hbar/\tau$. The invariant mass of the decay products is the energy of the decaying state in its rest frame, so it follows (T4.23).

Relativistic form. The PDG writes the amplitude of a resonance near its mass as $1/(m^2 - M^2 + iM\Gamma)$ [114, (49.10)]. Near the peak, $m^2 - M^2 = (m - M)(m + M) \approx 2M(m - M)$, so its squared modulus is $1/[4M^2(m - M)^2 + M^2\Gamma^2] = (1/4M^2)/[(m - M)^2 + \Gamma^2/4]$: the same Breit–Wigner, up to a constant. The two forms differ only far in the tails, where (as Section 2.16 warned) the models break down anyway.

Example: lifetimes from widths. With $\hbar = 6.582 \times 10^{-25}\,\mathrm{GeV\,s}$, the Z boson's width $\Gamma_Z = 2.4952\,\mathrm{GeV}$ means $\tau_Z = 6.582 \times 10^{-25}/2.4952 = 2.64 \times 10^{-25}\,\mathrm{s}$. The Standard Model predicts a width of a few MeV for a Higgs boson of 125 GeV [119, Sec. 4]; with $\Gamma_H = 4.1\,\mathrm{MeV}$, $\tau_H = 6.582 \times 10^{-25}/4.1 \times 10^{-3} = 1.6 \times 10^{-22}\,\mathrm{s}$. The Higgs boson lives six hundred times longer than the Z, and its natural line is six hundred times narrower.

T4.3.3 The detector's blur: resolution, Voigt and Crystal Ball

The question. The calorimeter does not measure a photon's energy exactly. *How large is the error, and how does it spread the invariant mass?*

The energy error. A photon makes an electromagnetic shower, and the calorimeter samples the number of charged particles in it. That number grows in proportion to the energy, and it fluctuates like a Poisson count, so its relative fluctuation falls like $1/\sqrt{E}$. On top of this, imperfect calibration from cell to cell adds a relative error that does not shrink with energy. The two are independent and add in quadrature,

$$\frac{\sigma_E}{E} = \frac{a}{\sqrt{E/\mathrm{GeV}}} \oplus c, \qquad x \oplus y \equiv \sqrt{x^2 + y^2}, \tag{T4.24}$$

with the design values $a \approx 10\%$ and $c \approx 0.7\%$ for the ATLAS electromagnetic calorimeter [112].

From photon energies to the mass. The photon directions are measured well enough that the error on the opening angle contributes negligibly [113, Sec. 5.2]; we keep only the energy errors. Take the logarithm of (T4.18) and vary E_1 and E_2:

$$\begin{aligned} \ln m_{\gamma\gamma} &\overset{(1)}{=} \tfrac{1}{2}\ln E_1 + \tfrac{1}{2}\ln E_2 + \tfrac{1}{2}\ln\bigl[2(1 - \cos\theta_{12})\bigr], \\ \frac{\delta m}{m} &\overset{(2)}{=} \frac{1}{2}\frac{\delta E_1}{E_1} + \frac{1}{2}\frac{\delta E_2}{E_2}, \qquad \frac{\sigma_m}{m} \overset{(3)}{=} \frac{1}{2}\sqrt{\left(\frac{\sigma_{E_1}}{E_1}\right)^2 + \left(\frac{\sigma_{E_2}}{E_2}\right)^2}. \end{aligned} \tag{T4.25}$$

(1) $m^2 = 2E_1E_2(1 - \cos\theta_{12})$; the logarithm turns the product into a sum, and the square root gives the factors $\frac{1}{2}$.

(2) Differentiate: $\delta(\ln x) = \delta x/x$, with the angle held fixed.

(3) The two energy errors are independent, so the variances of the two terms add (Section 3.6).

For two equal photons of 62.5 GeV, (T4.24) gives $\sigma_E/E = \sqrt{0.10^2/62.5 + 0.007^2} = 1.45\%$, and (T4.25) gives $\sigma_m/m = 1.45\%/\sqrt{2} = 1.02\%$, about 1.3 GeV at 125 GeV. In the boosted toy decays of the previous subsection the photons are usually more energetic and so better measured; smearing each energy with (T4.24) gives a mass spread of 1.170 GeV, and averaging (T4.25) over the same events predicts 1.169 GeV. Panel (b) of Figure T4.7 shows the smeared peak and the Gaussian of that width.

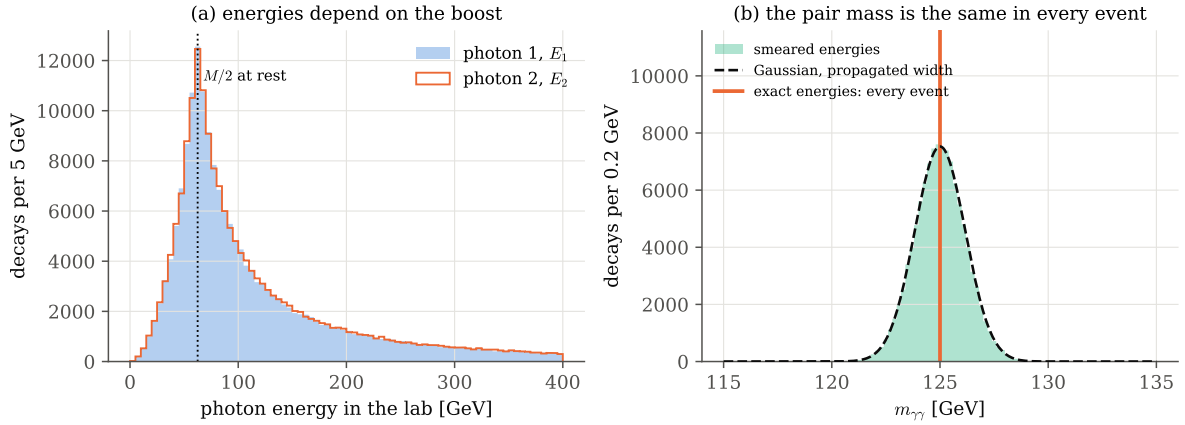

Figure T4.7: (a) Photon energies in 200 000 simulated Higgs decays with random boosts: anywhere from a few tens to several hundred GeV, nowhere near the 62.5 GeV of a decay at rest (dotted). (b) The invariant mass of the same pairs. With exact energies every event sits at 125 GeV (the vertical line). With energies smeared by the calorimeter resolution the pairs form a peak whose width is predicted by the error propagation (T4.25) (dashed).

Natural width and resolution together. The measured mass is the true mass of the decaying state, distributed as (T4.23), plus an independent measurement error, roughly Gaussian with width σ_m. The density of a sum of independent variables is the convolution of their densities, so the observed peak is the Voigt profile of (2.120). *Which of the two shapes wins?* It depends on the ratio Γ/σ_m.

- *The Z boson.* $\Gamma_Z = 2.50$ GeV and a dielectron mass resolution of about 1.5 GeV (CMS quotes 1.56 GeV in its barrel [119, Sec. 3]) are comparable. The full widths at half maximum are 2.50 GeV for the Breit–Wigner alone, 3.53 GeV for the Gaussian alone (2.355 σ), and 5.05 GeV for their convolution. Both effects matter, and a fit to the Z peak can separate them because their tails differ.
- *The Higgs boson.* $\Gamma_H \approx 4$ MeV against $\sigma_m \approx 1.6$ GeV. The Voigt and the Gaussian of the same σ differ by at most $0.0 \times 100\%$ of the peak height, with half-maximum widths 3.770 and 3.768 GeV. The width of the observed Higgs peak is entirely the detector's [119, Sec. 4]; the particle's own width cannot be read off it.

Key idea: Peak position and peak width

The position of a resonance peak in an invariant-mass histogram measures the particle's mass, because $m_{12}^2 = (p_1 + p_2)^2 = M^2$ in every decay. Its width combines the natural width $\Gamma = \hbar/\tau$ (Breit–Wigner) and the detector resolution σ_m (Gaussian core), and is dominated by whichever is larger; for the Higgs boson in two photons it is the resolution, about 1.6 GeV, against a natural width of 4 MeV.

Why the Gaussian is not enough: the Crystal Ball. A Gaussian error assumes many small, symmetric contributions. Some photons, however, lose a sizeable part of their energy before or outside the calorimeter: in the material in front of it, by converting, or by leaking out of the back or the sides of the shower. These losses only go one way, so the measured mass acquires a tail on the low side. ATLAS modelled its signal with a **Crystal Ball** function, a Gaussian core joined to a power-law tail, with $\sigma_{\mathrm{CB}} = 1.6\,\mathrm{GeV}$ and a full width at half maximum of 3.9 GeV for the inclusive sample [113, Sec. 5.4]. In the standardised variable $t = (m - \bar{m})/\sigma$ it is

$$f(t) \propto \begin{cases} e^{-t^2/2}, & t > -\alpha, \\ A\,(B - t)^{-n}, & t \le -\alpha, \end{cases} \tag{T4.26}$$

where $\alpha > 0$ says how many standard deviations below the peak the tail begins, and n how slowly it falls. *What fixes A and B?* We require the two pieces to join smoothly at $t = -\alpha$, with the same value and the same slope. The Gaussian piece has value $e^{-\alpha^2/2}$ and slope $-t\,e^{-t^2/2} = \alpha e^{-\alpha^2/2}$ there; the tail piece has value $A(B+\alpha)^{-n}$ and slope $nA(B-t)^{-n-1} = nA(B+\alpha)^{-n-1}$. So

$$\begin{aligned} A(B+\alpha)^{-n} &\overset{(1)}{=} e^{-\alpha^2/2}, & \frac{n}{B+\alpha}\,e^{-\alpha^2/2} &\overset{(2)}{=} \alpha\,e^{-\alpha^2/2} \\ \Longrightarrow \quad B &\overset{(3)}{=} \frac{n}{\alpha} - \alpha, & A &\overset{(4)}{=} \left(\frac{n}{\alpha}\right)^{n} e^{-\alpha^2/2}. \end{aligned} \tag{T4.27}$$

(1) Equal values at $t = -\alpha$.
(2) Equal slopes; the tail slope $nA(B+\alpha)^{-n-1}$ equals $\frac{n}{B+\alpha}A(B+\alpha)^{-n}$, and the first condition replaces $A(B+\alpha)^{-n}$.
(3) Solve the second condition for B.
(4) Insert $B + \alpha = n/\alpha$ into the first condition.

For $\alpha = 1.5$ and $n = 5$, $B = 1.833$ and $A = 133.6$. The tail then carries 10.4% of the probability, compared with 6.7% for the same region of a Gaussian, while the core, and so the full width at half maximum ($2.355\,\sigma$), is unchanged. Panel (c) of Figure T4.8 shows the difference on a logarithmic scale; it is invisible on a linear one, and yet a few per cent of the signal sits in the tail, where a narrow mass window would lose it.

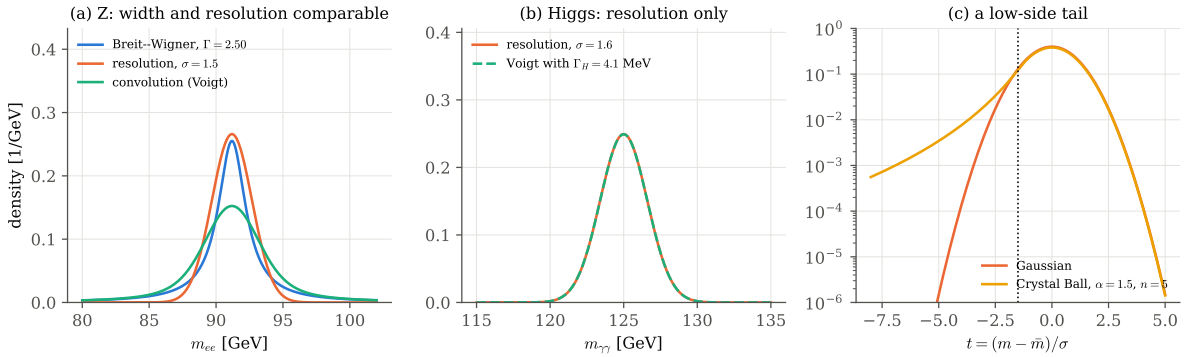

Figure T4.8: Line shapes. (a) For the Z boson, the natural Breit–Wigner width and a 1.5 GeV Gaussian resolution are comparable, and the observed peak is their convolution, wider than either. (b) For the Higgs boson the natural width is four hundred times smaller than the resolution; the convolution (dashed) cannot be told apart from the Gaussian. (c) A Crystal Ball function and a Gaussian with the same core, on a logarithmic scale: below $t = -\alpha$ (dotted) the Crystal Ball falls as a power law, modelling photons that lost energy before reaching the calorimeter.

Where this is used. The signal templates of Section T4.4 and of the capstone (Chapter 13) are peaks of exactly this kind, a Gaussian or Crystal Ball core at the hypothesised mass whose

width is set by (T4.25). The simulated signal of the open data (Section T4.7) has a core of 2.40 GeV and a visible low-side tail. The idea that the detector replaces a true value y by a measured value x with a known probability density, here a Gaussian or a Crystal Ball centred on y, is the *resolution function* of the unfolding problem in Section 6.14, where the question is reversed: given the blurred histogram, what was the true one?

T4.4 Signal and background: where the templates come from

The histogram of the diphoton mass $m_{\gamma\gamma}$ from Section T4.3 has, say, sixty bins of 1 GeV between 100 and 160 GeV. The statistics of Chapter 4 needs, for every bin i, the number of events ν_i we *expect* there. Two kinds of events fill the bins: Higgs decays (the signal) and everything else that produces two photon candidates (the background). Section T4.2 gave the total number of each kind, $\nu = \sigma L \varepsilon A$; Section T4.3 said roughly where the signal lands, in a narrow peak. What is still missing is the full predicted *shape* of each kind, bin by bin, and an honest normalisation of the background. Nobody can write those down from a formula: the shape of a detector's response to millions of different events is not a closed-form function.

The smallest example: two bins. Take only two bins. Bin 1 is a 10 GeV window around 125 GeV, bin 2 is everything else between 100 and 160 GeV. Write the expected counts as

$$\nu_1 = S\, f_1 + B\, g_1, \qquad \nu_2 = S\, f_2 + B\, g_2, \tag{T4.28}$$

where S and B are the expected total numbers of signal and background events, and f_j and g_j are the fractions of each that fall in bin j (so $f_1 + f_2 = 1$ and $g_1 + g_2 = 1$). There are two kinds of dial. The *normalisations* S and B say how many events of each kind there are; the *shapes* f_j and g_j say how they are shared among the bins. For the open data of Section T4.7 the numbers are roughly $S \approx 395$, $f_1 \approx 0.94$, $B \approx 151\,767$ and $g_1 \approx 0.17$: about 371 signal events and 26 254 background events in the window.

A naive choice: simulate everything. Suppose we took both S and B from the Standard Model prediction and a simulation of the detector. The background in the window then carries the uncertainty of the background prediction. Most of the background is genuine photon pairs, but about a quarter is jets that the detector mistook for photons (Section T4.4.3), and how often a jet fakes a photon depends on details of jet formation and of the calorimeter response that simulations reproduce far less precisely than the data count events [29, Sec. 4.2]. Even a 10% error on $B g_1$ is 2600 events, seven times the whole expected signal. The peak would drown in the uncertainty of the floor it sits on.

A better choice, and its price. The data themselves measure the background: away from 125 GeV the histogram contains almost no signal, so the bins on either side of the peak, the **sidebands**, show how many background events there are and how their number falls with mass. With 151 767 events the statistical error on the background level is a fraction of a per cent, not ten per cent. The price is an assumption: to carry the background from the sidebands into the window we must assume a smooth shape for it, and a wrong shape can create or hide a few events of fake signal (Section T4.4.3). The signal, on the other hand, has no sidebands; its shape and its expected size can only come from simulation, and its uncertainty is carried by the calibrations of Section T4.5.

So the division of labour is: signal from simulation, background from the data. Both templates can now be built, and with them the one number the search reports, the signal strength μ. In the language of Cranmer, these are the "simulation narrative" and the "data-driven narrative" of an analysis [29, Secs. 4.1–4.2].

T4.4.1 Simulated events: from the theory to a detector record

The question. Theory predicts the probability of producing two photons with given momenta. What we need is the probability that the *detector records* a photon pair with a given measured mass. How do we get from one to the other?

The answer is to simulate events one at a time, following each step a real event goes through, and then to histogram the results. A simulated event passes through four programs in turn (Figure T4.9) [29, Sec. 4.1], [113, Sec. 3].

1. *The hard process.* A **matrix-element generator** draws the momenta of the outgoing particles of the short-distance collision (for the signal, $gg \to H \to \gamma\gamma$) with the probability density predicted by perturbation theory, multiplied by the parton densities of the protons. ATLAS used Powheg for gluon fusion and vector-boson fusion in 2012 [113, Table 1].
2. *Parton shower and hadronisation.* Quarks and gluons radiate further gluons and then bind into hadrons; programs such as Pythia and Herwig model this with tuned phenomenological parameters. The remnants of the two protons, and the pile-up collisions of Section T4.2.2, are added here.
3. *Detector simulation.* Geant4 tracks every particle through a model of the detector material and records the energy it deposits in each channel [113, Sec. 3].
4. *Reconstruction.* The same programs that process real data turn the simulated deposits into photons, electrons, jets, each with its p_T, η and ϕ (Section T4.1).

Steps 1 and 2 are a model of nature, steps 3 and 4 a model of the experiment. The output has exactly the format of real data, plus the true momenta from step 1, so the same selection can be applied to both.

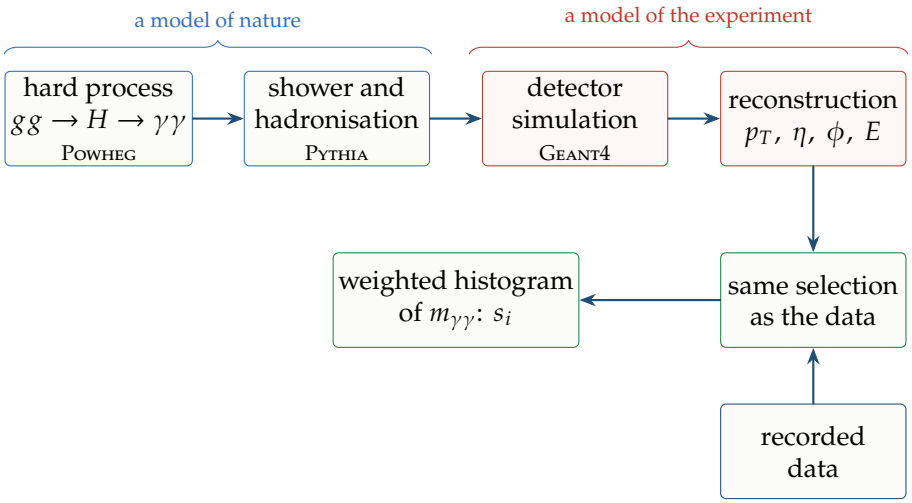

Figure T4.9: How a signal template is made. Each simulated event passes through the programs that model the collision (blue) and the programs that model the detector (red), and comes out in the same format as a recorded event. The selection used on the data is applied to it unchanged, and the surviving events, each with its weight, are histogrammed to give the expected signal count s_i in every bin.

From simulated events to a shape. If the detector were perfect, the distribution of an observable x (here $x = m_{\gamma\gamma}$) would be the normalised differential cross section, $f(x) = (1/\sigma_{\text{eff}})\,\mathrm{d}\sigma_{\text{eff}}/\mathrm{d}x$, with $\sigma_{\text{eff}} = \sigma\varepsilon A$ the effective cross section of (T4.15) [29, (17)]. With a real detector there is no formula, but there is a sample: the values $x_1, \ldots, x_N$ of the simulated events that pass the

selection are draws from the true $f(x)$, and a histogram of them estimates it [29, (18)]. This is the histogram estimate of a density of Section 6.13, with its bin-width trade-off; in a template it is usually harmless, because the bins are chosen narrower than the resolution σ_m of Section T4.3.3 and the simulated sample is large.

Example: what the generator list of 2012 says about the backgrounds. The ATLAS list of generators [113, Table 1] contains one program for the diphoton continuum ($q\bar{q}/gg \to \gamma\gamma$, Sherpa) and several for processes with a W, a Z or top quarks, which matter for the four-lepton and WW channels. It contains no simulation of a photon plus a jet faking a second photon. That background was taken from the data (Section T4.4.3). The list tells us which parts of a search trusted the simulation and which did not.

T4.4.2 Normalising a weighted simulation

The question. A simulated sample has a certain number of events, chosen by whoever generated it; it has nothing to do with the luminosity of the data. *How many real events does one simulated event stand for?*

The simplest case: unweighted events. Suppose the generator produced N_{gen} events of a process with cross section σ, each an independent draw from the produced events. The data contain on average σL produced events of this process. If $N_{\text{sel,i}}$ of the simulated events pass the selection and land in bin i, the fraction $N_{\text{sel,i}}/N_{\text{gen}}$ estimates the probability that a produced event does so (a Monte Carlo average of an indicator, as in the acceptance example of Section 6.11.4). Then $s_i = \sigma L\, N_{\text{sel,i}}/N_{\text{gen}}$: each simulated event counts for $\sigma L/N_{\text{gen}}$ real ones.

Weighted events. Modern generators do not produce equal events. A next-to-leading-order generator gives each event a weight w_e, sometimes negative, so that the *weighted* sample reproduces the predicted distribution. Later, small corrections that make the simulation agree with calibration data multiply each weight by **scale factors** (Section T4.7). The fraction of produced events in a region is then the fraction of the total weight in it, and

$$\begin{aligned} s_i &\overset{(1)}{=} \sigma L\ \mathrm{P}(\text{a produced event is selected and lands in bin } i) \\ &\overset{(2)}{=} \sigma L\, \frac{\sum_{e\in i} w_e}{\sum_{\text{all } e} w_e} \overset{(3)}{=} \sum_{e\in i} \Big(\frac{\sigma L}{W}\Big) w_e, \qquad W \equiv \sum_{\text{all } e} w_e . \end{aligned} \tag{T4.29}$$

(1) The expected number of produced events is σL (Section T4.2); thinning a Poisson count by a probability gives the expected count in bin i.

(2) The probability is estimated by the weighted fraction of simulated events, the self-normalised estimator of Section 6.12.4. The denominator runs over *all* generated events, before any selection; otherwise the efficiency would be lost.

(3) Bring the constant inside the sum: every selected event contributes $\sigma L\, w_e/W$ expected real events.

With all $w_e = 1$, $W = N_{\text{gen}}$ and (T4.29) is the unweighted rule. The capstone uses exactly this formula (Section 13.21.1).

How precise is a simulated template? The simulated sample is finite, so s_i has a statistical error of its own. Think of the simulated events landing in bin i as a Poisson number K of events with mean λ, each carrying an independent weight w. The sum $S_i = \sum_{k=1}^{K} w_k$ then has

$$\begin{aligned} \mathrm{Var}(S_i) &\overset{(1)}{=} \mathbb{E}\big[\mathrm{Var}(S_i \mid K)\big] + \mathrm{Var}\big[\mathbb{E}(S_i \mid K)\big] \overset{(2)}{=} \mathbb{E}[K]\,\mathrm{Var}(w) + \mathrm{Var}(K)\big(\mathbb{E}\,w\big)^2 \\ &\overset{(3)}{=} \lambda\big[\mathrm{Var}(w) + (\mathbb{E}\,w)^2\big] \overset{(4)}{=} \lambda\ \mathbb{E}[w^2] \ \approx\ \sum_{e\in i} w_e^2 . \end{aligned} \tag{T4.30}$$

(1) The law of total variance (1.52), conditioning on the number of events K.
(2) Given K, the sum of K independent weights has variance $K\,\mathrm{Var}(w)$ and mean $K\,\mathbb{E}\,w$.
(3) K is Poisson, so $\mathbb{E}\,K = \mathrm{Var}\,K = \lambda$.
(4) $\mathrm{Var}(w) + (\mathbb{E}\,w)^2 = \mathbb{E}[w^2]$; the expected sum of squared weights $\lambda\,\mathbb{E}[w^2]$ is estimated by the observed one.

So the Monte Carlo error of s_i is $(\sigma L/W)\sqrt{\sum_{e\in i} w_e^2}$. For unit weights it is $(\sigma L/N_{\mathrm{gen}})\sqrt{N_{\mathrm{sel,i}}}$, the familiar $1/\sqrt{N}$ of a count. Unequal weights make it larger, as if the sample contained only $N_{\mathrm{eff}} = \left(\sum w_e\right)^2/\sum w_e^2$ equal events.

Example: the expected Higgs signal in the open data. The gluon-fusion file of the open data (Section T4.7) stores $\sigma B = 0.102\,\mathrm{pb}$ and the sum of the weights of all generated events, $W = 55\,922\,616$. It contains 1 054 711 events, those that survived a two-photon preselection. With $L = 10\,\mathrm{fb}^{-1} = 10\,000\,\mathrm{pb}^{-1}$ each unit of weight stands for $\sigma BL/W = 0.102 \times 10\,000/55\,922\,616 = 1.82\times10^{-5}$ real events. The selection of Section T4.2.3 keeps a weighted fraction $\varepsilon A = 0.3872$, so

$$\nu_S = \sigma B\, L\, \varepsilon A = 1020 \times 0.3872 = 395$$

selected signal events between 100 and 160 GeV, with a Monte Carlo error from (T4.30) of 0.48 events. That error is a tenth of a per cent: with a million simulated events, the template's own statistical error is negligible next to the Poisson fluctuation of the data in the same region (about 160 events, Section T4.4.3). For small simulated samples it is not negligible, and HistFactory gives each bin a nuisance parameter for it, constrained by a Poisson term whose effective count is $(s_i/\delta s_i)^2$ [120, (9)].[1]

Example: several processes in one template. The signal has four production modes (gluon fusion, vector-boson fusion, and production with a W or a Z; Section T4.6), each simulated in its own file with its own σ and W. Processes that do not interfere quantum mechanically add incoherently, so their expected counts add bin by bin, $s_i = \sum_{\mathrm{samples}} s_i^{(k)}$, and the normalised shape is the mixture $f(x) = \sum_k \nu_k f_k(x)/\sum_k \nu_k$ [29, (20)–(21)], [Cowan §6.9]. Processes that *do* interfere must be simulated together as one sample. The 2012 analysis is an example: gluon fusion to a Higgs boson and gluon fusion directly to two photons lead to the same final state, their amplitudes interfere destructively, and ATLAS lowered the gluon-fusion rate by 2–5% to account for it [113, Sec. 5.4].

T4.4.3 The background from the data: sidebands

What is in the background? Three kinds of event give two photon candidates. Real photon pairs from quark–antiquark annihilation or gluon fusion through a quark loop (the *irreducible* background, $\gamma\gamma$). A photon and a jet in which one hadron, typically a neutral pion decaying to two nearly collinear photons, looks like a single photon (γj). Two such jets (jj). The last two are *reducible*: better identification and isolation reduce them. ATLAS measured the composition of its selected 2012 sample with data-driven techniques: 74% $\gamma\gamma$, 22% γj, 3% jj and 1% Drell–Yan electron pairs mistaken for photons [113, Sec. 5.2]. That decomposition was used only to study the background shape; the search itself fitted the background directly to the data.

The method. In every event category ATLAS fitted the $m_{\gamma\gamma}$ spectrum between 100 and 160 GeV with a smooth function whose parameters were free: a fourth-order Bernstein polynomial, the exponential of a second-order polynomial, or a single exponential, depending on the category

[1] The text of [120, Sec. 2.2.1] writes the effective count as $(\delta_b/\nu_b^{\mathrm{MC}})^2$, the inverse; the next sentence there, $\tau_b = (\nu_b^{\mathrm{MC}}/\delta_b)^2$, has it the right way round. For unit weights, $(s_i/\delta s_i)^2 = N_{\mathrm{sel,i}}$, as it should be.

[113, Sec. 5.5]. The function plays the role of the background template b_i, with its normalisation and shape parameters measured by the data themselves. Cranmer calls this the "effective model narrative": no physical model of the background, only a flexible enough curve [29, Secs. 4.2–4.3].

What could go wrong: the spurious signal. A smooth function that is not flexible enough can bend away from the true background shape near 125 GeV and leave a deficit or excess there that the fit then attributes to signal. ATLAS measured this directly. They fitted signal plus background models to very large simulated background samples, which contain no signal at all, and recorded the largest fitted "signal" over the mass range [113, Sec. 5.5]. A function was accepted only if this **spurious signal** was below 20% of the statistical error of the fitted signal; the remaining spurious signal, 0.2–4.6 events at 7 TeV and 0.3–6.8 events at 8 TeV depending on the category, was kept as a systematic uncertainty. The capstone repeats this test on the open data (Section 13.22.2).

Example: an exponential through the sidebands of the open data. As an illustration, the script `02_open_data.py` of Section T4.7 histograms the 151 767 selected diphoton masses of the 2016 open data in 1 GeV bins and, without a proper fit or uncertainties, draws a straight line through the logarithm of the counts in the bins outside 120–130 GeV. The slope is −0.0231 per GeV: the background falls by 2.3% for every GeV of mass. Extrapolated into the window, the exponential predicts $b = 26\,254$ background events between 120 and 130 GeV, where 26 457 events were recorded. The simulated Standard Model signal from Section T4.4.2, histogrammed with (T4.29), puts $s = 371.2$ expected events in the same window. Panel (a) of Figure T4.10 shows the three side by side.

The numbers give the problem its size. The signal is $s/b = 1.41\%$ of the background in the window, far too small to see by eye; the typical Poisson fluctuation of the background count is $\sqrt{b} = 162$ events; and the ratio $s/\sqrt{b} = 2.29$ is the rough number of such fluctuations the expected signal amounts to. Whether that is enough, and how much better the full histogram does than one window, is decided by the statistic q_0 and its Asimov approximation in Sections 4.16 and 4.16.3. The excess of recorded over predicted events, 26 457 − 26 254 = 203, is about one such fluctuation.

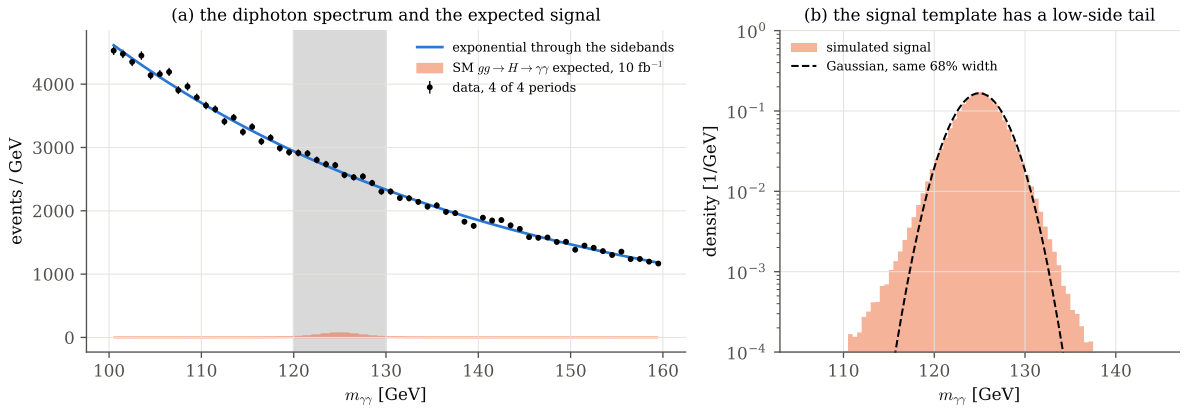

Figure T4.10: (a) The diphoton mass spectrum of the 2016 open data after the selection of Section T4.2.3, with an exponential drawn through the sidebands outside the grey window, and the expected Standard Model gluon-fusion signal (filled) at the bottom of the plot: a few dozen events per GeV under a background of thousands. (b) The simulated signal shape on a logarithmic scale against a Gaussian of the same central 68% width. The core is Gaussian; the low-mass side has the tail of photons that lost energy, the shape the Crystal Ball of (T4.26) was built for.

Example: the signal template's width and tail. Panel (b) of Figure T4.10 is the signal template of the open data. Its median is 125.0 GeV and half of its central 68% range is 2.40 GeV. Of the weighted signal, 93.1% lies within two such widths of the median (a Gaussian would have 95.4%), 0.83% lies more than three widths below and 0.54% more than three widths above (a Gaussian would have 0.13% on each side). This half-width is not the same quantity as the Crystal Ball core width $\sigma_{\mathrm{CB}} = 1.6$ GeV of the 2012 analysis: the central 68% range includes part of the tails, which a core width ignores. The asymmetry of the tails is the energy loss described in Section T4.3.3; Section 13.22.1 fits the shape properly.

T4.4.4 The signal strength

The question. The search must be able to say "there is no signal", "there is the predicted signal", and anything in between or beyond. *Which single number expresses that?*

For a fixed hypothesised mass m_H, the Standard Model fixes the cross section of every production mode, every branching fraction, and so the size and shape of the signal template. The searches of 2012 therefore did not fit the Higgs couplings themselves. They introduced one factor that scales the predicted signal [29, Sec. 4.1.2.1], [113, Sec. 7]:

$$\mu = \frac{\sigma\, B}{(\sigma\, B)_{\mathrm{SM}}}, \qquad \nu_i(\mu) = \mu\, s_i + b_i, \qquad s_i = (\sigma B)_{\mathrm{SM}}\, L\, \varepsilon A\, f_i. \tag{T4.31}$$

Here s_i is the Standard Model signal template in bin i (the expected count (T4.29), with the fraction f_i of the selected signal falling in that bin), b_i the background template, and μ the **signal strength**. The value $\mu = 0$ is the background-only hypothesis, the null hypothesis of the discovery test; $\mu = 1$ is the Standard Model Higgs boson; any other value is a signal of the predicted shape but a different size. The second relation is the template model (4.88) of Section 4.15, where its likelihood is written down.

Working definition T4.5 (signal strength)

The **signal strength** μ is the ratio of the true signal rate to the Standard Model prediction for the same mass hypothesis, $\mu = \sigma B/(\sigma B)_{\mathrm{SM}}$ [cross section times branching fraction into the final state that is searched]. *Operationally:* multiply the simulated signal template by μ, add the background template, and compare with the data bin by bin, $\nu_i = \mu s_i + b_i$.

What μ can and cannot tell apart. A diphoton search counts events of production times decay, so it measures only the product σB. A Higgs boson produced twice as often and decaying to photons half as often gives the same $\mu = 1$. Nor can it tell μ from anything else that multiplies the signal: a luminosity or a photon efficiency 10% higher than assumed gives exactly the same histogram as a μ 10% higher. Only an independent calibration separates the two, which is why every such factor enters the search as a nuisance parameter with its own calibration measurement (Section T4.5). Finally, one μ for all production modes is a convenience; a theory beyond the Standard Model would change the modes differently, and once a signal was seen ATLAS also fitted separate strengths $\mu_i = \sigma_i/\sigma_{i,\mathrm{SM}}$ for groups of modes [113, Sec. 9.3].

Example: what $\mu = 1.4$ would mean in the open data. ATLAS measured $\hat{\mu} = 1.4 \pm 0.3$ in 2012 (Section T4.6). If the true signal strength were 1.4, the 120–130 GeV window of the open data would hold $1.4 \times 371.2 = 520$ signal events on top of the background instead of 371, a difference of 150 events: less than one Poisson fluctuation of the background count (162). A single window of the open data cannot distinguish $\mu = 1$ from $\mu = 1.4$; the full histogram and the precise statistics of Section 4.15 are needed even to see the signal.

Key idea: Signal from simulation, background from the data

The expected count in bin i is $\nu_i = \mu s_i + b_i$. The signal template s_i is a weighted histogram of simulated events, normalised by $\sigma L w_e / W$ per event; the background template b_i is a smooth function whose parameters are measured by the sidebands of the data. The signal strength $\mu = \sigma B/(\sigma B)_{\mathrm{SM}}$ scales the predicted signal: $\mu = 0$ is no signal, $\mu = 1$ the Standard Model.

Where this is used. The template model $\nu_i = \mu s_i + b_i$ and its Poisson likelihood are Sections 4.15 and 4.15.1; the scan of a peak template over the mass axis is Section 4.14.3. The capstone builds the signal template from the four simulated production modes with (T4.29) and fits the background shape to the sidebands (Sections 13.22 and 13.22.1). The response of a detector to a true value, which the simulation chain of Figure T4.9 encodes, is the response matrix of the unfolding problem in Section 6.14 [Cowan §11.1].

T4.5 Systematic uncertainties: nuisance parameters and their calibrations

Every ingredient of the expected count $\nu_i = \mu s_i + b_i$ of Section T4.4 was measured or computed by someone, and none exactly. The luminosity L came from a calibration of the beams, the photon efficiency from a study of electrons, the energy scale that places the peak from the Z boson, the cross section from a perturbative calculation truncated at some order. *How does each of these imperfections enter the prediction, and what keeps it under control?*

The smallest example: one bin, one calibration. Take a single counting window with expected count $\nu = \mu\,\kappa\,s + b$. Here s is the nominal Standard Model signal in the window, b the background, and κ the ratio of the true value of luminosity times efficiency to the value assumed when s was computed; $\kappa = 1$ if the calibrations were perfect. The two dials μ and κ appear only as their product. Any data in this window are explained equally well by $(\mu, \kappa) = (1.4, 1)$ and by $(1, 1.4)$.

The naive choice. Fix $\kappa = 1$ and ignore it. If the true luminosity times efficiency is in fact 11% lower, the fitted μ comes out 11% low, and no amount of data reveals it: more events only make the wrong answer more precise.

The better choice, and its price. Measure κ separately, in a calibration that does not involve the Higgs signal at all, and carry its result and its error into the search. Then $\mu\kappa$ is measured by the window and κ by the calibration, and μ follows. The price is a floor on the precision. With infinite data in the window the product $\mu\kappa$ is known exactly, and the relative error on μ is still the relative error of the calibration. For the diphoton search of 2012, the photon efficiency alone was known to 11% at 8 TeV [113, Sec. 5.6], so μ could not have been measured better than about 11% however many collisions were recorded.

The lesson: a parameter the data cannot separate from the signal must be pinned down by its own measurement, and that measurement's precision becomes part of the result. Each such parameter is a **nuisance parameter** [a parameter the prediction depends on and that we must fit, but do not want to report], and the measurement that pins it down is an **auxiliary** or **calibration measurement** [29, Sec. 2.2], [114, §40.2.2.2]. A diphoton search has about a dozen such parameters, each with a size, an effect on the templates and a calibration behind it.

T4.5.1 Sources and their effects

Cranmer makes one distinction the bookkeeping depends on: the *source* of an uncertainty (for example, the calorimeter's energy calibration) is not the same thing as its *effect* on a particular template (the signal peak moves; the background shape hardly changes) [29, Sec. 4.1.4]. One source gets one nuisance parameter, even if it affects many templates, channels and data sets. ATLAS treated the luminosity as fully correlated across the diphoton, four-lepton and WW channels, and the photon and electron energy scales as five shared parameters [113, Sec. 8]. The effects come in three kinds, which HistFactory calls by the names in brackets [120, Table 1]:

- *Normalisation* (`OverallSys`): the whole template is multiplied by a factor near one. Luminosity, efficiencies and cross sections act this way.
- *Shape* (`HistoSys`): the fractions f_i themselves change. The energy scale moves the peak; the resolution widens or narrows it.
- *Bin by bin* (`StatError`, `ShapeSys`): each bin gets its own factor, for example for the finite simulated sample of (T4.30).

Figure T4.11 draws the sources of the 2012 diphoton search with the effect each one has.

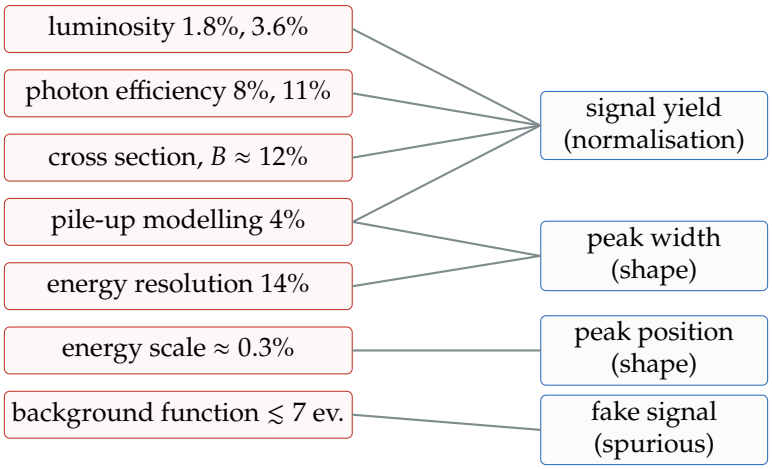

Figure T4.11: The main sources of systematic uncertainty in the 2012 diphoton search (left, with their sizes; two numbers are for the 7 and 8 TeV data) and the effect each has on the templates (right). Most sources only rescale the expected signal. The energy scale moves the peak, the resolution changes its width, and pile-up does both. The background function's uncertainty is a number of events of spurious signal per category.

Example: why the photon efficiency counts twice. Every selected event has two photons, and each passes the identification with probability ε_γ, so the yield is proportional to $\varepsilon_{\gamma 1}\varepsilon_{\gamma 2}$. A calibration error that moves both efficiencies in the same direction by $\delta\varepsilon_\gamma/\varepsilon_\gamma$ changes the yield by

$$\frac{\delta N}{N} \overset{(1)}{=} \frac{\delta\varepsilon_{\gamma 1}}{\varepsilon_{\gamma 1}} + \frac{\delta\varepsilon_{\gamma 2}}{\varepsilon_{\gamma 2}} \overset{(2)}{=} 2\,\frac{\delta\varepsilon_\gamma}{\varepsilon_\gamma}. \tag{T4.32}$$

(1) The logarithm of a product is the sum of the logarithms; differentiate.
(2) The same calibration applies to both photons, so the two errors are equal and add linearly, not in quadrature.

A per-photon uncertainty of 5.5% thus becomes the 11% on the yield quoted for the 8 TeV data.

Example: adding up the yield uncertainties. For the 8 TeV diphoton signal the experimental normalisation uncertainties are the photon efficiency (11%), pile-up (4%), luminosity (3.6%), trigger (1%) and isolation (0.5%) [113, Sec. 5.6]; the theory uncertainties on the gluon-fusion prediction are the QCD scale (+7/−8%, about 7.5%), the parton densities (8%) and the branching fraction (5%) [113, Sec. 8]. The sources are independent, so their variances add (Section 3.6):

$$\left(\frac{\delta\nu}{\nu}\right)_{\text{exp}} \overset{(1)}{=} \sqrt{11^2 + 4^2 + 3.6^2 + 1^2 + 0.5^2}\,\% = 12.3\%,$$
$$\left(\frac{\delta\nu}{\nu}\right)_{\text{th}} \overset{(1)}{=} \sqrt{7.5^2 + 8^2 + 5^2}\,\% = 12.1\%, \qquad \left(\frac{\delta\nu}{\nu}\right)_{\text{tot}} \overset{(2)}{=} \sqrt{12.3^2 + 12.1^2}\,\% = 17\%. \tag{T4.33}$$

(1) Independent relative errors on factors of a product add in quadrature.
(2) The experimental and theoretical groups are independent of each other as well.

The one large experimental term dominates its group: removing the luminosity entirely would lower 12.3% only to 11.8%. This is typical of quadrature sums and tells an analysis where improvement pays.

Example: the peak moves with the energy scale. Suppose every measured photon energy is too large by the same fraction δ: $E_j \to (1+\delta)E_j$. The angle between the photons is unchanged, so by (T4.18)

$$m'^2_{\gamma\gamma} \overset{(1)}{=} 2\,(1+\delta)E_1\,(1+\delta)E_2\,(1-\cos\theta_{12}) \overset{(2)}{=} (1+\delta)^2\, m^2_{\gamma\gamma}, \qquad \text{so} \qquad \frac{\delta m}{m} = \delta. \tag{T4.34}$$

(1) Insert the scaled energies into $m^2 = 2E_1E_2(1-\cos\theta_{12})$.
(2) Factor out $(1+\delta)^2$; the square root gives $m' = (1+\delta)m$.

A common scale error moves the whole peak by the same fraction and leaves its relative width unchanged. ATLAS quoted a systematic error of 0.4 GeV on the mass 126.0 GeV, dominated by the photon and electron energy scales [113, Sec. 9.3]: a scale known to about 0.3%. That is $0.3\% \times 125 = 0.375$ GeV of peak shift, a quarter of the peak's width.

What the three kinds of effect look like. The script `01_mass_lineshape.py` takes a Crystal Ball signal template of core width 1.6 GeV, the shape of (T4.26) with the 2012 width, and applies a ±0.3% energy-scale shift, a ±14% resolution change (the total ATLAS uncertainty on the mass resolution, itself the quadrature sum $\sqrt{12^2 + 6^2 + 4^2} = 14$ of calorimeter resolution, detector material and pile-up [113, Sec. 5.6]) and a ±11% yield change (Figure T4.12). The fraction of the signal inside a ±2 GeV window around 125 GeV is 75.5% nominally, 69.6% and 81.8% for the wider and narrower peak, and 74.3% after the scale shift. A shape uncertainty is therefore also a normalisation uncertainty for any analysis that counts in a fixed window, and the two must not be counted twice.

T4.5.2 From up and down variations to a continuous parameter

The question. A calibration study delivers, for each source, the template at its nominal value and at "plus one" and "minus one" standard deviation. The likelihood of Chapter 4 needs the template at *every* value of the nuisance parameter. *How is the gap filled?*

The convention is to define a parameter α for each source (not the tail parameter of the Crystal Ball (T4.26)) with $\alpha = 0$ the nominal value and $\alpha = \pm 1$ the one-standard-deviation variations, and to interpolate. The simplest rule, used for a normalisation factor $r(\alpha)$ with variations $r^{\pm}$ (HistFactory calls it η, which here would be confused with the pseudorapidity), is

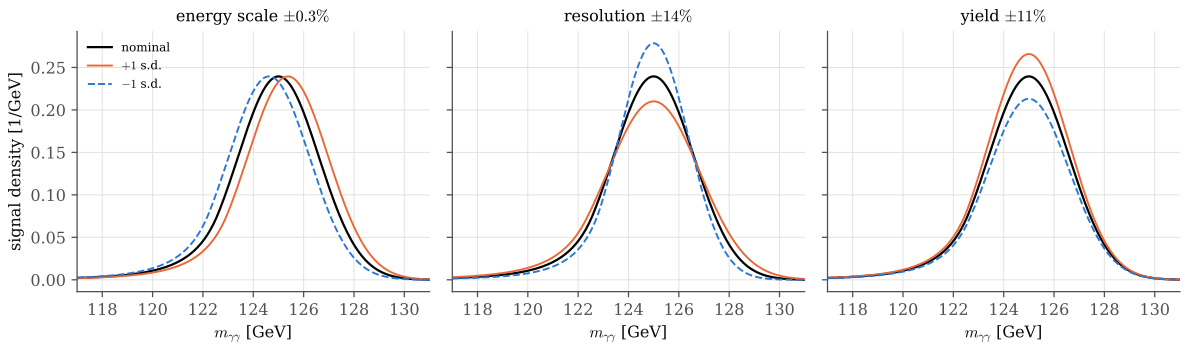

Figure T4.12: The three effects of a systematic uncertainty on a signal template, with "up" and "down" variations by one standard deviation. Left: an energy-scale shift of 0.3% slides the peak sideways by 0.4 GeV. Middle: a 14% change of the resolution makes the peak wider and lower, or narrower and taller, with the same area. Right: an 11% change of the yield rescales the peak without changing its shape.

piecewise linear [29, (23)–(25)]:

$$r(\alpha) = \begin{cases} 1 + \alpha\,(r^{+} - 1), & \alpha \geq 0, \\ 1 + \alpha\,(1 - r^{-}), & \alpha < 0, \end{cases} \tag{T4.35}$$

and the same rule, bin by bin, interpolates the up and down templates of a shape uncertainty. For the 8 TeV luminosity, $r^{\pm} = 1 \pm 0.036$; half a standard deviation up, $\alpha = 0.5$, scales the signal by 1.018. HistFactory assembles all of this into one expression for the expected count of sample s in bin b [120, (6)],

$$\nu_{sb} = \lambda\ \gamma_b\ \phi_s\ r_s(\boldsymbol{\alpha})\ \sigma_{sb}(\boldsymbol{\alpha}), \tag{T4.36}$$

which reads, in our notation: the luminosity $\lambda = L$; a per-bin factor γ_b for the Monte Carlo statistics; free factors ϕ_s, of which the signal strength μ is one; the interpolated normalisation (T4.35) (HistFactory's η_s); and the interpolated template σ_{sb}, our s_i or b_i. Every factor except ϕ_s comes with a constraint from its calibration.

Watch out: An up/down pair is not a measurement of the shape

Interpolating between three templates assumes the template changes smoothly and, in each bin separately, roughly linearly with α. A peak that *moves* violates this: halfway between a template shifted left and one shifted right, bin-by-bin interpolation gives a broadened or even two-humped peak, not a peak shifted halfway. Cranmer points to "horizontal" interpolation for such cases [29, Sec. 4.1.5]; the diphoton searches sidestep it because their signal model is an analytic function of the mass, whose mean can simply be shifted, $f(m \mid \bar{m}(1+\delta), \sigma_m)$.

T4.5.3 Calibrations: how a nuisance parameter is measured

A nuisance parameter is only as good as the measurement that constrains it. Two calibrations matter most for a diphoton search: the luminosity, which sets every normalisation, and the photon energy scale, which places the peak.

The luminosity: a van der Meer scan. Section T4.2.2 derived the luminosity from the overlap of two bunches, $L_{\text{inst}} \propto N_1 N_2 \int \rho_1 \rho_2 \, dx\, dy$. The bunch populations N_1, N_2 are measured by current monitors on the beams. The overlap integral is the hard part: the transverse sizes of the

beams at the collision point, a few tens of micrometres, cannot be measured directly with the needed precision. Van der Meer's idea is to measure the overlap by moving the beams. *What happens to the rate of collisions when one beam is displaced sideways by Δ?*

Let the x profiles of the two bunches be Gaussians of widths s_1 and s_2. The x part of the overlap at separation Δ is $\int g(x;s_1)\,g(x-\Delta;s_2)\,\mathrm{d}x$. This is the convolution integral (1.39): it is the probability density, at the value Δ, of the difference $X_1 - X_2$ of two independent Gaussian positions. A difference of independent Gaussians is Gaussian with the variances added, so

$$\int g(x;s_1)\,g(x-\Delta;s_2)\,\mathrm{d}x = \frac{1}{\sqrt{2\pi}\,\Sigma_x}\,e^{-\Delta^2/2\Sigma_x^2}, \qquad \Sigma_x = \sqrt{s_1^2+s_2^2}. \tag{T4.37}$$

For equal beams, $\Sigma_x = \sqrt{2}\,\sigma_x$ and this is (T4.10). The rate R of any process seen by a luminosity detector is proportional to the overlap, so scanning Δ and recording $R(\Delta)$ traces a Gaussian whose width is Σ_x. A second scan in y gives Σ_y. With them the head-on luminosity of one pair of bunches is known in absolute terms, $L_0 = f N_1 N_2/(2\pi\Sigma_x\Sigma_y)$, and the peak rate of the scan defines the detector's **visible cross section** $\sigma_{\mathrm{vis}} = R_0/L_0$. From then on, in ordinary running, every measured rate converts to a luminosity as $L_{\mathrm{inst}} = R/\sigma_{\mathrm{vis}}$.

The toy scan. The script `03_luminosity.py` simulates such a scan for one pair of LHC design bunches ($\sigma_x = 16.7\,\mu$m, so $\Sigma_x = 23.62\,\mu$m) and a luminosity detector with $\sigma_{\mathrm{vis}} = 60\,$mb. It counts Poisson events for 0.2 s at each of 25 separations between $\pm 5\Sigma_x$ and fits a Gaussian to the rates (Figure T4.13). The fit returns $\Sigma_x = 23.59 \pm 0.03\,\mu$m, a precision of 0.13%, and $\sigma_{\mathrm{vis}} = 60.04\,$mb against the true 60. Panel (b) checks the overlap formula itself: the integral done numerically on a grid agrees with $e^{-\Delta^2/4\sigma^2}$ to a relative 3.531×10^{-14}.

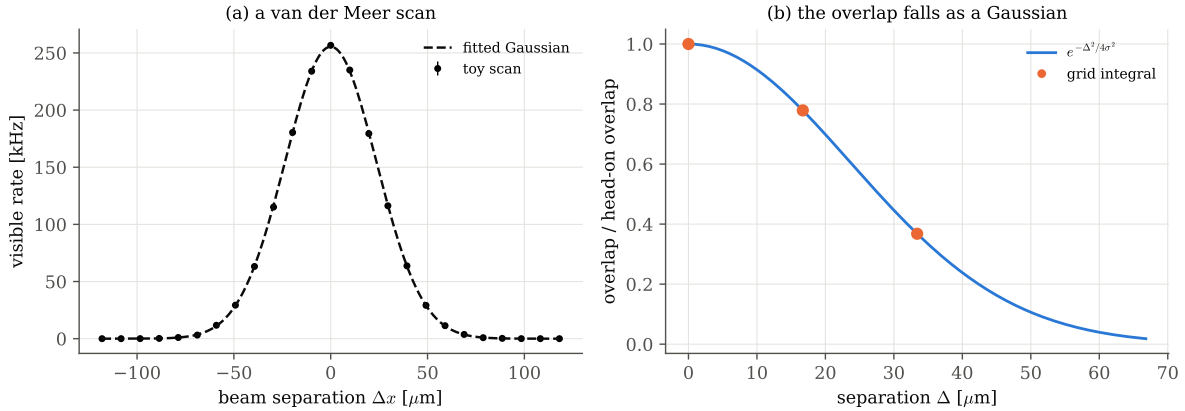

Figure T4.13: (a) A toy van der Meer scan: the collision rate seen by a luminosity detector as one beam is moved sideways across the other. The rate traces a Gaussian whose width is the combined size Σ_x of the two beams, which is what the luminosity formula needs. (b) The overlap of two equal Gaussian bunches falls with their separation as $e^{-\Delta^2/4\sigma^2}$; the points are the overlap integral computed numerically.

The toy's statistical precision, a tenth of a per cent, is far better than the luminosity uncertainties of 1.8% and 3.6% that ATLAS quoted for 2011 and 2012 [113, Sec. 4.3]. The real uncertainty comes from what the toy leaves out: bunch profiles that are not exactly Gaussian or do not factorise into an x part times a y part, the calibration of the separation Δ itself, and the stability of the luminosity detector between the scan, done in special conditions, and months of ordinary running. The toy shows the principle; the systematics of the real calibration set the number.

The energy scale: the Z boson as a standard candle. The Z boson's mass is known to 2 MeV, and $Z \to e^+e^-$ decays are plentiful. Electrons and photons make nearly the same showers in the calorimeter. So the electron pairs measure the energy scale: if the reconstructed m_{ee} peak sits at $(1+\delta)\,m_Z$, then by (T4.34) the electron energies are too large by the fraction δ, and they are corrected by $1/(1+\delta)$. ATLAS derived such η-dependent corrections, of order ±1%, from $Z \to e^+e^-$ events, and calibrated the photon identification and isolation efficiencies on electrons from Z decays and on photons radiated in $Z \to \ell^+\ell^-\gamma$ decays [113, Secs. 5.1, 5.6]. What remains uncertain is the transfer from electrons to photons (the material in front of the calorimeter affects them differently), which is why the material description appears among the scale and resolution uncertainties.

How a calibration enters the search. A calibration is a measurement with a result a_k and an error σ_k. Its probability, read as a function of the true parameter θ_k, is a likelihood factor that multiplies the likelihood of the search histogram [114, (40.17)], [29, Sec. 2.2]. Section 4.15.2 writes this full likelihood (4.89) with Gaussian constraint terms (4.90), and Section 4.15.3 removes the nuisance parameters by profiling.

Key idea: One source, one parameter, one calibration

Each source of systematic uncertainty is a nuisance parameter α_k, with $\alpha_k = 0$ nominal and $\alpha_k = \pm 1$ its one-standard-deviation variations. It can rescale templates (luminosity, efficiencies, cross sections), move or widen them (energy scale, resolution), or fake a signal (background function). Its value is constrained by an independent calibration measurement, whose likelihood multiplies that of the search.

Where this is used. The nuisance parameters $\boldsymbol{\theta} = (\beta, \kappa, \delta)$ of Section 4.15.2, a background normalisation, a signal yield and an energy-scale shift, are three of the sources above in their simplest form; their constraint terms are the calibrations of this section. In the capstone (Chapter 13), the selection script `code/ch13/31_hyy_select.py` reads the release's `photon_pt_syst` column (Section T4.7) to size the energy-scale variation, and the spurious-signal test of Section 13.22.2 sizes the uncertainty of the background function.

T4.6 The Higgs boson search of 2012

On 4 July 2012 the ATLAS and CMS collaborations reported, each with its own detector and its own analysis, an excess of events near 125 GeV that the background could hardly produce, and that looked like the decays of the Higgs boson [113, 119]. Those two papers use every piece assembled so far: cross sections and luminosities, invariant masses of photon and lepton pairs, simulated signal templates, background functions fitted to sidebands, a signal strength, nuisance parameters with calibrations, and finally a local and a global significance. The diphoton part of the search is also the template for the capstone of Chapter 13.

T4.6.1 Their question and their setup

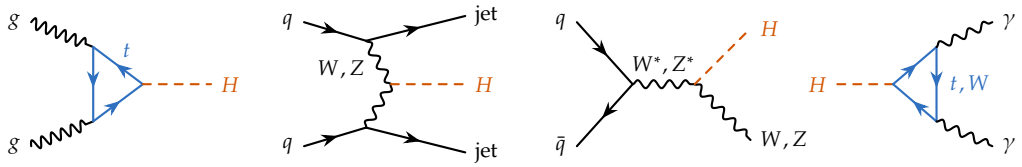
The question. Is there a particle with the properties of the Standard Model Higgs boson, and if so, at what mass? By 2011 the earlier experiments and the first LHC data had excluded most masses below 600 GeV except a window between 114 and 127 GeV, and both LHC experiments had seen excesses near 125 GeV of about three standard deviations [113, Sec. 1]. Three standard deviations had come and gone before. The 2012 data were to settle it.

What the theory fixes. For a given Higgs mass m_H, the Standard Model predicts everything

else: how often the boson is made, and how often it decays into each final state. There are four main ways to make it at the LHC [113, Sec. 3], drawn in Figure T4.14.

- *Gluon fusion* (ggF): two gluons make a Higgs boson through a loop of top quarks. About 88% of the diphoton signal at $m_H = 126.5\,\text{GeV}$.
- *Vector-boson fusion* (VBF): two quarks each radiate a W or Z, which fuse; the two quarks fly off as jets close to the beams. About 7%.
- *Associated production* with a W or Z (WH, ZH): a quark and an antiquark make a heavy vector boson that radiates the Higgs boson. About 3% and 2%.
- *Production with a top-quark pair* ($t\bar{t}H$): about 0.5%.

These are the fractions ATLAS quotes for its diphoton signal [113, Sec. 5.4]. The total cross section at $m_H = 125\,\text{GeV}$ was predicted to be 17.5 pb at $\sqrt{s} = 7\,\text{TeV}$ and 22.3 pb at 8 TeV [113, Sec. 3].



(a) ggF, 88% (b) VBF, 7% (c) WH, ZH, 5% (d) $H \to \gamma\gamma$

Figure T4.14: How a Higgs boson is made at the LHC (a–c, with the share of each mode in the 2012 diphoton signal; $t\bar{t}H$, 0.5%, is not drawn) and how it decays to two photons (d). The Higgs boson couples to mass, so it couples neither to the massless gluons nor to the photons directly; both (a) and (d) go through a loop of heavy charged particles, which is why the diphoton branching fraction is only about two per mille.

The channels. A Higgs boson of 125 GeV decays mostly to $b\bar{b}$, but the LHC makes b-quark pairs by the billion. Two final states combine a small branching fraction with a clean signature and an excellent mass resolution [113, Secs. 4–5], [119, Sec. 1]:

- $H \to \gamma\gamma$: two isolated photons, $\sigma B = 50\,\text{fb}$ at 8 TeV, mass resolution 1.6 GeV (Section T4.3.3);
- $H \to ZZ^{(*)} \to 4\ell$: two pairs of electrons or muons, one pair with the mass of a Z, $\sigma B = 2.8\,\text{fb}$ at 8 TeV, resolution 1.7–2.3 GeV.

The superscript $(*)$ says that one of the two Z bosons is off its mass shell: 125 GeV is not enough to make two real Z bosons of 91 GeV each. ATLAS added $H \to WW^{(*)} \to e\nu\mu\nu$, which has many more events but, with two neutrinos escaping, no peak in any mass. CMS also used $\tau\tau$ and $b\bar{b}$. The data sets were small by later standards; Table T4.1 collects them.

	ATLAS [113]	CMS [119]
data, 7 TeV (2011)	4.6–4.8 fb^{-1}	4.9–5.1 fb^{-1}
data, 8 TeV (2012)	5.8–5.9 fb^{-1}	5.0–5.3 fb^{-1}
channels	$\gamma\gamma$, 4ℓ, WW (+ $b\bar{b}$, $\tau\tau$ at 7 TeV)	$\gamma\gamma$, 4ℓ, WW, $\tau\tau$, $b\bar{b}$
pile-up per crossing	about 10 (7 TeV), 20 (8 TeV)	—
$\gamma\gamma$ events, 100–160 GeV	23 788 (7 TeV), 35 251 (8 TeV)	—

Table T4.1: The data of the two discovery papers. The luminosity ranges reflect the different data-quality requirements of the channels.

T4.6.2 Their expected counts, recomputed

The key equation. The expected number of selected signal events in each channel is (T4.15), $\nu_S = \sigma B\, L\, \varepsilon A$, with σB the predicted cross section times branching fraction, L the integrated luminosity and εA the fraction of produced events that survive the selection (Section T4.2.3). Both papers quote all four numbers or enough of them to recompute the others. Doing so shows what a discovery with 10 fb^{-1} looked like in events.

Example: the diphoton channel at 8 TeV. ATLAS expected $N_S = 110.5$ signal events in all categories together between 100 and 160 GeV, from $\sigma B = 50$ fb and $L = 5.9$ fb^{-1} [113, Table 4]. Then

$$\sigma B\, L = 50\,\text{fb} \times 5.9\,\text{fb}^{-1} = 295 \text{ produced}, \qquad \varepsilon A \overset{(1)}{=} \frac{N_S}{\sigma B L} = \frac{110.5}{295} = 0.375. \tag{T4.38}$$

(1) Solve $N_S = \sigma B L\, \varepsilon A$ for the selection efficiency.

ATLAS quotes an overall selection efficiency of "about 40%" [113, Sec. 5.4]. The recomputed 37.5% is a little lower because N_S also includes the 2–5% reduction of the gluon-fusion rate from interference (Section T4.4.2), and because "about" is about. The same selection kept $N_D = 35\,251$ data events in the same 60 GeV range. The signal was 0.3% of the selected events, concentrated in a few GeV.

Example: the four-lepton channel. The four-lepton signal is tiny: $\sigma B = 2.2$ fb at 7 TeV and 2.8 fb at 8 TeV [113, Sec. 4], so with 4.8 and 5.8 fb^{-1}

$$\sigma B L = 2.2 \times 4.8 + 2.8 \times 5.8 = 10.6 + 16.2 = 26.8 \text{ produced four-lepton decays.} \tag{T4.39}$$

In a window of ±5 GeV around 125 GeV ATLAS expected 5.3 signal events (2.09 + 2.29 + 0.90 in the 4μ, mixed and $4e$ sub-channels), an efficiency of 5.3/26.8 = 20%, and 4.9 background events, mostly non-resonant $ZZ^{(*)}$ production (2.4) and Z+jets and $t\bar{t}$ (2.5). It observed 13 [113, Table 3].

The two channels sit at opposite ends of the counting problem. In the diphoton channel thousands of background events per GeV surround a signal of a few dozen per GeV; the background is measured by the sidebands to high precision, and the question is whether a bump of a few per cent is real. In the four-lepton channel the signal and background are comparable, 5.3 against 4.9, and the question is whether 13 is too many for a Poisson count of mean 4.9, the small-count p-value of Section 4.1.4. Both questions have the same structure, $\nu = \mu s + b$ (Section T4.4.4); only the regime differs.

T4.6.3 What could have produced the excess?

What was seen. Both experiments saw more events than the background predicted, near 126 GeV in ATLAS and 125 GeV in CMS, in both the diphoton and the four-lepton channel (Figure T4.10 shows what such a spectrum looks like). *What could have produced it?* Before any number, the candidates.

A fluctuation of the background at this mass. Background events arrive as Poisson counts (Section T4.2.4), and a count can be high by chance. The probability that the background alone gives an excess at least as large as the one observed, at the mass where it was observed, is the local p-value p_0. For the ATLAS combination it was 1.7×10^{-9} at $m_H = 126.5$ GeV, a local significance of 5.9 standard deviations once the uncertainties of the energy scales and resolutions were included (6.0 without them); the Standard Model Higgs boson was expected

to give 4.9 on average [113, Sec. 9.2]. CMS found 5.0 standard deviations at 125.5 GeV, where 5.8 were expected [119, Sec. 7.1].

A fluctuation anywhere in the search range. The excess was not looked for at 126 GeV only; it could have appeared at any mass in the range searched, and a fluctuation somewhere is far more likely than a fluctuation at one fixed place. The global significance, discussed below, answers this version of the question: 5.1 standard deviations for ATLAS over 110–600 GeV.

A background shape that bends. If the smooth background function were wrong near 126 GeV, the fit would mistake the difference for signal. That possibility is the spurious signal of Section T4.4.3; it was measured in simulation and included in the likelihood as an extra uncertainty [113, Sec. 5.5].

An artefact of one detector. A calibration fault in the calorimeter could fake a diphoton bump. It could not also fake a four-lepton bump at the same mass, whose muons are measured by the tracker and the muon spectrometer. Nor could one detector's fault appear in the other experiment. The masses agree: $126.0 \pm 0.4\,(\text{stat}) \pm 0.4\,(\text{sys})$ GeV from ATLAS [113, Sec. 9.3] and $125.3 \pm 0.4 \pm 0.5$ GeV from CMS [119, Sec. 7], 0.7 GeV apart with a combined uncertainty of about 0.9 GeV.

A new particle. If the excess is a Higgs boson, its size should match the prediction, $\mu = 1$ in the notation of (T4.31). ATLAS measured $\hat{\mu} = 1.4 \pm 0.3$ at 126 GeV and CMS $\hat{\mu} = 0.87 \pm 0.23$, both compatible with one [113, Sec. 9.3], [119, Sec. 7]. Both papers add that a particle decaying to two photons cannot have spin one, and that decays to pairs of neutral vector bosons make it a neutral boson [113, Sec. 10], [119, Sec. 7].

Taken one at a time, each candidate except the last was either made improbable by a number or ruled out by a cross-check. Both collaborations therefore wrote "observation of a new particle". The first two candidates are the statistical part of the argument; we look at them more closely.

T4.6.4 Local and global significance

From p to Z. Particle physicists quote a p-value as the number Z of standard deviations a one-sided Gaussian tail would need to have the same probability, $p = 1 - \Phi(Z)$, with Φ the standard normal cumulative distribution (Section 4.9.1). Five standard deviations, $p = 2.9 \times 10^{-7}$, is the conventional threshold for "observation" (Section 4.9.2). The table below gives the values used in this section.

Z	3.28	4.5	4.6	5.0	5.1	5.3	5.9	6.0
$p = 1 - \Phi(Z)$	5.2×10^{-4}	3.4×10^{-6}	2.1×10^{-6}	2.9×10^{-7}	1.7×10^{-7}	5.8×10^{-8}	1.8×10^{-9}	9.9×10^{-10}

Local and global. The **local significance** answers: if there is only background, how probable is an excess at least this large *at this mass*? The **global significance** answers: how probable is an excess at least this large *anywhere in the range that was searched*? The second probability is larger, because the search effectively performs many tests, one for each place a peak could sit; this is the **look-elsewhere effect** [114, §40.3.2.2], [119, Sec. 4]. Their ratio, the trials factor, is roughly the number of independent places in the range. ATLAS states that it grows with the width of the searched mass range, with the significance of the excess, and with the sharpness of the peaks (a better mass resolution means narrower peaks and more independent places) [113, Sec. 7].

Example: the trials factors of 2012. Using the table above, the ratios of global to local p-values are:

- ATLAS, local 5.9: global 5.1 over 110–600 GeV, a trials factor $1.7 \times 10^{-7} / 1.8 \times 10^{-9} = 94$; global 5.3 over 110–150 GeV, a trials factor $5.8 \times 10^{-8} / 1.8 \times 10^{-9} = 32$ [113, Sec. 9.2].

- CMS, local 5.0: global 4.6 over 115–130 GeV, a factor 7; global 4.5 over 110–145 GeV, a factor 12 [119, Sec. 7.1].

The pattern follows the ranges: for CMS, widening the window from 15 to 35 GeV raised the trials factor from 7 to 12, and for ATLAS, widening it from 40 to 490 GeV raised it from 32 to 94. The factors of the two experiments cannot be compared directly, because the trials factor also grows with the significance itself (5.9 for ATLAS, 5.0 for CMS) and depends on each experiment's resolution. The range up to 600 GeV adds fewer places than its length suggests, because at high masses the peaks are wide (the 4ℓ resolution and the natural width grow with mass, Section T4.3.2) and the WW channel has no peak at all.

Recall: the toy scan of Chapter 4. Section 4.14.3 ran exactly this computation on simulated background-only spectra: sixty 1 GeV bins from 100 to 160 GeV, a Gaussian peak of width 1.5 GeV scanned over 105–155 GeV. There the biggest bump had a local significance of 3.28, which the global p-value of 0.0159 turned into 2.15 standard deviations, a trials factor of 31.3. The ATLAS search over 110–150 GeV is the closest real counterpart: a range of 40 against 50 GeV, peaks of comparable width, and a trials factor of 32 against 31. What is the same is the mechanism, many places for a fluctuation; what differs is the size of the excess. The toy bump was a fluctuation that the global correction rightly demoted; the 2012 excess survived it with more than five standard deviations, and the global significance, not the local one, is the number that justified the word "observation". How the global p-value is computed without millions of toy experiments is Section 4.14.4.

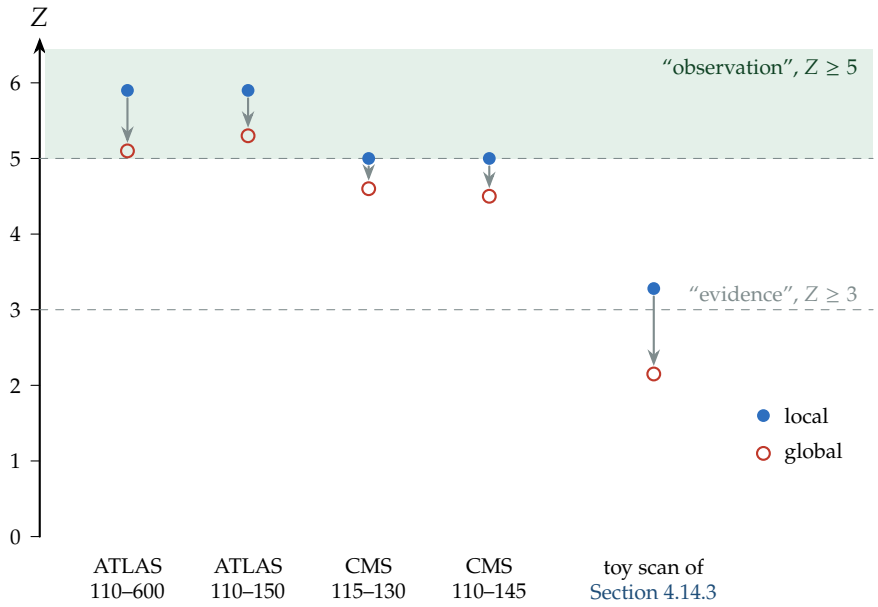


Figure T4.15: Local (filled) and global (open) significance of the largest excess, for the two 2012 searches with two search ranges each (in GeV), and for the simulated background-only scan of Chapter 4. Looking in a wider range always lowers the significance. The 2012 excesses stayed near or above five standard deviations after the correction; the toy bump, three standard deviations locally, dropped to about two.

T4.6.5 From 2012 to the open data

The capstone (Chapter 13) asks the 2012 diphoton question of the 2016 open data, with one channel instead of several. What carries over unchanged is the chain from collisions to expected counts: $\nu = \sigma B L \varepsilon A$ for the signal, a simulated template for its shape, a smooth function fitted to the sidebands for the background, μ for the size of the signal, nuisance parameters for the calibrations. What changes is the collision energy and so the cross section: the gluon-fusion $\sigma B(\gamma\gamma)$ stored in the open-data files is 0.102 pb = 102 fb at 13 TeV, twice the 50 fb of *all* production modes together at 8 TeV. With 10 fb^{-1} the open data therefore contain more Higgs bosons decaying to two photons than the whole 2012 diphoton sample of ATLAS. They also contain more background, and the open data were not processed with the full analysis machinery of the collaboration. Whether the bump appears, and how strongly, is the subject of Chapter 13.

The lesson in one line. A discovery is a chain of physical predictions, each with its calibration, ending in one comparison of counts; the statistics can only be as good as the expected counts ν_i it is given.

T4.7 The open data: what is in the files

In 2020 ATLAS released to the public a part of the proton collisions it recorded at $\sqrt{s} = 13$ TeV in 2016, together with simulated events for the main Standard Model processes [116, 118]. The capstone of Chapter 13 analyses its diphoton part. The files are not the raw detector output: they are tables with one row per recorded event and one column per reconstructed quantity, the reconstructed objects of Section T4.1 written out as numbers. Everything this chapter has introduced has a column, or a combination of columns, in these tables. Reading the columns correctly is the last physical step before the statistics.

The questions. What exactly is in a row? Which column is which quantity of this chapter, and in what units? And what does a real event look like when we compute its invariant mass by hand?

T4.7.1 The release

The recorded events come from the first four data-taking periods of 2016, about 270 million collisions written to disk. Only events taken while all relevant parts of the detector were working are kept, and after these quality requirements the data correspond to an integrated luminosity of $L = 10\,\text{fb}^{-1}$ [118, Sec. 2]. The format is a ROOT tree, a column-oriented table, with more than 80 columns (**branches**) [118, Sec. 2]. The overview of the release lists the photon requirements as reconstruction in the inner detector and electromagnetic calorimeter, $E_T > 25$ GeV, $|\eta| < 2.37$, tight identification and loose isolation [118, Table 1]. The diphoton files nevertheless keep candidates that fail the tight identification and record the result in a flag: requiring the flag on both photons keeps only 979 059 of the 7 798 424 data events (Figure T4.5). The flag must be checked.

The release is split into collections by final state. The diphoton collection, `GamGam`, holds four data files, one per period (A to D), and simulated Higgs bosons with $m_H = 125$ GeV decaying to two photons, one file per production mode (gluon fusion, vector-boson fusion, WH, ZH). It contains only events that passed a two-photon trigger and have two photon candidates. In all four data files the script `02_open_data.py` finds 7 798 424 events, every one of them with the photon trigger flag set and exactly two photon candidates stored (Figure T4.17d). The first two lines of the cut flow of Figure T4.5 therefore remove nothing: the release had already applied them.

Recall: the luminosity of the release. Section T4.2 used $L = 10\,\text{fb}^{-1}$ to predict 1020 produced and 395 selected gluon-fusion Higgs decays. The capstone uses $L = 10.06\,\text{fb}^{-1}$ (Section 13.21.1), the value the release's own analysis code multiplies by, of which the published "$10\,\text{fb}^{-1}$" is the rounded form. The two differ by 0.6%, a sixth of the 3.6% luminosity uncertainty of the 2012 data (Section T4.5.3); every expected count in this chapter would be 0.6% larger with the capstone's value.

T4.7.2 The columns

A row of the diphoton tree has three kinds of column (Figure T4.16). *Event-level numbers* describe the whole crossing: which run and event it is, which trigger fired, and for simulated events the weights. *Per-object vectors* hold one entry per reconstructed photon (or lepton, or jet): `photon_pt` is a list of transverse momenta, the first entry for the leading photon, the second for the next. *Normalisation constants* of the simulation, σB and the total weight W of (T4.29), are stored in every row of a simulated file. Table T4.2 lists the columns a diphoton analysis uses; the full list of the tree is written by the script to `results/chT4/02_branches.txt`.

event-level	one entry per photon	γ_1	γ_2	simulation only
runNumber	photon_pt	176.1	39.63	mcWeight
eventNumber	photon_eta	−0.834	0.095	scaleFactor_*
trigP = true	photon_phi	−0.294	0.567	XSection
photon_n = 2	photon_E	240.9	39.81	SumWeights
	photon_isTightID	true	true	photon_pt_syst

Figure T4.16: The anatomy of one row of the diphoton tree. Left: numbers that describe the whole event. Middle: vectors with one entry per photon candidate, here filled with the first selected data event (momenta and energies in GeV after dividing the stored MeV by 1000). Right: columns that are meaningful only for simulated events: the weights and the normalisation of (T4.29), and the energy-scale variation of each photon.

Four columns need a word beyond the table.

- *Isolation.* `photon_etcone20` adds up the transverse energy deposited in the calorimeter in a cone of radius $\Delta R = 0.2$ around the photon, excluding the photon's own shower. A photon from a Higgs decay is alone, so this sum is small; a "photon" that is really a neutral pion inside a jet is surrounded by the jet's other hadrons. Requiring less than 4 GeV, as ATLAS did in 2012 [113, Sec. 5.1], keeps 97.7% of simulated signal photons and only 56.0% of the photon candidates in the data (Figure T4.17c).
- *Conversion.* A photon crossing the inner detector may convert into an electron–positron pair before it reaches the calorimeter; its energy is then measured less well and its shower starts earlier. Of the selected photons in the data, 34.7% are converted. The 2012 analysis split events into categories by conversion status because the resolution differs (Section T4.6.2); the capstone uses the unconverted central category the same way.
- *Scale factors.* The simulation reproduces efficiencies only approximately. Each factor is the ratio of an efficiency measured in data (for example with photons from $Z \to \ell^+\ell^-\gamma$, Section T4.5.3) to the same efficiency in simulation, and multiplies the event's weight. The product $w_e = \texttt{mcWeight} \times \prod \texttt{scaleFactor}$ is the weight of (T4.29).
- *The energy-scale variation.* `photon_pt_syst` gives, for each simulated photon, how far its p_T moves when the energy scale is varied by its uncertainty. Its median relative size in the

column	meaning	symbol, section
`runNumber`, `eventNumber`	which data-taking run and which crossing	—
`trigP`	the photon trigger fired	Section T4.1
`photon_n`	number of photon candidates stored	—
`photon_pt`	transverse momentum, MeV	p_T, (T4.1)
`photon_eta`	pseudorapidity $-\ln\tan(\theta/2)$	η, (T4.4)
`photon_phi`	azimuth around the beam, rad	ϕ, Section T4.1.2
`photon_E`	energy, MeV	$E = p_T\cosh\eta$
`photon_isTightID`	shower shape passes the tight photon identification	ε, Section T4.2.3
`photon_etcone20`	calorimeter transverse energy in a cone $\Delta R < 0.2$ around the photon, MeV	isolation
`photon_ptcone30`	sum of track p_T in a cone $\Delta R < 0.3$, MeV	isolation
`photon_convType`	0 if unconverted, otherwise how it converted to e^+e^-	categories
`photon_pt_syst`	energy-scale variation of the photon's p_T, MeV (simulation)	δ, (T4.34)
`mcWeight`	generator weight of the event	w_e, (T4.29)
`scaleFactor_*`	data/simulation corrections of the photon efficiency (`_PHOTON`), the trigger efficiency (`_PhotonTRIGGER`) and the pile-up (`_PILEUP`)	factors of w_e
`XSection`	cross section times branching fraction, pb	σB
`SumWeights`	sum of the weights of all generated events	W, (T4.29)

Table T4.2: The columns a diphoton analysis reads, their meaning, and the symbol each carries. Momenta and energies are stored in MeV. The cone size $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2}$ is a distance in the (η, ϕ) plane.

selected signal is 0.71%. By (T4.34) this is directly the relative shift of the diphoton peak, the energy-scale nuisance parameter of Section T4.5.1. In the data files the column carries no information, as it must: a recorded energy has no "varied" version.

Watch out: The files store MeV

Momenta and energies in the 2016 release are in MeV, not GeV. An invariant mass computed without dividing by 1000 comes out near 125 000, and a cut "$p_T > 40$" applied to the raw column keeps every photon. The script checks the median p_T and divides by 1000 when it is above a thousand.

T4.7.3 One event by hand

The question. Take the first event of period A that passes the selection of Section T4.2.3. What is its diphoton mass, and do the columns agree with each other?

The two photons have, after conversion to GeV, $p_{T1} = 176.1$ and $p_{T2} = 39.63$ GeV, $\eta_1 = -0.8335$ and $\eta_2 = 0.0947$, $\phi_1 = -0.2942$ and $\phi_2 = 0.5673$ rad, and energies $E_1 = 240.9$ and $E_2 = 39.81$ GeV.

Check one: are the energies those of massless particles? For a photon, $E = |\boldsymbol{p}| = p_T\cosh\eta$ (T4.5). With $\cosh(0.8335) = 1.368$ and $\cosh(0.0947) = 1.0045$, $176.1 \times 1.368 = 240.9$ and $39.63 \times 1.0045 = 39.81$ GeV: both stored energies are reproduced to the last digit. The columns are consistent, and the photons are massless as they should be.

The mass from the detector variables. With (T4.19), $\Delta\eta = \eta_1 - \eta_2 = -0.9282$ and $\Delta\phi = \phi_1 - \phi_2 = -0.8615$,

$$m_{\gamma\gamma}^2 \overset{(1)}{=} 2\,p_{T1}p_{T2}\big(\cosh\Delta\eta - \cos\Delta\phi\big) \overset{(2)}{=} 2 \times 176.1 \times 39.63 \times (1.4626 - 0.6513)$$

$$\overset{(3)}{=} 13\,958 \times 0.8113 = 11\,324\,\text{GeV}^2, \qquad m_{\gamma\gamma} = 106.4\,\text{GeV}. \tag{T4.40}$$

(1) The diphoton mass in detector variables, (T4.19).
(2) $\cosh(-0.9282) = \cosh(0.9282) = 1.4626$ (cosh is even) and $\cos(-0.8615) = 0.6513$.
(3) Multiply out.

The mass from four-vectors. Build $p_x = p_T \cos\phi$, $p_y = p_T \sin\phi$, $p_z = p_T \sinh\eta$ for each photon and add: the pair has $\boldsymbol{P} = (202.0, -29.8, -160.6)$ GeV and $E = 280.7$ GeV, so $m^2 = E^2 - |\boldsymbol{P}|^2$ by (T4.17) gives $m = 106.4$ GeV again. The script finds 106.4 and 106.4 GeV for the two routes.

This event is not a Higgs boson candidate in any useful sense: its mass is 19 GeV below the peak, and in any case a single event is neither signal nor background (Section 13.21.1). It is a typical background event. The pair is strongly boosted along the beam, $P_z = -161$ GeV, which is the unknown parton motion of Section T4.1.2; the mass does not care.

T4.7.4 What the columns look like

Figure T4.17 histograms four columns for the data and for the simulated gluon-fusion signal, after the trigger and two-photon requirement and before any other cut.

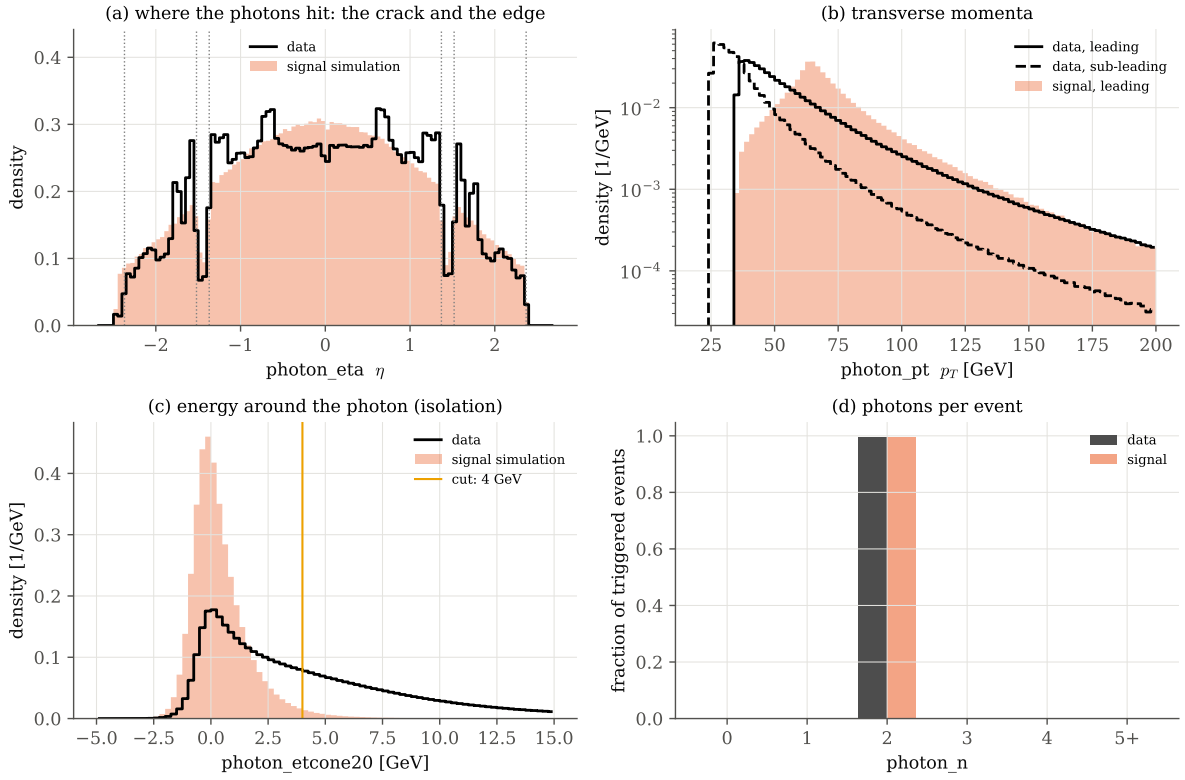

Figure T4.17: Four columns of the diphoton files, for recorded events (black) and simulated Higgs decays (filled). (a) Photon pseudorapidity: no photon beyond the calorimeter edge at $|\eta| = 2.37$, and a dip in the data at the barrel/end-cap gap $1.37 < |\eta| < 1.52$ (dotted lines). (b) Transverse momenta: the data fall steeply from the trigger thresholds, while the signal photons peak near half the Higgs mass. (c) Isolation energy: signal photons are alone, with a narrow peak near zero; the data have a long tail from jets faking photons, which the 4 GeV cut removes. (d) Every event in the files has exactly two photon candidates.

Example: reading the pseudorapidity panel. In panel (a) the signal photons spread smoothly over the calorimeter, more of them at small $|\eta|$, because the decay products of a Higgs boson

with modest longitudinal motion come out at all angles. The data have structure the signal lacks: the density of data candidates changes abruptly at the boundaries of the calorimeter regions, while the simulated signal, made of real photons, changes smoothly. The data are mostly fake photons from jets, and how often a jet passes as a photon depends on the calorimeter region. Of the data photon candidates, 3.2% sit inside the gap $1.37 < |\eta| < 1.52$, where the energy measurement is poor; the selection removes them. This is the acceptance cut of Section T4.2.3 seen in the raw columns.

Example: reading the momentum panel. In panel (b) the data start at the trigger and preselection thresholds, about 35 GeV for the leading and 25 GeV for the second photon, and fall over three orders of magnitude by 200 GeV. The signal's leading photon peaks near $m_H/2 = 62.5$ GeV, the energy of a photon from a Higgs boson at rest (Section T4.3.1), with a tail to higher values from the boost. Cuts on p_T therefore remove much of the low-mass background while keeping most of the signal; the capstone uses cuts relative to $m_{\gamma\gamma}$ instead, for the reason given in Section 13.21.1.

Recall: this selection and the capstone's. Section T4.2.3 followed the gluon-fusion signal through a selection modelled on the 2012 analysis: tight identification, $|\eta| < 2.37$ outside the gap, $p_T > 40$ and 30 GeV, calorimeter isolation below 4 GeV, and $100 < m_{\gamma\gamma} < 160$ GeV. It kept 151 767 data events and 395 expected signal events. The capstone (Section 13.21.1) uses the selection of the release's own example analysis: exactly two photons each passing tight identification with $p_T > 25$ GeV, both a calorimeter and a track isolation below 6.5% of the photon's p_T, the relative cuts $p_{T1}/m_{\gamma\gamma} > 0.35$ and $p_{T2}/m_{\gamma\gamma} > 0.25$, and $105 < m_{\gamma\gamma} < 160$ GeV. It keeps 76 394 data events and 357.2 gluon-fusion events (397.9 from all four production modes). The capstone's data sample is half as large as ours and its gluon-fusion signal 10% smaller: the extra track isolation and the relative isolation cut remove many more jets than signal photons, and the narrower mass range removes 5 GeV of the steepest part of the background. If the background under the peak falls in the same proportion as the whole sample, $s/\sqrt{b}$ in a fixed window grows by $0.9/\sqrt{0.5} \approx 1.3$, which is the purpose of the tighter selection; Section 13.21.1 shows its cut flow.

Where this is used. The capstone reads exactly the columns of Table T4.2: the photon momenta for $m_{\gamma\gamma}$ via (T4.19), the identification, isolation and conversion flags for the selection and the categories, and `mcWeight`, the scale factors, `XSection` and `SumWeights` for the signal template (T4.29).

T4.8 The symbols of a collider search

The statistics of a search treats each quantity of a collider measurement as a given number or function. Table T4.3 lists each one with its meaning, the relation that defines or computes it, a typical size for the diphoton search, and the places where it is used. Two symbols are easily confused and are kept apart throughout the book: μ is always the signal strength, never a mean; the mean number of events is always ν. The integrated luminosity is L and the likelihood is $\mathcal{L}$; HistFactory and Cranmer write λ for the luminosity for the same reason.

Table T4.3: The symbols of a collider search: meaning, working relation, typical size in the diphoton search, and where each is used.

symbol	meaning	working relation	typical size	used in
$\sqrt{s}$	collision energy of the two protons	—	7, 8, 13 TeV	Section T4.6 and Chapter 13
p_T	momentum transverse to the beam	$\lvert\boldsymbol{p}\rvert \sin\theta$, (T4.1)	25–200 GeV	Section T4.7 and Chapter 13
y	rapidity; shifts by a constant under a boost along the beam	$\frac{1}{2}\ln\frac{E+p_z}{E-p_z}$, (T4.2)	—	Section T4.1.2
η	pseudorapidity, a measure of the polar angle	$-\ln\tan\frac{\theta}{2}$, (T4.4)	$\lvert\eta\rvert < 2.37$	Section T4.7 and Chapter 13
ϕ	azimuth around the beam	—	$(-\pi, \pi]$	Chapter 13
σ	cross section of a process	$N = \sigma L$	$\sigma_{\text{inel}} = 78$ mb; $\sigma B = 0.102$ pb	Section T4.2 and Chapter 13
L_{inst}	instantaneous luminosity	$\frac{n_b f N_1 N_2}{4\pi\sigma_x\sigma_y} F$, (T4.11)	$10^{34}\,\text{cm}^{-2}\text{s}^{-1}$	Section T4.2.2
L	integrated luminosity	$\int L_{\text{inst}}\,\text{d}t$	$10\,\text{fb}^{-1}$	Section 4.15 and Chapter 13
$\bar{n}_{\text{pu}}$	collisions per bunch crossing (pile-up)	$\sigma_{\text{inel}} L_{\text{inst}}/n_b f$, (T4.13)	20–50	Section T4.2.2
A, ε	acceptance, efficiency	fraction of produced events kept	$\varepsilon A = 0.39$	Section T4.2.3 and Chapter 13
ν	expected number of selected events	$\sigma L \varepsilon A$, (T4.15); Poisson mean	395 signal	Section 4.15.1
$m_{\gamma\gamma}$	invariant mass of the photon pair	$m^2 = 2p_{T1}p_{T2} \times (\cosh\Delta\eta - \cos\Delta\phi)$, (T4.19)	100–160 GeV	Section 4.14.3 and Chapter 13
Γ, τ	natural width, lifetime	$\Gamma = \hbar/\tau$; Breit–Wigner (T4.23)	$\Gamma_H = 4$ MeV, $\Gamma_Z = 2.5$ GeV	Section T4.3.2
σ_E/E	calorimeter energy resolution	$a/\sqrt{E} \oplus c$, (T4.24)	1.4% at 62.5 GeV	Section T4.3.3
σ_m	mass resolution	$\frac{1}{2}\sqrt{\sum(\sigma_{E_j}/E_j)^2}\, m$, (T4.25)	1.2–1.6 GeV	Section 4.14.3 and Chapter 13
α, n	Crystal Ball tail start and power	(T4.26), (T4.27)	1.5, 5	Section 13.22.1
s_i, b_i	signal and background templates in bin i	$s_i = \sum_{e\in i}\sigma L w_e/W$, (T4.29); b_i from sidebands	$\sum s_i \approx 400$	Sections 4.15 and 13.22
w_e, W	weight of a simulated event, total weight	`mcWeight`×scale factors; `SumWeights`	$W = 5.6\times10^7$	Section T4.4.2
μ	signal strength	$\sigma B/(\sigma B)_{\text{SM}}$; $\nu_i = \mu s_i + b_i$, (T4.31)	1.4 ± 0.3 (ATLAS 2012)	Sections 4.15 and 4.16
α_k	nuisance parameter of source k	0 nominal, ±1 one s.d.; (T4.35)	—	Section 4.15.2
δ	energy-scale shift	$\delta m/m = \delta$, (T4.34)	0.3%	Section 4.15.2
Σ_x	combined width of two beams	$\sqrt{s_1^2 + s_2^2}$, (T4.37)	24 μm	Section T4.5.3
σ_{vis}	visible cross section of a luminosity detector	R_0/L_0	tens of mb	Section T4.5.3

symbol	meaning	working relation	typical size	used in
Z, p_0	significance, background-only p-value	$p_0 = 1 - \Phi(Z)$	5.9, 1.7×10^{-9}	Sections 4.9.1 and 4.14

Recap

- An event is a list of reconstructed particles, each with p_T, η, ϕ; the transverse plane and rapidity differences are used because the motion of the colliding partons along the beam is unknown.
- With the integrated luminosity fixed, the number of selected events of a process is Poisson with mean $\nu = \sigma L \varepsilon A$.
- The invariant mass of a decay's products equals the parent's mass in every event; the peak's width combines the natural width (Breit–Wigner) and the detector resolution (Gaussian or Crystal Ball core), and is dominated by the larger.
- The expected count in a bin is $\nu_i = \mu s_i + b_i$: signal templates from weighted simulation, background from the sidebands of the data, $\mu = \sigma B / (\sigma B)_{\mathrm{SM}}$.
- Every uncertain input is a nuisance parameter with its own calibration: van der Meer scans for the luminosity, Z decays for energy scale and efficiencies, simulated background samples for the spurious signal.
- In 2012 ATLAS saw a local 5.9σ and a global 5.1σ excess at 126 GeV, CMS a local 5.0σ at 125.5 GeV, with $\hat{\mu} = 1.4 \pm 0.3$ and 0.87 ± 0.23.
- The 2016 open data store, per event, the photon four-momenta in MeV, identification, isolation and conversion flags, and for simulation the weights, scale factors, σB and the total weight.

Chapter summary

concept	operational meaning	used later in
event, reconstructed object	one bunch crossing kept by the trigger, written as a list of photons, leptons, jets with (p_T, η, ϕ, E)	Chapter 13 (the data rows)
transverse plane, pseudorapidity	coordinates insensitive to the unknown parton motion along the beam; $\eta = -\ln\tan(\theta/2)$	Chapter 13 (acceptance cuts)
cross section, luminosity	$N = \sigma L$: the process's effective area times the beams' collision opportunities per area	Section 4.15, Chapter 13
acceptance, efficiency	fraction of produced events inside the detector and passing the selection; $\nu = \sigma L \varepsilon A$	Section 4.15.2, Chapter 13
Poisson counts	with L fixed, independent crossings and independent selection make every count Poisson	Section 4.15.1
invariant mass	$m^2 = (\sum E)^2 - \lvert\sum \boldsymbol{p}\rvert^2$, the parent's mass in every decay	Section 4.14.3, Chapter 13
natural width, Breit–Wigner	a finite lifetime spreads the mass as a Cauchy density of full width $\Gamma = \hbar/\tau$	Section 2.10.5 (recalled)
resolution, Crystal Ball	measurement error spreads the peak; Gaussian core plus a low-side power-law tail	Section 13.22.1, Section 6.14
template, Monte Carlo weight	expected count per bin from a weighted simulated sample, $\sigma L w_e / W$ per event	Section 4.15, Section 13.22

concept	operational meaning	used later in
sideband background, spurious signal	a smooth function fitted away from the peak; its possible bias measured on simulated background	Section 13.22.2
signal strength μ	$\sigma B/(\sigma B)_{\mathrm{SM}}$; $\nu_i = \mu s_i + b_i$; $\mu = 0$ is the null hypothesis	Section 4.16, Chapter 13
nuisance parameter, calibration	every uncertain input gets a parameter and the likelihood of its calibration measurement	Sections 4.15.2 and 4.15.3
van der Meer scan	the collision rate versus beam separation is a Gaussian of width $\Sigma = \sqrt{s_1^2 + s_2^2}$; it calibrates L	Section T4.5.3
local and global significance	p-value of an excess at its mass, or anywhere in the searched range; their ratio is the trials factor	Sections 4.14 and 4.14.4
open-data columns	`photon_pt`, `photon_eta`, `photon_phi`, `photon_E` (MeV), flags, weights, `XSection`, `SumWeights`	Section 13.21.1

Reading the literature. The kinematics of collider events (four-vectors, rapidity, pseudorapidity, invariant masses), the cross-section formulae and the luminosity of colliding beams are collected in the reviews of the Particle Data Group [114], which are the standard reference for every relation used here; its statistics review summarises the treatment of nuisance parameters and the look-elsewhere effect. Cranmer's lectures [29] explain how a collider analysis turns physics into a statistical model, in the three narratives (simulation, data-driven, effective model) used in Section T4.4, and the HistFactory note [120] writes that model down in the form LHC software uses. Cowan's textbook [Cowan §§6.9, 11.1] gives the extended likelihood and the response-matrix picture of a detector at an introductory level. The two discovery papers [113, 119] are short and readable once the vocabulary of this chapter is in hand; read the ATLAS diphoton section and the description of the statistical procedure first. The design of the LHC and of the ATLAS detector is documented in [112, 117], the inelastic cross section in [115], and the open-data release in [116, 118] together with the documentation on the CERN open-data portal.

Part III

Simulation, Fields and Forecasts

Chapter 6

Monte Carlo: Drawing Samples on a Deterministic Machine

Where this chapter is going

Every simulation in this book starts the same way: a line such as `rng.random(N)` hands us N numbers that behave like independent draws from the uniform distribution on $[0, 1)$. From them we build draws from any distribution we like, and averages over the draws estimate probabilities, expectation values and integrals that no formula gives us. The computer that produces those numbers is a deterministic machine: run the same program twice and it does exactly the same thing. So the numbers cannot be random. They are the output of a small dynamical system, a *state* that is updated by a fixed rule, and the only honest claim we can make about them is a statistical one: no test we care about can tell them apart from genuinely independent uniform draws.

That claim can fail, and it has failed in instructive ways. A generator has a finite number of states, so it must eventually repeat, and after that no new information enters a simulation. The simplest generators, the linear congruential ones, put their consecutive outputs on a crystal lattice: in three dimensions the triples of IBM's famous RANDU lie on just fifteen planes. Their lowest bits repeat with tiny periods. Modern generators (xorshift, the Mersenne Twister, and numpy's default PCG64) keep a larger state, update it by a rule that is cheap and has an enormous period, and pass it through an output function that hides the regularities the update leaves behind. Seeds and streams let us rerun any simulation bit for bit and run thousands of independent copies side by side. Whether a generator is good enough is a hypothesis test: H_0 is "independent and uniform", and the test statistics are histograms, correlations, runs and tuples. Finally, when the goal is an integral rather than a random process, we may drop randomness altogether: quasi-random points fill space more evenly than independent points and beat the $1/\sqrt{N}$ error.

From uniform numbers we then build draws from any distribution (inverse transform, Box–Muller, rejection and importance sampling), and averages over such draws obey a $\sigma/\sqrt{N}$ law that controls every Monte Carlo estimate. On the book's pipeline (Chapter 0), where a statistic S computed from the data must have its scatter $P(S \mid \theta)$ worked out before any physics can be inferred, Monte Carlo is how we find that scatter when no formula exists: we simulate the data many times and histogram the summary.

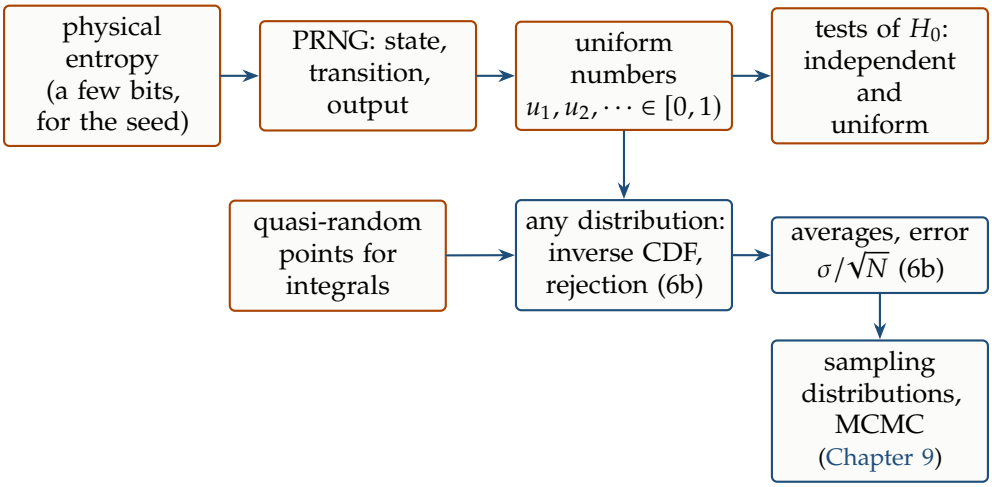

Figure 6.1: How the ideas of the chapter connect. A few bits of physical entropy seed a deterministic generator, whose output is accepted as uniform only after it survives statistical tests; quasi-random points replace the generator when the goal is an integral (orange boxes). Uniform numbers are then turned into draws from other distributions and averaged, with an error that falls as $1/\sqrt{N}$ (blue boxes). The results feed every sampling method of later chapters.

6.1 Random numbers from a machine that cannot be random

A simulation is only as good as the random numbers that drive it, and a computer cannot make random numbers. In Chapter 1 we settled the Monty Hall problem twice: once with a probability tree and once by letting the computer play hundreds of thousands of games and counting. The counting looked the more trustworthy of the two, because it needed no formula. But every one of those games was decided by numbers that a program produced, and a program is a list of instructions carried out exactly. So two questions arise. Where did the randomness come from? And how would we know if it were not good enough? Monty Hall is a good place to find out. Its answer rests on three numbers, the probability of what Monty did under each possible location of the car, and a simulation must get each of them right.

6.1.1 What a simulation of Monty Hall has to reproduce

Recall the game. A car is behind one of three doors A, B, C, each with probability $\frac{1}{3}$; goats are behind the other two. We pick door A. The host, Monty, knows where the car is. He always opens one of the two doors we did not pick, never the one with the car, and when both of those hide goats he chooses between them at random, like tossing a fair coin [Wasserman p. 14, Ex. 10]. He opens door C. Should we switch to B?

The event. Monty opened door C. Write E for it; every simulated game that ends this way counts towards it.

What could have made him open C? Monty's move depends on one thing we cannot see, where the car is. So the candidate explanations are the three places the car can be: H_A, H_B and H_C, the car behind A, B or C. For each one we ask: if the car were there, how likely was Monty to open C?

How probable is the event under each location? This is the step a simulation has to reproduce game by game. Monty knows where the car is, he never reveals it, and he never opens our door.

- Under H_A the car is behind our door A, so both B and C hide goats. Monty may open either and tosses his coin: $\mathrm{P}(E \mid H_A) = \frac{1}{2}$.

- Under H_B the car is behind B. He may not open our door A and may not reveal the car behind B, so C is the only door he can open: $\mathrm{P}(E \mid H_B) = 1$.
- Under H_C the car is behind C. Opening C would reveal it, so he never does: $\mathrm{P}(E \mid H_C) = 0$.

These three numbers are the second layer of the tree in Figure 6.2.

Only then the priors, and the normalisation. Before Monty acted, each location had prior probability $\mathrm{P}(H_A) = \mathrm{P}(H_B) = \mathrm{P}(H_C) = \frac{1}{3}$. We multiply each prior by the probability of the event under it, and divide by the sum of these products:

$$\mathrm{P}(H_B \mid E) \overset{(1)}{=} \frac{\mathrm{P}(E \mid H_B)\,\mathrm{P}(H_B)}{\mathrm{P}(E \mid H_A)\,\mathrm{P}(H_A) + \mathrm{P}(E \mid H_B)\,\mathrm{P}(H_B) + \mathrm{P}(E \mid H_C)\,\mathrm{P}(H_C)} \overset{(2)}{=} \frac{1 \cdot \frac{1}{3}}{\frac{1}{2} \cdot \frac{1}{3} + 1 \cdot \frac{1}{3} + 0 \cdot \frac{1}{3}} = \frac{1/3}{1/2} = \frac{2}{3}. \tag{6.1}$$

(1) Bayes' theorem (Chapter 5) for the three hypotheses, which are mutually exclusive and exhaustive: the denominator is the total probability $\mathrm{P}(E)$ of the observation, summed over every path in the tree that ends in "Monty opened C".

(2) The three probabilities of E found above and the equal priors. The denominator is $\mathrm{P}(E) = \frac{1}{6} + \frac{1}{3} = \frac{1}{2}$.

In the same way $\mathrm{P}(H_A \mid E) = \frac{1}{6}/\frac{1}{2} = \frac{1}{3}$ and $\mathrm{P}(H_C \mid E) = 0$. Switching to B wins with probability $\frac{2}{3}$.

The guess "one door is gone, so the other two are fifty–fifty" fails because it ignores the information in Monty's choice: the event we saw was not equally likely under the two surviving hypotheses. Among the games in which the car is behind B, he opens C every time; among those in which it is behind our door A, only half the time. So the opening we saw is twice as probable under H_B as under H_A, and the two surviving posteriors carry that same factor of two.

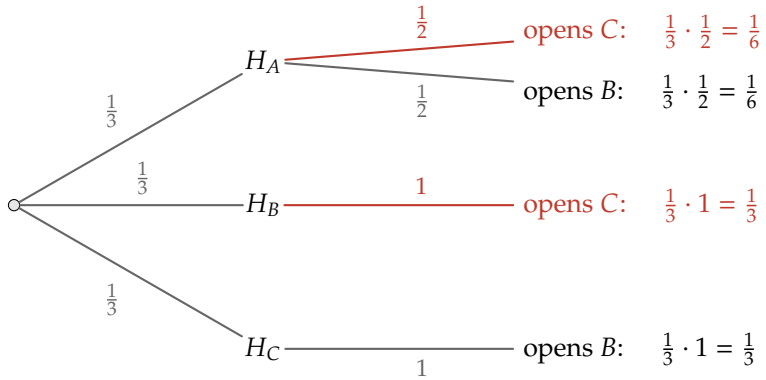

Figure 6.2: The Monty Hall tree when we have picked door A. The first split is the location of the car (the prior, $\frac{1}{3}$ each). The second split is Monty's choice under each location: a fair coin under H_A, a forced choice under H_B and H_C. The red leaves are the paths that end in the observation "Monty opened C"; their weights $\frac{1}{6}$ and $\frac{1}{3}$ are in the ratio $1 : 2$, which is the posterior.

A simulation follows the same tree forwards. For each game it draws the car's location (the first split), then Monty's choice (the second split), then keeps the games that ended in "Monty opened C" and counts where the car was (Chapter 1 did exactly this). The simulation contains no formula for the posterior, but it must reproduce the three probabilities $\mathrm{P}(E \mid H_A) = \frac{1}{2}$, $\mathrm{P}(E \mid H_B) = 1$, $\mathrm{P}(E \mid H_C) = 0$ as frequencies. The last two are forced by Monty's rules. The first is produced by nothing but the random numbers that toss Monty's coin. If those numbers are wrong, the simulation computes the posterior of a different game.

Example: the same game with a bad coin. A simulation needs two random integers x per game. The first places the car: its remainder on division by 3 picks the door. The second tosses Monty's coin: its remainder on division by 2 picks heads or tails. Here is the heart of such a simulation.

Listing 6.1: One simulated game per pair of integers (`code/ch06/01_monty_generators.py`)

```
    """ints has 2N entries; game k uses ints[2k] for the car and ints[2k+1] for the coin."""
    car = ints[0::2] % 3                        # 0 = A, 1 = B, 2 = C
    coin = ints[1::2] % 2                       # Monty's tie-break when the car is behind A
    # We picked A. Monty opens a door that is neither ours nor the car's.
    opened = np.where(car == 0, np.where(coin == 1, 2, 1),   # free choice: B or C
                      np.where(car == 1, 2, 1))              # forced choice
    lik = np.array([np.mean(opened[car == h] == 2) for h in range(3)])   # P(open C | H)
    sel = opened == 2
    post = np.array([np.mean(car[sel] == h) for h in range(3)])          # P(H | open C)
    switch = np.mean(car != 0)
    return lik, post, switch
```

Line 29 places the car, line 30 tosses the coin. Lines 32–33 are Monty's rules; line 34 measures $\mathrm{P}(E \mid H)$ as the fraction of games with the car behind each door in which he opened C; lines 35–36 select the games with "Monty opened C" and count where the car was. We feed it integers from two sources. The first is numpy's generator, through `rng_for`. The second is a textbook generator with a long history, the rule $x \mapsto (1664525\,x + 1013904223) \bmod 2^{32}$, which we will meet again in Section 6.2. Both play 300,000 games.

With numpy's integers the measured probabilities of E are 0.500, 1 and 0 under H_A, H_B, H_C, and among the games with "Monty opened C" the car was behind A in a fraction 0.333 and behind B in 0.667: the answer $\frac{1}{3}$, $\frac{2}{3}$ of (6.1). With the textbook generator started from the seed 2026, the coin always comes up the same way. Monty, facing a free choice, *never* opens C: the measured $\mathrm{P}(E \mid H_A)$ is 0.000, and among the games in which he opened C the car was behind B in a fraction 1.000. Started from the seed 2027, the coin always comes up the other way, Monty *always* opens C when he may, $\mathrm{P}(E \mid H_A)$ becomes 1.000, and the car was behind B in only 0.501 of the selected games. That is the fifty–fifty answer of the wrong intuition, now "confirmed" by a simulation (Figure 6.3).

This failure is dangerous because nothing gives it away. First, the fraction of all games that switching wins is 0.667 with numpy, 0.667 and 0.667 with the textbook generator: the headline number is right in all three runs, because it does not involve the coin. The damage is visible only in the conditional question. Second, nothing crashed and nothing looked odd; the car's location, taken from the same generator, is perfectly uniform. The cause, derived in Section 6.2, is that the lowest bit of this generator alternates $0, 1, 0, 1, \ldots$, so every second integer, the one used for the coin, has the same lowest bit.

6.1.2 What we ask of a stream of random numbers

The example shows what a source of random numbers must do. A simulation turns numbers $u_1, u_2, \ldots$ into events, and every probability it reports is a frequency of those events. So the simulation is correct if the u_i behave, for the purpose at hand, like **independent draws from the uniform distribution** [every u_i equally likely to fall anywhere in $[0, 1)$, and knowing some of them tells nothing about the others] on $[0, 1)$, whose density is

$$g(u) = \begin{cases} 1, & 0 \le u < 1, \\ 0, & \text{otherwise} \end{cases} \tag{6.2}$$

[Cowan (3.1)].

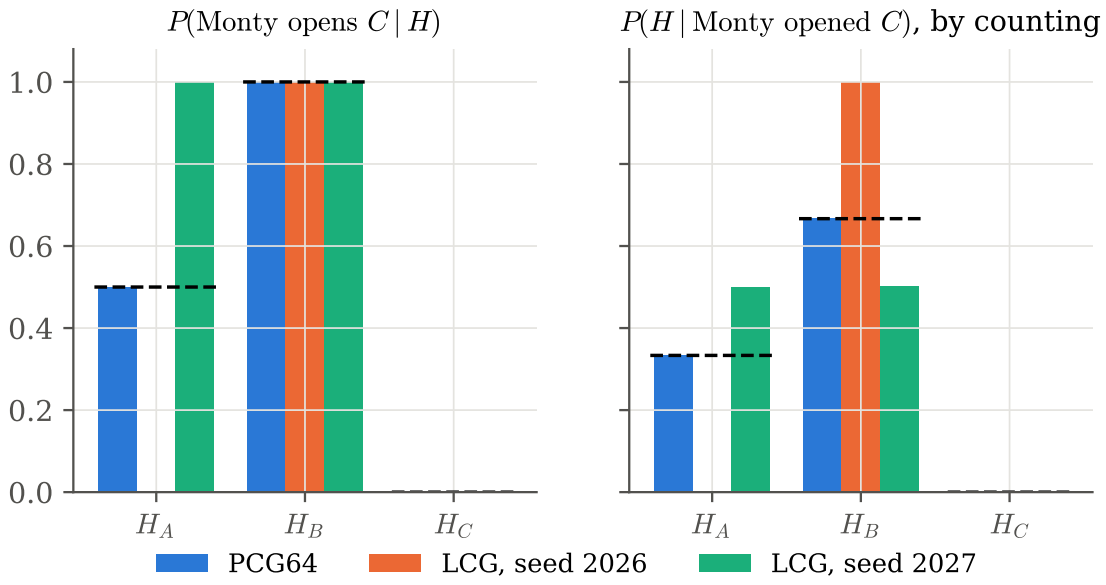

Figure 6.3: Monty Hall simulated with three sources of integers. Left: the measured probability that Monty opens C under each location of the car. With PCG64 (blue) it is $\frac{1}{2}$, 1, 0 (dashed). With the textbook generator the coin never varies, so under H_A Monty either never (orange) or always (green) opens C. Right: where the car was, among the games in which Monty opened C. The wrong probability under H_A produces the wrong posterior: 0 and 1, or $\frac{1}{2}$ and $\frac{1}{2}$, instead of $\frac{1}{3}$ and $\frac{2}{3}$.

Every Monte Carlo method assumes such numbers. Monte Carlo integration takes them for granted: to estimate $\int_a^b h(x)\,\mathrm{d}x$ we "generate $X_1, \ldots, X_N \sim \mathrm{Unif}(a, b)$" and average [Wasserman p. 404, (24.2)]. So does the idea of representing a distribution by a large sample of representative values [Kruschke §7.1]: the numbers x built from the u_i are treated as simulated measurements, and the probability of any region is estimated from how many of them fall in it. The payoff is greatest in many dimensions, where integrating a joint density over a complicated region by other methods may not be feasible [Cowan Ch. 3]. In practice we ask a stream of numbers for five things at once.

1. *Statistical quality:* no test that matters for our application can distinguish the numbers from independent uniform draws.
2. *A long period:* the sequence must not repeat within any computation we will ever run.
3. *Reproducibility:* running the program again gives the same numbers, so that a result can be checked and a bug can be found.
4. *Speed:* a large simulation consumes 10^9 to 10^{12} numbers.
5. *Independent streams:* many simulations running at once each need their own numbers, with no hidden relations between them.

The obvious source of randomness is physics. Cowan mentions tossing a coin [Cowan §3.1]; real devices time radioactive decays, amplify the thermal (Johnson) noise of a resistor or the shot noise of a diode, or measure which output port a single photon takes at a beam splitter, where quantum mechanics itself guarantees that no hidden variable decides the outcome [Lambert §12.7, fn. 3]. The operating system of every computer collects such **physical entropy** [bits whose values nobody, including the computer itself, could have predicted] from the timing jitter of keystrokes, disk and network interrupts, and from hardware noise sources on the processor chip. Physical entropy fails requirements 3 to 5 of the list above. It cannot be

replayed, so no result can be reproduced (requirement 3). It is far too slow to feed one large simulation, let alone many running at once (requirements 4 and 5). And its raw bits are biased and correlated, so they must be post-processed before use. We therefore use it for one thing only: to choose a starting point, the seed. Everything else comes from an algorithm.

Working definition 6.1 (pseudorandom number generator)

A **pseudorandom number generator** (PRNG) is a finite set S of **states** [all the bit patterns its memory can hold], a **transition function** $f : S \to S$, an **output function** g from states to numbers, and a **seed** [the state s_0 we start from, chosen by us]. It produces

$$s_{n+1} = f(s_n), \qquad u_n = g(s_n), \qquad n = 1, 2, \ldots$$

The sequence $u_1, u_2, \ldots$ is completely determined by s_0. It is called **pseudorandom** [Cowan §3.1] because it is accepted as random only in the operational sense of requirement 1. *Operational test:* apply statistical tests of the hypothesis "independent and uniform" (Section 6.6), and above all check that the application gives the same answer with a second, unrelated generator.

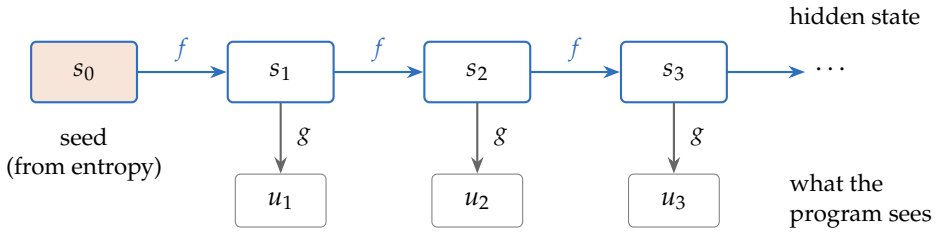

Figure 6.4: A pseudorandom number generator as a deterministic dynamical system. The state (top row) is updated by the same transition f at every step; the program sees only the outputs $g(s_n)$ (bottom row). The seed, the only input from outside, is the orange box.

A generator is thus a discrete dynamical system, like the Poincaré map of a chaotic pendulum. Its apparent randomness comes from the same place as chaos: nearby states are sent far apart, so after a few steps the output looks unrelated to the input [Lambert §12.7]. Kruschke's summary is exact: PRNGs "are not actually random; they are in fact deterministic. But the properties of the sequences they generate mimic the properties of random processes," and every sampling method relies heavily on how well they do so [Kruschke p. 74, fn. 4].

6.1.3 A finite machine must repeat

A generator has finitely many states, so it must eventually come back to a state it has visited, and from then on it repeats. Here is why. The state space S is finite: a generator with b bits of state has $|S| = 2^b$ states. Take the first $|S| + 1$ states $s_0, s_1, \ldots, s_{|S|}$. There are more of them than there are distinct states, so two must coincide (the **pigeonhole principle** [$n + 1$ letters in n pigeonholes put two letters in one hole]): $s_i = s_j$ for some $i < j \le |S|$. From there on the sequence repeats:

$$s_{j+k} \overset{(1)}{=} f^k(s_j) \overset{(2)}{=} f^k(s_i) \overset{(3)}{=} s_{i+k} \qquad \text{for every } k \ge 0. \tag{6.3}$$

(1) s_{j+k} is obtained from s_j by applying f k times; f^k means f composed k times.
(2) $s_j = s_i$, and a function gives the same output for the same input.
(3) The same statement read from s_i.

So the sequence of states, and with it the sequence of outputs, is **eventually periodic**: after a **tail** of i steps it runs round a cycle whose length P, the **period**, is at most $j - i \le |S|$. Can the tail be avoided? Yes, if f is a bijection [every state has exactly one predecessor]: applying f^{-1} to $s_i = s_j$ gives $s_{i-1} = s_{j-1}$, and i applications give $s_0 = s_{j-i}$, so the seed itself lies on the cycle. Good generators are designed to be bijections with a single cycle through (almost) all 2^b states.

Example: von Neumann's middle-square rule. The first proposal for a computer generator (von Neumann, in the 1940s) was to square a four-digit number and keep the middle four digits of the eight-digit square. Starting from 2916,

$$2916^2 = 08\,5030\,56 \;\to\; 5030, \qquad 5030^2 = 25\,3009\,00 \;\to\; 3009,$$
$$3009^2 = 09\,0540\,81 \;\to\; 0540, \qquad 0540^2 = 00\,2916\,00 \;\to\; 2916,$$

where the square is padded with leading zeros to eight digits. After four steps we are back at the seed: a period of 4 out of 10^4 possible states. This is not bad luck. Running the rule from all 10^4 seeds, every sequence repeats a value within 111 steps (43.7 on average), and 20% of the seeds end stuck at 0, since $0^2 = 0$. The middle-square map is not a bijection (the squares of x and of numbers close to x share middle digits), so many states funnel into a few short cycles. So a "chaotic-looking" rule is not enough; we need one whose cycles we can prove something about. Linear generators (Section 6.2) are such rules.

Example: what the period does to a Monte Carlo estimate. A generator that has gone round its cycle adds no new information, yet the error bar of a simulation keeps shrinking as if it did. To see this, estimate π from pairs (u_1, u_2) of uniform numbers. The pair falls inside the quarter disc $u_1^2 + u_2^2 < 1$ with probability $p = \pi/4$ (the area of a quarter of the unit disc), so $\hat{\pi} = 4\times$(fraction of pairs inside). The usual standard error of a fraction, $\sqrt{p(1-p)/N}$, gives the error bar $4\sqrt{\hat{p}(1-\hat{p})/N}$ that a script would report (it is derived with the error of a Monte Carlo average in Section 6.11.2); here $\hat{p}$ is the fraction of pairs inside and N the number of pairs. Now take the pairs from the tiny generator $x \mapsto (1229\,x + 1) \bmod 2048$ of Lambert's exercise [Lambert Problem 12.7], whose period is 2048 numbers, i.e. 1024 pairs. Figure 6.5 shows what happens. Up to about a thousand pairs the estimate behaves like any other. After one period, each new pair is one we have already seen, so the estimate stops improving: with 10^6 pairs it is 3.0899, off by -0.0517. The reported error bar knows nothing of this and keeps shrinking as $1/\sqrt{N}$, down to 0.0017, so the script reports an estimate that is wrong by thirty of its own standard errors. With PCG64 the same 10^6 pairs give 3.1389 ± 0.0016, within two standard errors of π, as it should be.

Watch out: The error bar cannot see the generator

A standard error $s/\sqrt{N}$ is computed under the assumption that the N draws are independent. If the generator repeats, or if its draws are correlated, the formula still returns a small number. Nothing in the output of a simulation warns us; only knowledge of the generator, or a rerun with an unrelated generator, does.

A modern generator never runs out of period: at 10^9 numbers per second, PCG64's period of $2^{128} \approx 3.4 \times 10^{38}$ would take 10^{22} years. What remains is requirement 1: making the numbers statistically indistinguishable from independent uniform draws in every way that could matter, and finding out when they are not.

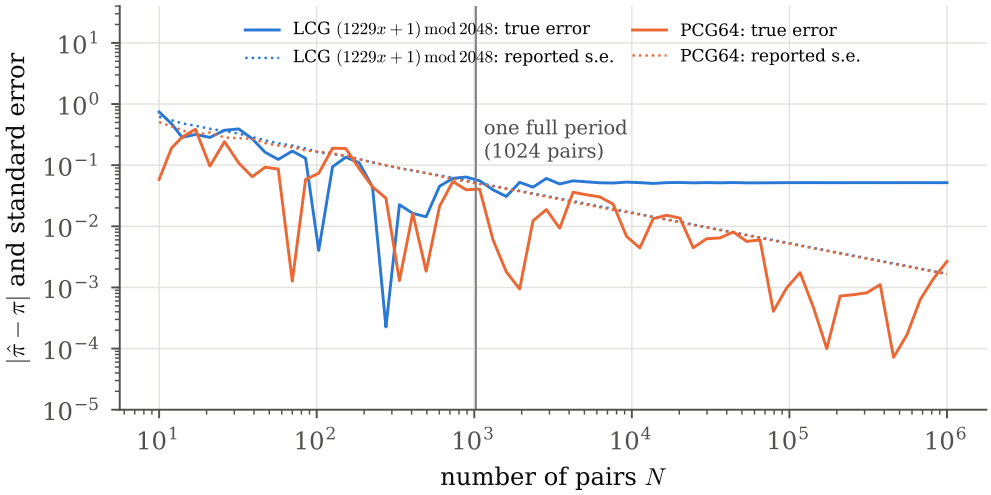

Figure 6.5: Estimating π from N pairs of uniform numbers. Solid: the actual error $|\hat{\pi} - \pi|$; dotted: the standard error the script reports. With PCG64 (orange) the actual error scatters around the reported one, both falling as $1/\sqrt{N}$. With a generator of period 2048 (blue) the actual error freezes at 0.05 once the sequence has gone round its cycle (vertical line), while the reported error keeps falling.

6.2 Linear congruential generators

The generator that broke Monty's coin in Section 6.1.1 is a *linear congruential generator*, the oldest family still in use and, until the 1990s, the default in most scientific libraries. It deserves a careful look for two reasons. It is simple enough that we can prove everything about it: its period, which of its bits are good and which are bad, and where its points lie. And the generator numpy uses today, PCG64, has a linear congruential generator inside it. So we ask two questions. With one multiplication and one addition per step, how long a sequence can we get before it repeats? And which parts of each number can we trust?

6.2.1 The rule and its closed form

Pick three integers, a **modulus** m, a **multiplier** a and an **increment** c, with $0 < a < m$ and $0 \le c < m$. From a seed x_0 in $\{0, 1, \ldots, m-1\}$ generate

$$x_{n+1} = (a\,x_n + c) \bmod m, \qquad u_n = \frac{x_n}{m}, \tag{6.4}$$

where $y \bmod m$ [the remainder of the integer y on division by m, always in $0, \ldots, m-1$] keeps the state in range [Cowan (3.2)–(3.3)], [Lambert Problem 12.7]. The state is one integer, the transition is $x \mapsto (ax + c) \bmod m$, and the output divides by m. With $c = 0$ the generator is called **multiplicative**; this is the form Cowan presents, and there x_n is never 0 (a zero state would stay zero), so $u_n = x_n/m$ lies strictly between 0 and 1 [Cowan §3.1]. Implementing it takes four lines:

Listing 6.2: A linear congruential generator (`code/ch06/lib_prng.py`)

```
def lcg_ints(a: int, c: int, m: int, seed: int, n: int) -> np.ndarray:
    """Return x_1, ..., x_n of the LCG (the seed x_0 itself is not returned)."""
    out = np.empty(n, dtype=np.int64 if m <= 2**62 else object)
    x = seed % m
    for i in range(n):
        x = (a * x + c) % m
```

```
29          out[i] = x
30      return out
```

Python integers never overflow, so line 28 is exactly (6.4). In C or Fortran one chooses $m = 2^{32}$ or 2^{64}, and the reduction mod$m$ is then free: it is what the hardware does anyway when an unsigned product overflows.

Where is the state after n steps? Applying the rule n times answers this with a closed form that we will use repeatedly. For $a \neq 1$,

$$\begin{aligned} x_n &\overset{(1)}{=} a\,x_{n-1} + c \overset{(2)}{=} a^2 x_{n-2} + ac + c \overset{(3)}{=} a^n x_0 + c\,(a^{n-1} + \cdots + a + 1) \\ &\overset{(4)}{=} a^n x_0 + c\,\frac{a^n - 1}{a - 1} \pmod{m}. \end{aligned} \tag{6.5}$$

(1) The rule (6.4); the notation " $(\mathrm{mod}\ m)$" at the end means every equality in the chain holds up to multiples of m. Reducing after each step or once at the end gives the same remainder, because remainders of sums and products depend only on the remainders of the terms.
(2) Substitute the rule for x_{n-1}.
(3) Repeat n times; each step multiplies what is there by a and adds c.
(4) Geometric sum. The fraction $(a^n - 1)/(a - 1)$ is an integer (it equals the sum on the previous line), so this is an integer identity before we reduce.

In particular, for a multiplicative generator $x_n = a^n x_0 \bmod m$: the whole sequence is powers of a.

Example: Lambert's toy generator. Take $a = 2$, $c = 3$, $m = 10$ and the seed $x_0 = 5$ [Lambert Problem 12.7.2]:

$$5 \;\to\; (2 \cdot 5 + 3) \bmod 10 = 3 \;\to\; 9 \;\to\; (21 \bmod 10) = 1 \;\to\; 5 \;\to\; 3 \;\to \cdots$$

The sequence comes back to the seed after 4 steps, although there are 10 states: the period is 4. Figure 6.6 shows the transition of every state. The seed 7 is a fixed point ($2 \cdot 7 + 3 = 17 \to 7$), and the seeds $0, 2, 4, 6, 8$ each lead into the cycle or the fixed point after one step, so they have a tail. The rule is not a bijection: 3 has two predecessors, 0 and 5, because $2x$ and $2(x + 5)$ differ by 10. Whenever a shares a factor with m, two states that differ by $m/\gcd(a, m)$ are sent to the same place, and the tails of Eq. (6.3) appear.

6.2.2 How long can the period be?

Multiplicative generators with a prime modulus. Let $c = 0$ and m prime, and start from any $x_0 \neq 0$. When does the sequence come back to its seed? By (6.5) $x_n = a^n x_0 \bmod m$, so it returns exactly when

$$\begin{aligned} x_n = x_0 \quad &\overset{(1)}{\iff} \quad a^n x_0 \equiv x_0 \pmod{m} \quad \overset{(2)}{\iff} \quad (a^n - 1)\,x_0 \equiv 0 \pmod{m} \\ &\overset{(3)}{\iff} \quad a^n \equiv 1 \pmod{m}. \end{aligned} \tag{6.6}$$

(1) The closed form (6.5) with $c = 0$; "$\equiv \pmod{m}$" means "differs by a multiple of m".
(2) Move x_0 to the left and factor.
(3) m is prime and does not divide x_0 (because $0 < x_0 < m$), so it must divide $a^n - 1$. A prime that divides a product divides one of the factors.

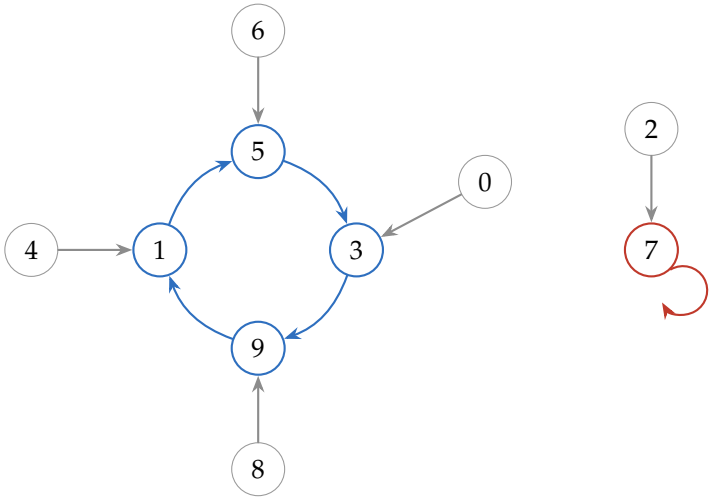

Figure 6.6: Every state of $x \mapsto (2x + 3) \bmod 10$ and where it goes. The seeds 1, 3, 5, 9 lie on a cycle of length 4 (blue); the seed 7 is a fixed point (red); the even seeds are not on any cycle and fall into one after a single step (grey). Because 2 and 10 share the factor 2, two states always share each image.

The period is therefore the smallest $n \geq 1$ with $a^n \equiv 1 \pmod{m}$, the **order** of a modulo m, and it is the same for every seed. How large can it be? Fermat's little theorem says $a^{m-1} \equiv 1 \pmod{m}$ for prime m. Call the order P and write $m - 1 = qP + r$ with $0 \leq r < P$. Then $a^r = a^{m-1}(a^P)^{-q} \equiv 1$, and since P is the smallest positive power that gives 1, r must be 0. So the order divides $m - 1$, and the period is at most $m - 1$ (all states except 0). It equals $m - 1$ exactly when a is a **primitive root** [its powers $a, a^2, \ldots, a^{m-1}$ run through all nonzero remainders].

Example: the two multipliers modulo 7. With $m = 7$ and $a = 3$, starting from 1: $1 \to 3 \to 9 \bmod 7 = 2 \to 6 \to 18 \bmod 7 = 4 \to 12 \bmod 7 = 5 \to 15 \bmod 7 = 1$. The period is $6 = m - 1$; 3 is a primitive root. With $a = 2$: $1 \to 2 \to 4 \to 8 \bmod 7 = 1$, period 3, because $2^3 = 8 \equiv 1$. From the seed 3 the same multiplier gives $3 \to 6 \to 5 \to 3$, a different cycle of the same length: the six nonzero states split into two cycles of three.

Cowan's example generator is of this kind: $m = 2147483399$ is prime and $a = 40692$ has period $m - 1 \approx 2 \times 10^9$ [Cowan §3.1], [121]. In the 1980s that was respectable. Today a single core produces 10^9 numbers per second, so the whole period is used up in about

$$\frac{2.1 \times 10^9 \text{ numbers}}{10^9 \text{ numbers/s}} \approx 2 \text{ s},$$

and a simulation that runs for an hour would go round the cycle about seventeen hundred times. L'Ecuyer's remedy in the same paper was to combine two such generators with different prime moduli, so that the period becomes of the order of the product of the two periods (about 2×10^{18}); this idea of a small cheap transition with a very large period runs through all modern designs. Cowan's example of a much longer period is the RANMAR generator, about 10^{43} [Cowan §3.1].

Full period with an increment. With $c \neq 0$ the state 0 is allowed, so all m states could in principle form one cycle. Which choices of a, c and m achieve this? A classical theorem gives the exact answer.

Key idea: Full period of $x \mapsto (ax + c) \bmod m$ (Hull and Dobell)

The generator has period m for every seed if and only if

1. c and m have no common factor, $\gcd(c, m) = 1$;
2. $a - 1$ is divisible by every prime that divides m;
3. $a - 1$ is divisible by 4 if m is divisible by 4.

Why the first condition is needed can be seen in three lines. Suppose $d = \gcd(c, m) > 1$ and start from $x_0 = 0$. By (6.5), $x_n = c\,(a^{n-1} + \cdots + 1) \bmod m$. Every term is a multiple of d, and reducing modulo m (itself a multiple of d) keeps it a multiple of d. So only the m/d multiples of d are ever visited, and the period is at most $m/d < m$. The second and third conditions force $a \equiv 1$ modulo every prime that divides m (and modulo 4 when 4 divides m). The map then behaves enough like $x \mapsto x + c$, which steps through every remainder in turn, that it too visits every state before returning. Their proof is elementary number theory, and nothing later depends on it.

Example: a full cycle of sixteen. For $m = 16 = 2^4$ take $a = 5$, $c = 3$. Then $\gcd(3, 16) = 1$, and $a - 1 = 4$ is divisible by 2 (the only prime in 16) and by 4. From $x_0 = 0$ the sequence is

$$3,\ 2,\ 13,\ 4,\ 7,\ 6,\ 1,\ 8,\ 11,\ 10,\ 5,\ 12,\ 15,\ 14,\ 9,\ 0,$$

all sixteen states once each. Lambert's generator $x \mapsto (1229x + 1) \bmod 2048$ with $2048 = 2^{11}$, also satisfies the conditions ($c = 1$; $1228 = 4 \cdot 307$), and indeed its period is 2048. So does his second, $x \mapsto (1597x + 51749) \bmod 244944$ [Lambert Problem 12.7.6]: here $244944 = 2^4 \cdot 3^7 \cdot 7$, 51749 is divisible by none of $2, 3, 7$, and $1596 = 2^2 \cdot 3 \cdot 7 \cdot 19$ is divisible by 2, 3, 7 and 4, and the period comes out as 244944. Lambert's question "what is the maximum period?" [Lambert Problem 12.7.1] has the answer m, reached exactly under these three conditions.

6.2.3 The low bits of a power-of-two modulus

Look again at the sixteen numbers above and write down only whether each is odd or even: $1, 0, 1, 0, \ldots$. The lowest bit alternates. This is not an accident of the example. Suppose $m = 2^k$ and look at the lowest j bits of the state, i.e. at $x_n \bmod 2^j$ with $j \le k$. Then

$$x_{n+1} \bmod 2^j \overset{(1)}{=} \big((ax_n + c) \bmod 2^k\big) \bmod 2^j \overset{(2)}{=} (ax_n + c) \bmod 2^j \overset{(3)}{=} \big(a\,(x_n \bmod 2^j) + c\big) \bmod 2^j. \tag{6.7}$$

(1) The rule (6.4) with $m = 2^k$, then reduction modulo 2^j.
(2) 2^j divides 2^k, so removing multiples of 2^k does not change the remainder modulo 2^j.
(3) Replacing x_n by its remainder changes ax_n by a multiple of 2^j.

The lowest j bits therefore form an LCG of their own, with modulus 2^j and no input from the higher bits. It has only 2^j states, so its period is at most 2^j: the lowest bit has period at most 2, the lowest two bits at most 4, and so on. For $j = 1$, a odd and c odd (as the full-period conditions require), $x_{n+1} \equiv x_n + 1 \pmod 2$: the parity flips at every step.

Example: the bits of a 32-bit generator. Figure 6.7 shows the 32 bits of the first 64 outputs of $x \mapsto (1664525x + 1013904223) \bmod 2^{32}$, the generator of the Monty example. The measured periods of bits 0, 1, 2, 3 are 2, 4, 8, 16, and bit 11 has period 4096: bit j has period exactly 2^{j+1}. The Monty simulation of Section 6.1.1 drew two integers per game and took the coin from the

second, x mod 2, which is bit 0 of every second output. Since bit 0 alternates, every second output has the same parity, and the coin never changes. The cure is never to use the low bits of such a generator. Take the *high* bits instead, e.g. $\lfloor 2u_n \rfloor$ with $u_n = x_n/2^{32}$, whose period is the full 2^{32}.

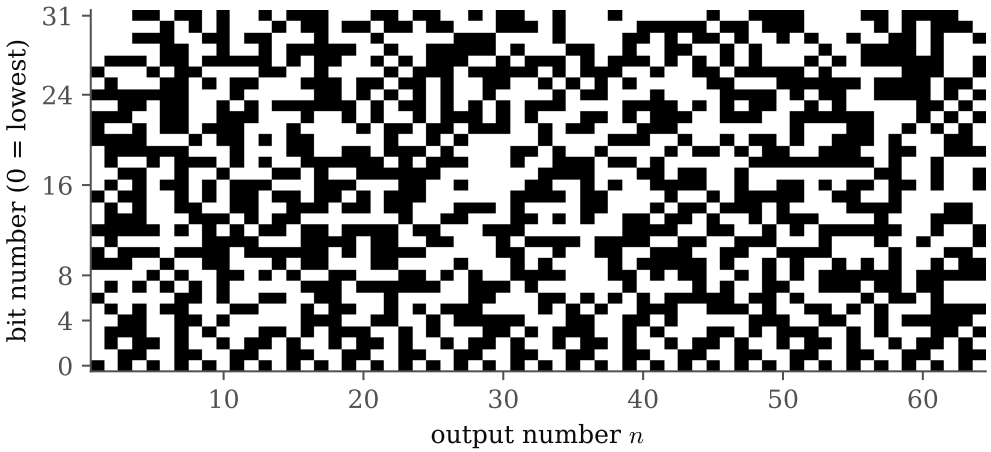

Figure 6.7: The bits of the first 64 outputs of the 32-bit linear congruential generator used in the Monty example (black = 1). The lowest rows are periodic with periods 2, 4, 8, ...; only the upper rows look random. The lowest row alternates, which is why taking x mod 2 from every second output gave Monty a coin that never changes.

Watch out: The remainder trick

Writing `x % n` to get an integer in $0, \ldots, n-1$ uses the *lowest* bits of x. For a power-of-two linear congruential generator those are the worst bits it has. It also has a bias whenever n does not divide the number of possible values of x. Library functions such as `rng.integers(n)` avoid both problems.

A full period says nothing about how the numbers are arranged within it. The tiny generator $x \mapsto (1229x + 1) \bmod 2048$ visits every one of its 2048 states, yet the left panel of Figure 6.8, which plots each output against the next, shows that consecutive pairs lie on six parallel lines (one of them very short) [Lambert Problem 12.7.5]. Lambert's larger generator and RANDU look fine in the same plot. The lines come from a lattice that every linear congruential generator carries (Section 6.3); for RANDU that lattice shows up in three dimensions.

6.3 Random numbers fall mainly in the planes

Many simulations use the uniform numbers in groups. A point in a detector volume needs three coordinates; a photon's direction needs two angles and its energy a third number; a rejection-sampling step (taken up later in the chapter) needs a candidate and a test value. Group consecutive outputs of a linear congruential generator into t-tuples $(u_n, u_{n+1}, \ldots, u_{n+t-1})$ and plot them as points in the unit cube $[0, 1)^t$. For independent uniform numbers the points would fill the cube evenly. In 1968 Marsaglia showed that for *every* multiplicative linear congruential generator they do something else: they lie on a family of parallel hyperplanes, and for some generators on very few of them [122]. The six lines in the left panel of Figure 6.8 were the two-dimensional case. So three questions follow. Where exactly do the t-tuples lie? How many planes are there? And how do we measure how bad that is?

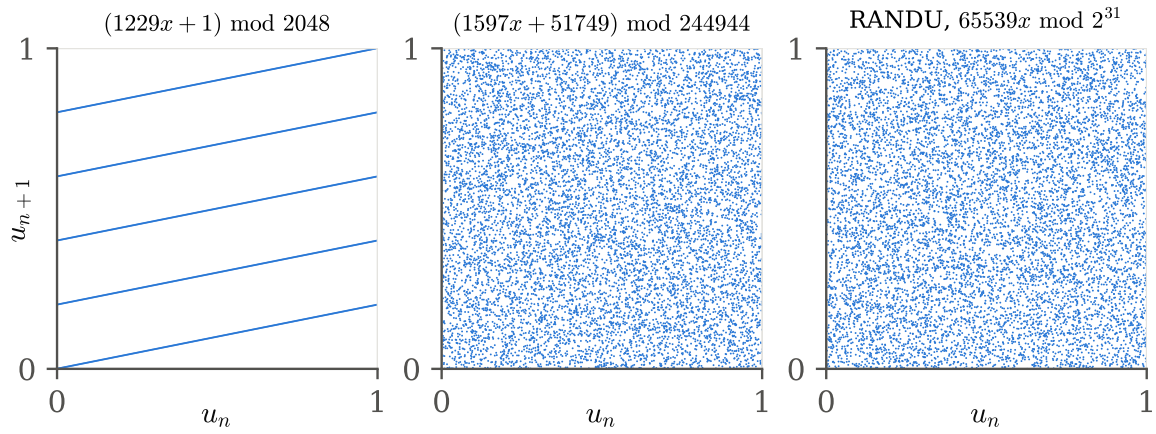

Figure 6.8: Consecutive pairs (u_n, u_{n+1}) from three linear congruential generators. Left: all 2048 pairs of $x \mapsto (1229x + 1) \bmod 2048$ lie on a few parallel lines. Middle and right: 10^4 pairs from Lambert's second generator and from RANDU, which show no structure at this resolution.

6.3.1 Why the points form a lattice

The points are far from independent because a whole t-tuple is fixed by one number, the state at its start. Take a multiplicative generator, $x_{n+1} = a x_n \bmod m$ (Eq. (6.4) with $c = 0$), and its outputs $u_n = x_n/m$. By the closed form (6.5), $x_{n+j} = a^j x_n \bmod m$, i.e. $a^j x_n$ minus some integer multiple $k_j m$ of m. Dividing by m, the t-tuple that starts at x_n is

$$\boldsymbol{u} \equiv (u_n, u_{n+1}, \ldots, u_{n+t-1}) \overset{(1)}{=} \frac{x_n}{m}\,(1, a, a^2, \ldots, a^{t-1}) - (0, k_1, k_2, \ldots, k_{t-1}). \tag{6.8}$$

(1) $u_{n+j} = x_{n+j}/m = (a^j x_n - k_j m)/m = a^j x_n/m - k_j$ for $j = 1, \ldots, t-1$, and $u_n = x_n/m$.

Every tuple is therefore an integer multiple of the single vector $\boldsymbol{v} = (1, a, \ldots, a^{t-1})/m$ plus a vector of integers. The set of all such combinations $\{x\,\boldsymbol{v} + \boldsymbol{z} : \; x \in \mathbb{Z},\; \boldsymbol{z} \in \mathbb{Z}^t\}$ is a **lattice** [a regular, crystal-like grid of points: all integer combinations of a few fixed vectors]. The generator's tuples are the points of this lattice that fall in the unit cube (at most $m - 1$ of them, one for each state). In crystal language: the points of a generator are the atoms of a crystal, and a crystal is organised in lattice planes.

Where do the planes come from? A family of parallel planes is described by a normal vector $\boldsymbol{h}$: the planes are $\boldsymbol{h} \cdot \boldsymbol{u} = k$ for $k = 0, \pm 1, \pm 2, \ldots$. So we ask which integer vectors $\boldsymbol{h} = (h_1, \ldots, h_t)$ make $\boldsymbol{h} \cdot \boldsymbol{u}$ an integer for every tuple. The answer is every $\boldsymbol{h}$ with

$$h_1 + a\,h_2 + a^2 h_3 + \cdots + a^{t-1} h_t \equiv 0 \pmod{m}. \tag{6.9}$$

To check it, compute $\boldsymbol{h} \cdot \boldsymbol{u}$ for any tuple:

$$\boldsymbol{h} \cdot \boldsymbol{u} \overset{(1)}{=} \frac{x_n}{m}\left(h_1 + a h_2 + \cdots + a^{t-1} h_t\right) - \sum_{j \geq 1} h_{j+1} k_j \overset{(2)}{=} x_n\, q - \sum_{j \geq 1} h_{j+1} k_j \;\in\; \mathbb{Z}, \tag{6.10}$$

(1) Dot $\boldsymbol{h}$ into (6.8).

(2) By (6.9) the bracket is $q\,m$ for some integer q; what is left is a sum of products of integers.

so every tuple lies on one of the parallel hyperplanes $\boldsymbol{h} \cdot \boldsymbol{u} = k$, $k \in \mathbb{Z}$. The integer vectors that satisfy (6.9) form a lattice of their own, the **dual lattice** [the integer vectors $\boldsymbol{h}$ with $\boldsymbol{h} \cdot \boldsymbol{u}$ an integer for every point of the generator], and each nonzero $\boldsymbol{h}$ in it defines one family of planes. Two facts about such a family follow from elementary geometry.

- *Spacing.* The planes $\boldsymbol{h}\cdot\boldsymbol{u} = k$ and $\boldsymbol{h}\cdot\boldsymbol{u} = k+1$ are a distance $1/|\boldsymbol{h}|$ apart, with $|\boldsymbol{h}| = \sqrt{h_1^2 + \cdots + h_t^2}$. (A plane $\boldsymbol{h}\cdot\boldsymbol{u} = k$ lies at distance $k/|\boldsymbol{h}|$ from the origin, along the unit normal $\boldsymbol{h}/|\boldsymbol{h}|$.)
- *Number.* Inside the unit cube, $\boldsymbol{h}\cdot\boldsymbol{u}$ lies strictly between $\sum_{h_i<0} h_i$ and $\sum_{h_i>0} h_i$, an open interval of length $|h_1| + \cdots + |h_t|$. It therefore contains at most $|h_1| + \cdots + |h_t|$ integers, and the points lie on at most that many planes. (When the endpoints are integers that the points never reach, as for a multiplicative generator, the interval contains one fewer, $|h_1| + \cdots + |h_t| - 1$.)

So a *short* dual vector is bad news: it means few planes, far apart, with nothing in between. For an increment $c \neq 0$ the tuples are the same lattice shifted by a constant vector, so the planes are the same, merely displaced.

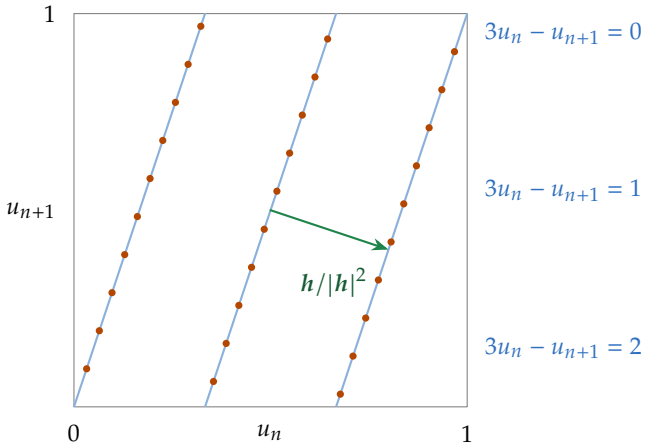

Figure 6.9: All 30 pairs (u_n, u_{n+1}) of the toy generator $x \mapsto 3x \bmod 31$ (orange dots). The dual vector $\boldsymbol{h} = (3, -1)$ satisfies $3 - 3\cdot 1 \equiv 0$, so every pair has $3u_n - u_{n+1}$ equal to 0, 1 or 2 and lies on one of three parallel lines (blue). The green arrow joins two neighbouring lines along their common normal; its length is the gap $1/|\boldsymbol{h}| = 1/\sqrt{10}$.

Example: the toy generator modulo 31. For $x \mapsto 3x \bmod 31$ in two dimensions, condition (6.9) reads $h_1 + 3h_2 \equiv 0 \pmod{31}$. The vector $\boldsymbol{h} = (3, -1)$ satisfies it ($3 - 3 = 0$), so every pair has $3u_n - u_{n+1} \in \mathbb{Z}$. Inside the square $3u_n - u_{n+1}$ lies between -1 and 3, so it is 0, 1 or 2 (the value -1 would need $u_{n+1} = 1$ and $u_n = 0$, which cannot occur): three lines, a distance $1/\sqrt{3^2 + 1^2} = 0.32$ apart (Figure 6.9). No shorter dual vector exists: the only other candidates with $|\boldsymbol{h}| \le \sqrt{10}$ are $(\pm 1, 0)$, $(0, \pm 1)$, $(\pm 1, \pm 1)$, $(\pm 2, \pm 1)$, $(\pm 1, \pm 2)$ and so on, and none gives $h_1 + 3h_2$ divisible by 31.

Example: Lambert's generator. For $x \mapsto (1229x + 1) \bmod 2048$ the vector $\boldsymbol{h} = (1, -5)$ works: $1 - 5\cdot 1229 = -6144 = -3\cdot 2048$. So $u_n - 5u_{n+1}$ takes only integer values (shifted by the constant $-5/2048$ that the increment contributes), at most $|1| + |-5| = 6$ of them, and the pairs lie on six lines a distance $1/\sqrt{26} = 0.20$ apart. That is the left panel of Figure 6.8. A good generator with 2048 states could have spread its pairs over lines a few hundredths apart.

6.3.2 RANDU's fifteen planes

RANDU was the generator supplied with IBM's System/360 scientific library in the 1960s, and it was copied into many other systems. It is multiplicative, with

$$x_{n+1} = 65539\, x_n \bmod 2^{31}, \qquad 65539 = 2^{16} + 3,$$

seeded with an odd x_0. The multiplier was chosen because multiplying by $2^{16}+3$ is a shift and two additions, fast on the hardware of the time. That choice is its downfall. To see why, ask how three consecutive outputs are related. Two steps multiply the state by a^2, $x_{n+2} = a^2 x_n \bmod 2^{31}$, so we need a^2 modulo 2^{31}:

$$a^2 \overset{(1)}{=} (2^{16}+3)^2 \overset{(2)}{=} 2^{32} + 6\cdot 2^{16} + 9 \overset{(3)}{=} 6\cdot 2^{16} + 9 \pmod{2^{31}}$$
$$\overset{(4)}{=} 6(2^{16}+3) - 18 + 9 \overset{(5)}{=} 6a - 9 \pmod{2^{31}}. \tag{6.11}$$

(1) $a = 65539 = 2^{16}+3$.
(2) $(p+q)^2 = p^2 + 2pq + q^2$ with $p = 2^{16}$, $q = 3$.
(3) $2^{32} = 2\cdot 2^{31}$ is a multiple of the modulus.
(4) Write $6\cdot 2^{16} = 6(2^{16}+3) - 18$.
(5) Collect: $-18+9 = -9$, and $2^{16}+3 = a$.

So a^2 is a small combination of a and 1. Multiplying (6.11) by x_n gives $x_{n+2} = a^2 x_n \equiv 6a x_n - 9x_n \equiv 6x_{n+1} - 9x_n$, that is, every output is fixed by the two before it:

$$x_{n+2} - 6x_{n+1} + 9x_n \equiv 0 \pmod{2^{31}} \quad\Longrightarrow\quad 9u_n - 6u_{n+1} + u_{n+2} \in \mathbb{Z}. \tag{6.12}$$

This is (6.10) with the dual vector $\boldsymbol{h} = (9,-6,1)$. Inside the cube $9u_n - 6u_{n+1} + u_{n+2}$ lies strictly between -6 and 10, so it is one of the fifteen integers $-5,-4,\ldots,9$. *All* triples of RANDU lie on fifteen parallel planes, a distance $1/\sqrt{81+36+1} = 1/\sqrt{118} \approx 0.092$ apart. A small ball of diameter just under 0.09 can sit between two neighbouring planes and contain no point at all. Knuth's verdict, quoted ever since, was that the very name RANDU is enough to bring dismay into the eyes and stomachs of many computer scientists.

The script `04_randu_planes.py` generates 30000 consecutive triples from the seed 1, computes $9u_n - 6u_{n+1} + u_{n+2}$ for each, and checks that it is an exact integer; it takes exactly 15 values, from -5 to 9. The planes are invisible from a generic viewpoint, but looking along them (viewing direction $(1, 1.5, 0)$, which is perpendicular to the normal $(9,-6,1)$) they appear edge-on as fifteen lines (Figure 6.10). This is Marsaglia's classic picture [122].

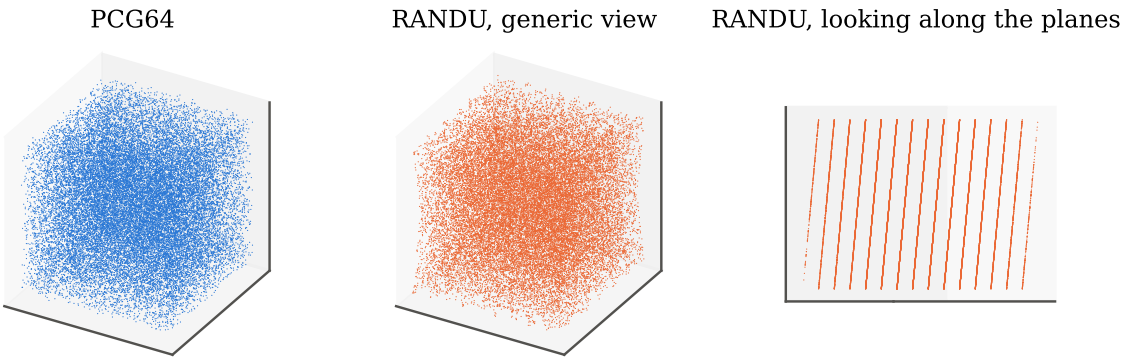

Figure 6.10: Thirty thousand consecutive triples (u_n, u_{n+1}, u_{n+2}) in the unit cube. Left: from PCG64. Middle: from RANDU, seen from the same generic angle; nothing looks wrong. Right: RANDU seen along the direction $(1, 1.5, 0)$, which lies in its planes $9u_n - 6u_{n+1} + u_{n+2} = k$; the planes appear edge-on, fifteen of them.

What does this do to a physics simulation? Anything that uses three consecutive numbers as a point in space samples only fifteen slices of the space. A detector acceptance computed by throwing points into a cube, a random walk in three dimensions, or a three-body phase-space generator would all be biased, and the bias does not shrink with N: it is a property of the generator, not a statistical fluctuation.

6.3.3 The spectral test

How do we measure how bad a generator's lattice is in t dimensions? By the widest gap between its planes, because a wide gap is a slab of the cube that no tuple ever visits. The gap of a family is $1/|\boldsymbol{h}|$, so the widest gap belongs to the shortest nonzero dual vector. Its length

$$v_t = \min\{|\boldsymbol{h}| : \boldsymbol{h} \in \mathbb{Z}^t,\ \boldsymbol{h} \neq \boldsymbol{0},\ h_1 + a h_2 + \cdots + a^{t-1} h_t \equiv 0 \pmod{m}\}, \qquad d_t = \frac{1}{v_t}, \tag{6.13}$$

gives the largest distance d_t between adjacent hyperplanes that hold all the t-tuples. Computing v_t for $t = 2, \ldots, 6$ or 8 is the **spectral test** (the name comes from its origin in Fourier analysis: $\boldsymbol{h}$ is a wave vector in which the empirical density of the points has a spike, the lattice Bragg peak of the crystal). A small d_t means that even the most widely spaced family of planes is dense, so the points come close to filling the cube.

Working definition 6.2 (spectral test)

For a linear congruential generator with multiplier a and modulus m, and a dimension t: find the shortest nonzero integer vector $\boldsymbol{h}$ with $h_1 + a h_2 + \cdots + a^{t-1} h_t \equiv 0 \pmod{m}$. Its length is v_t; the t-tuples lie on hyperplanes $\boldsymbol{h} \cdot \boldsymbol{u} \in \mathbb{Z}$ a distance $d_t = 1/v_t$ apart. *Operational test:* compare d_t with the smallest gap any lattice with m points per unit volume could have (Eq. (6.15)); a generator whose d_t is many times larger fails.

Finding the shortest vector of a lattice is a classic problem, and in low dimension it is easy: the script `05_spectral_test.py` writes down a basis of the dual lattice, namely $(m, 0, \ldots, 0)$ and $(-a^{j-1} \bmod m)\, \boldsymbol{e}_1 + \boldsymbol{e}_j$ for $j = 2, \ldots, t$ (any solution of (6.9) is an integer combination of these), reduces it with the Lenstra–Lenstra–Lovász (LLL) algorithm [repeated Gram–Schmidt-like steps that make the basis vectors short and nearly orthogonal], and then searches small integer combinations of the reduced vectors for the shortest one. For RANDU in $t = 3$ it finds $\boldsymbol{h} = (9, -6, 1)$ with $v_3 = 10.86$, confirming (6.12). The same calculation for three classic generators is plotted in Figure 6.11.

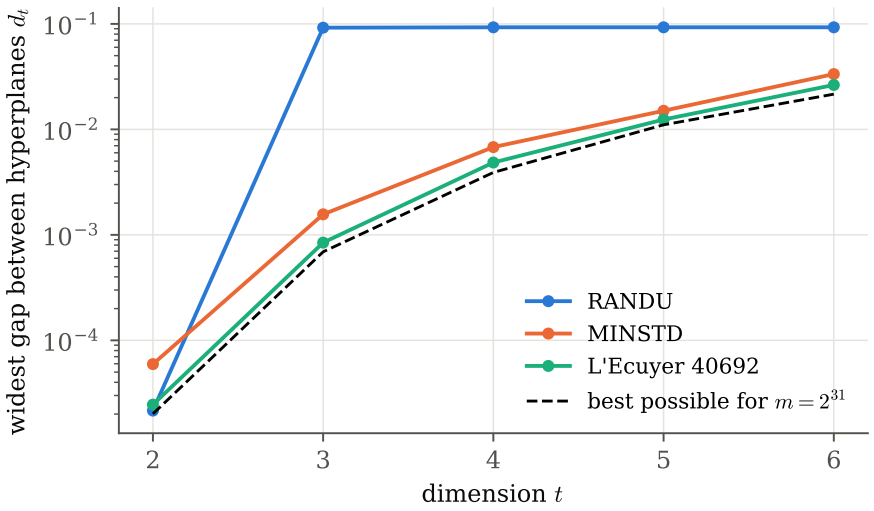

Figure 6.11: The spectral test for three multiplicative generators with $m \approx 2^{31}$: the widest gap d_t between the hyperplanes that hold the t-tuples. The dashed line is the smallest gap any lattice with 2^{31} points per unit volume can have. RANDU is near-ideal in two dimensions and then jumps to $d_3 \approx 0.09$, where it stays. MINSTD ($a = 16807$, $m = 2^{31} - 1$) and L'Ecuyer's $a = 40692$ stay within a factor of about three of the ideal.

How small can the gap be? Even the best multiplier leaves gaps of a certain size, and Minkowski's theorem tells us how large. A lattice with one point per state has m points per unit volume: the volume of its unit cell is $1/m$, and its dual lattice has unit-cell volume m (the reciprocal lattice of a crystal has the inverse cell volume, the same fact from solid-state physics). A lattice cannot have arbitrarily long shortest vectors at fixed cell volume. **Minkowski's theorem** [a convex region, symmetric about the origin, with volume larger than 2^t times the cell volume must contain a nonzero lattice point] makes this precise. Apply it to the **cross-polytope** $\{\boldsymbol{h} : |h_1| + \cdots + |h_t| \le r\}$, the t-dimensional octahedron:

$$\operatorname{vol}\{|h_1| + \cdots + |h_t| \le r\} \overset{(1)}{=} 2^t \frac{r^t}{t!} \overset{(2)}{\ge} 2^t\, m \qquad \Longleftrightarrow \qquad r \;\ge\; (t!\, m)^{1/t}. \tag{6.14}$$

(1) The octahedron is 2^t copies (one per sign pattern) of the simplex $\{h_i \ge 0,\ \sum h_i \le r\}$, whose volume is $r^t/t!$ (for $t = 2$, a triangle of area $r^2/2$; for $t = 3$, a tetrahedron of volume $r^3/6$).
(2) Minkowski's condition, with the dual cell volume m.

So for $r = (t!\, m)^{1/t}$ the octahedron contains a nonzero dual vector $\boldsymbol{h}$ with $|h_1| + \cdots + |h_t| \le r$, and by the "number" bullet above, the t-tuples lie on at most $(t!\, m)^{1/t}$ hyperplanes. This is Marsaglia's theorem [122]: *every* multiplicative generator with modulus m puts its t-tuples on at most $(t!\, m)^{1/t}$ parallel hyperplanes. For $m = 2^{32}$ the bound is 2954 planes in three dimensions and only 42 in ten. No choice of multiplier can avoid it; a good choice only avoids being much worse. The sharpest statement of the same kind uses the Hermite constants γ_t of lattice theory [the largest possible value of (shortest vector)^2/(cell volume)$^{2/t}$ over all lattices in t dimensions] and gives the smallest possible gap,

$$d_t \;\ge\; \frac{1}{\gamma_t^{1/2}\, m^{1/t}}, \qquad \gamma_2 = \left(\tfrac{4}{3}\right)^{1/2},\ \gamma_3 = 2^{1/3},\ \gamma_4 = 2^{1/2},\ \ldots, \tag{6.15}$$

the dashed line in Figure 6.11: for $m = 2^{31}$ and $t = 3$ it is 6.905×10^{-4}, a hundred times smaller than RANDU's gap.

Example: two generators that pass. MINSTD, $x \mapsto 16807\, x \bmod (2^{31} - 1)$, the "minimal standard" of the 1990s, has $d_2 = 5.950 \times 10^{-5}$ and $d_3 = 0.001565$, and L'Ecuyer's $a = 40692$ from Cowan's example has $d_2 = 2.457 \times 10^{-5}$ [Cowan §3.1]. Both stay close to (6.15) in every dimension plotted. But in high dimension even the best possible gap grows, because $m^{1/t}$ shrinks as t grows: at $t = 6$ MINSTD has $d_6 = 0.03343$, and the six-tuples of any 2^{31}-state generator lie on at most $(6! \cdot 2^{31})^{1/6} \approx 108$ planes. A simulation that consumes numbers in groups of six or more (and most do) sees this structure. The modulus has to be much larger, which is exactly what the 128-bit linear congruential generator inside PCG64 provides (Section 6.4); tables of multipliers with good lattice structure, found by running the spectral test over many candidates, are given in [123].

Watch out: Two-dimensional plots certify nothing

RANDU's pair plot (Figure 6.8, right) and its d_2 are close to ideal. Its defect appears only in three dimensions. A generator has to be examined in every dimension in which the application uses it.

6.4 Modern generators: a bigger state and a better output function

The linear congruential generators of Sections 6.2 and 6.3 fail in two ways. Their state is small, so the period is short and, by Marsaglia's bound, the tuples lie on few hyperplanes. And their

output is the state itself (divided by m), so every regularity of the state, the short periods of the low bits and the lattice, shows up directly in the numbers. Modern generators repair both. They keep the picture of Figure 6.4 (a state s, a transition f, an output g) but choose a large state with a transition that is cheap and provably has a huge period, and an output function that hides whatever structure the transition leaves behind. For three widely used generators we ask the same three questions: what is the state, how is it updated, and what does the output function do to it? The three are xorshift, the Mersenne Twister (the default of Python's `random` module and of numpy's older `RandomState`) and PCG64 (numpy's default today).

6.4.1 Xorshift: a linear map on bits

Marsaglia's xorshift generators [124] keep a single 64-bit word x and update it with three operations of the form "shift x by a few bits and combine the result with x by **exclusive or**" [bitwise addition without carry, $0 \oplus 0 = 1 \oplus 1 = 0$, $0 \oplus 1 = 1 \oplus 0 = 1$]:

Listing 6.3: Xorshift64 with shifts 13, 7, 17 (`code/ch06/lib_prng.py`)

```
88 def xorshift64(seed: int, n: int) -> list[int]:
89     x, out = seed & M64, []
90     assert x != 0, "the all-zero state maps to itself"
91     for _ in range(n):
92         x ^= (x << 13) & M64
93         x ^= x >> 7
94         x ^= (x << 17) & M64
95         out.append(x)
96     return out
```

Line 92 shifts x left by 13 bits (dropping bits that fall off the top) and XORs it into x; line 93 does the same with a right shift by 7; line 94 with a left shift by 17.

Example: one step by hand. Start from $x = 1$, a single bit at position 0. Line 92: $1 \ll 13 = 2^{13} = 8192$, and $1 \oplus 8192 = 8193$ (bits 0 and 13). Line 93: $8193 \gg 7 = 64$ (bit 13 moves to bit 6, bit 0 falls off), and $8193 \oplus 64 = 8257$ (bits $0, 6, 13$). Line 94: $8257 \ll 17$ has bits $17, 23, 30$, none of which overlaps bits $0, 6, 13$, so the XOR is a sum: $8257 + 8257 \cdot 2^{17} = 1082269761$ (bits $0, 6, 13, 17, 23, 30$). One bit has become six; after a few more steps every bit of the state depends on many bits of the seed.

Why the period is $2^{64} - 1$. How can we know the period without stepping through 10^{19} states? Each of the three lines is linear in the bits, so one step is a matrix, and the period is the smallest power of that matrix that gives the identity. To see the matrix, write the state as a column vector $\boldsymbol{x} \in \{0,1\}^{64}$ of its bits and do arithmetic modulo 2, where XOR is addition. A left shift by k is a matrix L^k (L has ones just below the diagonal), a right shift is R^k, and the three lines of the update are the matrices $\mathbb{1} + L^{13}$, $\mathbb{1} + R^7$, $\mathbb{1} + L^{17}$. So one step is a fixed 64×64 matrix over the two-element field,

$$\boldsymbol{x}_{n+1} = T\,\boldsymbol{x}_n, \qquad T = (\mathbb{1} + L^{17})(\mathbb{1} + R^{7})(\mathbb{1} + L^{13}) \pmod 2, \tag{6.16}$$

and the n-th state is $T^n \boldsymbol{x}_0$. The zero state is fixed ($T\mathbf{0} = \mathbf{0}$), so the largest possible period is $2^{64} - 1$, a single cycle through all nonzero states. That happens exactly when the smallest $n \geq 1$ with $T^n = \mathbb{1}$ is $N = 2^{64} - 1$. The script `06_modern_generators.py` builds T column by column (column j is the image of the state with only bit j set), checks $T\boldsymbol{x} = \text{xorshift}(\boldsymbol{x})$ for random $\boldsymbol{x}$, and

then checks the period with eight matrix powers (T^N and the seven powers $T^{N/p}$). The logic is

$$T^N = \mathbb{1} \text{ and } T^{N/p} \neq \mathbb{1} \text{ for every prime } p \mid N \overset{(1)}{\Longrightarrow} \text{order of } T \text{ divides } N \text{ but no } N/p \overset{(2)}{\Longrightarrow} \text{order of } T = N. \tag{6.17}$$

(1) If $T^n = \mathbb{1}$ and $T^N = \mathbb{1}$, then $T^{\gcd(n,N)} = \mathbb{1}$, so the smallest such n (the order) divides N.
(2) A proper divisor d of N divides N/p for at least one prime p in the factorisation of N, and then $T^{N/p} = (T^d)^{N/(pd)} = \mathbb{1}$, which was excluded.

Here $2^{64} - 1 = 3 \cdot 5 \cdot 17 \cdot 257 \cdot 641 \cdot 65537 \cdot 6700417$, and each matrix power takes 64 squarings by repeated squaring. Both conditions hold, so xorshift64 with shifts $(13, 7, 17)$ has period $2^{64} - 1$: no search through 10^{19} states was needed.

The linearity that proves the period is also xorshift's weakness. Since $T^n(\boldsymbol{x}_0 \oplus \boldsymbol{y}_0) = T^n\boldsymbol{x}_0 \oplus T^n\boldsymbol{y}_0$, the stream from the seed $s_1 \oplus s_2$ is the XOR of the streams from s_1 and s_2; the script checks this for 50 outputs. Any statistic that is linear over bits, such as the rank of a matrix built from output bits or the length of the shortest linear recurrence that reproduces a bit sequence, detects the generator. Modern variants (xorshift128+, xoshiro) add a nonlinear output step, an integer addition or multiplication, for this reason.

6.4.2 The Mersenne Twister

The Mersenne Twister MT19937 [125] is a much larger linear generator over bits. Its state is 624 words of 32 bits. The transition ("twist") replaces each word by the XOR of the word 397 places ahead with a bit-mixed combination of the top bit of the word itself and the lower 31 bits of its neighbour:

Listing 6.4: MT19937: twist (transition) and tempering (output) (`code/ch06/lib_prng.py`)

```
112     def _twist(self):
113         mt = self.mt
114         for k in range(624):
115             y = (mt[k] & 0x80000000) | (mt[(k + 1) % 624] & 0x7FFFFFFF)
116             mt[k] = mt[(k + 397) % 624] ^ (y >> 1) ^ (0x9908B0DF if y & 1 else 0)
117         self.i = 0
118 
119     def next32(self) -> int:
120         if self.i >= 624:
121             self._twist()
122         y = self.mt[self.i]
123         self.i += 1
124         y ^= y >> 11                        # tempering: an invertible scramble
125         y ^= (y << 7) & 0x9D2C5680
126         y ^= (y << 15) & 0xEFC60000
127         y ^= y >> 18
128         return y
```

Lines 115–116 are the recurrence $\boldsymbol{x}_{k+624} = \boldsymbol{x}_{k+397} \oplus (\boldsymbol{x}_k^{\text{upper}} \mid \boldsymbol{x}_{k+1}^{\text{lower}})A$, where the multiplication by the matrix A is "shift right by one, and XOR the constant `0x9908B0DF` if the bit shifted out was 1". Only $32 \cdot 624 - 31 = 19937$ bits of the state take part (the lower 31 bits of one word are never used), and the constants are chosen so that the transition, a 19937×19937 matrix over the bits, has order $2^{19937} - 1$. That number is a **Mersenne prime** [a prime of the form $2^p - 1$], which gives the generator its name and makes the period check (6.17) a single condition, since N has no prime factor other than itself. The period, about 10^{6001}, can never be exhausted.

The output function, **tempering** (lines 124–127), applies four more shift-and-XOR steps to the word before returning it. Each step is invertible, so it does not change the period; it

redistributes bits so that the top bits of the outputs, which a program uses first, are well mixed. The designers proved that MT19937 is **623-dimensionally equidistributed** to 32-bit accuracy [over a full period, every sequence of 623 consecutive 32-bit outputs occurs equally often, except that the all-zero sequence occurs once less]. No linear congruential generator comes close to this in high dimension. The script reproduces numpy's MT19937 output exactly: 10,000 of the first 10,000 outputs agree, starting from the conventional seed 5489.

Two weaknesses remain, and both come from linearity. First, the generator is *predictable*. Tempering is invertible, so each output reveals one full word of the state; 624 consecutive outputs reveal all of it. The script takes 624 outputs from the middle of numpy's stream, undoes the tempering (the `untemper` function, a few lines), and predicts the next 1000 outputs: 1,000 of them are right. For physics this does not matter, since a simulation is not an adversary; for cryptography it disqualifies the generator. Second, it fails statistical tests aimed at linearity. In the TestU01 battery (Section 6.6) MT19937 passes everything except two linear-complexity tests [126], which measure how long a linear recurrence is needed to reproduce a sequence of output bits; for MT19937 it is 19937, far shorter than for a random sequence of the same length. It is also slow to recover from a state with very few one-bits, and its 2.5 kilobytes of state are large for a GPU thread.

6.4.3 PCG64: a linear congruential generator with a permuted output

O'Neill's insight was that the linear congruential generator is a fine transition function if the modulus is large, and that its problems all come from using the state as the output [127]. PCG ("permuted congruential generator") keeps a 128-bit linear congruential state and passes it through a small nonlinear permutation. This is PCG64, the default bit generator of numpy's `default_rng` and of `rng_for`, written out in full:

Listing 6.5: PCG64: 128-bit LCG state, XSL-RR output (`code/ch06/lib_prng.py`)

```
141 class PCG64:
142     """Bit-for-bit the same as numpy.random.PCG64 when given its (state, inc)."""
143
144     def __init__(self, state: int, inc: int):
145         self.state, self.inc = state & M128, inc & M128   # inc is odd
146
147     def next64(self) -> int:
148         self.state = (self.state * PCG_MULT + self.inc) & M128     # transition: an LCG mod
    2^128
149         s = self.state
150         return rotr64(((s >> 64) ^ s) & M64, s >> 122)           # output: xor-fold, then
    rotate
```

Line 148 is the transition: $s \mapsto (as + c) \bmod 2^{128}$, with the 128-bit multiplier `PCG_MULT` and an odd increment c (`inc`). By the Hull–Dobell conditions of Section 6.2 (c odd, $a - 1$ divisible by 4) the period is 2^{128} for every increment, and different increments give different sequences, so the increment selects a **stream**. Line 150 is the output function **XSL-RR** ("xor-shift low, random rotation", Figure 6.12), in two steps:

1. *Fold:* $(s \gg 64) \oplus s$, keeping the low 64 bits, XORs the high half of the state onto the low half. Each output bit i now combines state bit i (a poor, low bit) with state bit $i + 64$ (a good, high bit).
2. *Rotate:* rotate the 64-bit result right by $r = s \gg 122$, the value of the top six state bits, a number between 0 and 63.

The rotation is what hides the bad bits. The top six bits are the best bits of the state (by (6.7) their period is the full 2^{128}), and they choose, at every step, which bit of the folded word ends

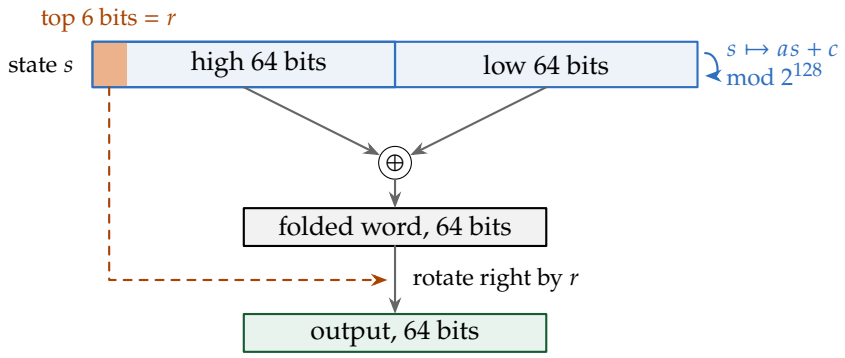

Figure 6.12: The output function of PCG64. The 128-bit state is updated by a linear congruential step (blue loop). The output XORs the high half of the state onto the low half, then rotates the 64-bit result by an amount r read from the top six state bits (orange), the bits with the longest period. The rotation moves every output bit around from step to step, so the short periods of the low state bits never reach a fixed output position.

up in which position of the output. A fixed output position therefore sees a different state bit from step to step, and the short periods of the low bits (Figure 6.7) and the lattice of Section 6.3 are scrambled away. The multiplication and addition in line 148 are cheap (a few machine instructions on 64-bit hardware), and the state is only 256 bits including the increment.

The class `PCG64` is not an imitation: given numpy's internal state (`like_numpy`, lines 152–155 of the library), it produces numpy's bits. Of the first 100,000 outputs of `numpy.random.PCG64`, 100,000 agree exactly. Every random number in this book has come out of the ten lines above.

PCG64 passes all the tests of TestU01's largest battery [127]. One caveat was found later: two PCG64 streams whose increments and starting states are related in a particular way produce correlated outputs, because the fold-and-rotate output mixes too little for such pairs. Seeding through numpy's SeedSequence (Section 6.5) chooses state and increment as unrelated hashes and avoids it; for simulations with enormous numbers of parallel streams numpy also offers `PCG64DXSM`, the same state with a stronger, multiplicative output function.

Example: what the permutation does, at toy size. The effect is easiest to see on a generator small enough to plot completely. Take a 16-bit state with the classic multiplier $a = 25173$ and increment $c = 13849$ (full period 2^{16} by Hull–Dobell), and produce an 8-bit output in two ways: by keeping the top 8 bits of the state (a truncated LCG, the usual practice before PCG), or by PCG's $16 \to 8$ bit output XSH-RR, which XORs the state with itself shifted right by 5, keeps bits 5 to 12, and rotates them by the value of the top 3 bits. Figure 6.13 plots each output against the next for the whole period. The truncated LCG shows rows of the lattice; the permuted output does not.

Counting makes the same point. There are $K = 256^2 = 65536$ possible pairs of 8-bit outputs, and one period gives $n = 65536$ consecutive pairs. How many distinct pairs would a truly random sequence of that length produce? Take one particular pair. A random sequence hits it at least once with probability

$$1 - \left(1 - \frac{1}{K}\right)^n \overset{(1)}{=} 1 - \exp\left[n \ln\left(1 - \frac{1}{K}\right)\right] \overset{(2)}{=} 1 - \exp\left[-\frac{n}{K} + O\left(\frac{n}{K^2}\right)\right] \overset{(3)}{=} 1 - e^{-1} + O(K^{-1}) \approx 0.632. \tag{6.18}$$

(1) Each of the n pairs misses the given pair with probability $1 - 1/K$, independently; $y^n = e^{n \ln y}$.
(2) $\ln(1 - \epsilon) = -\epsilon - \epsilon^2/2 - \ldots$ with $\epsilon = 1/K$.

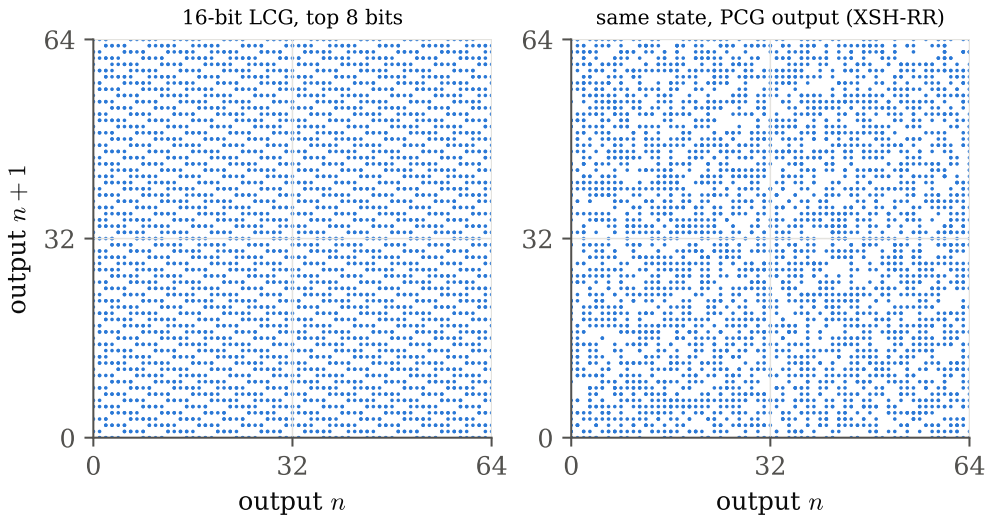

Figure 6.13: A 16-bit linear congruential state turned into 8-bit outputs in two ways; each dot is a pair of consecutive outputs (a corner of the full 256×256 plot is shown). Left: keeping the top 8 bits; the pairs fall on regular rows, the lattice of Section 6.3. Right: PCG's xorshift-and-rotate output applied to the same state; the regular rows are gone.

(3) $n = K$.

Multiplying by the K possible pairs, about $K(1 - e^{-1}) \approx 41{,}428$ distinct pairs are expected, with a standard deviation of about 80 (the variance of the number of empty cells is approximately $Ke^{-1}(1 - 2e^{-1})$). The permuted output produces 41,488 distinct pairs (63.3%), as expected. The truncated LCG produces 40,960 (62.5%), about six standard deviations too few: its pairs are too regular to spread as randomly as random pairs do.

6.4.4 Counter-based generators, and a summary

A different design removes the transition function altogether. A **counter-based generator** uses the state $s_n = n$, a plain counter, and puts all the work into the output: $u_n = g_k(n)$, where g_k is a bijective scramble of 64 or 128 bits controlled by a key k, built from a few rounds of a simplified block cipher [128]. Jumping ahead by any amount is free (just set n), and every key gives an independent stream, which suits GPUs where each of thousands of threads needs its own numbers. Numpy provides one of them as `Philox`.

Every modern design splits the work the same way. The transition only needs to guarantee a long period, which a linear rule, over integers or over bits, does with a proof. The output function supplies the statistical quality, by mixing the good and bad parts of the state nonlinearly. Whether the result is good enough is decided not by the design but by statistical tests (Section 6.6).

6.5 Seeds, streams and reproducible parallel simulations

A realistic Monte Carlo study is not one run but thousands. To estimate the covariance of a power-spectrum estimator in Chapter 8 we will simulate a thousand skies; a detector study runs the same event simulation on hundreds of cluster nodes at once. Each job needs its own stream of random numbers. Three things must be true of these streams. Each must be *reproducible*: if job 417 produced a strange map, we must be able to regenerate exactly that map to find out why. They must be *different*: two jobs with the same stream would produce the same sky twice and silently halve our sample. And they must be *unrelated*: no simple relation between the

Taxonomy: Generators and what is inside them

generator	state	transition / output	period	known weakness
RANDU	31 bits	$65539x \bmod 2^{31}$ / $x/2^{31}$	2^{29}	triples on 15 planes
MINSTD	31 bits	$16807x \bmod (2^{31}-1)$ / x/m	$2^{31}-2$	short period, lattice for $t \gtrsim 5$
xorshift64	64 bits	three shift-XORs / the state	$2^{64}-1$	linear over bits
MT19937	19937 bits	linear twist / tempering	$2^{19937}-1$	linear over bits, predictable
PCG64	128 + 128 bits	LCG mod 2^{128} / XSL-RR	2^{128} per stream	streams with specially related seeds can be correlated
Philox	counter + key	$n \mapsto n+1$ / keyed scramble	2^{256}	none known for simulation

numbers of different jobs, or the thousand skies are not a thousand independent draws. So the question is: how do we seed many streams so that all three hold? The helper `rng_for`, which makes every random stream used here, is one answer, and we follow it down to the bits.

6.5.1 Why "seed = job number" can go wrong

The obvious recipe is to seed job j with the integer j. It is safe only if the generator forgets where it started. Nearby seeds are nearby states, and some transitions keep nearby states related forever.

Example: RANDU from the seeds 1 and 3. RANDU (Section 6.3) is multiplicative: by (6.5), $x_n = a^n x_0 \bmod 2^{31}$. Start one stream from $x_0 = 1$ and another from $x'_0 = 3$. Then

$$x'_n \overset{(1)}{=} a^n \cdot 3 \bmod 2^{31} \overset{(2)}{=} 3\,x_n \bmod 2^{31}, \qquad \text{so} \qquad u'_n \overset{(3)}{=} 3u_n \bmod 1. \tag{6.19}$$

(1) The closed form with $c = 0$ and seed 3.
(2) $a^n \cdot 3 = 3 \cdot a^n$, and $a^n \equiv x_n$ for the stream from the seed 1; reducing before or after multiplying by 3 gives the same remainder.
(3) Divide by 2^{31}: $u'_n = x'_n/2^{31}$ is the fractional part of $3u_n$.

So the second stream is a fixed function of the first. Each stream on its own is as good (or as bad) as RANDU, but plotted against each other they lie on three lines (Figure 6.14, left); the script confirms $u'_n = 3u_n \bmod 1$ to the last bit. For any multiplicative generator, the seeds x_0 and kx_0 give streams related by multiplication by k.

Example: random 32-bit seeds collide. The opposite recipe, a random seed per job, has its own trap if the seed is small. Many older interfaces accept a 32-bit integer, so there are only $K = 2^{32} \approx 4.3 \times 10^9$ seeds. How likely is it that two of n jobs draw the same one? This is the birthday problem, with K seeds in place of 365 days. The chance that n independently chosen seeds are all different is

$$\mathrm{P}(\text{all } n \text{ seeds different}) \overset{(1)}{=} \prod_{k=0}^{n-1}\Big(1-\frac{k}{K}\Big) \overset{(2)}{=} \exp\Big[\sum_{k=0}^{n-1}\ln\Big(1-\frac{k}{K}\Big)\Big] \overset{(3)}{\approx} \exp\Big[-\sum_{k=0}^{n-1}\frac{k}{K}\Big] \overset{(4)}{=} \exp\Big[-\frac{n(n-1)}{2K}\Big]. \tag{6.20}$$

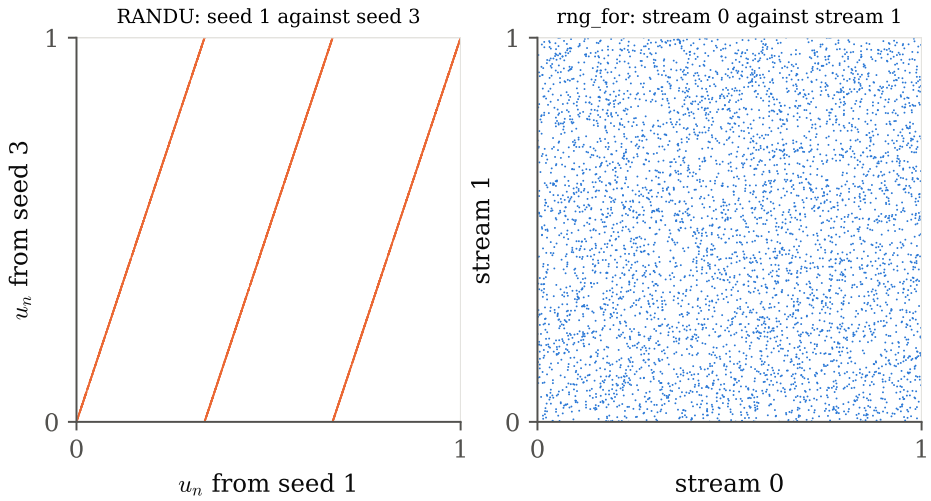

Figure 6.14: Two streams plotted against each other, 5000 numbers each. Left: RANDU started from the seeds 1 and 3; the second stream is the fractional part of three times the first, so the points lie on three lines. Right: streams 0 and 1 of `rng_for` for the same script; no relation is visible.

(1) The $(k+1)$-th seed must avoid the k values already taken, which has probability $1 - k/K$, independently of the earlier draws.
(2) A product is the exponential of the sum of the logarithms.
(3) $\ln(1-\epsilon) \approx -\epsilon$ for $\epsilon = k/K \ll 1$.
(4) $\sum_{k=0}^{n-1} k = n(n-1)/2$.

With $n = 10^3$ jobs a collision has probability 0.0001, with 10^4 jobs 0.012, and with 10^5 jobs 0.688: more likely than not, two of a hundred thousand simulations are identical. The exact product and the approximation agree to three digits. With 128-bit seeds and the same 10^5 jobs the probability is 1.469×10^{-29}. Seeds must be long.

6.5.2 SeedSequence: hashing a seed into a state

Numpy solves both problems by never putting a user's seed directly into the generator's state. A **SeedSequence** takes any collection of nonnegative integers as **entropy** [here, the numbers that identify the job: a base seed and a stream index] and mixes them with a hash function into a pool of 128 bits. Every input bit affects every pool bit, so the entropies $[s, 0]$ and $[s, 1]$, which differ in one bit, give pools that look unrelated. From the pool it then generates as many state words as the generator needs, again through a hash. The two problems of the examples disappear: nearby inputs no longer give nearby states, and the state is drawn from 2^{128} or more possibilities. The method `spawn(n)` makes n child sequences by appending the child's index to the entropy, so that a job can in turn seed its own sub-jobs, and the resulting tree of streams is reproducible from the single root.

The helper `rng_for` of `code/common.py` is three lines:

Listing 6.6: Every random stream in the book is made here (`code/common.py`)

```
122 def rng_for(chapter: str, name: str, stream: int = 0) -> np.random.Generator:
123     """Reproducible PCG64 generator seeded from the script identity (+ optional stream
        index)."""
124     key = f"{chapter}/{name}" + (f"/salt{SEED_SALT}" if SEED_SALT else "")
125     seed = int.from_bytes(hashlib.sha256(key.encode()).digest()[:8], "little")
126     return np.random.Generator(np.random.PCG64(np.random.SeedSequence([seed, stream])))
```

Line 124 builds the script's name, e.g. `"ch06/07_seeds_streams"` (the optional salt is the testing switch of Section 0.6; in the book's own runs it is empty). Line 125 turns that name into a 64-bit integer: the first eight bytes of its SHA-256 hash. For this script it is 16002383964210800950. The name, not a number typed by hand, is the seed, so two scripts can never share a stream by accident, and renaming a script is the only way to change its random numbers. Line 126 feeds [seed, stream] into a SeedSequence and hands the result to PCG64. The script `07_seeds_streams.py` follows the path down to the bits (Figure 6.15):

Listing 6.7: rng_for traced by hand: SeedSequence words to the PCG64 state (`code/ch06/07_seeds_streams.py`)

```
36 ss = np.random.SeedSequence([seed, 0])
37 w = ss.generate_state(4, np.uint64)                    # four 64-bit words of mixed entropy
38 initstate = (int(w[0]) << 64) | int(w[1])
39 initseq = (int(w[2]) << 64) | int(w[3])
40 inc = ((initseq << 1) | 1) & M128                      # the increment must be odd
41 st = 0
42 st = (st * 0x2360ED051FC65DA44385DF649FCCF645 + inc) & M128   # PCG's seeding: step, add,
       step
43 st = (st + initstate) & M128
44 st = (st * 0x2360ED051FC65DA44385DF649FCCF645 + inc) & M128
```

Line 37 asks the SeedSequence for four 64-bit words. The first two become a 128-bit starting value (line 38), the last two the stream selector (line 39), from which line 40 makes the odd increment $c = 2 \times \text{selector} + 1$ of the linear congruential step of Section 6.4. Lines 41–44 are PCG's seeding rule: one step from zero, add the starting value, one more step. The state and increment obtained this way are identical to the ones inside numpy's generator, and so are the next 1000 outputs of the `PCG64` class of Section 6.4. So nothing in the random numbers is hidden: every operation from the name of a script to its first output is now explicit.

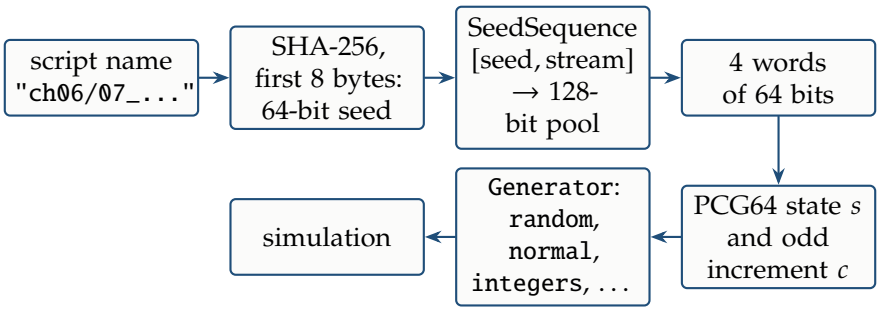

Figure 6.15: What `rng_for` does. The script's name is hashed to a 64-bit seed; the seed and a stream index are mixed by a SeedSequence into a 128-bit pool, which generates four 64-bit words; these fix the 128-bit state and the odd increment of PCG64. The `Generator` object then turns the 64-bit outputs into numbers of any distribution.

Example: eight streams of one script. `rng_for("ch06", "07_seeds_streams", stream=k)` for $k = 0, \ldots, 7$ gives eight streams. From 10^6 numbers of each, the script computes all 28 correlation coefficients r between pairs of streams. Under independence each r is approximately Gaussian with mean 0 and standard deviation $1/\sqrt{N} = 0.0010$ (derived in Section 6.6), so the 28 values of $r\sqrt{N}$ should look like 28 draws from $\mathcal{N}(0,1)$. Their standard deviation is 1.10, the largest $|r|$ is 0.0032, and a Kolmogorov–Smirnov test of $\mathcal{N}(0,1)$ (Chapter 4) gives $p = 0.28$: no sign of any relation. The right panel of Figure 6.14 shows two of the streams against each other.

How likely is it that two streams overlap? Suppose a generator has a single cycle of length P and each of n jobs starts at an independent random point of it and consumes L numbers.

Two jobs overlap if their starting points are within L of each other. Fix where the first job starts; the second overlaps it if it starts in a window of $2L$ positions (L before and L after), out of P. So one pair overlaps with probability about $2L/P$. There are $n(n-1)/2$ pairs, so P(any overlap) $\lesssim n^2L/P$. For $n = 10^4$ jobs of $L = 10^{12}$ numbers each (a large simulation campaign) and $P = 2^{128} \approx 3.4 \times 10^{38}$, this is $10^{20}/3.4 \times 10^{38} \approx 3 \times 10^{-19}$. With PCG64 the streams also have different increments and are therefore different sequences altogether. Numpy additionally offers `jumped()`, which advances a PCG64 state by about $(\phi - 1)\,2^{128}$ steps (ϕ the golden ratio) as if that many numbers had been drawn, for the rare case in which non-overlapping blocks of one single stream are wanted.

Key idea: Seeding many simulations

Seed once, with a long seed (from physical entropy, or from a hash of a name). Derive every stream from it by a SeedSequence (a stream index, or `spawn`), never by adding job numbers to a seed. Record the root seed next to the results: it is all that is needed to regenerate any simulation exactly.

6.5.3 From 64 bits to a floating-point number

The generator produces integers; a simulation wants $u \in [0, 1)$. A double-precision number has a 53-bit significand, so numpy keeps the top 53 of the 64 output bits (the best ones) and scales:

$$u = \left\lfloor x/2^{11} \right\rfloor \cdot 2^{-53} = \frac{k}{2^{53}}, \qquad k \in \{0, 1, \ldots, 2^{53} - 1\} \text{ equally likely.} \tag{6.21}$$

The script checks that numpy's `random()` is exactly this, and the function `to_double` of the library implements it. The values form a grid of spacing $2^{-53} \approx 1.1 \times 10^{-16}$. The value $u = 1$ never occurs. The value $u = 0$ occurs, with probability 2^{-53}: rare, but at 10^9 draws per second it happens about once every

$$\frac{2^{53}}{10^9 \text{ s}^{-1}} \approx 9 \times 10^6 \text{ s} \approx 104 \text{ days}$$

of computing, which a large campaign easily exceeds. Cowan's generator excluded both endpoints [Cowan (3.3)]; numpy's includes 0.

Watch out: $\ln u$ with $u = 0$

The recipe $x = -\tau \ln u$ for exponential decay times (inverse-transform sampling, Section 6.8) returns $+\infty$ when $u = 0$. Use $x = -\tau \ln(1 - u)$, whose argument lies in $(0, 1]$, or the library's `rng.exponential`, which handles this.

6.6 Testing a generator: randomness as a null hypothesis

A dice manufacturer who wants to know whether its dice are fair does not inspect the dice; it rolls them many times and checks that the results behave like those of ideal, unbiased dice [Lambert §12.2]. A generator is tested the same way. We cannot prove that a deterministic sequence is random, since it is not; what we can do is state the property we need as a hypothesis and look for evidence against it. This is the logic of Chapter 4, applied to a stream of numbers.

- The null hypothesis H_0: the numbers $u_1, \ldots, u_N$ are independent draws from the uniform distribution (6.2). As in Chapter 4, we take this as the null because it is the case whose distribution we know: for truly random uniform numbers we can compute the distribution of any statistic built from them.

- A test statistic $T(u_1, \dots, u_N)$ that is sensitive to one particular way in which H_0 could fail: unequal frequencies, correlation between neighbours, too many or too few ups and downs, structure in triples.
- The p-value: how often truly random numbers would give a value of T as far out as the one we got, or further in the same direction.

A generator "fails" a test when the p-value is tiny, and keeps being tiny when the test is repeated with fresh numbers. So two questions follow. Which statistics catch which defects? And why must a good generator pass all of them, while no finite set of them can prove it good?

6.6.1 Four tests, each derived

1. Equal frequencies: the χ^2 test of a histogram. The simplest defect is that some values come up more often than others. To look for it, divide $[0, 1)$ into k equal bins and count the numbers O_j that fall into bin j. Under H_0 each number lands in bin j with probability $1/k$, independently, so the expected count is $E = N/k$ and the counts are multinomial. The statistic

$$X^2 = \sum_{j=1}^{k} \frac{(O_j - E)^2}{E} \tag{6.22}$$

is small when the counts are close to their expectation. What value should we expect under H_0? Its mean follows in one line:

$$\mathbb{E}[X^2] \overset{(1)}{=} \sum_{j=1}^{k} \frac{\operatorname{Var}(O_j)}{E} \overset{(2)}{=} k \, \frac{N\frac{1}{k}\left(1-\frac{1}{k}\right)}{N/k} \overset{(3)}{=} k - 1. \tag{6.23}$$

(1) $\mathbb{E}[(O_j - E)^2] = \operatorname{Var}(O_j)$ because $E = \mathbb{E}[O_j]$.
(2) Each O_j is binomial with N trials and success probability $1/k$, so $\operatorname{Var}(O_j) = N \cdot \frac{1}{k}(1 - \frac{1}{k})$ (Chapter 2); all k terms are equal.
(3) Cancel N/k.

The mean is $k - 1$, not k, because the counts obey one constraint, $\sum_j O_j = N$: only $k - 1$ of them are free. For large E each $(O_j - E)/\sqrt{E}$ is nearly Gaussian, and X^2 is then distributed as χ^2 with $k - 1$ degrees of freedom, the goodness-of-fit result of Chapter 4. We use $k = 64$ bins, so H_0 predicts $X^2 \approx 63 \pm 11$ (the χ^2_ν distribution has variance 2ν).

2. Neighbours: the serial correlation. A generator can have perfect frequencies and still let each number influence the next. The lag-one **serial correlation** is the correlation coefficient of the pairs (u_i, u_{i+1}),

$$r = \frac{\sum_{i=1}^{N-1}(u_i - \bar{u})(u_{i+1} - \bar{u})}{\sum_{i=1}^{N}(u_i - \bar{u})^2},$$

with $\bar{u}$ the mean of the u_i. Under H_0 the true correlation is 0, so the question is how far from 0 the measured r strays by chance alone. Its spread is easy to find if we replace $\bar{u}$ by its expectation $\frac{1}{2}$ (the error this makes is of relative order $1/N$). Write $v_i = u_i - \frac{1}{2}$, which has mean 0 and variance $\frac{1}{12}$ (the variance of a uniform variable on an interval of length 1). Then for the numerator $S = \sum_i v_i v_{i+1}$,

$$\begin{aligned} \operatorname{Var}(S) &\overset{(1)}{=} \sum_i \mathbb{E}[v_i^2 v_{i+1}^2] + 2\sum_i \mathbb{E}[v_i v_{i+1}\, v_{i+1} v_{i+2}] + (\text{terms with no shared index}) \\ &\overset{(2)}{=} (N-1)\,\mathbb{E}[v^2]^2 + 2\sum_i \mathbb{E}[v_i]\,\mathbb{E}[v_{i+1}^2]\,\mathbb{E}[v_{i+2}] + 0 \overset{(3)}{=} \frac{N-1}{144}, \end{aligned} \tag{6.24}$$

(1) $\mathbb{E}[S] = \sum_i \mathbb{E}[v_i]\,\mathbb{E}[v_{i+1}] = 0$, so $\mathrm{Var}(S) = \mathbb{E}[S^2]$. Expanding the square gives products of two terms $v_i v_{i+1}$ and $v_j v_{j+1}$: the diagonal ($j = i$), neighbours that share one index ($j = i \pm 1$), and pairs with no index in common.
(2) Independence factorises every expectation. The diagonal gives $\mathbb{E}[v_i^2]\,\mathbb{E}[v_{i+1}^2] = (\frac{1}{12})^2$. A shared-index term contains the unshared v_i and v_{i+2} once each, and $\mathbb{E}[v] = 0$; a term with no shared index contains four factors of which at least one appears once, so it vanishes too.
(3) $(\frac{1}{12})^2 = \frac{1}{144}$.

The denominator is close to its mean $N/12$, so $\mathrm{Var}(r) \approx \frac{N/144}{(N/12)^2} = \frac{1}{N}$. The statistic $z = r\sqrt{N}$ is therefore approximately standard normal under H_0 (the central limit theorem applied to S), and $|z| > 3$ has probability 0.3%.

3. Ups and downs: the runs test. Write + when a number is larger than the one before it and − when it is smaller. A **run** is a maximal block of equal signs (Figure 6.16). A sequence that oscillates too regularly has too many runs; one that drifts has too few. How many runs should independent numbers give? Count the sign changes: the number of runs is $R = 1+$ (number of sign changes), and a sign change happens at u_i exactly when u_i is the largest or the smallest of the three numbers u_{i-1}, u_i, u_{i+1}. Under H_0 the six orderings of three independent continuous numbers are equally likely, and in four of them the middle one is the largest or the smallest. So

$$\mathbb{E}[R] \overset{(1)}{=} 1 + \sum_{i=2}^{N-1} \mathrm{P}(u_i \text{ is a turning point}) \overset{(2)}{=} 1 + (N-2)\,\frac{4}{6} \overset{(3)}{=} \frac{2N-1}{3}. \tag{6.25}$$

(1) R is 1 plus a sum of indicator variables, one for each interior position, and the expectation of an indicator is its probability.
(2) Four of the six equally likely orderings.
(3) $1 + \frac{2N-4}{3} = \frac{2N-1}{3}$.

The variance, $(16N - 29)/90$, comes from the same counting done for pairs of positions (neighbouring turning points are not independent, which is why it is not simply $N \cdot \frac{2}{3} \cdot \frac{1}{3}$). Then $z = (R - \mathbb{E}[R])/\sqrt{\mathrm{Var}\,R}$ is approximately standard normal under H_0.

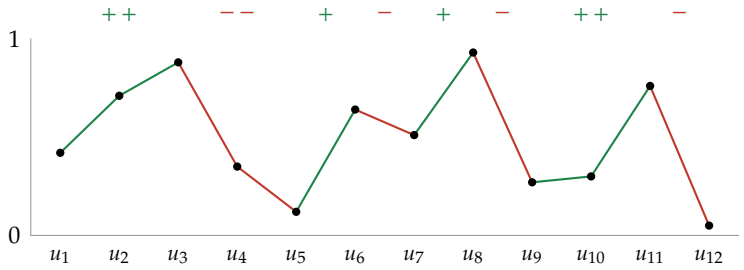

Figure 6.16: Runs up and down in twelve numbers. Rising steps are green, falling steps red. The signs of the steps form eight runs (++, −−, +, −, +, −, ++, −), against $\mathbb{E}[R] = (2 \cdot 12 - 1)/3 \approx 7.7$ for independent uniform numbers.

4. Triples: the χ^2 test in three dimensions. A generator can pass every test on single numbers and on neighbouring pairs and still fail in three dimensions, as RANDU does (Section 6.3). To look there, group the numbers into non-overlapping triples, treat each as a point in the unit cube, divide the cube into $20^3 = 8000$ cells and apply (6.22) to the cell counts: X^2 should be 7999 ± 126. A generator whose triples lie on a few planes leaves whole cells empty, and X^2 becomes huge.

6.6.2 Four generators under the four tests

The script `08_randomness_tests.py` applies the four tests to $N = 999999$ numbers from each of four generators: PCG64, MT19937, RANDU and the small generator $x \mapsto (1229x + 1) \bmod 2048$ of Section 6.2. Table 6.1 lists the statistics and the p-values (two-sided for the normal statistics, the upper tail for X^2).

	histogram X^2 ($\nu = 63$)	serial z	runs z	triples X^2 ($\nu = 7999$)
PCG64	69.93 ($p = 0.256$)	−0.69 (0.493)	1.84 (0.066)	7748 (0.977)
MT19937	69.53 (0.267)	−0.40 (0.693)	0.16 (0.873)	8144 (0.126)
RANDU	46.66 (0.939)	−0.49 (0.624)	1.02 (0.306)	2.473×10^5 ($< 10^{-300}$)
LCG, $m = 2048$	0.02259 (1.000)	197.09 ($< 10^{-300}$)	−156.69 ($< 10^{-300}$)	4.870×10^6 ($< 10^{-300}$)

Table 6.1: Four tests of H_0 (independent and uniform) on 999999 numbers from each generator. Entries are the statistic and, in brackets, its p-value.

Reading the table. PCG64 and MT19937 pass everything: every statistic is where H_0 puts it, and the p-values are unremarkable numbers between 0 and 1. RANDU passes the first three tests just as well. Its frequencies are uniform, its neighbours uncorrelated, its runs normal, which is why it was used for years. The triple test destroys it: $X^2 = 2.473 \times 10^5$ where 7999 ± 126 was expected, because its triples occupy only fifteen planes of the cube (Figure 6.10). The small generator fails in a way that deserves a second look. Its serial correlation is $z = 197.09$, i.e. $r \approx 0.2$: its pairs lie on the six lines of slope $\frac{1}{5}$ in Figure 6.8, so u_{n+1} tends to rise with u_n with slope about $\frac{1}{5}$. Its runs and triples fail as badly. And its histogram is *too good*: $X^2 = 0.02259$ where 63 ± 11 was expected. Over each full period the generator visits every one of its 2048 states exactly once, so each of the 64 bins gets exactly 32 numbers per period; the counts have none of the multinomial scatter that independent numbers would have. The upper-tail p-value is 1, but the lower tail tells the story: under H_0 an X^2 this small has probability 9.9×10^{-97}. A fit that is too good is as much evidence against H_0 as one that is too bad.

The p-value is itself a random variable, and under H_0 it is uniformly distributed on $[0, 1]$. The reason is that the p-value is the distribution function of the statistic evaluated at the statistic, and a continuous random variable pushed through its own distribution function is uniform (the fact behind inverse-transform sampling, Section 6.8.1). So a good generator gives p-values spread evenly over $[0, 1]$, and a p-value of 0.01 appears once in a hundred tests. The left panel of Figure 6.17 checks this for 400 histogram tests on fresh batches of 10^4 PCG64 numbers; a Kolmogorov–Smirnov test of their uniformity gives $p = 0.36$. The right panel shows where the triple statistics of the table fall relative to the χ^2_{7999} density.

Watch out: One small p-value is not a failure

Run a hundred tests on a perfect generator and about one will give $p < 0.01$. A defect shows itself as a p-value that is small again and again with fresh numbers, or that becomes smaller as N grows (for a real defect the statistic grows with N). Conversely, passing a test says only that this particular defect, at this sample size, is absent.

6.6.3 Batteries of tests

Serious testing uses hundreds of statistics, each designed around a way in which real generators have failed: gaps between repeated values (birthday spacings), matrix ranks and linear

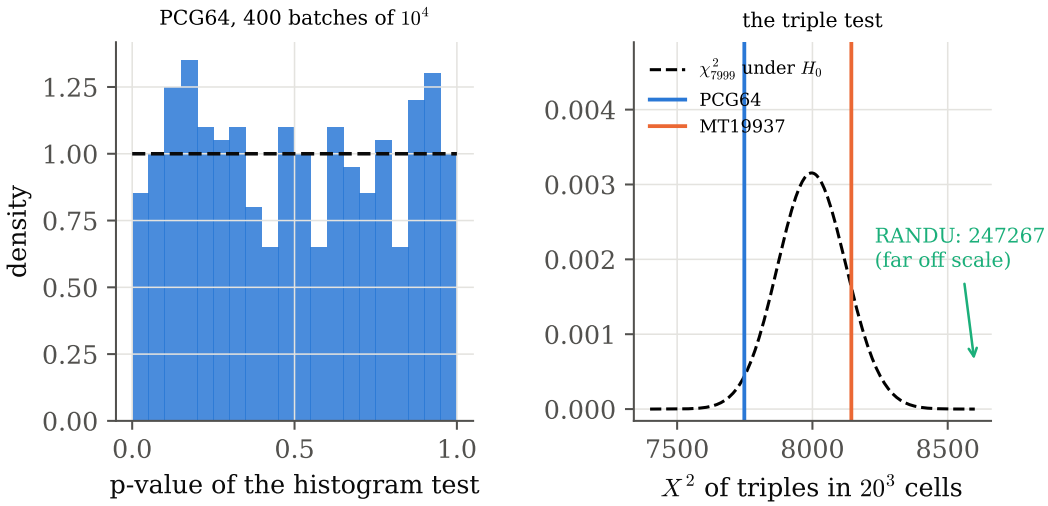

Figure 6.17: Left: the p-values of 400 histogram tests on independent batches of PCG64 numbers are spread uniformly over $[0, 1]$, as they must be under H_0. Right: the triple statistic X^2 for PCG64 and MT19937 (vertical lines) sits inside its χ^2_{7999} density under H_0 (dashed); RANDU's value, about thirty times larger, is far off the scale.

complexity of the output bits (the tests that catch xorshift and the Mersenne Twister, Section 6.4), random walks, the collision counts of many balls in many cells, and so on. The standard collection is TestU01 [126], organised in three batteries of increasing size and running time: SmallCrush (minutes), Crush and BigCrush (hours, more than a hundred test statistics on about 2^{38} numbers). Its authors ran it on the generators in common use in 2007: the power-of-two linear congruential generators and RANDU fail the smaller batteries, MT19937 passes BigCrush except for the two linear-complexity tests, and several generators then shipping in popular software failed badly. PCG64 passes BigCrush [127].

What no battery can do is certify a generator for *every* application. Each test is a single statistic, and a deterministic sequence always has some statistic that exposes it (for instance "replay the generator from the seed and compare"). The practical rules that follow are simple: use a modern generator that passes BigCrush; never use the low bits of a power-of-two linear congruential generator; and for a result that matters, repeat the simulation with a second generator of an unrelated design (numpy offers PCG64, MT19937, Philox and SFC64 behind the same interface) and check that the answer does not change. That last check would have caught the Monty Hall failure of Section 6.1.1 at once.

6.7 When randomness is not the point: quasi-random numbers

Return to the oldest use of random numbers in this chapter: an integral $I = \int h(x)\,\mathrm{d}x$ over the unit cube $[0, 1]^d$, estimated by the average of h at N uniform points [Wasserman p. 404, (24.2)]. The error of that average falls as $\sigma/\sqrt{N}$ (derived in Section 6.11.2), with σ the standard deviation of $h(X)$ for a uniform point X. For an integral, independence costs us accuracy. Independent points clump by chance and leave gaps by chance, and the $1/\sqrt{N}$ is exactly the size of those chance fluctuations. For an integral we do not need points that are unpredictable. We need points that cover the cube evenly. A regular grid does that, but in d dimensions it needs n^d points for n per axis, and it cannot be extended one point at a time. So the question is: are there point sets that can be extended one point at a time and still fill the cube more evenly than chance? And if so, how much accuracy does that buy?

6.7.1 Van der Corput and Sobol sequences

In one dimension there is a simple construction. Write $n = 1, 2, 3, \ldots$ in binary and mirror the digits about the binary point: $n = (b_k \ldots b_2 b_1)_2$ becomes $\phi(n) = (0.b_1 b_2 \ldots b_k)_2$, the **radical inverse** of n. For example,

$$\phi(6) \overset{(1)}{=} \phi\big((110)_2\big) \overset{(2)}{=} (0.011)_2 \overset{(3)}{=} 0 \cdot \tfrac{1}{2} + 1 \cdot \tfrac{1}{4} + 1 \cdot \tfrac{1}{8} = \tfrac{3}{8}. \tag{6.26}$$

(1) $6 = 4 + 2 = (110)_2$.
(2) Read the digits from the right, after the binary point.
(3) The i-th digit after the point is worth 2^{-i}.

The **van der Corput sequence** $\phi(1), \phi(2), \ldots$ begins $\frac{1}{2}, \frac{1}{4}, \frac{3}{4}, \frac{1}{8}, \frac{5}{8}, \frac{3}{8}, \frac{7}{8}, \frac{1}{16}, \ldots$ (the script `09_sobol.py` prints the first eight). Every new point lands in a largest gap left by the earlier ones (Figure 6.18): after 2^m points, each interval $[j/2^m, (j+1)/2^m)$ contains exactly one of them. Why does mirroring the digits do this? The last binary digit of n alternates fastest, and it becomes the first digit of $\phi(n)$, so consecutive points jump between the two halves of the interval; the next digit chooses the quarter, and so on.

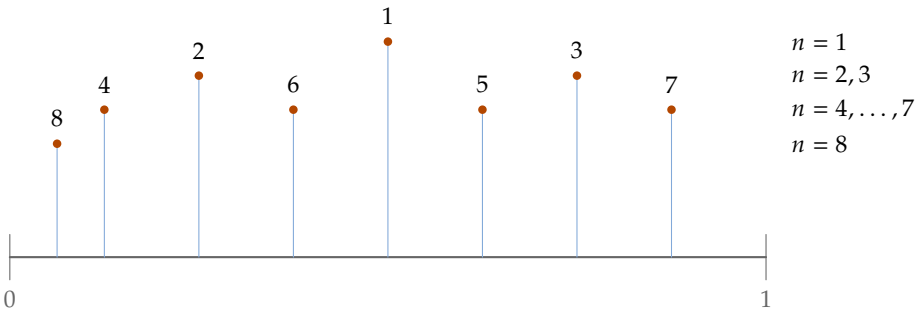

Figure 6.18: The first eight points of the van der Corput sequence, drawn at a height that marks the generation they belong to. The first point halves the interval, the next two halve the halves, the next four halve the quarters. After 2^m points every interval of length 2^{-m} holds exactly one point.

Sobol generalised this to d dimensions [129]. Coordinate j of the n-th point is built from the binary digits $b_1, b_2, \ldots$ of n as $x_{n,j} = b_1 v_{j,1} \oplus b_2 v_{j,2} \oplus \cdots$, an XOR of fixed binary fractions $v_{j,i}$, the **direction numbers** of coordinate j. For the first coordinate $v_{1,i} = 2^{-i}$, which is the van der Corput sequence; for the others the direction numbers are derived from different primitive polynomials over the bits, chosen so that the coordinates do not line up. The result is a **digital net**: the first 2^m points of a two-dimensional Sobol sequence have exactly one point in every rectangle $[a2^{-i}, (a+1)2^{-i}) \times [b2^{i-m}, (b+1)2^{i-m})$, for every $i = 0, \ldots, m$. With $m = 8$ and $i = 4$, every cell of a 16×16 grid contains exactly one of the first 256 points. Independent points do not do this: the chance that a given cell is empty is $(1 - \frac{1}{256})^{256} \approx e^{-1}$, so about 94 of the 256 cells should be empty. In Figure 6.19, 256 PCG64 points leave 92 cells empty and 256 Sobol points leave 0.

6.7.2 Why even points integrate better

Why should evenly spread points give a smaller error? To answer this we first need a number for how evenly N points cover the cube. That number is the **star discrepancy**

$$D_N^* = \sup_{\boldsymbol{y} \in [0,1]^d} \left| \frac{\#\{i : \boldsymbol{x}_i \in [\boldsymbol{0}, \boldsymbol{y})\}}{N} - y_1 y_2 \cdots y_d \right|,$$

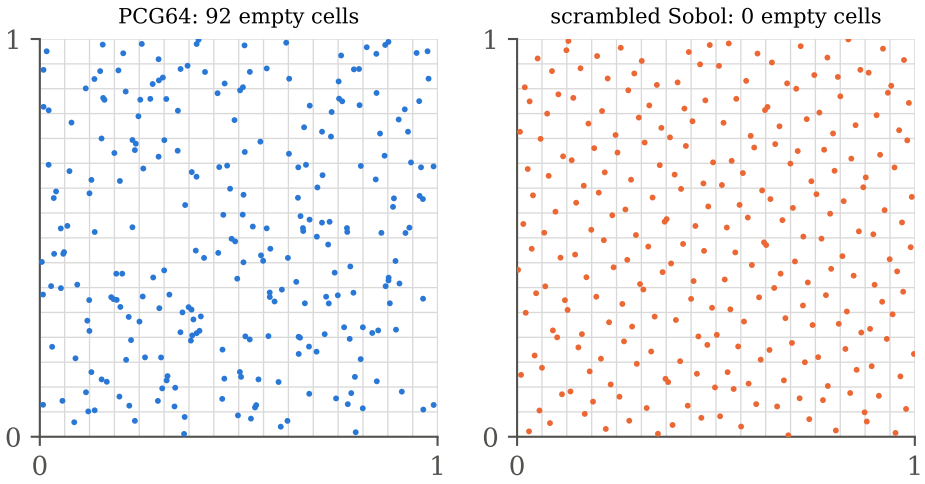

Figure 6.19: 256 points in the unit square with a 16×16 grid. Left: independent uniform points from PCG64, which clump and leave about a third of the cells empty. Right: the first 256 points of a scrambled Sobol sequence, exactly one per cell.

the worst difference, over all boxes with one corner at the origin, between the fraction of points in the box and the volume of the box. In one dimension it has a simple meaning: $D_N^* = \sup_y |F_N(y) - y|$, the largest gap between the **empirical distribution function** $F_N(y)$ [the fraction of the points below y] and the uniform distribution function y, which is the Kolmogorov–Smirnov statistic of Chapter 4. The answer to our question is that the integration error is bounded by the discrepancy. In one dimension, for a function h with a continuous derivative,

$$\begin{aligned}
\frac{1}{N}\sum_{i=1}^{N} h(x_i) - \int_0^1 h(x)\,\mathrm{d}x &\overset{(1)}{=} \int_0^1 h(x)\,\mathrm{d}\big[F_N(x) - x\big] \\
&\overset{(2)}{=} \Big[h(x)\big(F_N(x) - x\big)\Big]_0^1 - \int_0^1 \big(F_N(x) - x\big)\,h'(x)\,\mathrm{d}x \\
&\overset{(3)}{=} -\int_0^1 \big(F_N(x) - x\big)\,h'(x)\,\mathrm{d}x, \\
\left|\frac{1}{N}\sum_{i=1}^{N} h(x_i) - \int_0^1 h\,\mathrm{d}x\right| &\overset{(4)}{\le} \sup_x |F_N(x) - x| \int_0^1 |h'(x)|\,\mathrm{d}x \overset{(5)}{=} D_N^*\,V(h).
\end{aligned} \tag{6.27}$$

(1) F_N jumps by $1/N$ at each point, so integrating against $\mathrm{d}F_N$ gives the average $\frac{1}{N}\sum h(x_i)$; integrating against $\mathrm{d}x$ gives the integral (a Stieltjes integral is just this bookkeeping).
(2) Integration by parts.
(3) At $x = 0$, $F_N(0) = 0$ (no point lies below 0); at $x = 1$, $F_N(1) = 1$. Both boundary terms vanish.
(4) Bound the integrand by the largest value of $|F_N - x|$ times $|h'|$.
(5) $V(h) = \int_0^1 |h'|\,\mathrm{d}x$ is the total variation of h, how much it goes up and down.

The error is a product of two factors, one belonging to the integrand (its variation) and one belonging to the points (their discrepancy). In d dimensions the same statement, with a suitable multidimensional variation $V_{\mathrm{HK}}(h)$, is the **Koksma–Hlawka inequality**, $|\text{error}| \le V_{\mathrm{HK}}(h)\,D_N^*$.

Key idea: Discrepancy against chance

For independent uniform points the discrepancy, like any Kolmogorov–Smirnov statistic, shrinks only as $N^{-1/2}$. For a Sobol sequence it shrinks as $(\ln N)^d/N$. For an integrand of bounded variation the Monte Carlo error $\propto N^{-1/2}$ is therefore replaced by a quasi-Monte Carlo error of order $(\ln N)^d/N$, which for moderate d and practical N behaves close to N^{-1}.

Example: a smooth integrand and one with a jump, in five dimensions. Take $d = 5$ and two integrands with known integrals: the smooth product $h(\boldsymbol{x}) = \prod_{i=1}^{5} \frac{\pi}{2} \sin \pi x_i$, whose integral is 1 (each factor integrates to $\frac{\pi}{2} \cdot \frac{2}{\pi} = 1$), and the indicator of the ball of radius $\frac{1}{2}$ about the centre of the cube, whose integral is the ball's volume $\pi^{5/2}(\frac{1}{2})^5/\Gamma(\frac{7}{2}) = 0.1645$. For $N = 2^4, \ldots, 2^{16}$ the script estimates both with PCG64 points and with scrambled Sobol points, repeats everything 40 times with independent randomisations, and plots the root-mean-square error (Figure 6.20). With PCG64 both errors fall with slope -0.51 on the log–log plot, the $N^{-1/2}$ law. With Sobol points the smooth integrand's error falls with slope -1.08, and at $N = 2^{16}$ it is 135 times smaller than the Monte Carlo error; to get the same accuracy by Monte Carlo would need about $135^2 \approx 2 \times 10^4$ times more points. For the ball the slope is only -0.57 and the gain a factor 2.5. The indicator of a ball has a jump across a curved surface, and its Hardy–Krause variation is infinite for $d \geq 2$, so the Koksma–Hlawka bound gives nothing; the points still help a little, because the part of the cube away from the surface is integrated well.

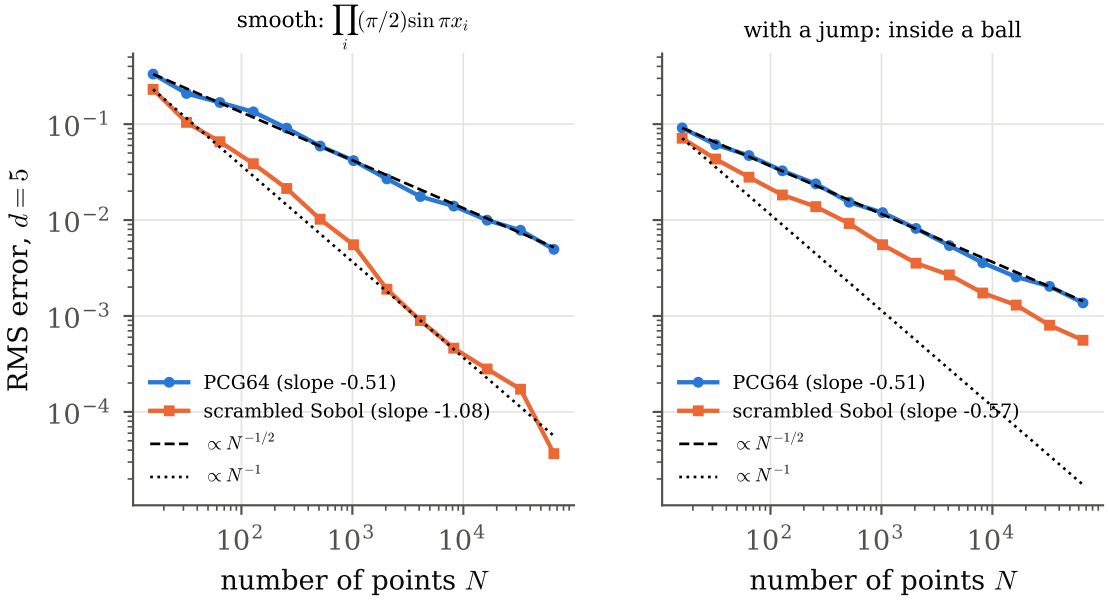

Figure 6.20: Root-mean-square error of the estimate of a five-dimensional integral against the number of points, over 40 independent randomisations. Left: a smooth integrand; the Sobol error (orange) falls about as N^{-1} (dotted), the Monte Carlo error (blue) as $N^{-1/2}$ (dashed). Right: the indicator of a ball, which has a jump; the Sobol points gain only a constant factor.

Without randomisation a quasi-random estimate has no error bar. An unscrambled Sobol sequence is deterministic, and its error, though small, cannot be estimated from the points themselves: the N points are not independent, so the formula $s/\sqrt{N}$ does not apply. **Scrambling** applies random permutations to the binary digits of every coordinate in a way that keeps the net property of Figure 6.19 but makes each individual point uniform on the cube. The estimate is then unbiased, and R independent scramblings give R independent estimates whose scatter is an honest error bar. This is how the RMS errors in Figure 6.20 were measured.

Quasi-random points are not random numbers. Sobol points are built to be as dependent as possible, each one filling the gaps left by the others. Used where independence matters (Monty's coin, the steps of a random walk, the proposals and acceptance tests of MCMC in Chapter 9) they give wrong answers. They replace a generator only in the estimation of an integral, where the dimension d is the number of uniform numbers used per sample.

How this is used in real research: Random numbers in research code

Generators. Research code in Python uses `numpy.random.default_rng` (PCG64) or, for massively parallel work, `PCG64DXSM` or `Philox`. Detector simulation with Geant4 uses the MixMax generator of the CLHEP library by default; Pythia 8 uses its own implementation of the Marsaglia–Zaman–Tsang generator; lattice field theory codes traditionally use Lüscher's RANLUX, whose "luxury level" trades speed for proven decorrelation. The old warnings (Sections 6.2 and 6.3) concern code that still calls C's `rand()` or a home-made linear congruential generator.
Seeds. A simulation campaign has one root seed, recorded with the outputs; every job derives its stream from it with `SeedSequence.spawn` or a job index, as `rng_for` does. Cosmological simulation suites store the seed of every realisation, so that any single CMB map or N-body initial condition can be regenerated exactly when it turns out to be an outlier.
Verification and research. Every numerical experiment with generators so far *verified* something we could also compute: the Monty Hall posterior, π, integrals with known values, lattice planes derived by hand. That is the right way to validate a generator. In research the same machinery becomes the instrument: the covariance of a masked, noisy power-spectrum estimator in Chapter 8 has no formula, and its only definition is a histogram over simulations. There the generator's quality can no longer be checked against an answer, and the rules above (a modern generator, long seeds, SeedSequence streams, a rerun with a second generator) are what make the result trustworthy. Quasi-Monte Carlo is used where the integrand is smooth and moderately low-dimensional: option pricing in finance, radiative-transfer and rendering integrals, and phase-space integration of smooth matrix elements, for which scrambled Sobol points are available as `scipy.stats.qmc.Sobol`.

Every simulation rests on one object: a stream of numbers that must behave like independent uniform draws on $[0, 1)$. Such a stream comes from a deterministic state machine, so its quality is a property we test, and its seeds and streams are choices we record. Uniform numbers can then be turned into draws from any distribution (Section 6.8), and averages over those draws into estimates with an error we can quote (Section 6.11.2).

Recap

- A simulation reproduces probabilities as frequencies, so it is only as good as its random numbers: a coin taken from the lowest bit of a linear congruential generator changed Monty's $\mathrm{P}(E \mid H_A)$ from $\frac{1}{2}$ to 0 or 1, and with it the posterior.
- A pseudorandom number generator is a deterministic state machine (state, transition, output, seed). Finite state forces a period; after it the estimate stops improving while the reported error bar keeps shrinking.
- Linear congruential generators $x \mapsto (ax + c) \bmod m$: period m under the Hull–Dobell conditions, the order of a for prime m; the low j bits of a power-of-two modulus have period 2^j.
- Their t-tuples lie on hyperplanes $\boldsymbol{h} \cdot \boldsymbol{u} \in \mathbb{Z}$ for every dual vector $\boldsymbol{h}$; RANDU's triples lie on 15 planes ($9u_n - 6u_{n+1} + u_{n+2} \in \mathbb{Z}$). The spectral test measures the widest gap

$d_t = 1/v_t$; Marsaglia's bound allows at most $(t!\,m)^{1/t}$ planes.

- Modern generators separate a cheap long-period transition (xorshift and MT19937, linear over bits; the 128-bit LCG of PCG64) from a mixing output function (tempering; XSL-RR). Our ten-line PCG64 reproduces numpy's bits.
- Seeds: long, hashed through a SeedSequence, one root recorded; streams by index or spawn. Numpy's doubles are $k/2^{53}$ and can be 0.
- Testing: H_0 = independent and uniform. Histogram χ^2, serial correlation ($\operatorname{Var} r \approx 1/N$), runs ($\mathbb{E}\,R = (2N-1)/3$), triples; RANDU passes three and fails the fourth; too good a fit also rejects H_0.
- Quasi-random (Sobol) points fill space evenly; for smooth integrands the error falls close to N^{-1} instead of $N^{-1/2}$ (Koksma–Hlawka), but they are not random numbers.

6.8 Uniform numbers into any distribution: the inverse CDF

A muon stops in a block of scintillator and decays. We want to simulate a million such decays, each with its own decay time, to see how a detector with a 100 ns dead time distorts the measured lifetime.

What we have. The pseudorandom generators of the first part of this chapter give us, on demand, numbers $u_1, u_2, \ldots$ that behave like independent draws from the uniform distribution on $[0, 1)$.

What we need. Decay times are not uniform. They are exponential, with density $e^{-t/\tau}/\tau$, where $\tau = 2.197\,\mu$s is the muon lifetime. Other simulations need other shapes: cosmic-ray energies follow a steep power law, and the number of photons in a CCD pixel is Poisson. So every simulation in physics starts with the same small question.

The question. Given a supply of uniform numbers U, which function $x(U)$ turns them into numbers that follow a prescribed distribution?

To answer it we first ask the reverse question: if we feed a random variable into its own cumulative distribution function, how is the result distributed? The answer to that turns into a one-line recipe.

6.8.1 Why $F(X)$ is uniform

Recall the **cumulative distribution function** (CDF) of a random variable X, $F(x) = \mathrm{P}(X \le x)$ [the probability that X comes out at or below x. It climbs from 0 to 1], and for a continuous X it is the integral of the density, $F(x) = \int_{-\infty}^{x} p(x')\,\mathrm{d}x'$ (Chapter 1). Suppose for the moment that F is continuous and strictly increasing, so that it has an ordinary inverse F^{-1}: for every $u \in (0, 1)$ there is exactly one x with $F(x) = u$. That x is the u-quantile, the value below which a fraction u of the probability lies.

Now feed X into its own CDF and ask how the new number $F(X)$ is distributed. For any $u \in (0, 1)$,

$$\mathrm{P}\big(F(X) \le u\big) \overset{(1)}{=} \mathrm{P}\big(X \le F^{-1}(u)\big) \overset{(2)}{=} F\big(F^{-1}(u)\big) \overset{(3)}{=} u. \tag{6.28}$$

(1) F is strictly increasing, so $F(X) \le u$ happens exactly when $X \le F^{-1}(u)$: applying the increasing function F^{-1} to both sides of an inequality keeps its direction.

(2) This is the definition of F, evaluated at the point $F^{-1}(u)$.
(3) F^{-1} undoes F.

So $F(X)$ is uniform on $[0,1]$, whatever the distribution of X: its CDF is $\mathrm{P}(F(X) \le u) = u$, and that is the CDF of the uniform distribution. This is the **probability integral transform** [CasellaBerger Thm 2.1.10], already met in Chapter 1 and behind the uniform distribution of p-values under the null hypothesis in Chapter 4. In words: $F(X)$ is the fraction of the distribution lying below the value we drew, and every fraction between 0 and 1 is equally likely.

Read backwards, the same fact is a recipe. Take U uniform and set $X = F^{-1}(U)$. Then for every x,

$$\mathrm{P}\big(F^{-1}(U) \le x\big) \overset{(1)}{=} \mathrm{P}\big(U \le F(x)\big) \overset{(2)}{=} F(x), \tag{6.29}$$

(1) Apply the increasing function F to both sides of $F^{-1}(U) \le x$.
(2) U is uniform, so $\mathrm{P}(U \le c) = c$ for any $c \in [0,1]$, here $c = F(x)$.

so $F^{-1}(U)$ has exactly the CDF F we wanted.

The same step can be read as a matching condition. Each value u is sent to one value x, so the probability that U lands in a small strip $[u, u + \mathrm{d}u]$ must equal the probability that X lands in the matching interval $[x, x + \mathrm{d}x]$. The first is $\mathrm{d}u$, because U is uniform; the second is $p(x)\,\mathrm{d}x$. Setting them equal gives $\mathrm{d}u = p(x)\,\mathrm{d}x$, which integrates to $u = F(x)$ [Cowan (3.4)].

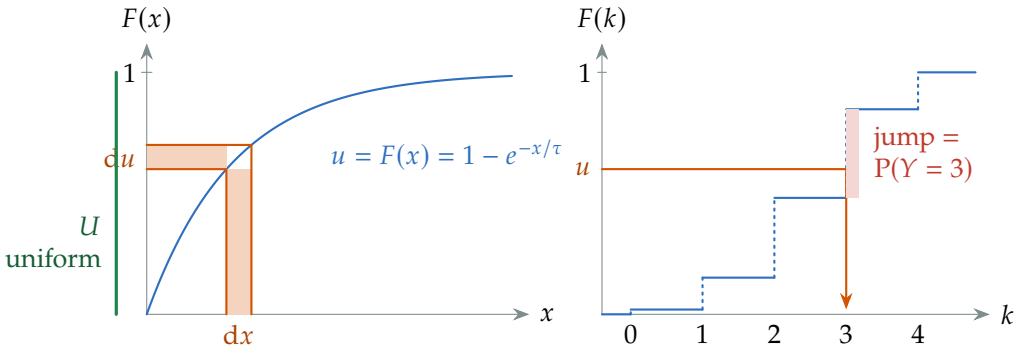

Figure 6.21: The inverse-CDF method. Left: a uniform number u on the vertical axis is carried across to the curve $u = F(x)$ (an exponential CDF, drawn for $\tau = 1$) and down to $x = F^{-1}(u)$. A strip of height $\mathrm{d}u$ lands on an interval of width $\mathrm{d}x = \mathrm{d}u/p(x)$, narrow where the curve is steep, so values pile up where the density is high. Right: for a discrete variable the CDF is a staircase, and u selects the step it falls under; the chance of selecting k is the height of the jump at k.

Figure 6.21 (left) shows the same thing as a picture. The uniform number lives on the vertical axis, where every strip of height $\mathrm{d}u$ is equally likely. Where F is steep, the density $p = F'$ is large, and a strip of fixed height maps onto a narrow interval of x: many draws crowd into a small range. Where F is flat, the same strip is stretched over a wide interval, and the draws are sparse.

Working definition 6.3 (inverse-transform sampling)

To draw X with CDF F: draw $U \sim \mathrm{Uniform}(0,1)$ and return $X = F^{-1}(U)$ [the U-quantile of the target, the value below which a fraction U of the probability lies]. For a CDF with jumps or flat stretches use the **generalised inverse** $F^{-1}(u) = \min\{x : F(x) \ge u\}$. *Operational test:* it needs a closed form (or a fast numerical solution) of $F(x) = u$ for x.

6.8.2 Continuous examples: decay times and power laws

Example: muon decay times. A muon at rest decays with lifetime τ, so its decay time t has density $p(t) = e^{-t/\tau}/\tau$ for $t \geq 0$ (the waiting time of a Poisson process, Chapter 2). Solve $F(t) = u$:

$$u = F(t) \overset{(1)}{=} \int_0^t \frac{e^{-t'/\tau}}{\tau}\,\mathrm{d}t' \overset{(2)}{=} 1 - e^{-t/\tau} \quad\Longrightarrow\quad t = F^{-1}(u) \overset{(3)}{=} -\tau \ln(1-u). \tag{6.30}$$

(1) The CDF is the integral of the density from the lowest possible time, 0.
(2) The antiderivative of $e^{-t'/\tau}/\tau$ is $-e^{-t'/\tau}$.
(3) Rearrange to $e^{-t/\tau} = 1 - u$ and take the natural logarithm of both sides.

The same formula appears as [Cowan (3.5)–(3.7)] and as [CasellaBerger Ex. 5.6.3]. Since $1 - U$ is uniform whenever U is, $t = -\tau \ln U$ works equally well.

Does it work? With $N = 100000$ uniforms, the script below gives a sample mean $\bar{t} = 2.196\,\mu$s, against the true mean $\tau = 2.197\,\mu$s. Its standard error, the sample standard deviation divided by $\sqrt{N}$ (Chapter 3), is $0.006967\,\mu$s. The sample standard deviation itself is $2.203\,\mu$s; for an exponential it should equal the mean, and it does. The histogram lies on the density (Figure 6.22, left).

Example: a cosmic-ray power law. Above about 10 GeV the flux of cosmic rays falls roughly as $E^{-\gamma}$ with spectral index $\gamma \approx 2.7$ [the power with which the number of particles per unit energy drops]. To simulate primaries between $E_{\min}$ and $E_{\max}$ we normalise the density on that range and invert its CDF. Write $\gamma \neq 1$ and abbreviate $a = E_{\min}^{1-\gamma}$ and $b = E_{\max}^{1-\gamma}$ (with $\gamma > 1$, $a > b$):

$$p(E) \overset{(1)}{=} \frac{(\gamma-1)\,E^{-\gamma}}{a-b}, \qquad F(E) \overset{(2)}{=} \int_{E_{\min}}^{E} \frac{(\gamma-1)E'^{-\gamma}}{a-b}\,\mathrm{d}E' \overset{(3)}{=} \frac{a - E^{1-\gamma}}{a-b},$$
$$E = F^{-1}(u) \overset{(4)}{=} \left[a - u\,(a-b)\right]^{1/(1-\gamma)}. \tag{6.31}$$

(1) The normalisation: $\int_{E_{\min}}^{E_{\max}} E^{-\gamma}\mathrm{d}E = \left[E^{1-\gamma}/(1-\gamma)\right]_{E_{\min}}^{E_{\max}} = (a-b)/(\gamma-1)$, and p is $E^{-\gamma}$ divided by this.
(2) The CDF is the integral of the density from the lower end of the range.
(3) The same antiderivative, now between $E_{\min}$ and E: $(\gamma-1)\,[E_{\min}^{1-\gamma} - E^{1-\gamma}]/(\gamma-1)$ divided by $a - b$.
(4) Set $F(E) = u$, so $E^{1-\gamma} = a - u(a-b)$, and raise both sides to the power $1/(1-\gamma)$.

Check the ends: $u = 0$ gives $E = a^{1/(1-\gamma)} = E_{\min}$ and $u = 1$ gives $E_{\max}$.

Now the numbers, with $\gamma = 2.7$, $E_{\min} = 10$ GeV and $E_{\max} = 10^6$ GeV. The exact fraction of primaries above 1 TeV is $1 - F(10^3\,\text{GeV}) = 3.981 \times 10^{-4}$. Among 1000000 simulated energies, 394 are above 1 TeV, a fraction 3.940×10^{-4}. The expected count is 398, and a Poisson count of 398 fluctuates by about $\sqrt{398} \approx 20$, so the simulation agrees within one standard deviation. The largest of the million energies is only $4.31e+04$ GeV: a steep spectrum rarely reaches its upper cut-off. That is why air-shower arrays, which hunt the highest energies, must cover square kilometres. On logarithmic axes the histogram is a straight line of slope -2.7 (Figure 6.22, middle).

Example: isotropic directions. A source that emits isotropically sends equal numbers of particles into equal solid angles. Which two numbers should we draw, and from what? Write the solid-angle element in the polar angle θ and the azimuth ϕ: $\mathrm{d}\Omega = \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi = \mathrm{d}(\cos\theta)\,\mathrm{d}\phi$

up to a sign, because $\mathrm{d}(\cos\theta) = -\sin\theta\,\mathrm{d}\theta$. Equal solid angles are therefore equal areas in the variables $(\cos\theta, \phi)$. So "uniform in solid angle" means that $\cos\theta$ is uniform on $[-1, 1]$ and ϕ is uniform on $[0, 2\pi)$, independently. Both inverse CDFs are straight lines: $\cos\theta = 2u_1 - 1$ and $\phi = 2\pi u_2$. The common mistake is to draw θ uniform on $[0, \pi]$. That piles directions up at the poles, because a step in θ near a pole sweeps out less solid angle than the same step near the equator. We will use these isotropic directions in Section 6.11.4 to compute the acceptance of a detector.

6.8.3 Discrete outcomes by cumulative sums

A discrete random variable Y taking values $y_1 < y_2 < \dots$ has a staircase CDF (Figure 6.21, right). The jump at y_{i+1} has height $F(y_{i+1}) - F(y_i) = \mathrm{P}(Y = y_{i+1})$. The generalised inverse of the recipe box above says: draw U and return the value y_{i+1} whose step contains it, that is, the one with $F(y_i) \le U < F(y_{i+1})$ (with the conventions $y_0 = -\infty$ and $F(y_0) = 0$). Why does this give each value with the right probability? One line:

$$\mathrm{P}\big(F(y_i) \le U < F(y_{i+1})\big) \overset{(1)}{=} F(y_{i+1}) - F(y_i) \overset{(2)}{=} \mathrm{P}(Y = y_{i+1}). \tag{6.32}$$

(1) For a uniform U the probability of landing in an interval is its length.
(2) The CDF jumps at y_{i+1} by exactly the probability of that value.

This is [CasellaBerger (5.6.7)]. In words: lay the probabilities $\mathrm{P}(Y = y_1), \mathrm{P}(Y = y_2), \dots$ end to end along $[0, 1]$ like segments of a ruler, throw U at the ruler, and report the segment it hits.

Example: a binomial table. For $Y \sim \mathrm{Binomial}(4, 5/8)$, the probabilities are $\binom{4}{k}(5/8)^k(3/8)^{4-k}$. For example $\mathrm{P}(Y = 0) = (3/8)^4 = 81/4096$ and $\mathrm{P}(Y = 1) = 4 \cdot (5/8)(3/8)^3 = 540/4096$. The cumulative sums are $F(0) = 0.01978$, $F(1) = 0.1516$, $F(2) = 0.4812$, $F(3) = 0.8474$, $F(4) = 1$, which rounds to Casella and Berger's table 0.020, 0.152, 0.481, 0.847 [CasellaBerger (5.6.8)]. So $U = 0.6$ gives $Y = 3$, because $0.481 \le 0.6 < 0.847$. Over 100000 draws, the largest difference between an observed frequency and its exact probability is 0.001509. That is the size we should expect: a frequency estimated from N draws scatters by its binomial standard error $\sqrt{p(1-p)/N}$, which is about 0.0015 for a probability near $p = 1/3$.

Example: Poisson counts. A PMT pixel that sees on average $\lambda = 3.5$ photons per exposure gives Poisson(3.5) counts. The range is infinite, but the cumulative sum reaches 1 to double precision well before $k = 30$, so a table of 30 entries suffices. Over 100000 draws, the sample mean is 3.499 and the sample variance 3.546, both close to λ, as a Poisson variable requires. For large tables one searches by bisection, or starts the search near the mean [CasellaBerger p. 203].

6.8.4 The code

Listing 6.8: Decay times, power-law energies and discrete counts by the inverse CDF (`code/ch06/21_inverse_cdf.py`)

```
# ------------------------------------------------------------- 1. exponential decay times
tau = 2.197                                   # muon lifetime in microseconds
u = rng.random(N)
t = -tau * np.log(1.0 - u)                    # inverse CDF of 1 - exp(-t/tau)
out.update(SixBInvTmean=t.mean(), SixBInvTstd=t.std(ddof=1),
           SixBInvTse=t.std(ddof=1) / np.sqrt(N))

```

```
# ------------------------------------------------------------- 2. power-law energies
g, Emin, Emax = 2.7, 10.0, 1.0e6
a, b = Emin ** (1 - g), Emax ** (1 - g)
E = (a - rng.random(N * 10) * (a - b)) ** (1.0 / (1 - g))   # 10^6 energies
frac_TeV = np.mean(E > 1000.0)
exact_TeV = (1000.0 ** (1 - g) - b) / (a - b)
out.update(SixBInvNE=E.size, SixBInvFracTeV=frac_TeV, SixBInvExactTeV=exact_TeV,
           SixBInvCountTeV=int(np.sum(E > 1000.0)), SixBInvEmax=E.max())

# ------------------------------------------------------------- 3. discrete via
    cumulative sums
k4 = np.arange(5)
p4 = stats.binom.pmf(k4, 4, 5 / 8)
cum4 = np.cumsum(p4)                                  # 0.020, 0.152, 0.481, 0.847, 1
y4 = np.searchsorted(cum4, rng.random(N), side="right")     # first k with U < F(k)
freq4 = np.bincount(y4, minlength=5) / N

lam = 3.5
kp = np.arange(0, 30)
cump = np.cumsum(stats.poisson.pmf(kp, lam))
yp = np.searchsorted(cump, rng.random(N), side="right")
freqp = np.bincount(yp, minlength=kp.size)[: kp.size] / N
```

Line 32 is (6.30): `rng.random` returns numbers in $[0, 1)$, so $1 - u$ is never zero and the logarithm is always finite (with $-\tau \ln u$ the rare draw $u = 0$ would give infinity). Line 39 is (6.31), applied to a million uniforms at once. Lines 48–49 are the discrete recipe: `np.cumsum` builds the ruler of cumulative probabilities, and `np.searchsorted(cum, u, side="right")` returns, for each u, the index of the first entry of the ruler that is strictly larger than u, which is the k with $F(k-1) \le u < F(k)$. Lines 52–56 do the same for the Poisson table.

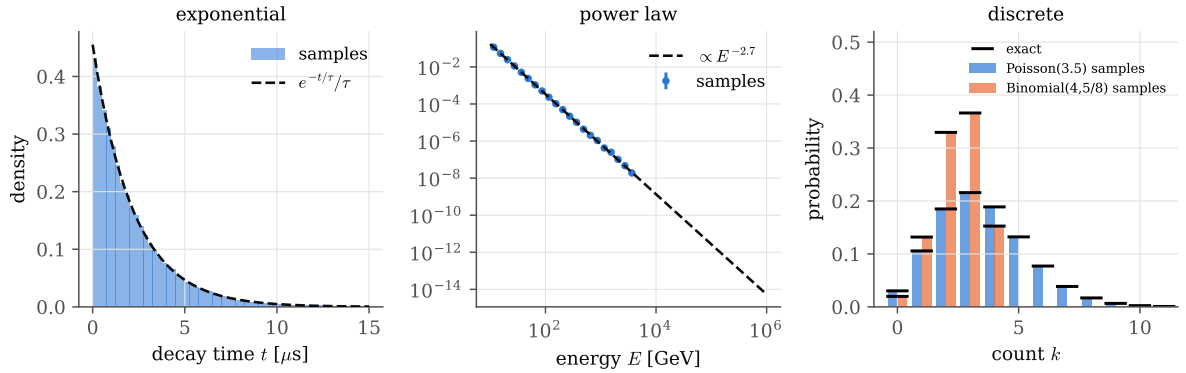

Figure 6.22: Samples made by the inverse-CDF method, against the exact distributions (black dashed). Left: 10^5 muon decay times. Middle: 10^6 energies from an $E^{-2.7}$ spectrum between 10 GeV and 10^6 GeV, on logarithmic axes, with $\sqrt{n}$ error bars on bins holding at least ten events; no simulated energy comes near the upper cut-off. Right: frequencies of Poisson and binomial counts made by cumulative sums, with the exact probabilities as black ticks.

Watch out: Inverting the wrong thing

The recipe needs the inverse of the *cumulative* distribution, not of the density: $x = p^{-1}(u)$ produces nonsense. And a formula for F is not enough: we must be able to solve $F(x) = u$ for x. The Gaussian CDF Φ has no closed-form inverse, which is why the next section needs a different trick.

The inverse-CDF method has one more property that the later methods lack: it is *monotone*. Nearby values of u give nearby values of x, and the x's come out in the same order as the u's.

So any structure put into the uniform numbers, for instance the evenly spread quasi-random points of this chapter's first part or the strata of Section 6.15, passes straight through to the target distribution. Casella and Berger call it a *direct* method: one uniform in, one draw out, with nothing thrown away [CasellaBerger §5.6.1].

6.9 Gaussian numbers: Box–Muller and the Cholesky factor

Gaussian noise is everywhere in a simulation. The thermal noise of an amplifier, the detector noise of a gravitational-wave interferometer, the smearing of a calorimeter's energy measurement and the primordial fluctuations of the CMB are all modelled as Gaussian. So we need a fast, exact way to turn uniform numbers into standard normal numbers $Z \sim \mathcal{N}(0,1)$, and then into correlated Gaussian vectors with any covariance matrix we like.

The inverse-CDF method of Section 6.8 stalls here, because it needs us to solve $F(x) = u$ for x. The Gaussian CDF,

$$\Phi(z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{z} e^{-t^2/2}\,\mathrm{d}t,$$

has no closed form, and neither does its inverse. A second route also fails. Sums of logarithms of uniforms build χ^2, gamma and beta variables, for example

$$-2\sum_{j=1}^{\nu} \ln U_j \sim \chi^2_{2\nu},$$

since each $-2\ln U_j$ is an exponential of mean 2, which is a χ^2_2 variable. But these sums only produce an *even* number of degrees of freedom. So they never give $\chi^2_1 = Z^2$, and hence never a single normal [CasellaBerger (5.6.5)]. The way out is to stop asking for one Gaussian and ask for two.

6.9.1 Two Gaussians are easier than one

The question. Which pair of functions of two independent uniforms (U_1, U_2) gives two independent standard normals (X, Y)?

Work backwards from the answer. Two independent standard normals have joint density

$$p(x,y) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2} \cdot \frac{1}{\sqrt{2\pi}} e^{-y^2/2} = \frac{1}{2\pi}\, e^{-(x^2+y^2)/2}.$$

This depends only on the distance $r = \sqrt{x^2+y^2}$ from the origin, so it is rotationally symmetric, like the Maxwell velocity distribution in two dimensions. A round density is simplest in round coordinates, so switch to polar coordinates $x = r\cos\theta$, $y = r\sin\theta$. There the area element is $\mathrm{d}x\,\mathrm{d}y = r\,\mathrm{d}r\,\mathrm{d}\theta$ (the Jacobian of polar coordinates, Figure 6.23). The probability in a small patch must be the same whichever coordinates we use to describe it:

$$p_{R,\Theta}(r,\theta)\,\mathrm{d}r\,\mathrm{d}\theta \overset{(1)}{=} p(x,y)\,\mathrm{d}x\,\mathrm{d}y \overset{(2)}{=} \frac{1}{2\pi} e^{-r^2/2}\, r\,\mathrm{d}r\,\mathrm{d}\theta \overset{(3)}{=} \underbrace{\frac{1}{2\pi}\,\mathrm{d}\theta}_{\Theta}\ \underbrace{r\,e^{-r^2/2}\,\mathrm{d}r}_{R}. \tag{6.33}$$

(1) Probability is conserved under a change of variables: the patch $[r, r+\mathrm{d}r] \times [\theta, \theta+\mathrm{d}\theta]$ and its image in the plane hold the same probability.

(2) Insert the density, which is $e^{-r^2/2}/2\pi$, and the polar area element $r\,\mathrm{d}r\,\mathrm{d}\theta$.

(3) The expression is a product of a function of θ alone and a function of r alone, so R and Θ are independent. Θ is uniform on $[0, 2\pi)$ with density $1/2\pi$, and R has density $r\,e^{-r^2/2}$ on $r \geq 0$ (the Rayleigh distribution of Chapter 2).

So the problem has split into two easy pieces: make a uniform angle, and make an independent radius with density $r\,e^{-r^2/2}$.

The angle. $\Theta = 2\pi U_2$.

The radius. It is easier to make its square, $S = R^2$. Since $\mathrm{d}s = 2r\,\mathrm{d}r$, the density of S is $p_S(s)\,\mathrm{d}s = r\,e^{-r^2/2}\mathrm{d}r = \frac{1}{2}e^{-s/2}\mathrm{d}s$, an exponential with mean 2. (It is χ^2_2, the sum of two squared standard normals.) An exponential we already know how to make: (6.30) with $\tau = 2$ gives $S = -2\ln U_1$, and $R = \sqrt{S}$.

Putting the pieces together gives the **Box–Muller transform** [130], [CasellaBerger Ex. 5.6.4]:

$$R = \sqrt{-2\ln U_1}, \qquad \Theta = 2\pi U_2, \qquad X = R\cos\Theta, \qquad Y = R\sin\Theta. \tag{6.34}$$

We built (6.34) piece by piece, working backwards. Now check it forwards: start from (U_1, U_2), whose density is 1 on the unit square, and compute the density of (X, Y). First invert the map: $U_1 = e^{-(X^2+Y^2)/2}$ and $U_2 = \theta(X, Y)/2\pi$, with θ the polar angle of the point (X, Y). For a one-to-one change of variables, the new density is the old density times the absolute value of the Jacobian determinant of the inverse map:

$$\begin{aligned} p(x,y) &\overset{(1)}{=} 1 \cdot \left|\det\begin{pmatrix} \partial u_1/\partial x & \partial u_1/\partial y \\ \partial u_2/\partial x & \partial u_2/\partial y \end{pmatrix}\right| \overset{(2)}{=} \left|\det\begin{pmatrix} -x\,u_1 & -y\,u_1 \\ -\dfrac{y}{2\pi r^2} & \dfrac{x}{2\pi r^2} \end{pmatrix}\right| \\ &\overset{(3)}{=} \left|-\frac{u_1\,(x^2+y^2)}{2\pi r^2}\right| \overset{(4)}{=} \frac{1}{2\pi}e^{-(x^2+y^2)/2} = \frac{e^{-x^2/2}}{\sqrt{2\pi}}\cdot\frac{e^{-y^2/2}}{\sqrt{2\pi}}. \end{aligned} \tag{6.35}$$

(1) The multivariate change-of-variables rule of Chapter 1, with input density 1.

(2) Differentiate $u_1 = e^{-(x^2+y^2)/2}$, which gives $-x\,u_1$ and $-y\,u_1$. For the angle, $\theta = \arctan(y/x)$ has $\partial\theta/\partial x = -y/r^2$ and $\partial\theta/\partial y = x/r^2$, and $u_2 = \theta/2\pi$.

(3) The determinant is $(-xu_1)(x/2\pi r^2) - (-yu_1)(-y/2\pi r^2)$.

(4) $x^2 + y^2 = r^2$ cancels, and $u_1 = e^{-r^2/2}$.

The result is the product of two standard normal densities, so X and Y are independent $\mathcal{N}(0, 1)$: every pair of uniforms gives two Gaussians, exactly, with no approximation and nothing thrown away.

Example: checking a hundred thousand pairs. The script below applies (6.34) to $N = 100000$ pairs of uniforms. If the outputs are independent standard normals, five things should hold, and we check each against its expected scatter.

- Means near 0: they are 3.503×10^{-4} and 9.210×10^{-4}, with standard error $1/\sqrt{N} \approx 0.003$.
- Variances near 1: they are 1.006 and 1.001, with standard error $\sqrt{2/N} \approx 0.0045$.
- No correlation: the sample correlation is 0.003211.
- $X^2 + Y^2$ exponential with mean 2: its mean is 2.007.
- Gaussian tails: the fourth moment $\mathbb{E}[X^4]$ is 3.054, against 3 for a Gaussian.

A Kolmogorov–Smirnov test of X against $\mathcal{N}(0, 1)$ (Chapter 4) gives $p = 0.9435$. Figure 6.24 shows the input square, the output cloud and the histograms.

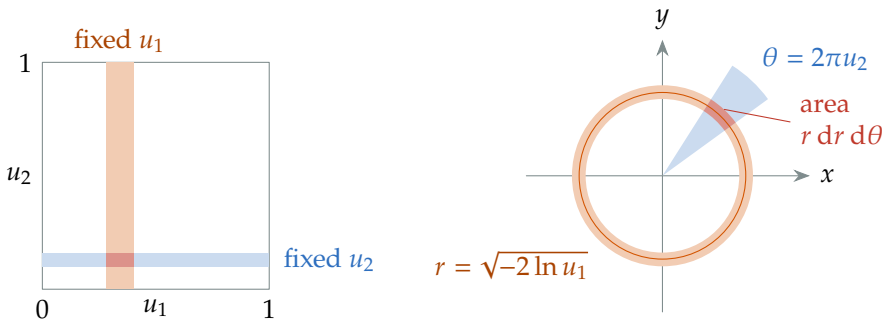

Figure 6.23: The Box–Muller map. A vertical strip of the unit square (fixed u_1) becomes a thin ring of radius $\sqrt{-2\ln u_1}$; a horizontal strip (fixed u_2) becomes a wedge at angle $2\pi u_2$, which reaches every radius (it is cut at the edge of the plot). Their overlap, the small red rectangle, is carried to the red patch of area $r\,\mathrm{d}r\,\mathrm{d}\theta$. Small u_1 gives large radii, but the logarithm makes those rare, which produces the Gaussian tails.

Listing 6.9: Box–Muller and its polar variant (`code/ch06/22_box_muller.py`)

```
28 def box_muller(u1, u2):
29     r = np.sqrt(-2.0 * np.log(u1))              # radius: R^2 = -2 ln U1 is exponential,
       mean 2
30     th = 2.0 * np.pi * u2                       # angle: uniform on [0, 2 pi)
31     return r * np.cos(th), r * np.sin(th)
32
33
34 u1 = 1.0 - rng.random(N)                       # in (0, 1], so log(u1) is finite
35 u2 = rng.random(N)
36 x, y = box_muller(u1, u2)
37
38 # polar method: points uniform in the square, keep those inside the unit disc
39 v = 2.0 * rng.random((N, 2)) - 1.0
40 s = np.sum(v**2, axis=1)
41 keep = (s < 1.0) & (s > 0.0)
42 vk, sk = v[keep], s[keep]
43 fac = np.sqrt(-2.0 * np.log(sk) / sk)
44 xp = vk[:, 0] * fac
```

Line 29 is the radius, line 30 the angle, line 31 the two outputs. Line 34 uses $1 - u$ so that u_1 lies in $(0, 1]$ and $\ln u_1$ is finite.

Example: the polar method. Lines 38–44 implement a variant due to Marsaglia and Bray [131] that avoids computing a sine and a cosine. Box–Muller needs two things: a uniform number for the radius, and the cosine and sine of a uniform angle. The polar method gets both from one random point in the unit disc.

The recipe. Draw (V_1, V_2) uniform in the square $[-1, 1]^2$, and keep the pair only if $S = V_1^2 + V_2^2 < 1$, that is, only if the point lies in the unit disc. A kept point is uniform in the disc.

Why it works. Its angle is uniform, so $V_1/\sqrt{S}$ and $V_2/\sqrt{S}$ are the cosine and sine of a uniform angle. Its S is uniform on $(0, 1)$, because the fraction of the disc within radius $\sqrt{s}$ is $\pi s/\pi = s$; and S is independent of the angle. So S can play the role of U_1, and $X = V_1\sqrt{-2\ln S/S}$, $Y = V_2\sqrt{-2\ln S/S}$ are again independent normals.

The price. Some pairs are thrown away. The kept fraction is the area of the disc over the area of the square, $\pi/4 = 0.785$, and the script finds 0.7847. Throwing candidates away to shape a distribution is the whole idea of the next section.

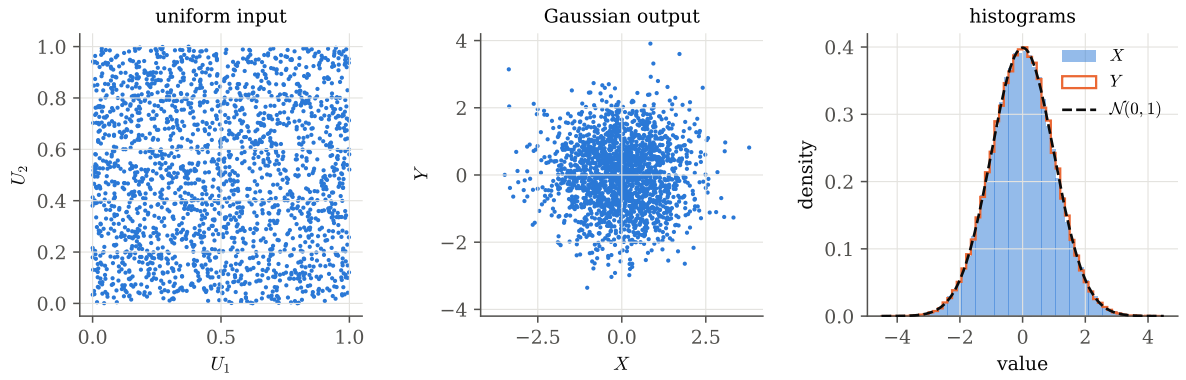

Figure 6.24: Box–Muller in action. Left: 2000 pairs of uniforms. Middle: the same pairs after the map (6.34), a round Gaussian cloud. Right: the histograms of all 10^5 values of X and of Y lie on the standard normal density (black dashed).

Watch out: Twelve uniforms minus six

An old shortcut makes a "Gaussian" as $U_1 + \cdots + U_{12} - 6$, which has mean 0 and variance $12 \times \frac{1}{12} = 1$ and is close to normal by the central limit theorem (Chapter 2). It can never exceed 6 in magnitude, and its tails are wrong long before that. A simulation of the background tail beyond 5σ, which is exactly where a discovery claim lives, would be wrong. Use an exact method.

6.9.2 Correlated Gaussian vectors: the Cholesky factor

Box–Muller gives independent standard normals. Physics needs correlated ones: the pixel values of a CMB map, the strain in two detectors driven by a common environmental noise, the residuals of a fit with a non-diagonal covariance matrix (Chapter 3). The target is a Gaussian vector $\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{C})$ of dimension n with a prescribed mean vector $\boldsymbol{\mu}$ and covariance matrix $\mathbf{C}$.

The question. Which linear map turns a vector $\boldsymbol{z}$ of n independent standard normals, whose covariance is the identity $\mathbb{1}$, into a vector with covariance $\mathbf{C}$?

Try $\boldsymbol{X} = \boldsymbol{\mu} + \mathbf{L}\boldsymbol{z}$ for some $n \times n$ matrix $\mathbf{L}$. The transformation rule for covariance matrices under a linear map, $\mathrm{Cov}(\mathbf{A}\boldsymbol{z}) = \mathbf{A}\,\mathrm{Cov}(\boldsymbol{z})\mathbf{A}^{\mathsf{T}}$ (Chapter 1), gives

$$\mathrm{Cov}(\boldsymbol{X}) \overset{(1)}{=} \mathrm{Cov}(\mathbf{L}\boldsymbol{z}) \overset{(2)}{=} \mathbf{L}\,\mathrm{Cov}(\boldsymbol{z})\,\mathbf{L}^{\mathsf{T}} \overset{(3)}{=} \mathbf{L}\,\mathbb{1}\,\mathbf{L}^{\mathsf{T}} = \mathbf{L}\mathbf{L}^{\mathsf{T}}. \tag{6.36}$$

(1) Adding the constant $\boldsymbol{\mu}$ shifts the vector but not its fluctuations.
(2) The covariance of a linear transformation: $\mathbb{E}[(\mathbf{L}\boldsymbol{z})(\mathbf{L}\boldsymbol{z})^{\mathsf{T}}] = \mathbf{L}\,\mathbb{E}[\boldsymbol{z}\boldsymbol{z}^{\mathsf{T}}]\,\mathbf{L}^{\mathsf{T}}$, since $\boldsymbol{z}$ has mean zero.
(3) The components of $\boldsymbol{z}$ are independent with unit variance.

So any $\mathbf{L}$ with $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$ gives the right covariance. The result is also Gaussian, because a linear combination of Gaussians is Gaussian (Chapter 2). For a symmetric positive definite $\mathbf{C}$ there is exactly one lower-triangular such $\mathbf{L}$ with positive diagonal, the **Cholesky factor** [a "square root" of $\mathbf{C}$ with zeros above the diagonal]. It costs about $n^3/3$ operations to compute.

Example: two correlated variables. For $n = 2$ with standard deviations σ_x, σ_y and correlation coefficient ρ, write $\mathbf{L} = \left(\begin{smallmatrix} l_{11} & 0 \\ l_{21} & l_{22} \end{smallmatrix}\right)$ and match $\mathbf{L}\mathbf{L}^{\mathsf{T}}$ to $\mathbf{C}$ entry by entry:

$$\begin{pmatrix} l_{11}^2 & l_{11}l_{21} \\ l_{11}l_{21} & l_{21}^2 + l_{22}^2 \end{pmatrix} \overset{(1)}{=} \begin{pmatrix} \sigma_x^2 & \rho\sigma_x\sigma_y \\ \rho\sigma_x\sigma_y & \sigma_y^2 \end{pmatrix} \Longrightarrow\; l_{11} \overset{(2)}{=} \sigma_x, \quad l_{21} \overset{(3)}{=} \rho\sigma_y, \quad l_{22} \overset{(4)}{=} \sigma_y\sqrt{1-\rho^2}. \tag{6.37}$$

(1) Multiply out $\mathbf{L}\mathbf{L}^{\mathsf{T}}$ and require it to equal the 2×2 covariance matrix.
(2) The top-left entry, taking the positive root.
(3) The off-diagonal entry, divided by $l_{11} = \sigma_x$.
(4) The bottom-right entry: $l_{22}^2 = \sigma_y^2 - \rho^2\sigma_y^2$.

So $x = \mu_x + \sigma_x z_1$ and $y = \mu_y + \rho\sigma_y z_1 + \sigma_y\sqrt{1-\rho^2}\, z_2$. In words: y copies a fraction ρ of the fluctuation z_1 of x, in units of its own width σ_y, and adds fresh noise z_2 of its own (the same example as Chapter 2). For $\sigma_x = 1$, $\sigma_y = 2$, $\rho = 0.8$ this gives $l_{21} = 1.6$ and $l_{22} = 1.2$. From 50 000 draws the sample covariances are 1.006, 1.609 and 4.011, against 1, 1.6 and 4, and the sample correlation is 0.8009.

Example: a correlated field on a line. A random field is a random function of position. On a grid of n points it is simply a random vector of n values. "Statistically homogeneous" means that the covariance of the values at two points depends only on their separation r. Take $n = 200$ points on $[0, 20]$ and the exponential correlation $C(r) = e^{-|r|/\ell}$ with correlation length $\ell = 2$, so $\mathbf{C}_{ij} = e^{-|x_i - x_j|/\ell}$. The script factors this 200×200 matrix and draws $M = 4000$ fields $\boldsymbol{f} = \mathbf{L}\boldsymbol{z}$.

Listing 6.10: A correlated one-dimensional Gaussian field by the Cholesky factor (`code/ch06/23_cholesky_field.py`)

```
39 n, Lbox, ell, M = 200, 20.0, 2.0, 4000
40 xg = np.linspace(0, Lbox, n)
41 C = np.exp(-np.abs(xg[:, None] - xg[None, :]) / ell)
42 L = np.linalg.cholesky(C)
43 Z = rng.standard_normal((M, n))
44 F = Z @ L.T                                   # M realisations, each row one field
45 Fbad = Z @ C.T                                # the pitfall: multiply by C instead
       of L
```

Line 41 builds the covariance matrix from the separations of all pairs of points, line 42 factors it, and line 44 multiplies a whole stack of white-noise vectors by $\mathbf{L}^{\mathsf{T}}$ from the right, which is the row-vector form of $\mathbf{L}\boldsymbol{z}$.

What comes out? The realisations (Figure 6.25, left) wander smoothly over distances of order ℓ, while the white noise they are made from jumps from point to point. The correlation function estimated from the realisations follows $e^{-r/\ell}$: at $r = \ell$ it is 0.3608, against $e^{-1} = 0.368$. The sample covariance matrix has 40 000 entries. The largest deviation of any of them from $\mathbf{C}$ is 0.06748. A single entry has standard error $\sqrt{2/M} = 0.02236$, so this is about three standard errors, which is what the largest of 40 000 roughly Gaussian errors should be.

The orange points of Figure 6.25 show a tempting mistake: multiplying the white noise by $\mathbf{C}$ itself. By (6.36) with $\mathbf{L}$ replaced by $\mathbf{C}$, the result has covariance $\mathbf{C}\mathbf{C}^{\mathsf{T}} = \mathbf{C}^2$, not $\mathbf{C}$; its correlation at $r = \ell$ is 0.746 instead of 0.368.

Key idea: Colouring white noise

Any Gaussian vector with covariance $\mathbf{C}$ is a linear map of white noise: $\boldsymbol{X} = \boldsymbol{\mu} + \mathbf{L}\boldsymbol{z}$ with $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$ and $\boldsymbol{z}$ a vector of independent standard normals made by Box–Muller. Conversely, $\mathbf{L}^{-1}(\boldsymbol{X} - \boldsymbol{\mu})$ is white again, which is how correlated residuals are "whitened" before a χ^2 is formed.

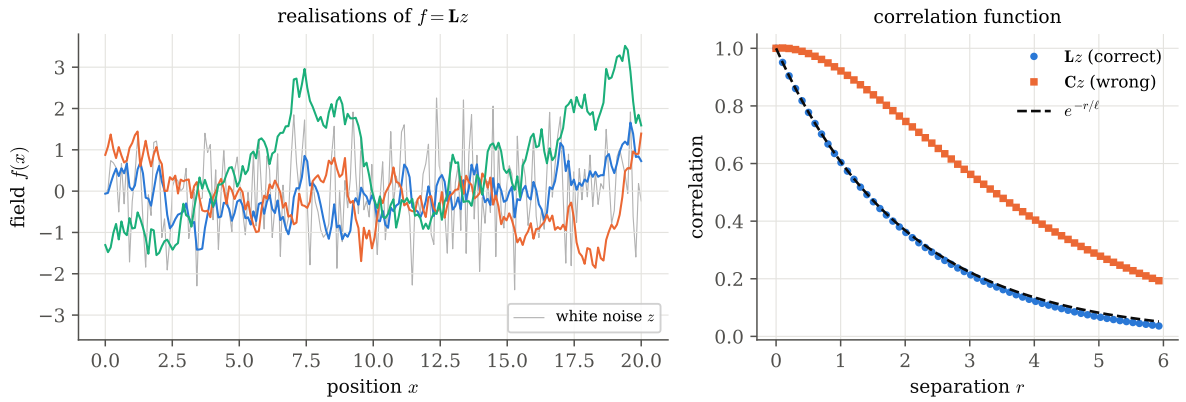

Figure 6.25: A correlated Gaussian field made from white noise. Left: three realisations of $\boldsymbol{f} = \mathbf{L}\boldsymbol{z}$ with correlation length $\ell = 2$, and one of the white-noise vectors $\boldsymbol{z}$ (grey) they are built from. Right: the correlation function averaged over 4000 realisations follows $e^{-r/\ell}$ (blue). Multiplying by $\mathbf{C}$ instead of its Cholesky factor gives correlations that are far too long (orange).

The Cholesky factor costs $n^3/3$ operations and n^2 memory. For a CMB map with 5×10^7 pixels that is hopeless. A statistically isotropic field offers a way round. Expand it in spherical harmonics; its harmonic coefficients $a_{\ell m}$ are then uncorrelated, with variances given by the power spectrum C_ℓ. So in the harmonic basis the covariance is diagonal, and its "Cholesky factor" is simply $\sqrt{C_\ell}$ [one independent Gaussian per mode, scaled by the square root of the power spectrum]. Simulating a CMB sky is therefore Box–Muller followed by a spherical-harmonic transform, which is how Chapter 7 and Chapter 8 make maps. Cholesky remains the tool for small, dense covariance matrices: the correlated residuals of a fit, a few correlated nuisance parameters, or a masked patch of sky.

6.10 Rejection sampling: throwing points under a curve

In the reaction $e^+e^- \to \mu^+\mu^-$ at energies well below the Z pole, the muons come out with the angular distribution

$$f(x) = \tfrac{3}{8}\,(1 + x^2), \qquad x = \cos\theta \in [-1, 1], \tag{6.38}$$

where θ is the angle between the outgoing μ^- and the incoming e^- [Cowan (3.8)]. To simulate events we need draws of x from this density. The inverse-CDF method of Section 6.8 sets the CDF equal to a uniform number u and solves for x. Here that means solving the cubic $F(x) = \frac{1}{8}(x^3 + 3x + 4) = u$ for every event. That can still be done. Add the forward–backward asymmetry, or multiply by a detector efficiency, and the CDF can no longer be inverted by hand. The posterior densities of Chapter 5 are worse still: we can compute their value at any point, but we know nothing about their CDF. So we need a method that uses only the *values* of f.

The question. If all we can do is evaluate $f(x)$, and draw from some simpler density g, how do we produce draws from f?

6.10.1 Points uniform under a curve

The key fact is geometric. Draw the graph of a density f and consider the region under it, $A_f = \{(x, y) : 0 < y < f(x)\}$. Its area is $\int f\,\mathrm{d}x = 1$. Now pick a point (X, Y) uniformly in that region, so its joint density is 1 on A_f and 0 elsewhere. The density of its horizontal coordinate

alone is the marginal (Chapter 1), obtained by integrating out the vertical coordinate:

$$p_X(x) \overset{(1)}{=} \int p_{X,Y}(x,y)\,\mathrm{d}y \overset{(2)}{=} \int_0^{f(x)} 1\,\mathrm{d}y \overset{(3)}{=} f(x). \tag{6.39}$$

(1) The marginal density of X averages out the nuisance coordinate Y.
(2) The joint density is 1 for $0 < y < f(x)$ and zero otherwise.
(3) The length of the vertical slice of A_f at x is the height of the curve.

So *the x-coordinates of points spread uniformly under the graph of f are draws from f*. In words: a tall part of the curve holds more of the points, in proportion to its height. The same holds if we only know f up to a constant factor $c > 0$. The region under cf has area c, so a uniform point in it has joint density $1/c$, and the x-marginal is $cf(x)/c = f(x)$ again. So we never need the normalising constant of f.

How do we get points uniform under f? Doing it directly is as hard as drawing from f itself. Instead, we make points uniform under a *larger* curve that we know how to sample, and keep only those that happen to fall under f. The kept points cover the region under f evenly, because every part of it was covered evenly before we threw anything away. So they are uniform under f. This is von Neumann's acceptance–rejection method [Cowan §3.3].

6.10.2 The algorithm and why it works

Choose an **envelope** density g [a density we can already sample, for instance by the inverse CDF] and a constant M with $f(x) \le Mg(x)$ for every x. Then repeat:

1. draw a candidate $V \sim g$ and, independently, $U \sim \mathrm{Uniform}(0,1)$;
2. if $U < f(V)/\big(Mg(V)\big)$, accept and return V; otherwise reject and go back to step 1.

In the picture of points under a curve (Section 6.10.1), step 1 puts the point $(V,\, U\,Mg(V))$ uniformly under the curve Mg: its horizontal position V has density g, and its height $U\,Mg(V)$ is uniform between 0 and $Mg(V)$. Step 2 keeps the point if it also lies under f, because $U\,Mg(V) < f(V)$ is the same condition as $U < f(V)/Mg(V)$.

The question. Why are the kept values exact draws from f, and not something only close to it? A kept value is a candidate V for which the event "accept" happened. So what we need is the CDF of V given acceptance, $\mathrm{P}(V \le y \mid \text{accept})$. By the definition of conditional probability this is $\mathrm{P}(V \le y,\ \text{accept})/\mathrm{P}(\text{accept})$, so we need two probabilities [CasellaBerger Thm 5.6.8].

First, how often is a candidate accepted?

$$\mathrm{P}(\text{accept}) \overset{(1)}{=} \int g(v)\ \mathrm{P}\Big(U < \frac{f(v)}{Mg(v)}\Big)\,\mathrm{d}v \overset{(2)}{=} \int g(v)\,\frac{f(v)}{Mg(v)}\,\mathrm{d}v \overset{(3)}{=} \frac{1}{M}\int f(v)\,\mathrm{d}v \overset{(4)}{=} \frac{1}{M}. \tag{6.40}$$

(1) Law of total probability over the value v of the candidate, which has density g (Chapter 1).
(2) U is uniform and $f(v)/Mg(v) \le 1$ by the choice of M, so the probability that U lies below it is the number itself.
(3) The g's cancel.
(4) f is a normalised density.

Second, how often is a candidate both accepted and below a value y? It is the same integral, stopped at y. *Then divide*, which gives the CDF we want:

$$\mathrm{P}(V \le y,\ \text{accept}) \overset{(1)}{=} \int_{-\infty}^{y} g(v)\,\frac{f(v)}{Mg(v)}\,\mathrm{d}v \overset{(2)}{=} \frac{F(y)}{M}, \qquad \mathrm{P}(V \le y \mid \text{accept}) \overset{(3)}{=} \frac{F(y)/M}{1/M} = F(y). \tag{6.41}$$

(1) As in (6.40), but only candidates below y count.
(2) The g's cancel, and $\int_{-\infty}^{y} f = F(y)$.
(3) The definition of conditional probability (Chapter 1), with (6.40) in the denominator.

What it means. The accepted values have CDF F, so they are exact draws from f, with no approximation. In the language of Chapter 1, accepting is *conditioning*. We generate candidates from a larger sample space and keep only the outcomes in the event "the point fell under f". Keeping only that event turns the distribution g of the candidates into the distribution f of the survivors.

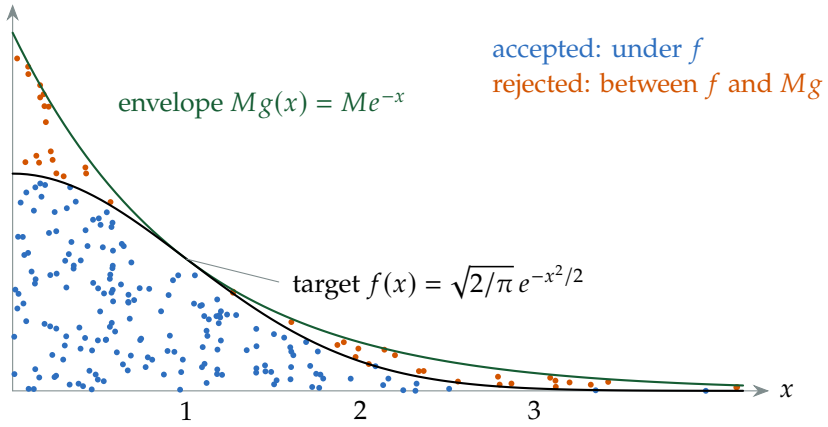

Figure 6.26: Rejection sampling as throwing points under a curve. Each candidate x is drawn from the exponential density g and given a height uniform between 0 and $Mg(x)$ (green), so the points are uniform under the green curve. The points that fall under the target f (black) are kept; their x-coordinates are distributed as f. The fraction kept is the area under f divided by the area under Mg, which is $1/M$. The two curves touch at $x = 1$, where f/g is largest.

The cost. Each candidate is accepted independently with probability $1/M$, by (6.40). So the number K of candidates needed for one accepted value is geometric, $\mathrm{P}(K = k) = (1-1/M)^{k-1}/M$: $k-1$ rejections followed by one acceptance. Its mean is $\mathbb{E}\,K = \sum_k k\,(1-1/M)^{k-1}/M = M$ [CasellaBerger (5.6.12)]. So M is the average cost of one draw, counted in candidates.

The best envelope. Since M is the cost, the best envelope is the one with the smallest M. Two choices achieve that. First, take $M = \sup_x f(x)/g(x)$ exactly: this is the smallest value that still keeps Mg above f everywhere. Second, choose g as close in shape to f as possible, so that this supremum is itself close to 1.

Working definition 6.4 (rejection sampling)

Target f (known up to a constant), envelope g that we can sample, and $M = \sup_x f(x)/g(x) < \infty$ [the factor that lifts g above f everywhere]. Draw $V \sim g$, $U \sim \mathrm{Uniform}(0,1)$; keep V if $U\,Mg(V) < f(V)$. *Cost:* on average M candidates per accepted draw; acceptance rate $1/M$. *Requirement:* f/g must be bounded, so g needs tails at least as heavy as f's.

6.10.3 Three worked examples

Example: the muon-pair angle in a box. The simplest envelope is a box. For (6.38) on $[-1,1]$, the largest value of f is $f_{\max} = f(\pm 1) = 3/4$. Take g uniform on $[-1,1]$, so $g = 1/2$ and $M = f_{\max}/g = 3/2$. The recipe becomes three steps: draw x uniform on $[-1,1]$, draw u uniform on $[0, f_{\max}]$, and keep x if $u < f(x)$ [Cowan §3.3]. The predicted acceptance is $1/M = 2/3$: the area under f (one) divided by the area of the box ($2 \times 3/4$). Out of 200000 candidates the script

accepts a fraction 0.6666. To check the shape as well, compare the mean of x^2 over accepted values, 0.399, with its exact value, $\int_{-1}^{1} x^2 \cdot \frac{3}{8}(1+x^2)\,dx = \frac{3}{8}\left(\frac{2}{3}+\frac{2}{5}\right) = \frac{2}{5}$. Figure 6.27 (left and middle) reproduces Cowan's Figure 3.2.

Example: a half-normal under an exponential. Take $f(x) = \sqrt{2/\pi}\,e^{-x^2/2}$ for $x > 0$, the distribution of $|Z|$ for a standard normal Z, and the envelope $g(x) = e^{-x}$, which we sample as $-\ln(1-u)$. The ratio and its maximum:

$$\frac{f(x)}{g(x)} \overset{(1)}{=} \sqrt{\frac{2}{\pi}}\, e^{\,x-x^2/2} \overset{(2)}{=} \sqrt{\frac{2}{\pi}}\, e^{1/2}\, e^{-(x-1)^2/2} \quad\Longrightarrow\quad M = \sup_x \frac{f}{g} \overset{(3)}{=} \sqrt{\frac{2e}{\pi}} = 1.315. \tag{6.42}$$

(1) Divide the two densities: $e^{-x^2/2}/e^{-x} = e^{x-x^2/2}$.
(2) Complete the square: $x - \frac{1}{2}x^2 = \frac{1}{2} - \frac{1}{2}(x-1)^2$.
(3) The Gaussian factor is at most 1, reached at $x = 1$, where the two curves touch (Figure 6.26).

So a fraction $1/M = 0.7602$ of candidates should survive; the script finds 0.7601. The number of candidates per accepted value averages 1.316, against M, and its histogram is the geometric distribution (Figure 6.28). The accepted values have mean 0.7978, against $\mathbb{E}\,|Z| = \sqrt{2/\pi} = 0.7979$. Attaching a random sign to each accepted value gives a full standard normal. That is a third Gaussian generator, after Box–Muller and the polar method.

Example: a Beta density with non-integer parameters. Take $Y \sim \text{Beta}(a, b)$ with $a = 2.7$ and $b = 6.3$. The recipes of Section 6.9 that build gamma and beta variables from logarithms of uniforms need integer parameters, so they do not apply here, and there is no other simple transformation from uniforms. Rejection needs none: put the density on $[0, 1]$ inside a box of width 1 and height $c = \max_y f_Y(y)$ [CasellaBerger Ex. 5.6.7]. Here g is uniform on $[0, 1]$, so $M = c$. The maximum is at the mode $y = (a-1)/(a+b-2) = 1.7/7$, where $c = 2.67$. So the acceptance should be $1/c = 0.3746$; the script finds 0.3729. The mean of accepted values is 0.3, against $a/(a+b) = 0.3$.

Can a better envelope help? A Beta(2, 6) envelope is closer in shape to the target, and needs only $M = 1.67$ candidates per draw instead of 2.67. But each Beta(2, 6) candidate itself costs several uniforms. So which algorithm is faster depends on the cost of a candidate as well as on M [CasellaBerger Ex. 5.6.9].

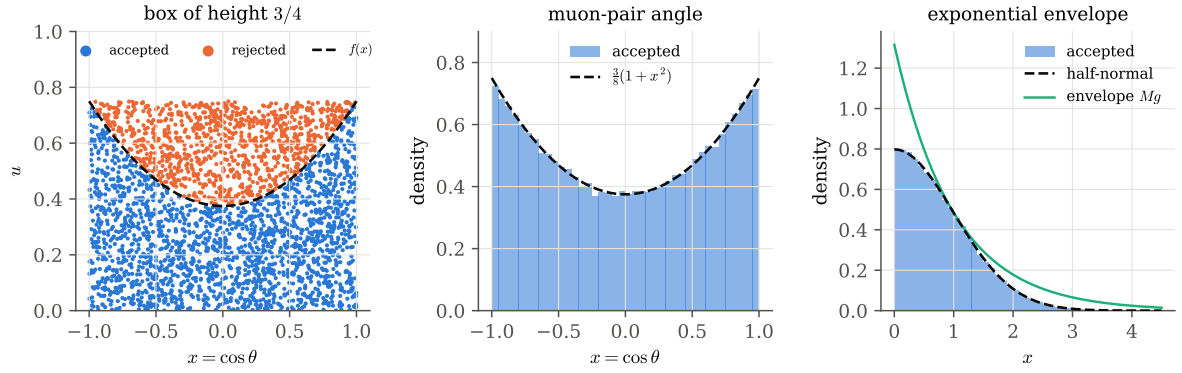

Figure 6.27: Rejection sampling at work. Left: 3000 candidate points uniform in the box of height 3/4; those under $f(x) = \frac{3}{8}(1+x^2)$ (blue) are kept. Middle: the histogram of all kept $x = \cos\theta$ values follows the muon-pair angular distribution. Right: half-normal values kept from exponential candidates, with the envelope Mg (green) touching the target at $x = 1$.

Listing 6.11: Half-normal draws from exponential candidates (`code/ch06/24_rejection.py`)

```
39 # ------------------------------------------------------------- 2. half-normal under an
       exponential
40 M2 = np.sqrt(2.0 * np.e / np.pi)
41 v = -np.log(1.0 - rng.random(N))                # candidate from g(x) = e^{-x} (inverse CDF)
42 u = rng.random(N)
43 ratio = np.sqrt(2.0 / np.pi) * np.exp(-v**2 / 2) / (M2 * np.exp(-v))
44 acc2 = u < ratio
45 hn = v[acc2]
```

Line 41 draws the candidates by the inverse CDF of Section 6.8, line 43 computes the acceptance probability $f(V)/Mg(V)$ for all of them at once, and line 44 keeps the candidates whose uniform number falls below it. The loop "repeat until accepted" of the algorithm has become a filter applied to a fixed number of candidates at once. This is how rejection is usually coded in numpy. The price is that N candidates give about N/M accepted values, not exactly N.

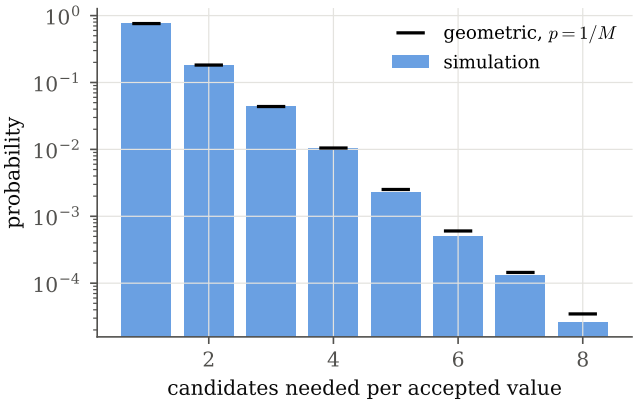

Figure 6.28: How many exponential candidates it takes to get one half-normal value. The frequencies (bars, logarithmic scale) fall by a factor $1 - 1/M$ per extra candidate, the geometric distribution with success probability $1/M$ (black ticks).

6.10.4 When rejection fails: tails and dimension

Rejection fails in two ways. The first is in the tails. The method needs a finite $M = \sup f/g$, so that Mg lies above f everywhere. If the target has heavier tails than the envelope, then far out f is much larger than g, the ratio f/g grows without bound, and no finite M exists. A Cauchy envelope for a Gaussian target works, since the Cauchy tails, falling as x^{-2}, outlast $e^{-x^2/2}$. A Gaussian envelope for a Cauchy target cannot work, however large we make M [CasellaBerger p. 207]. The same condition on the tails comes back, in a sharper form, for importance sampling in Section 6.12.

The second failure is in high dimension, and it is worse because nothing visibly breaks: the acceptance rate just collapses. In d dimensions the envelope has to cover the target in every direction at once, and the wasted volume multiplies. The cleanest example is the uniform distribution in the unit ball, sampled from the cube $[-1, 1]^d$ around it. The acceptance is the volume of the ball over the volume of the cube:

$$\frac{1}{M} \overset{(1)}{=} \frac{\pi^{d/2}/\Gamma(d/2+1)}{2^d}, \qquad \text{so} \qquad \frac{1}{M} = \frac{\pi}{4} = 0.785 \ \text{ for } d = 2,$$
$$\frac{1}{M} \overset{(2)}{=} \frac{\pi^5}{5!\,2^{10}} = 0.0025 \ \text{ for } d = 10, \qquad \frac{1}{M} \overset{(3)}{=} \frac{\pi^{10}}{10!\,2^{20}} = 2.5 \times 10^{-8} \ \text{ for } d = 20. \tag{6.43}$$

(1) The volume of the unit ball in d dimensions is $\pi^{d/2}/\Gamma(d/2+1)$; the cube of side 2 has volume 2^d.
(2) $\Gamma(6) = 5! = 120$, so $306.0/(120 \times 1024)$.
(3) $\Gamma(11) = 10! = 3\,628\,800$, and $\pi^{10} = 93\,648$.

In two dimensions (the polar method of Section 6.9.1) we keep 79% of the candidates. In twenty dimensions we keep one candidate in forty million. A cosmological posterior with twenty parameters is far more concentrated inside its prior than a ball is inside a cube, so rejection from the prior is hopeless there. This is the practical reason for the Markov chain methods of Chapter 9, which never try to cover the whole space at once.

Rejection also hides inside some recipes that do not use the word. In a dose–response study, ten response probabilities $p_1, \dots, p_{10}$, one per dose, each have an independent Beta posterior, but physics says they must be ordered, $p_1 \le \cdots \le p_{10}$. The recipe is: draw all ten, and throw the draw away if it is not ordered [Wasserman Ex. 24.4, p. 407]. That is rejection sampling. By exactly the argument of (6.41), the kept draws come from the posterior restricted to the ordered region, and the acceptance rate is the posterior probability of that region.

Key idea: Accepting is conditioning

Points uniform under the graph of a density have x-coordinates distributed as that density. Rejection sampling makes points uniform under an easy envelope Mg and keeps those under f; the survivors are exact draws from f, at an average cost of M candidates each. It needs only values of f up to a constant, and it breaks down when f/g is unbounded or when the dimension is large.

6.11 Monte Carlo integration and the $1/\sqrt{N}$ law

Almost every number we want out of a probability model is an integral. The posterior mean of a parameter is $\int \theta\, p(\theta \mid \boldsymbol{d})\, \mathrm{d}\theta$. The marginal posterior of one cosmological parameter is an integral over the other five. The normalising constant of Bayes' theorem, the evidence, is an integral of likelihood times prior over the whole parameter space [Wasserman §24.1, p. 403], [Lambert §12.3]. The acceptance of a detector is an integral of the emission density over the directions that hit it. Most of these integrals have no closed form. Even a one-parameter model with a Poisson likelihood and a log-normal prior gives one, and each added parameter makes it harder [Lambert §12.3]. Grids and quadrature rules work in one or two dimensions. Beyond that the number of grid points, n^D for n points per axis in D dimensions, becomes too large to evaluate [Lambert §12.4–12.5].

The samplers built so far (the inverse CDF, Box–Muller and rejection) give another way, resting on two facts: an average over random draws estimates an expectation, and every integral can be written as an expectation. Lambert tells the first fact as a story about a box with a die inside. We cannot see the die, but we can shake the box and read the face through a small window. The average of many readings estimates the mean of the die, without our knowing how many faces it has or how it is loaded [Lambert §12.6].

The question. If we estimate an integral by averaging a function over N random draws, how large is the error, and how does it depend on N and on the dimension?

6.11.1 An integral is an expectation

Start with a one-dimensional integral $I = \int_a^b h(x)\,dx$. Multiply and divide by $b-a$ [Wasserman (24.1)]:

$$I \overset{(1)}{=} \int_a^b \underbrace{h(x)\,(b-a)}_{w(x)}\,\underbrace{\frac{1}{b-a}}_{f(x)}\,dx \overset{(2)}{=} \mathbb{E}_f\big[w(X)\big], \qquad X \sim \text{Uniform}(a,b). \tag{6.44}$$

(1) Nothing has changed: we multiplied and divided by the same constant.
(2) $f(x) = 1/(b-a)$ is the uniform density on $[a,b]$, and an integral of a function against a density is the expectation of that function.

More generally, any integral of the form $I = \int h(x)f(x)\,dx$ with f a density is $\mathbb{E}_f[h(X)]$ [Wasserman (24.3)], and the variable x can have any number of dimensions. Draw $X_1, \dots, X_N$ independently from f and average:

$$\hat{I} = \frac{1}{N}\sum_{i=1}^{N} h(X_i). \tag{6.45}$$

By the law of large numbers (Chapter 3), $\hat{I} \to I$ as $N \to \infty$ [Wasserman (24.2)], [CasellaBerger (5.6.4)].

Working definition 6.5 (Monte Carlo estimate of an integral)

Write the integral as an expectation, $I = \mathbb{E}_f[h(X)]$ [choose a density f we can sample, and put everything else into h]. Draw N independent $X_i \sim f$ and report

$$\hat{I} = \frac{1}{N}\sum_i h(X_i) \;\pm\; \frac{s}{\sqrt{N}}, \qquad s^2 = \frac{1}{N-1}\sum_i \big(h(X_i) - \hat{I}\big)^2.$$

The error bar is itself estimated from the same draws.

6.11.2 Why the error falls as $1/\sqrt{N}$

The estimator $\hat{I}$ of (6.45) is an average of N independent terms $h(X_i)$. How far is it from I? Call $\mu = \mathbb{E}_f[h(X)] = I$ and $\sigma^2 = \text{Var}_f[h(X)]$ the mean and variance of a single term. The mean and the variance of the average then follow in two lines each:

$$\mathbb{E}[\hat{I}] \overset{(1)}{=} \frac{1}{N}\sum_{i=1}^{N} \mathbb{E}[h(X_i)] \overset{(2)}{=} I,$$

$$\text{Var}[\hat{I}] \overset{(3)}{=} \frac{1}{N^2}\sum_{i=1}^{N} \text{Var}[h(X_i)] \overset{(4)}{=} \frac{N\sigma^2}{N^2} = \frac{\sigma^2}{N}. \tag{6.46}$$

(1) Expectation is linear.
(2) Each X_i has density f, so each term has mean I.
(3) The X_i are independent, so the variance of the sum is the sum of the variances, and a constant factor $1/N$ comes out squared.
(4) Each term has variance σ^2.

So $\hat{I}$ is unbiased, and its standard error, the square root of its variance, is $\sigma/\sqrt{N}$. This is the same law that made the error of a sample mean shrink in Chapter 3. The central limit

theorem (Chapter 2) adds the shape: for large N, $\hat{I}$ is approximately Gaussian, $\hat{I} \approx \mathcal{N}(I, \sigma^2/N)$. We do not know σ, so we replace it by s, the standard deviation of the N values $h(X_i)$, $s^2 = \frac{1}{N-1}\sum_i \big(h(X_i) - \hat{I}\big)^2$. Then $\hat{I} \pm 1.96\, s/\sqrt{N}$ is an approximate 95% confidence interval: in 95% of repeated Monte Carlo runs it covers the true I [Wasserman p. 405]. The CLT needs $\sigma^2 < \infty$; Section 6.12 shows what happens when it is not.

Two facts about $\sigma/\sqrt{N}$ matter most. First, the factor $1/\sqrt{N}$ is slow: to gain one decimal digit we need a hundred times more draws. Second, nothing in (6.46) refers to the dimension of x. A thousand-dimensional integral has error $\sigma/\sqrt{N}$ exactly like a one-dimensional one; only σ can depend on the problem.

Key idea: The Monte Carlo error law

The average of h over N independent draws from f estimates $\int hf$ with standard error $\sigma/\sqrt{N}$, where $\sigma^2 = \mathrm{Var}_f[h]$. The rate $N^{-1/2}$ does not depend on the dimension; the constant σ does depend on how well f matches where h is large, and every variance-reduction method works on σ.

Example: $\int_0^1 x^3\,dx$. Here f is uniform on $[0,1]$ and $h(x) = x^3$, so $I = 1/4$ and $\sigma^2 = \mathbb{E}[U^6] - (\mathbb{E}[U^3])^2 = \frac{1}{7} - \frac{1}{16} = \frac{9}{112}$, that is $\sigma = 0.2835$. With $N = 10000$ uniforms the script finds $\hat{I} = 0.2509 \pm 0.002818$, where the error bar is $s/\sqrt{N}$; the prediction is $\sigma/\sqrt{N} = 0.0028$, and Wasserman reports 0.248 ± 0.0028 [Wasserman Ex. 24.1]. To see the law itself, the script repeats the estimate 2000 times at each of thirteen values of N from 10 to 10^5 and measures the root-mean-square error. On a log–log plot the points fall on a line of slope -0.5014 (Figure 6.29, left), and at $N = 10^5$ the measured RMS error is 0.9852 times $\sigma/\sqrt{N}$.

Example: a probability is the mean of an indicator. To compute $\Phi(2) = \mathrm{P}(Z \le 2)$ for $Z \sim \mathcal{N}(0,1)$, write it as $\int h(s)\,\varphi(s)\,ds$ with φ the standard normal density and $h(s) = 1$ if $s \le 2$, 0 otherwise [Wasserman Ex. 24.2]. The Monte Carlo estimate is then the fraction of normal draws below 2. Each term is a Bernoulli variable with $\sigma^2 = p(1-p)$, so the standard error is the binomial $\sqrt{p(1-p)/N}$. The script gives 0.9761 ± 0.001527 for $N = 10^4$ and $0.9775 \pm 4.691 \times 10^{-4}$ for $N = 10^5$, against 0.9772. Every probability of an event can be computed this way: simulate the experiment and count. Casella and Berger's example asks for the probability that at least t of c electronic components with exponential lifetimes survive h hours; the Monte Carlo answer is the fraction of simulated batches in which they do [CasellaBerger Ex. 5.6.2].

6.11.3 Grids lose in high dimension

A grid rule beats $1/\sqrt{N}$ easily in one dimension, and loses that advantage as the dimension grows. Take the midpoint rule with spacing Δ: it replaces h on each cell by its value at the cell's midpoint. For a smooth integrand its error is of order Δ^2. Why? Expand h in a Taylor series about the midpoint. The linear term is odd about the midpoint, so it integrates to zero over the cell, and the first term that survives is quadratic. Now spend N points in d dimensions. A grid gives only $n = N^{1/d}$ points per axis, so

$$\text{grid error} \;\propto\; \Delta^2 \overset{(1)}{=} \left(\frac{1}{n}\right)^2 \overset{(2)}{=} N^{-2/d}, \qquad \text{Monte Carlo error} \;=\; \sigma\, N^{-1/2}. \tag{6.47}$$

(1) On the unit cube the spacing is $\Delta = 1/n$.
(2) $N = n^d$ points on a grid with n points per axis.

The two rates are equal when $2/d = 1/2$, at $d = 4$. Below four dimensions the grid wins; above it Monte Carlo wins, and by a margin that grows with d [Cowan §3.4]. (Gaussian quadrature or Simpson's rule raise the power 2, which moves the crossover but not the conclusion; the grid still needs n^d points.)

Example: the same integral in 1, 2, 4 and 8 dimensions. On the unit cube take the product

$$h(\boldsymbol{x}) = \prod_{i=1}^{d} \tfrac{\pi}{2} \sin(\pi x_i).$$

Each factor integrates to one, so $I_d = 1$ in every dimension. For Monte Carlo with uniform draws,

$$\sigma_d^2 \overset{(1)}{=} \mathbb{E}[h^2] - I_d^2 \overset{(2)}{=} \prod_{i=1}^{d} \mathbb{E}\left[\tfrac{\pi^2}{4} \sin^2(\pi U_i)\right] - 1 \overset{(3)}{=} \left(\frac{\pi^2}{8}\right)^d - 1. \tag{6.48}$$

(1) The variance is the mean square minus the square of the mean.
(2) The coordinates are independent, so the expectation of the product is the product of the expectations.
(3) $\mathbb{E}[\sin^2(\pi U)] = \tfrac{1}{2}$ for U uniform on $[0, 1]$.

So $\sigma_1 = 0.4834$ and $\sigma_8 = 2.09$. Figure 6.29 (right) compares the two methods for the same number of function evaluations. With about 10^6 points, the grid error is 1.028×10^{-13} in one dimension, 4.114×10^{-7} in two, 0.002437 in four (456976 points) and 0.09592 in eight ($6^8 = 1679616$ points), while the Monte Carlo errors are 3.418×10^{-4}, 5.110×10^{-4}, 0.001697 and 0.001612. In eight dimensions a grid of 1.7 million points has only six points per axis, and it is sixty times worse than the same number of random points.

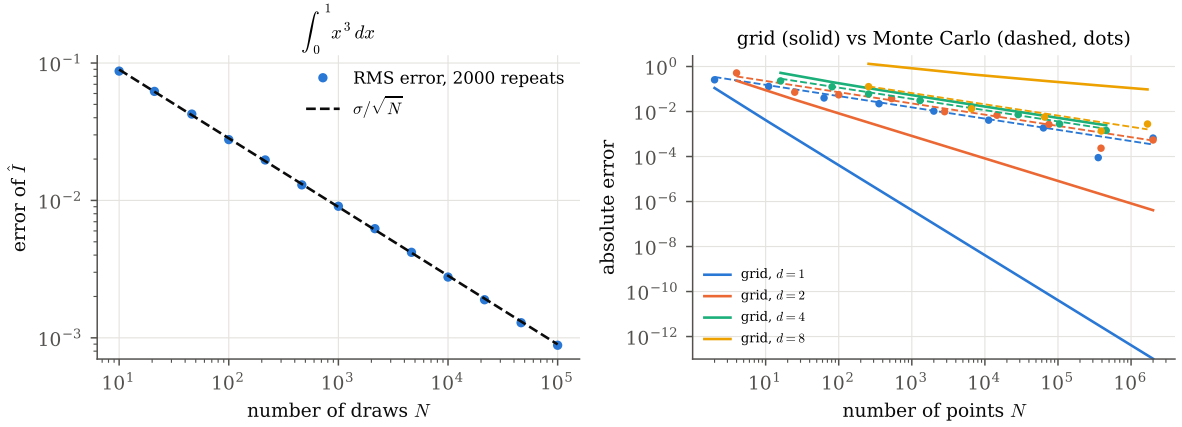

Figure 6.29: The $1/\sqrt{N}$ law. Left: RMS error of the Monte Carlo estimate of $\int_0^1 x^3 \mathrm{d}x$ over 2000 repeats, against $\sigma/\sqrt{N}$ (black dashed). Right: the error for $\int \prod \tfrac{\pi}{2} \sin(\pi x_i)\, \mathrm{d}^d x = 1$ with N points. Solid lines: midpoint grid, error $\propto N^{-2/d}$. Dashed lines and dots: Monte Carlo, error $\sigma_d/\sqrt{N}$ with slope $-1/2$ in every dimension. The grid wins for $d = 1, 2$, roughly ties at $d = 4$ and loses badly at $d = 8$.

Watch out: Dimension-independent is not dimension-free

The *rate* $N^{-1/2}$ does not depend on d, but σ_d can grow exponentially with d, as (6.48) shows: $(\pi^2/8)^{d/2}$. It grows much faster when the integrand is concentrated in a small part of the

region we sample. The evidence estimated by averaging the likelihood over prior draws was exactly that failure (Chapter 5). Monte Carlo beats the curse of dimensionality only when the sampling density f follows the integrand, which is what importance sampling and MCMC are for.

Example: a posterior by simulation. Integrals over posteriors are where Monte Carlo pays most. Suppose $X \sim \text{Binomial}(n, p_1)$ and $Y \sim \text{Binomial}(m, p_2)$ are the numbers of events passing a selection cut in two runs, out of n and m events. We want the difference of the two efficiencies, $\delta = p_2 - p_1$ [Wasserman Ex. 24.3]. With flat priors the posterior factorises into $p_1 \mid X \sim \text{Beta}(X+1, n-X+1)$ and $p_2 \mid Y \sim \text{Beta}(Y+1, m-Y+1)$ (Chapter 5). So we can draw (p_1, p_2) pairs exactly, form $\delta = p_2 - p_1$ for each pair, and make a histogram. The posterior of δ is a double integral, and we never have to write it down.

For $n = m = 10$, $X = 8$, $Y = 6$, 100000 draws give:

- a posterior mean $-0.1667 \pm 5.748 \times 10^{-4}$ (exact: $\frac{7}{12} - \frac{9}{12} = -\frac{1}{6}$);
- a 95% posterior interval $[-0.5134,\ 0.1967]$, from the 2.5% and 97.5% quantiles of the draws (Wasserman: $(-0.52, 0.20)$ from 1000 draws);
- a posterior probability $\text{P}(\delta < 0 \mid \boldsymbol{d}) = 0.8196$ that the second run has the lower efficiency (Figure 6.30).

Each of these is a summary of the draws standing in for the same summary of the posterior. A quantile of the draws estimates a quantile of the posterior. The fraction of draws in a region estimates the probability of the region. The histogram estimates the density, which is the subject of Section 6.13.

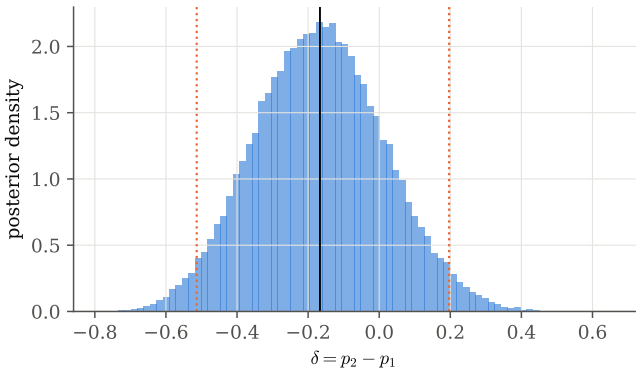

Figure 6.30: Posterior of the difference $\delta = p_2 - p_1$ of two binomial probabilities, from 10^5 pairs of Beta draws. The solid line is the posterior mean, the dotted lines the 2.5% and 97.5% quantiles of the draws.

6.11.4 Example: the acceptance of a detector

A radioactive source sits at distance d in front of a flat square scintillator of side a, centred on the axis. It emits isotropically, that is, equally in all directions. What fraction of the decays hits the scintillator? The answer is the **geometric acceptance** $\epsilon = \Omega/4\pi$ [the solid angle subtended by the detector as a fraction of the full sphere]. In the Monte Carlo form it is the mean of an indicator: emit N particles in isotropic directions (Section 6.8.2: $\cos\theta = 2u_1 - 1$, $\phi = 2\pi u_2$), follow each straight line to the plane $z = d$, and count the fraction that lands inside the square.

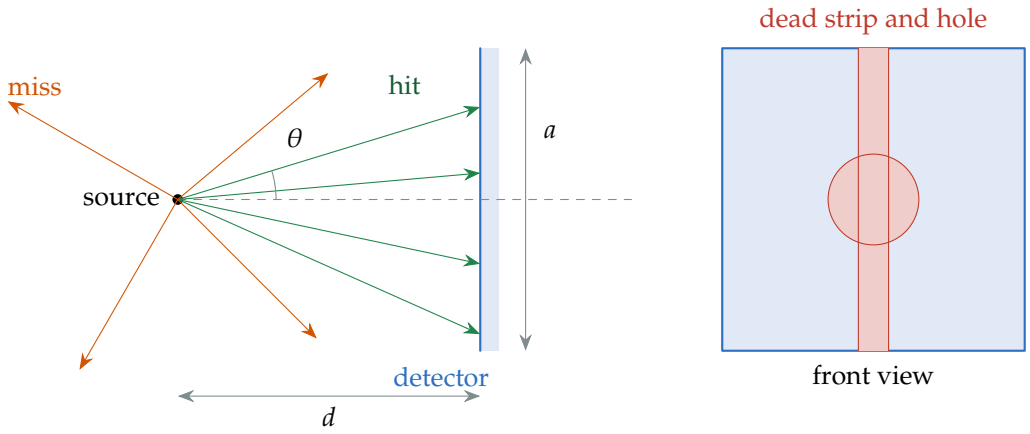

Figure 6.31: Left: side view of a point source at distance d from a square detector of side a. Isotropic rays either hit the detector (green) or miss it (orange); the acceptance is the fraction that hits. Right: the same detector seen from the source, with an insensitive strip and a central hole, the kind of geometry for which no closed form exists.

Verification. For the plain square the solid angle can be computed. With the detector in the plane $z = d$, a surface element $\mathrm{d}x\,\mathrm{d}y$ at distance $\rho = \sqrt{x^2+y^2+d^2}$ subtends $\mathrm{d}\Omega = d\,\mathrm{d}x\,\mathrm{d}y/\rho^3$ (area times the cosine of the angle of incidence d/ρ, divided by ρ^2). Doing the y integral and then the x integral with the standard antiderivatives gives

$$\Omega \overset{(1)}{=} \int_{-a/2}^{a/2}\!\!\int_{-a/2}^{a/2} \frac{d\,\mathrm{d}y\,\mathrm{d}x}{(x^2+y^2+d^2)^{3/2}} \overset{(2)}{=} \int_{-a/2}^{a/2} \frac{a\,d\,\mathrm{d}x}{(x^2+d^2)\sqrt{x^2+d^2+a^2/4}}$$
$$\overset{(3)}{=} 4\arctan\frac{a^2}{2d\sqrt{2a^2+4d^2}} \overset{(4)}{=} 4\arcsin\frac{a^2}{a^2+4d^2}. \tag{6.49}$$

(1) The solid angle is the integral of $\mathrm{d}\Omega$ over the square.

(2) With $q^2 = x^2+d^2$: $\int_{-a/2}^{a/2} \mathrm{d}y/(q^2+y^2)^{3/2} = \left[y/(q^2\sqrt{q^2+y^2})\right]_{-a/2}^{a/2} = a/\left(q^2\sqrt{q^2+a^2/4}\right)$.

(3) With $p = d$ and $r^2 = d^2 + a^2/4$, use the antiderivative (check it by differentiating)

$$\int \frac{\mathrm{d}x}{(x^2+p^2)\sqrt{x^2+r^2}} = \frac{1}{p\sqrt{r^2-p^2}}\arctan\frac{x\sqrt{r^2-p^2}}{p\sqrt{x^2+r^2}},$$

with $\sqrt{r^2-p^2} = a/2$. The two limits contribute equally.

(4) If $\tan\alpha = T$ then $\sin\alpha = T/\sqrt{1+T^2}$; here $1+T^2 = (a^2+4d^2)^2/\left(4d^2(2a^2+4d^2)\right)$.

For $d = a/2$ the square is one face of a cube centred on the source, so by symmetry it must catch exactly $1/6$ of the particles; indeed (6.49) gives $4\arcsin\frac{1}{2} = 2\pi/3 = 4\pi/6$. With $a = 10\,\mathrm{cm}$ and $N = 1000000$ particles the Monte Carlo acceptance is $0.1668 \pm 3.728\times10^{-4}$ at $d = 5\,\mathrm{cm}$ (exact $1/6$, pull 0.473), $0.06375 \pm 2.443\times10^{-4}$ at $d = 10\,\mathrm{cm}$ (exact 0.06409, pull -1.425) and $0.01875 \pm 1.356\times10^{-4}$ at $d = 20\,\mathrm{cm}$ (exact 0.01873). The error bars are binomial, $\sqrt{\epsilon(1-\epsilon)/N}$, and the pulls [the difference from the exact value in units of the error bar] are of order one, as they should be.

Listing 6.12: Isotropic emission and the crossing point with the detector plane (`code/ch06/26_acceptance.py`)

```
def isotropic(n):
    cth = 2.0 * rng.random(n) - 1.0            # cos(theta) uniform on [-1, 1]
    phi = 2.0 * np.pi * rng.random(n)          # phi uniform on [0, 2 pi)
```

```
36      return cth, phi
37
38
39  def hits(cth, phi, a, d):
40      """Crossing point with the plane z = d for upward particles (NaN otherwise)."""
41      up = cth > 0
42      sth = np.sqrt(1.0 - cth**2)
43      with np.errstate(divide="ignore", invalid="ignore"):
44          rho = np.where(up, d * sth / cth, np.nan)
45      return rho * np.cos(phi), rho * np.sin(phi)
```

Lines 34–35 are the isotropic directions of Section 6.8.2. Lines 41–45 follow each upward-going particle to the plane $z = d$: it travels a transverse distance $d \tan\theta$ before reaching it, in the azimuthal direction ϕ.

Research. Now put a 1 cm insensitive strip down the middle of the scintillator (a gap between two tiles) and a hole of radius 1.5 cm for the beam pipe (Figure 6.31, right). No formula is at hand, but the Monte Carlo number is as easy as before: at $d = 5$ cm the live acceptance is $0.1321 \pm 3.386 \times 10^{-4}$, a fraction 0.7925 of the full square's. The same code with realistic geometry, a position-dependent efficiency, multiple scattering and energy thresholds is how every experiment computes its acceptance (Figure 6.32).

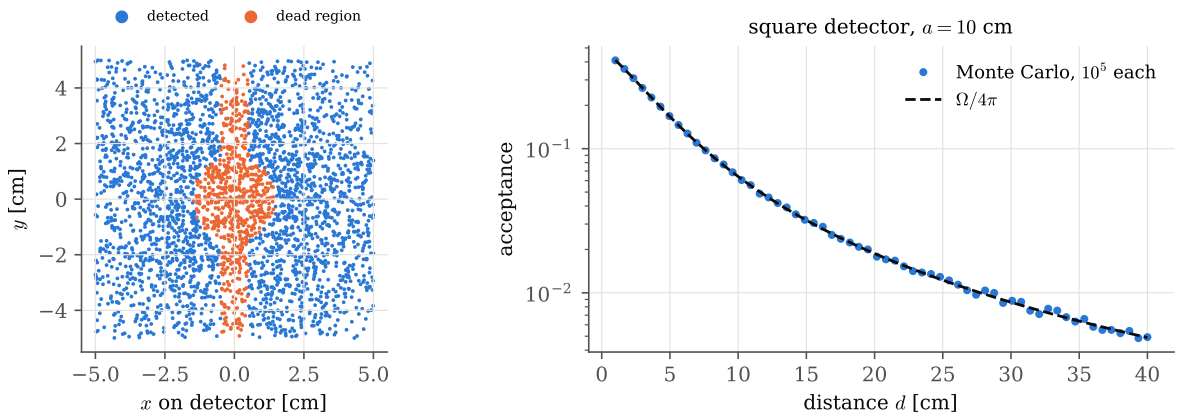

Figure 6.32: Detector acceptance by Monte Carlo. Left: where the particles that reach the square cross it, for $d = 5$ cm; those in the dead strip and the central hole (orange) are lost. Right: acceptance of the plain square against distance, 10^5 particles per point, on the exact $\Omega/4\pi$ of (6.49).

How this is used in real research: Why physics runs on sampling

The two uses of the acceptance calculation are the two uses of Monte Carlo in research. Against (6.49) it *verifies*: the code, the random numbers and the error bars are checked against a known answer. With the dead strip it *is the answer*: no formula exists and the simulation is the instrument. A collider analysis chains the two stages Cowan describes [Cowan §3.4]. An **event generator** such as Pythia [132] samples the four-momenta of the final-state particles from the differential cross section: hard scattering, parton showers and hadronisation, each by inverse-CDF, rejection and veto steps of exactly the kinds in this chapter. A **detector simulation** such as Geant4 [133] then samples each particle's interactions with the material: ionisation, multiple scattering, showers. The output is treated like real data: it gives the acceptance and efficiency, the response matrix for unfolding, and the distribution of a test statistic under the background-only hypothesis (Chapter 4). In cosmology the same role is played by simulated skies pushed through the

mask, beam and noise of the instrument (Chapter 8). In the pipeline from physical model to inference, sampling is how we *derive the sampling distribution of a summary* whenever the algebra gives out.

6.12 Importance sampling, and why g needs thicker tails than f

A search for a rare background fluctuation needs the probability that a standard normal test statistic exceeds 3, $\mathrm{P}(Z > 3) = 0.00135$. Estimated by plain Monte Carlo with $N = 100$ draws, it is the fraction of draws above 3 (Section 6.11.2). Most runs of 100 draws contain no such draw at all: in 20000 repeated runs, a fraction 0.8739 returned exactly zero. Why? The integrand is the indicator $h(x) = \mathbf{1}[x > 3]$, equal to 1 above 3 and 0 below. Nearly every draw lands below 3, where h is zero, and tells us nothing. So the trouble is not the factor $1/\sqrt{N}$ but the constant σ in front of it: we sampled from a density that rarely visits the region that matters.

A second problem has the same shape. In Bayesian inference the density we need to average over, the posterior, is usually one we cannot sample at all, while a simpler density that resembles it is easy to sample [Wasserman §24.3]. Both problems have the same fix: draw from a density of our choosing, and correct each draw with a weight.

The question. If we draw from a density g instead of f, how do we still estimate $\int hf$, and which g make the estimate better or worse?

6.12.1 Reweighting

Let g be any density that is positive wherever $h(x)f(x) \neq 0$. Multiply and divide by it [Wasserman (24.4)]:

$$I = \int h(x)f(x)\,\mathrm{d}x \overset{(1)}{=} \int \frac{h(x)f(x)}{g(x)}\,g(x)\,\mathrm{d}x \overset{(2)}{=} \mathbb{E}_g\Big[h(X)\,w(X)\Big], \qquad w(x) \equiv \frac{f(x)}{g(x)}. \tag{6.50}$$

(1) Multiplying and dividing by $g(x)$ changes nothing where $g > 0$; where $g = 0$ the integrand hf vanishes by assumption, so no part of the integral is lost.
(2) An integral against the density g is an expectation under g.

So draw $X_1, \ldots, X_N \sim g$ and average the weighted values [Wasserman (24.5)]:

$$\hat{I}_g = \frac{1}{N}\sum_{i=1}^{N} h(X_i)\,w(X_i). \tag{6.51}$$

The **importance weight** $w = f/g$ [how much more often f would have produced this value than g did] corrects for sampling from the wrong density: values that g over-produces get weights below one, values it under-produces get weights above one. By (6.46) applied to the terms hw under g, $\hat{I}_g$ is unbiased and its variance is $\mathrm{Var}_g[hw]/N$, with [Wasserman (24.6)]

$$\mathrm{Var}_g[hw] \overset{(1)}{=} \mathbb{E}_g\big[h^2w^2\big] - I^2 \overset{(2)}{=} \int \frac{h^2(x)f^2(x)}{g^2(x)}\,g(x)\,\mathrm{d}x - I^2 \overset{(3)}{=} \int \frac{h^2(x)f^2(x)}{g(x)}\,\mathrm{d}x - I^2. \tag{6.52}$$

(1) Variance is the mean square minus the square of the mean, and the mean of hw under g is I by (6.50).
(2) Write the expectation under g as an integral, with $w = f/g$.
(3) One factor of g cancels.

Everything about the quality of importance sampling is in the last integral, and the key feature is that g sits in its *denominator*. Where g is much smaller than f (and $h \neq 0$), the integrand $h^2 f^2/g$ is large. If g falls off faster than f in the tails, the integrand grows there instead of dying away, and the integral diverges.

Working definition 6.6 (importance sampling)

To estimate $I = \int hf$, draw $X_i \sim g$ and average $h(X_i)\, f(X_i)/g(X_i)$ [each draw weighted by how much likelier it is under f than under g]. *Unbiased* whenever $g > 0$ where $hf \neq 0$. *Standard error* $\sqrt{(\int h^2 f^2/g - I^2)/N}$, estimated by the sample standard deviation of the $h_i w_i$ over $\sqrt{N}$ when it is finite.

6.12.2 The tail rule, shown

We can see the divergence in the simplest possible case. Let the target be the standard normal, $f = \mathcal{N}(0,1)$, and estimate its normalisation: take $h = 1$, so $I = \int f = 1$. Put another way, if we knew only the unnormalised curve $e^{-x^2/2}$, we would be estimating its area $Z = \sqrt{2\pi}$, and the ratio $\hat{Z}/Z$ is the same number as $\hat{I}$. This is the evidence problem of Chapter 5 in miniature. Sample from $g = \mathcal{N}(0, s^2)$, a Gaussian of adjustable width s. With $h = 1$ the second moment of the terms in (6.52) is the mean square weight,

$$\mathbb{E}_g[w^2] = \int \frac{f^2}{g}\,\mathrm{d}x \overset{(1)}{=} \int \frac{e^{-x^2}/2\pi}{e^{-x^2/2s^2}/\sqrt{2\pi}\,s}\,\mathrm{d}x \overset{(2)}{=} \frac{s}{\sqrt{2\pi}} \int \exp\!\left[-x^2\left(1 - \frac{1}{2s^2}\right)\right]\mathrm{d}x$$
$$\overset{(3)}{=} \frac{s}{\sqrt{2\pi}} \sqrt{\frac{\pi}{1 - 1/2s^2}} \overset{(4)}{=} \frac{s^2}{\sqrt{2s^2 - 1}} \qquad \text{if } s^2 > \tfrac{1}{2}, \qquad \text{and } \infty \text{ if } s^2 \leq \tfrac{1}{2}. \quad (6.53)$$

(1) $f^2 = e^{-x^2}/2\pi$ and $g = e^{-x^2/2s^2}/(\sqrt{2\pi}\,s)$.
(2) Collect the constants and the exponents: $-x^2 + x^2/2s^2$.
(3) $\int e^{-cx^2}\mathrm{d}x = \sqrt{\pi/c}$ for $c > 0$. If $c = 1 - 1/2s^2 \leq 0$ the integrand does not decay and the integral is infinite.
(4) $s\sqrt{1/(2 - 1/s^2)} = s \cdot s/\sqrt{2s^2 - 1}$.

Since $I = 1$, the variance of one weight is $\mathbb{E}_g[w^2] - 1 = s^2/\sqrt{2s^2 - 1} - 1$, and this is also its variance relative to the answer. It is zero at $s = 1$, when $g = f$ and every weight is exactly 1. For $s > 1$ (g wider than f) it grows only slowly: at $s = 1.5$ it is 0.2027. For $s < 1$ (g narrower) it grows fast and becomes infinite at $s = 1/\sqrt{2}$, although g is still a perfectly good Gaussian that covers the whole real line. Figure 6.33 shows the measured scatter of $\hat{Z}/Z$ over 400 runs of $N = 1000$ draws against s: on the theory curve for $s > 1/\sqrt{2}$, erratic and large below.

What does an infinite variance look like in a single run? The weights are $w = f/g = s\, e^{x^2(1/2s^2 - 1/2)}$. For $s = 0.5$ that is $\frac{1}{2}e^{3x^2/2}$: modest near the centre, and astronomically large for the rare draw far out in the tail of g. The mean of w is still finite, so the estimate still converges, by the law of large numbers. But the central limit theorem needs a finite variance, so it no longer applies, and the error does not shrink as $1/\sqrt{N}$. In practice, most of the time the running estimate sits a little *low*, because the large weights that should balance it have not been drawn yet. Then one draw lands in the tail and the estimate jumps (Figure 6.34, left). With 200000 draws, three independent runs at $s = 0.5$ end with a spread of 0.03349 in $\hat{Z}/Z$, against 7.316×10^{-4} at $s = 1.5$. The **effective sample size** $(\sum w_i)^2/\sum w_i^2$ [the number of equally weighted draws that would carry the same information] is a fraction 0.03809 of N at $s = 0.5$ and 0.8318 at $s = 1.5$.

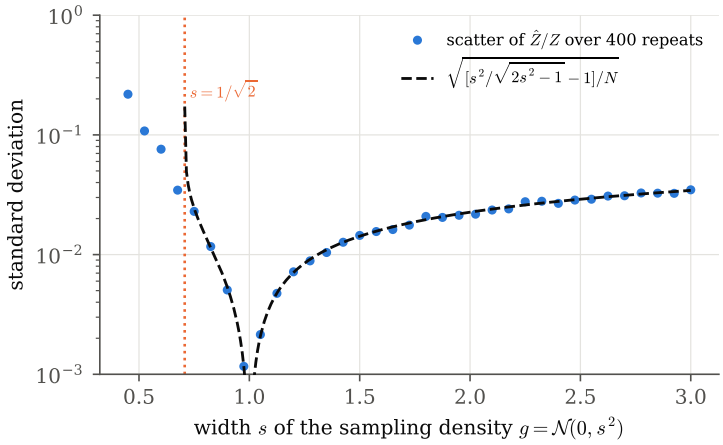

Figure 6.33: How the width of the sampling density controls importance sampling. Each point is the standard deviation of the estimate of the normalisation of a standard normal, from 400 runs of 1000 draws from $g = \mathcal{N}(0, s^2)$. It vanishes at $s = 1$ ($g = f$), rises gently for wider g, and diverges at $s = 1/\sqrt{2}$; below that the variance is infinite and the scatter over a finite number of runs is erratic.

Key idea: Thicker tails than the target

A basic rule in importance sampling is to sample from a density g with thicker tails than f [Wasserman p. 409]. The variance of the estimate contains $\int h^2 f^2/g$, with g in the denominator. If g falls off faster than f, the weights f/g grow without bound in the tails and the variance is infinite. A good g is similar in shape to f (or to $|h|f$) and a little wider.

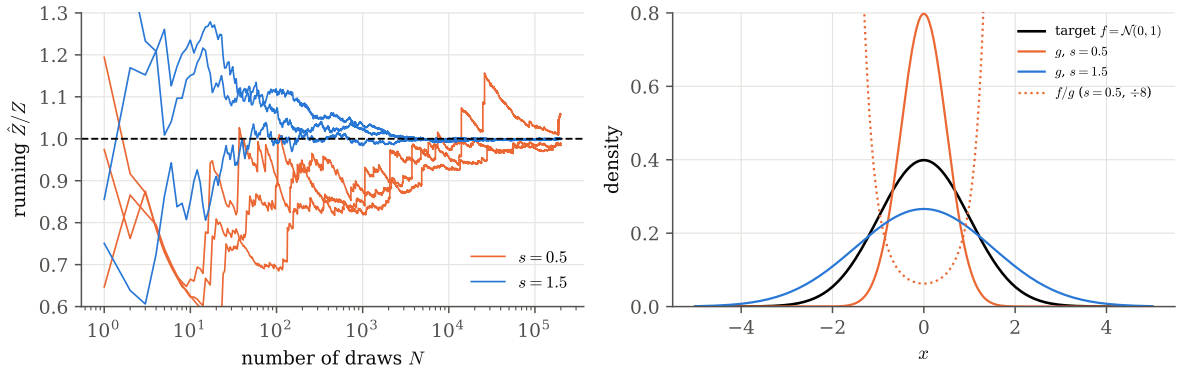

Figure 6.34: Left: running estimates of the normalisation of a standard normal, three runs each, with a narrow sampling density ($s = 0.5$, orange) and a wide one ($s = 1.5$, blue). The narrow one drifts and jumps whenever a rare tail draw arrives with a huge weight. Right: the target and the two sampling densities; the dotted curve is the weight f/g for $s = 0.5$ (scaled down by 8), which grows without bound in the tails.

Watch out: The error bar lies before the estimate does

With infinite variance the sample standard deviation of the weights is finite in every run, so $s/\sqrt{N}$ always prints a number. It is too small most of the time, because the draws that would reveal the true spread are the rare ones that have not happened yet. Check the effective sample size and the largest single weight's share of the total, and plot the running estimate.

6.12.3 The best g, and a tail probability

Which g minimises the variance? In (6.52) the term I^2 is fixed, so only the second moment $\mathbb{E}_g[h^2w^2]$ depends on g. We first find a floor below which it cannot go, whatever g we pick. The tool is the inequality $\mathbb{E}[Y^2] \geq (\mathbb{E}|Y|)^2$, a case of Jensen's inequality, which holds because the variance of $|Y|$ cannot be negative. With $Y = hw$ it gives

$$\mathbb{E}_g\big[h^2w^2\big] \overset{(1)}{\geq} \Big(\mathbb{E}_g\big[|h|w\big]\Big)^2 \overset{(2)}{=} \Big(\int |h(x)|\,\frac{f(x)}{g(x)}\,g(x)\,\mathrm{d}x\Big)^2 \overset{(3)}{=} \Big(\int |h|f\,\mathrm{d}x\Big)^2. \tag{6.54}$$

(1) $\mathbb{E}[Y^2] - (\mathbb{E}|Y|)^2 = \mathrm{Var}|Y| \geq 0$, with $Y = hw$.
(2) Write the expectation as an integral against g.
(3) g cancels.

Can any g reach this floor? Equality needs $|h|w$ to have zero variance, that is, to take the same value at every draw. The choice $g^*(x) = |h(x)|f(x)/\int|h|f$ does exactly that: then $|h|w = |h|f/g^* = \int|h|f$ for every draw [Wasserman Thm 24.5]. For $h \geq 0$ the estimator itself then has zero variance: every single draw returns the exact answer. This is only of theoretical interest. To normalise g^* we need $\int|h|f$, which is the integral we wanted in the first place [Wasserman p. 410]. What it teaches in practice is a guideline: make g resemble $|h|f$, the place where the integrand actually lives, and give it thicker tails.

Example: $\mathrm{P}(Z > 3)$**.** For $h = \mathbf{1}[x > 3]$ and $f = \mathcal{N}(0,1)$, the ideal g^* is the normal density truncated to $x > 3$. A simple imitation is $g = \mathcal{N}(4,1)$, centred beyond the threshold [Wasserman Ex. 24.6]. The weight is $w = f/g = \exp[-x^2/2 + (x-4)^2/2] = e^{8-4x}$, and the second moment of the estimator's terms can be done exactly:

$$\mathbb{E}_g[h^2w^2] \overset{(1)}{=} \int_3^\infty \frac{f^2}{g}\,\mathrm{d}x \overset{(2)}{=} \int_3^\infty \frac{1}{\sqrt{2\pi}}\,e^{-x^2+(x-4)^2/2}\,\mathrm{d}x \overset{(3)}{=} e^{16}\int_3^\infty \frac{e^{-(x+4)^2/2}}{\sqrt{2\pi}}\,\mathrm{d}x \overset{(4)}{=} e^{16}\big[1-\Phi(7)\big]. \tag{6.55}$$

(1) (6.52) with $h^2 = h = \mathbf{1}[x > 3]$.
(2) $f^2/g = \big(e^{-x^2}/2\pi\big)\big/\big(e^{-(x-4)^2/2}/\sqrt{2\pi}\big)$.
(3) Complete the square: $-x^2 + \frac{1}{2}(x-4)^2 = -\frac{1}{2}x^2 - 4x + 8 = -\frac{1}{2}(x+4)^2 + 16$.
(4) Substitute $t = x + 4$: the integral is the normal tail beyond 7.

This is 1.137×10^{-5}, so the standard deviation of $\hat{I}_g$ with $N = 100$ is $\sqrt{(1.137\times10^{-5} - p^2)/100} = 3.090 \times 10^{-4}$, against the plain binomial $\sqrt{p(1-p)/100} = 0.003672$. Over 20000 repeated runs the script measures 0.003667 for plain Monte Carlo and 3.086×10^{-4} for importance sampling, a gain of 11.88 in standard deviation, or about 140 in the number of draws needed for a given precision.[1] The means of the two estimators are 0.001346 and 0.001352, both unbiased for $p = 0.00135$.

The same device is how particle physicists reweight simulated events. Events generated under one set of parameters (a parton distribution set, a value of a coupling, a Wilson coefficient) are reused for another by the weight $w = f_{\text{new}}/f_{\text{old}}$ of each event's kinematics, and the effective sample size tells us when the old sample is too far from the new model to be trusted. The tail rule applies exactly: reweighting towards a harder spectrum than the one generated puts huge weights on the few high-energy events.

[1] Wasserman reports the reduction as "a factor of 20" [Wasserman p. 410], from simulated values 0.0039 and 0.0002 that he labels as variances but that are standard deviations. (A variance of 0.0039 is impossible here: the plain estimator's variance is $p(1-p)/100 \approx 1.3 \times 10^{-5}$.) The exact standard deviations from (6.55) are 0.0037 and 0.00031, a factor of 11.9, which our simulation reproduces; his second value, 0.0002, is low, and the ratio of his rounded numbers, 19.5, is quoted as 20.

6.12.4 Self-normalised importance sampling for posteriors

For a posterior we know $f(\theta) \propto \mathcal{L}(\theta)\pi(\theta)$, the likelihood times the prior, only up to the evidence, which is the unknown normalising constant. So importance sampling as written cannot be used directly: the weight f/g needs f itself. The way round it is to work with the unnormalised posterior $\tilde{f} = \mathcal{L}\pi$ and the weight $w = \tilde{f}/g$. The posterior mean is a ratio of two integrals, and each can be estimated from the same draws $\theta_j \sim g$ [Wasserman Ex. 24.7]:

$$\mathbb{E}[\theta \mid \boldsymbol{d}] \overset{(1)}{=} \frac{\int \theta\, \tilde{f}(\theta)\, \mathrm{d}\theta}{\int \tilde{f}(\theta)\, \mathrm{d}\theta} \overset{(2)}{=} \frac{\mathbb{E}_g[\theta\, w(\theta)]}{\mathbb{E}_g[w(\theta)]} \approx \frac{\sum_j \theta_j\, w_j}{\sum_j w_j}. \tag{6.56}$$

(1) The evidence $\int \tilde{f}$ normalises the posterior, so it divides the unnormalised integral.
(2) Importance sampling (6.50) applied to numerator and denominator separately.

The unknown constant cancels between numerator and denominator. The price is a small bias: a ratio of two unbiased averages is not itself unbiased for finite N. The bias vanishes as N grows (the estimator is **consistent**), and the tail rule applies to it just as before.

Example: a measurement with an outlier. Model three measurements as $x_i = \theta + \epsilon_i$ with Student-t noise of $\nu = 3$ degrees of freedom, a heavy-tailed noise model that tolerates occasional wild values [Wasserman Ex. 24.7], and a flat prior on θ. Take the data $x = (-4, 0.5, 1)$, where the first point is an outlier. The posterior mean, by numerical quadrature, is 0.1204.

The tails decide the sampler. The t_3 density is proportional to $(1 + t^2/3)^{-2}$, so each likelihood factor falls off as $|\theta|^{-4}$, and the posterior, a product of three such factors, has polynomial tails $\propto |\theta|^{-12}$. Try $g = \mathcal{N}(0, 1)$, whose tails are Gaussian: the weight $\tilde{f}/g$ grows like $e^{\theta^2/2}|\theta|^{-12}$, and the variance (6.52) is infinite. Try $g = \mathrm{Cauchy}(0, 1)$, with tails $\propto \theta^{-2}$, heavier than the posterior's: the weight is bounded.

The numbers. Over 2000 runs of 1000 draws each, the Normal sampler gives estimates with median 0.1471, standard deviation 0.1335 and a 1–99% range $[-0.2624, 0.2387]$; the Cauchy sampler gives median 0.1202, standard deviation 0.03204 and range $[0.04202, 0.1915]$. The typical Normal-sampler answer is pulled towards the bulk of the data. The reason is that the region around the outlier, which pulls the posterior mean down, is almost never sampled. Wasserman's two-point version shows the same: -0.74 from a Normal sampler and -0.53 from a Cauchy sampler, against the true -0.54 [Wasserman p. 411].

Listing 6.13: Self-normalised importance sampling of a posterior mean (`code/ch06/27_importance.py`)

```
120 for name, g in [("Norm", stats.norm(loc=0.0, scale=1.0)), ("Cauchy", stats.cauchy(loc=0.0,
        scale=1.0))]:
121     ests = []
122     for _ in range(2000):
123         th = g.rvs(size=1000, random_state=rng)
124         w = like(th) / g.pdf(th)
125         ests.append(np.sum(w * th) / np.sum(w))     # self-normalised: the constant of f
        cancels
```

Line 124 is the weight, the unnormalised posterior over the sampling density, and line 125 is (6.56). Nothing in the loop knows the evidence.

Importance sampling returns in the rest of the book. Nested sampling and the evidence estimators of Chapter 5 are importance sampling with cleverly chosen g. An MCMC chain (Chapter 9) can be reweighted to a slightly different prior or likelihood with the weights $p_{\mathrm{new}}/p_{\mathrm{old}}$, subject to the same tail rule. And Casella and Berger's condition $M < \infty$ for rejection

sampling (Section 6.10.4) is the same requirement in its strongest form: rejection needs f/g bounded, importance sampling needs only $\int f^2/g < \infty$.

6.13 A histogram of samples approximates the density

To see the distribution that a pile of samples came from, we histogram them. Every method so far ends with such a pile: decay times, directions, posterior draws of the difference $\delta = p_2 - p_1$ of two efficiencies. From Chapter 9 on, a Markov chain will hand us a pile of parameter values and nothing else, with no formula for the posterior at all. Wasserman states the idea for posterior draws: if $\theta_1, \dots, \theta_B$ are drawn from $p(\theta \mid \boldsymbol{d})$, then a histogram of $\theta_1, \dots, \theta_B$ approximates the posterior density [Wasserman §11.4, p. 180]. Kruschke builds his whole approach to Bayesian computation on it. A distribution is represented by a large sample of representative values, as an opinion poll represents a population, and the larger the sample, the better the representation [Kruschke §7.1].

The idea is not special to posteriors. It also gives the probability distribution of the position of a particle: we plot the histogram of x for a large set of random values of the time t. Take a classical oscillator $x(t) = A\cos\omega t$, observed at a random moment. It is found at position x with some probability density, and we can obtain that density without any algebra: sample many random times, compute x at each, and histogram. Here the sampling prescription is "the time is uniform". As Section 1.11.3 showed, the equation of motion alone fixes no distribution; choosing the position uniformly instead would give a different one.

The question. How close is a histogram of N samples to the density that produced them, and what error bar belongs on each bin?

6.13.1 What a bin count is

Divide the range into bins of width Δ, and let bin k be the interval $[b_k, b_{k+1})$. Each sample falls into bin k with probability

$$p_k = \int_{b_k}^{b_{k+1}} f(x)\,\mathrm{d}x = F(b_{k+1}) - F(b_k),$$

independently of the other samples. So the count n_k in bin k is the number of successes in N independent trials with success probability p_k: it is Binomial(N, p_k) (Chapter 2). The natural estimate of the density is the fraction of samples in the bin per unit length, $\hat{f}_k = n_k/(N\Delta)$.

Working definition 6.7 (histogram density estimate)

$\hat{f}_k = n_k/(N\Delta)$ [the fraction of the N samples that fell in bin k, divided by the bin width]. It estimates the *bin-averaged* density p_k/Δ, with standard error

$$\delta\hat{f}_k = \frac{\sqrt{Np_k(1-p_k)}}{N\Delta} \approx \frac{\sqrt{n_k(1-n_k/N)}}{N\Delta} \approx \frac{\sqrt{n_k}}{N\Delta} \quad (p_k \ll 1).$$

The mean and variance follow from those of the binomial:

$$\mathbb{E}[\hat{f}_k] \overset{(1)}{=} \frac{\mathbb{E}[n_k]}{N\Delta} \overset{(2)}{=} \frac{Np_k}{N\Delta} = \frac{p_k}{\Delta}, \qquad \mathrm{Var}[\hat{f}_k] \overset{(3)}{=} \frac{\mathrm{Var}[n_k]}{N^2\Delta^2} \overset{(4)}{=} \frac{p_k(1-p_k)}{N\Delta^2}, \qquad \frac{\delta\hat{f}_k}{\mathbb{E}[\hat{f}_k]} \overset{(5)}{=} \sqrt{\frac{1-p_k}{Np_k}}. \tag{6.57}$$

(1) $N\Delta$ is a constant.
(2) A binomial count has mean Np_k.
(3) A constant factor comes out of a variance squared.
(4) A binomial count has variance $Np_k(1-p_k)$.
(5) The standard deviation divided by the mean.

So the relative error of a bin is about $1/\sqrt{Np_k}$, one over the square root of the expected count in that bin. A bin expected to hold 100 samples is good to 10%, whatever N is. When there are many bins, each p_k is small, $1-p_k \approx 1$, and the binomial is close to a Poisson distribution with mean Np_k. This gives the familiar $\sqrt{n}$ error bar.

Are the bins independent of each other? With N fixed, not quite: the counts must add up to N, so a sample in one bin is a sample missing from the others. They are multinomial and slightly anticorrelated, $\mathrm{Cov}(n_j, n_k) = -Np_jp_k$, which is negligible when all the p_k are small. If N is itself a Poisson count, as in a counting experiment with a fixed exposure, the bin counts are exactly independent Poisson variables.

What a bin estimates is the density *averaged over the bin*, not its value at the centre. Expand f about the bin centre c to see the difference:

$$\frac{p_k}{\Delta} \overset{(1)}{=} \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2} f(c+s)\,\mathrm{d}s \overset{(2)}{=} \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2}\Big[f(c)+f'(c)\,s+\tfrac{1}{2}f''(c)\,s^2+\dots\Big]\mathrm{d}s \overset{(3)}{=} f(c)+\frac{\Delta^2}{24}f''(c)+\dots \tag{6.58}$$

(1) Substitute $x = c + s$ in the integral over the bin.
(2) Taylor expansion of f about the centre.
(3) The linear term integrates to zero over a symmetric interval, and $\int_{-\Delta/2}^{\Delta/2} s^2\,\mathrm{d}s = \Delta^3/12$.

So a histogram is biased by $\Delta^2 f''/24$ as an estimate of f at the bin centres, and the bias is largest where the density curves sharply.

How wide should the bins be? Narrow bins reduce the bias but, by (6.57), raise the relative error, since each bin holds fewer samples. The squared bias falls like Δ^4 and the variance rises like $1/(N\Delta)$. Their sum is smallest where the two are balanced, $\Delta^4 \propto 1/(N\Delta)$, that is $\Delta \propto N^{-1/5}$. Both terms are then of order $N^{-4/5}$, so the error falls like $N^{-2/5}$: the histogram converges to the density more slowly than $1/\sqrt{N}$. For comparing a histogram with a model, the bias can be avoided altogether: compare n_k with the model's expected count Np_k computed from the CDF, which is exact for any bin width.

6.13.2 The oscillator seen at random times

We now put the histogram to work on the oscillator of the opening of this section, $x(t) = A\cos\omega t$ with amplitude A and angular frequency ω. We pick the observation time t uniformly over one period $T = 2\pi/\omega$. To have something to compare the histogram with, we first need the exact density of x. It follows from the change of variables of Chapter 1. Each value of x in $(-A, A)$ is reached at two times per period, once moving left and once moving right, and at each of them the speed is $|\mathrm{d}x/\mathrm{d}t| = A\omega|\sin\omega t| = \omega\sqrt{A^2-x^2}$:

$$p(x) \overset{(1)}{=} \sum_{2\text{ times}} p_t(t)\left|\frac{\mathrm{d}t}{\mathrm{d}x}\right| \overset{(2)}{=} 2\cdot\frac{1}{T}\cdot\frac{1}{\omega\sqrt{A^2-x^2}} \overset{(3)}{=} \frac{1}{\pi\sqrt{A^2-x^2}}, \qquad F(x) \overset{(4)}{=} \frac{1}{2}+\frac{1}{\pi}\arcsin\frac{x}{A}. \tag{6.59}$$

(1) The probability of finding x in $\mathrm{d}x$ is the probability that t falls in the time intervals that map onto $\mathrm{d}x$, summed over both branches.
(2) t is uniform over the period, $p_t = 1/T$, and the speed is the same on both branches.

(3) $\omega T = 2\pi$.
(4) Integrate: $\int \mathrm{d}x/\sqrt{A^2 - x^2} = \arcsin(x/A)$, with $F(-A) = 0$.

This is the arcsine density of Section 1.11.3. It diverges at the turning points $x = \pm A$, where the oscillator is slow and spends most of its time. It is lowest at the centre, where the oscillator moves fastest. The divergence is integrable, so the total probability is still one. Classical statistical mechanics makes the same statement: picking a random time is the same as picking a random point on the phase-space orbit, so the fraction of time the system spends in a region is the probability of finding it there. A Markov chain (Chapter 9) uses exactly this: the fraction of time the chain spends in a region is its estimate of the region's probability.

Listing 6.14: The oscillator position at random times, histogrammed with binomial error bars (`code/ch06/28_histogram_density.py`)

```
A, omega, N, K = 1.0, 2 * np.pi, 10_000, 40
t = rng.random(N) * (2 * np.pi / omega)          # random times over one period
x = A * np.cos(omega * t)
edges = np.linspace(-A, A, K + 1)
Delta = edges[1] - edges[0]
n_k, _ = np.histogram(x, bins=edges)
F = lambda x: 0.5 + np.arcsin(np.clip(x / A, -1, 1)) / np.pi
p_k = np.diff(F(edges))
dens = n_k / (N * Delta)
err = np.sqrt(n_k * (1 - n_k / N)) / (N * Delta)
pull = (n_k - N * p_k) / np.sqrt(N * p_k * (1 - p_k))
chi2 = np.sum((n_k - N * p_k) ** 2 / (N * p_k))  # Pearson chi^2, K - 1 degrees of freedom
```

Line 31 draws the random times and line 32 evaluates the trajectory at each; nothing else is needed to generate the distribution. Lines 33–38 build the histogram and convert counts into a density. Line 37 computes the exact bin probabilities p_k from the CDF (6.59), line 39 the error bars of (6.57), and lines 40–41 the pull of each bin and the χ^2 of the whole histogram.

Example: how good is it? With $N = 10000$ random times and $K = 40$ bins on $[-A, A]$ (Figure 6.35), the Pearson statistic $\sum_k (n_k - Np_k)^2/Np_k$ is 35.74 for 39 degrees of freedom (K bins minus one, because the counts must add up to N), a p-value of 0.6193 (Chapter 4). The pulls $(n_k - Np_k)/\sqrt{Np_k(1-p_k)}$ have standard deviation 0.9676, close to one, which says that the binomial error bars are the right size. The relative error in a central bin is 0.07862 and in the end bin 0.02982, because the end bins hold many more samples.

Example: the bin average is not the value at the centre. In the central bin the bin-averaged density $p_k/\Delta = 0.3184$ equals the density at the centre, 0.3184, to four digits, because the density is flat there. In the last bin, $[0.95A, A)$, the average is $2.022/A$ while the density at the bin centre is only $1.433/A$: the divergence at $x = A$ lies inside the bin, and the Taylor expansion (6.58) fails completely there. A histogram drawn over the curve $1/\pi\sqrt{A^2 - x^2}$ therefore seems to overshoot at the ends, and a χ^2 against the density at the bin centres would reject a perfect sample. The green staircase in Figure 6.35, the exact bin averages, is what the histogram estimates.

Example: summaries from a representative sample. Kruschke's illustration represents a Beta(15, 7) density, which could be the posterior for the probability of heads after 14 heads in 20 tosses with a flat prior, by random samples of increasing size [Kruschke Fig. 7.1]. The exact mode is 0.7 and the exact 95% highest-density interval (the shortest interval holding 95% of the probability, Chapter 5) is $[0.4907, 0.8639]$. From the samples we estimate the mode as the centre of the tallest histogram bin and the HDI as the shortest interval containing 95% of the sorted draws. With $N = 500$ the script finds a mode of 0.67 and an HDI of $[0.4766, 0.8445]$; with

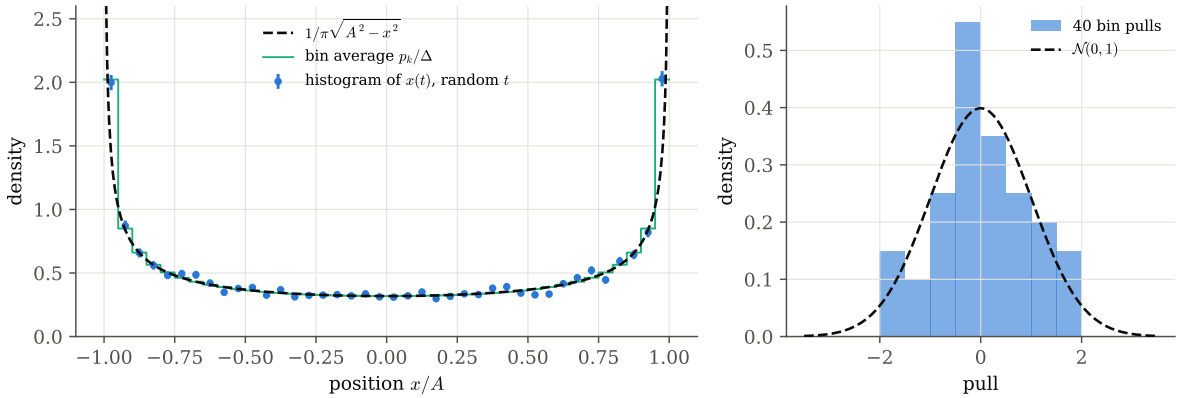

Figure 6.35: The position of a classical oscillator at 10^4 random times. Left: the histogram as a density with binomial error bars, the arcsine density (black dashed) and its exact bin averages (green staircase); the histogram follows the staircase, which lies above the curve in the end bins because the density diverges inside them. Right: the pulls of the 40 bins are distributed as a standard normal.

$N = 5000$, 0.71 and $[0.4882, 0.8656]$; with $N = 50000$, 0.71 and $[0.4907, 0.8637]$ (Figure 6.36). The interval limits settle to within 0.01 of the exact ones at $N = 5000$, as the $1/\sqrt{N}$ law predicts. The mode is the slowest summary to settle, because it depends on the height of a single bin, which is the noisiest thing a histogram offers. Kruschke's numbers (0.723 and $[0.477, 0.875]$ at $N = 500$) scatter about the truth in the same way.

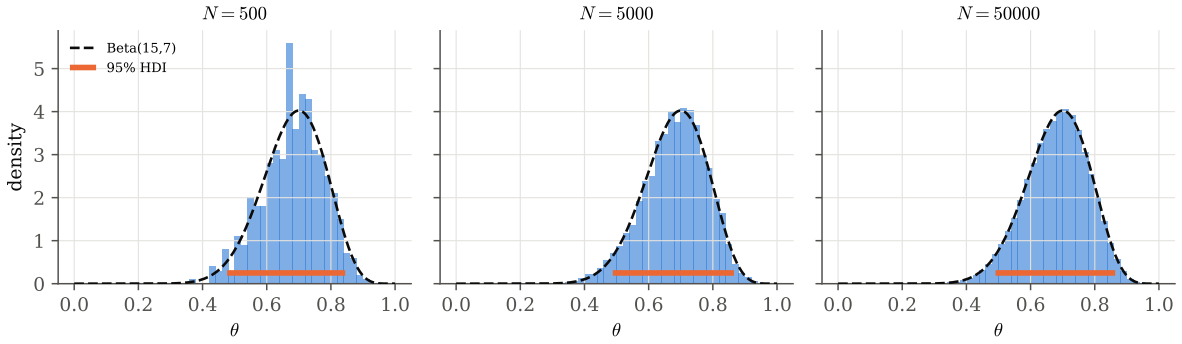

Figure 6.36: A Beta(15, 7) density represented by 500, 5000 and 50 000 random samples, with the 95% highest-density interval found from each sample (orange bar). The histogram becomes smoother and the interval converges on the exact one as N grows.

Watch out: Empty bins and the density at the centre

Two mistakes are common when a simulated histogram is compared with a model. The first is to compare $n_k/(N\Delta)$ with f at the bin centre instead of with p_k/Δ; it fails wherever f curves sharply or diverges. The second is to put bins with zero or very few expected counts into a Pearson χ^2, where the Gaussian approximation behind χ^2 fails; use the Poisson likelihood of Chapter 3 instead, or merge the sparse bins.

6.14 Unfolding: undoing the detector with a response matrix from simulation

A calorimeter never tells us the energy a photon had. It tells us the energy it measured, which is the true energy plus a random error, and sometimes it tells us nothing because the photon went through a crack. So the histogram an experiment records is not the spectrum nature produced. It is that spectrum smeared out by the resolution and thinned out by the efficiency. A sharp peak comes out broad, two nearby peaks merge, a steep edge is softened. To compare our measurement with another experiment's, whose detector smears differently, or with a theory written down twenty years later, we would like to report the spectrum *before* the detector touched it. Undoing the detector is called **unfolding** [Cowan §11].

We have met both halves of this before. In Example 1.43 a falling exponential spectrum of true photon energies (mean $\beta = 20\,\text{GeV}$) was pushed through a Gaussian resolution of $\sigma = 5\,\text{GeV}$, and the measured spectrum came out as the marginal $f(x) = \int f(x \mid E) f(E)\,\mathrm{d}E$: the tail was raised by a constant factor and some events were measured at negative energy. That was the forward direction, from truth to measurement, and it had a closed form because the detector was a perfect Gaussian. In Section 6.11.4 the detector had a dead strip and a hole, no closed form existed, and a Monte Carlo of particles thrown at it was the only way to learn what fraction it caught; there we noted that the same kind of simulation supplies the "response matrix for unfolding". And in Section 6.13.1 we learned what a bin count is: a binomial, nearly Poisson, number whose error is about the square root of its expectation. Unfolding puts the three together and turns them around. The forward map is now a matrix that we learn by simulation, the data are Poisson bin counts, and the direction is backward, from the measured histogram to the true one. The backward direction is where all the difficulty lives.

The question. Given a measured histogram $n_1, \dots, n_N$ and a simulation of the detector, what is our best estimate of the true histogram, and how far can we trust the error bars we put on it?

6.14.1 From the true histogram to the measured one

Every event has two numbers attached to it: its true value y (the energy the photon really had), which we never see, and its measured value x. Two things can happen between them [Cowan §11.1]. The event may not be recorded at all; the probability that it is recorded is the **efficiency** $\varepsilon(y)$, which can depend on the true value (low energies may fall below threshold). And if it is recorded, the measured value scatters around the true one with a conditional density $s(x \mid y)$, the **resolution function** [the density of the measured x for an event whose true value is y, given that it was recorded], normalised so that $\int s(x \mid y)\,\mathrm{d}x = 1$.

We describe the truth by a histogram, because we do not know its functional form. Split the range of y into M bins. Let μ_j be the *expected* number of events whose true value falls in bin j; this is $\mu_{\text{tot}}\, p_j$, with $p_j = \int_{\text{bin } j} f_{\text{true}}(y)\,\mathrm{d}y$ the probability of bin j and μ_{tot} the expected total. The vector $\boldsymbol{\mu} = (\mu_1, \dots, \mu_M)$ is the **true histogram** we want. The measured values are histogrammed into N bins with counts $\boldsymbol{n} = (n_1, \dots, n_N)$ and expectations $\nu_i = \mathbb{E}[n_i]$. How is ν_i built from $\boldsymbol{\mu}$? An event lands in observed bin i by first having some true value y, then being recorded, then being measured inside bin i. Summing over the ways this can happen is the law of total probability (Chapter 1):

$$\nu_i \overset{(1)}{=} \mu_{\text{tot}} \int \mathrm{d}y\; f_{\text{true}}(y)\, \varepsilon(y) \int_{\text{bin } i} s(x \mid y)\,\mathrm{d}x$$

$$\overset{(2)}{=} \sum_{j=1}^{M} \mu_{\text{tot}} \int_{\text{bin } j} \mathrm{d}y \; f_{\text{true}}(y)\, \varepsilon(y) \int_{\text{bin } i} s(x \mid y)\, \mathrm{d}x \overset{(3)}{=} \sum_{j=1}^{M} R_{ij}\, \mu_j, \tag{6.60}$$

with

$$R_{ij} = \frac{\int_{\text{bin } j} \mathrm{d}y\, f_{\text{true}}(y)\, \varepsilon(y) \int_{\text{bin } i} s(x \mid y)\, \mathrm{d}x}{\int_{\text{bin } j} f_{\text{true}}(y)\, \mathrm{d}y} = \frac{\mathrm{P}(\text{true in bin } j \text{ and observed in bin } i)}{\mathrm{P}(\text{true in bin } j)}. \tag{6.61}$$

(1) The expected number in bin i is μ_{tot} times the probability that one event ends there: average over the true value y (density f_{true}) the probability of being recorded (ε) and then measured inside bin i (the integral of s).
(2) Cut the y integral into the M true bins.
(3) Multiply and divide each term by $\mu_j = \mu_{\text{tot}} \int_{\text{bin } j} f_{\text{true}}\, \mathrm{d}y$; the ratio left over is R_{ij}.

The second form of (6.61) is a joint probability divided by a marginal, so R_{ij} is a conditional probability.

Working definition 6.8 (response matrix)

$R_{ij} = \mathrm{P}(\text{observed in bin } i \mid \text{true value in bin } j)$ [of the events created in true bin j, the fraction that are recorded and land in measured bin i]. It maps the true histogram to the expected measured one, $\boldsymbol{\nu} = \mathbf{R}\boldsymbol{\mu} + \boldsymbol{\beta}$, where β_i is the expected background in bin i [Cowan eqs. 11.9, 11.12].

Each column of $\mathbf{R}$ says where the events of one true bin go. If we add up a column, we add up the probabilities of all the places a recorded event can land, and what is missing is the probability that it was not recorded:

$$\sum_{i=1}^{N} R_{ij} \overset{(1)}{=} \frac{\int_{\text{bin } j} \mathrm{d}y\, f_{\text{true}}(y)\, \varepsilon(y) \int s(x \mid y)\, \mathrm{d}x}{\int_{\text{bin } j} f_{\text{true}}(y)\, \mathrm{d}y} \overset{(2)}{=} \frac{\int_{\text{bin } j} f_{\text{true}}(y)\, \varepsilon(y)\, \mathrm{d}y}{\int_{\text{bin } j} f_{\text{true}}(y)\, \mathrm{d}y} \equiv \varepsilon_j. \tag{6.62}$$

(1) The N observed bins together cover the whole measured range, so the sum of the integrals over bin i is one integral over all x.
(2) $\int s(x \mid y)\, \mathrm{d}x = 1$; what remains is the efficiency averaged over bin j.

So the column sums are the efficiencies of the true bins, and they are less than one whenever events can be lost. The off-diagonal elements are **migrations**: events created in one bin and measured in another. They are what smears out fine structure.

The response matrix comes from simulation. Look again at (6.61): it contains f_{true}, the very thing we want to find. Inside a narrow bin, however, the efficiency and resolution hardly change with y, and then f_{true} cancels between numerator and denominator. In practice we therefore build $\mathbf{R}$ from a simulation that uses a plausible guess for the truth, exactly as in Section 6.11.4: generate N_j events with true value in bin j, push each through the detector simulation, and count how many, N_{ij}, land in measured bin i. Then $\hat{R}_{ij} = N_{ij}/N_j$, a binomial fraction with error $\sqrt{R_{ij}(1 - R_{ij})/N_j}$ (Section 6.13.1). The residual dependence on the guessed truth is a systematic error of the method, and so is any imperfection of the detector simulation [Cowan p. 157].

Example: a two-peak spectrum and a Gaussian detector. We use a test case modelled on Cowan's [Cowan Fig. 11.1]. The true variable y lives on $[0, 1]$, split into $M = N = 20$ bins of width $\Delta = 0.05$. The truth is a flat floor holding 20% of the events plus two Gaussian peaks of width

0.08 at $y = 0.3$ and 0.7, with $\mu_{\text{tot}} = 20\,000$ expected events. The detector records $x = y + \mathcal{N}(0, \sigma^2)$ with $\sigma = 1.5$ bin widths; an event smeared outside $[0, 1]$ is lost, which is our efficiency. We build $\mathbf{R}$ from 2×10^6 simulated events generated *flat* in y, since the analyser does not know the truth.

Listing 6.15: The response matrix from simulated events (`code/ch06/30_unfolding.py`)

```
56 N_mc = 2_000_000
57 y_mc = rng.random(N_mc)                  # simulated truth, flat
58 x_mc = y_mc + sigma * rng.standard_normal(N_mc)
59 H, _, _ = np.histogram2d(x_mc, y_mc, bins=[edges, edges])   # H[i, j]: observed i, true j
60 gen_j = np.histogram(y_mc, bins=edges)[0]
61 R = H / gen_j                            # R_ij = N(obs i, true j) / N(true j)
62 eff = R.sum(axis=0)                      # column sums = efficiency of each true bin
63 nu = R @ mu                              # expected observed histogram
```

Lines 57–58 are the whole detector: a flat truth and a Gaussian error. Line 59 fills the two-dimensional histogram N_{ij} of (measured, true) bins, line 60 counts the generated events per true bin, and line 61 divides, which is $\hat{R}_{ij} = N_{ij}/N_j$. Line 62 takes the column sums (6.62) and line 63 folds the truth, $\boldsymbol{\nu} = \mathbf{R}\boldsymbol{\mu}$.

An event created in a central bin stays there with probability 25.7%, moves one bin left or right with probability 41.6% in total, and moves two or more bins with probability 32.7%. The central columns sum to 1, while the two edge columns sum to 0.628: more than a third of the events created in an edge bin are smeared out of the range. The binomial error of a central element is 0.62% of its value. Had we simulated with the true two-peak shape instead of a flat one, the folded histogram $\mathbf{R}\boldsymbol{\mu}$ would change by up to 3.94% in some bin. That is the size of the model dependence that our bins, which are not narrow compared with the peaks, leave behind. Figure 6.37 shows the chain from truth to data.

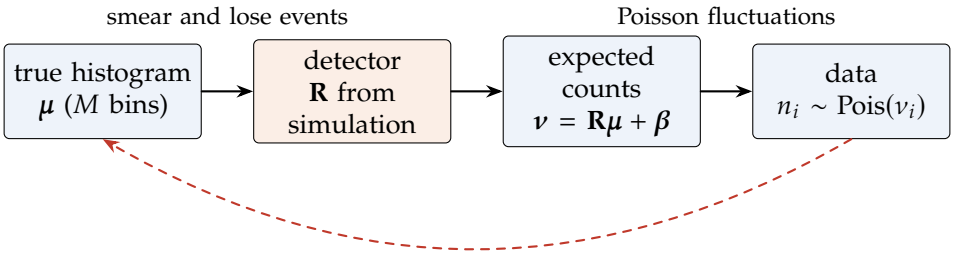

Figure 6.37: The forward chain. The true histogram is pushed through the response matrix, which smears it and loses some events, and adds a background; the counts we record fluctuate about the result. Unfolding is the dashed return path, from the data back to the true histogram.

6.14.2 The obvious answer: invert the matrix

If $M = N$ and $\mathbf{R}$ is invertible, the forward relation can be solved for the truth, $\boldsymbol{\mu} = \mathbf{R}^{-1}(\boldsymbol{\nu} - \boldsymbol{\beta})$. We do not know $\boldsymbol{\nu}$, but the data $\boldsymbol{n}$ estimate it without bias, so the obvious estimator is [Cowan §11.2]

$$\hat{\boldsymbol{\mu}} = \mathbf{R}^{-1}(\boldsymbol{n} - \boldsymbol{\beta}). \tag{6.63}$$

Is it a good estimator? Its mean and covariance follow from linearity, with $\mathbf{V}$ the covariance matrix of the data, $V_{ij} = \text{Cov}(n_i, n_j)$:

$$\mathbb{E}[\hat{\boldsymbol{\mu}}] \overset{(1)}{=} \mathbf{R}^{-1}\big(\mathbb{E}[\boldsymbol{n}] - \boldsymbol{\beta}\big) \overset{(2)}{=} \mathbf{R}^{-1}(\boldsymbol{\nu} - \boldsymbol{\beta}) \overset{(3)}{=} \boldsymbol{\mu},$$

$$\mathbf{U} \equiv \mathrm{Cov}(\hat{\boldsymbol{\mu}}) \overset{(4)}{=} \mathbf{R}^{-1}\,\mathbf{V}\,(\mathbf{R}^{-1})^{\mathsf{T}}, \qquad U_{ij} \overset{(5)}{=} \sum_k (R^{-1})_{ik}(R^{-1})_{jk}\,\nu_k. \tag{6.64}$$

(1) The expectation of a fixed matrix times a random vector is the matrix times the expectation; $\boldsymbol{\beta}$ is a constant.
(2) $\mathbb{E}[n_i] = \nu_i$ by definition.
(3) The forward relation $\boldsymbol{\nu} = \mathbf{R}\boldsymbol{\mu} + \boldsymbol{\beta}$.
(4) The covariance of a linear map, $\mathrm{Cov}(\mathbf{A}\boldsymbol{n}) = \mathbf{A}\,\mathrm{Cov}(\boldsymbol{n})\mathbf{A}^{\mathsf{T}}$, as in (6.36); the constant $\boldsymbol{\beta}$ does not fluctuate.
(5) Independent Poisson counts have $V_{kl} = \delta_{kl}\nu_k$.

So the naive inverse is *unbiased*. It is also the maximum-likelihood estimator. With independent Poisson counts the log-likelihood (Section 3.11.1) is $\ln L(\boldsymbol{\mu}) = \sum_i (n_i \ln \nu_i - \nu_i)$ up to a constant, with $\nu_i = \sum_j R_{ij}\mu_j + \beta_i$, and setting its derivatives to zero gives

$$\frac{\partial \ln L}{\partial \mu_k} \overset{(1)}{=} \sum_i \frac{\partial \ln L}{\partial \nu_i}\frac{\partial \nu_i}{\partial \mu_k} \overset{(2)}{=} \sum_i \left(\frac{n_i}{\nu_i} - 1\right) R_{ik} = 0. \tag{6.65}$$

(1) Chain rule through the ν_i.
(2) $\partial(n_i \ln \nu_i - \nu_i)/\partial\nu_i = n_i/\nu_i - 1$ and $\partial\nu_i/\partial\mu_k = R_{ik}$.

For an invertible $\mathbf{R}$ the only way all M sums vanish is $n_i/\nu_i - 1 = 0$ for every i, so $\hat{\boldsymbol{\nu}} = \boldsymbol{n}$ and $\hat{\boldsymbol{\mu}}$ is (6.63). Its covariance is even the smallest any unbiased estimator can have: the Fisher information (Section 3.12.3) is $-\mathbb{E}[\partial^2 \ln L/\partial\mu_k\partial\mu_l] = \sum_i R_{ik}R_{il}/\nu_i$, that is $\mathbf{R}^{\mathsf{T}}\mathbf{V}^{-1}\mathbf{R}$, and its inverse is $\mathbf{R}^{-1}\mathbf{V}(\mathbf{R}^{\mathsf{T}})^{-1}$, the $\mathbf{U}$ of (6.64) [Cowan eqs. 11.21–11.26]. Unbiased, maximum likelihood, minimum variance: on paper it is the best estimator there is.

Example: what it gives. Figure 6.38 shows our two-peak truth (a), its folded version $\boldsymbol{\nu} = \mathbf{R}\boldsymbol{\mu}$ (b), one Poisson data set (c), and the naive inverse of that data set (d). The data have relative errors between 2.5% and 7.1%. The inverse oscillates wildly from bin to bin, with values of both signs in the tens of thousands, and its error bars are as large as the values. In the central bin the true content is 436 and the standard deviation of the estimate is 32000, which is 1120 times the Poisson error of a single measured bin. Neighbouring bins have correlation coefficient −0.726: when one bin goes up, its neighbour goes down. A toy study (Section 6.14.6) confirms that the estimator is nevertheless unbiased: the mean of 2000 toy unfoldings agrees with $\boldsymbol{\mu}$ in every bin, the largest deviation being 1.98 standard errors of that mean.

Why it fails: the simplest smearing first. The failure is not a bug, and to see where it comes from we shrink the problem to two bins [134]. Let an event stay in its bin with probability $(1+\epsilon)/2$ and cross to the other with probability $(1-\epsilon)/2$, with $0 < \epsilon \le 1$. A perfect detector has $\epsilon = 1$; a detector that can hardly tell the bins apart has $\epsilon \ll 1$. No event is lost, so

$$\mathbf{R} = \frac{1}{2}\begin{pmatrix} 1+\epsilon & 1-\epsilon \\ 1-\epsilon & 1+\epsilon \end{pmatrix}.$$

Which patterns does this matrix leave alone, apart from a factor? Try the sum pattern $\boldsymbol{u}_+ = (1,1)/\sqrt{2}$ and the difference pattern $\boldsymbol{u}_- = (1,-1)/\sqrt{2}$:

$$\mathbf{R}\boldsymbol{u}_+ \overset{(1)}{=} \frac{1}{2\sqrt{2}}\begin{pmatrix} (1+\epsilon)+(1-\epsilon) \\ (1-\epsilon)+(1+\epsilon) \end{pmatrix} = 1\cdot\boldsymbol{u}_+, \qquad \mathbf{R}\boldsymbol{u}_- \overset{(2)}{=} \frac{1}{2\sqrt{2}}\begin{pmatrix} (1+\epsilon)-(1-\epsilon) \\ (1-\epsilon)-(1+\epsilon) \end{pmatrix} = \epsilon\,\boldsymbol{u}_-. \tag{6.66}$$

(1) Each component is a row of $\mathbf{R}$ times $(1,1)/\sqrt{2}$.

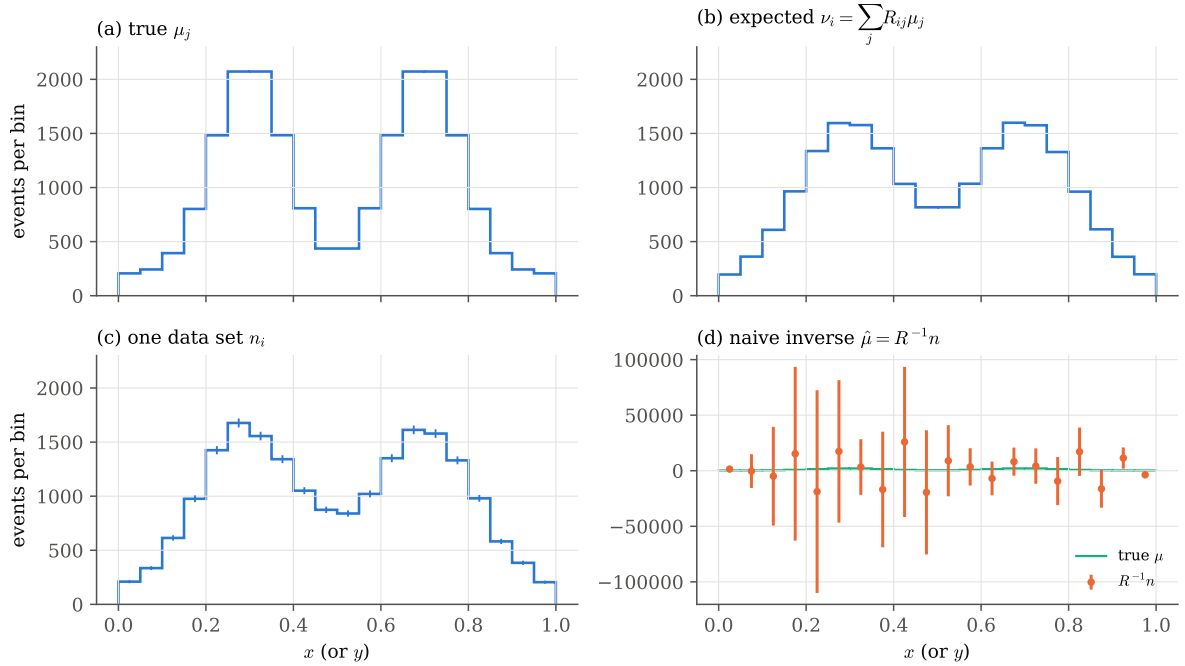

Figure 6.38: (a) The true histogram: two peaks on a flat floor. (b) What the detector makes of it on average: the peaks are lower and broader and the dip is filled in. (c) One simulated data set, with Poisson error bars of a few per cent. (d) The data set unfolded by inverting the response matrix. Note the vertical scale: the estimates swing between about $\pm 10^5$ and the true histogram (green) is a thin line near zero.

(2) The same with $(1, -1)/\sqrt{2}$.

So the detector passes the total number of events unchanged (eigenvalue 1) and multiplies the difference between the bins by ϵ (eigenvalue ϵ). Write the truth in these patterns, $\boldsymbol{\mu} = s\,\boldsymbol{u}_+ + d\,\boldsymbol{u}_-$, with $s = (\mu_1 + \mu_2)/\sqrt{2}$ and $d = (\mu_1 - \mu_2)/\sqrt{2}$. Then $\boldsymbol{\nu} = s\,\boldsymbol{u}_+ + \epsilon d\,\boldsymbol{u}_-$: the measured difference is the true difference shrunk by ϵ. Inverting means dividing the measured difference by ϵ.

Now add the noise. Suppose both bins expect about $\bar{\nu}$ events, so that $\mathbf{V} \approx \bar{\nu}\,\mathbb{1}$. A rotation to the patterns $\boldsymbol{u}_\pm$ keeps this covariance as it is, so the measured sum and measured difference, $n_s = \boldsymbol{u}_+ \cdot \boldsymbol{n}$ and $n_d = \boldsymbol{u}_- \cdot \boldsymbol{n}$, each carry noise of variance $\bar{\nu}$, independently. The inverse estimates $\hat{s} = n_s$ and $\hat{d} = n_d/\epsilon$, so

$$\begin{aligned} \mathrm{Var}(\hat{d}) &\overset{(1)}{=} \frac{\bar{\nu}}{\epsilon^2}, \qquad \mathrm{Var}(\hat{\mu}_1) \overset{(2)}{=} \frac{\mathrm{Var}(\hat{s}) + \mathrm{Var}(\hat{d})}{2} = \frac{\bar{\nu}}{2}\left(1 + \frac{1}{\epsilon^2}\right), \\ \rho(\hat{\mu}_1, \hat{\mu}_2) &\overset{(3)}{=} \frac{\mathrm{Var}(\hat{s}) - \mathrm{Var}(\hat{d})}{\mathrm{Var}(\hat{s}) + \mathrm{Var}(\hat{d})} = \frac{\epsilon^2 - 1}{\epsilon^2 + 1}. \end{aligned} \tag{6.67}$$

(1) Dividing by ϵ multiplies a variance by $1/\epsilon^2$.
(2) $\hat{\mu}_1 = (\hat{s} + \hat{d})/\sqrt{2}$ and $\hat{s}, \hat{d}$ are independent.
(3) $\hat{\mu}_2 = (\hat{s} - \hat{d})/\sqrt{2}$, so $\mathrm{Cov}(\hat{\mu}_1, \hat{\mu}_2) = (\mathrm{Var}\,\hat{s} - \mathrm{Var}\,\hat{d})/2$; divide by the common variance of (2).

Put in numbers: $\bar{\nu} = 1000$ and $\epsilon = 0.1$. Each measured bin is good to $\sqrt{1000} \approx 32$ events, but each unfolded bin has standard deviation $\sqrt{500 \times 101} \approx 225$, seven times worse, and the two unfolded bins are correlated with $\rho = -0.98$. The reason is plain. With $\epsilon = 0.1$ the detector shrinks a true difference of 100 events to a measured difference of 10, which is smaller than the Poisson noise of that difference, $\sqrt{2 \times 1000} \approx 45$. The measured difference is then mostly noise, and dividing by ϵ blows that noise up ten times and paints it back onto the two bins

with opposite signs.

Gaussian smearing: many patterns, each shrunk. A real detector has many bins, and the same reasoning applies pattern by pattern. Take Gaussian smearing on a ring of M bins of width Δ (a periodic range of length $L = M\Delta$, so that no bin is at an edge), and let $R_{ij} = r(i-j)$ depend only on how many bins the event moved, with $r(m) \approx \Delta\, g(m\Delta)$ and g the Gaussian density of standard deviation σ. Which patterns does it leave alone? On a ring every bin looks the same, so try a wave, $v_j = e^{\mathrm{i}qj\Delta}/\sqrt{M}$ with wavenumber $q = 2\pi k/L$, $k = 0, 1, \ldots, M-1$:

$$(\mathbf{R}\boldsymbol{v})_i \overset{(1)}{=} \sum_j r(i-j)\,\frac{e^{\mathrm{i}qj\Delta}}{\sqrt{M}} \overset{(2)}{=} \frac{e^{\mathrm{i}qi\Delta}}{\sqrt{M}} \sum_m r(m)\,e^{-\mathrm{i}qm\Delta} \overset{(3)}{=} v_i \int g(x)\,e^{-\mathrm{i}qx}\,\mathrm{d}x \overset{(4)}{=} e^{-q^2\sigma^2/2}\,v_i. \tag{6.68}$$

(1) Matrix times vector.
(2) Substitute $m = i - j$; on the ring m runs over all M shifts, and $e^{\mathrm{i}qj\Delta} = e^{\mathrm{i}qi\Delta}e^{-\mathrm{i}qm\Delta}$.
(3) $r(m) \approx \Delta\, g(m\Delta)$, and a sum of Δ times a smooth function over a grid of spacing Δ is its integral, with $x = m\Delta$.
(4) The Fourier transform of a Gaussian density. Complete the square as in Example 1.43: $-x^2/2\sigma^2 - \mathrm{i}qx = -(x + \mathrm{i}q\sigma^2)^2/2\sigma^2 - q^2\sigma^2/2$; the shifted Gaussian still integrates to one.

A wave of wavenumber q is passed through with its amplitude multiplied by $\lambda_q = e^{-q^2\sigma^2/2}$. Long waves ($q\sigma \ll 1$) pass almost untouched; waves shorter than the resolution are crushed. This is the precise sense in which "smearing removes fine structure". The data contain the shrunken waves plus Poisson noise, and the noise is spread evenly over all waves: with $\mathbf{V} \approx \bar{\nu}\mathbb{1}$, each wave component of $\boldsymbol{n}$ has variance $\bar{\nu}$, as in the two-bin case. Inverting divides wave k by λ_k, so using $\mathbf{R}^{-1} = \sum_k \lambda_k^{-1}\boldsymbol{v}_k\boldsymbol{v}_k^\dagger$ in (6.64),

$$U_{jj} \overset{(1)}{=} \bar{\nu}\sum_k \lambda_k^{-2}\,|v_{k,j}|^2 \overset{(2)}{=} \frac{\bar{\nu}}{M}\sum_k e^{q_k^2\sigma^2}. \tag{6.69}$$

(1) $\mathbf{U} = \bar{\nu}\,\mathbf{R}^{-1}(\mathbf{R}^{-1})^\dagger = \bar{\nu}\sum_k \lambda_k^{-2}\boldsymbol{v}_k\boldsymbol{v}_k^\dagger$, because the waves are orthonormal and the λ_k are real.
(2) $|v_{k,j}|^2 = 1/M$ for every wave, and $\lambda_k^{-2} = e^{q_k^2\sigma^2}$.

The sum is dominated by the shortest wave. In our test case $\sigma = 1.5\Delta$, and on an interval with edges, rather than a ring, the natural waves are cosines with a whole number of half wavelengths, $q_k = \pi k/L$. The shortest has $q\sigma = \pi \times 19 \times 0.075 \approx 4.5$, so the formula predicts a gain of 4.447×10^{-5} for it. The singular values of our simulated $\mathbf{R}$ (the gains of its patterns; for a symmetric matrix they are the absolute eigenvalues) run from 0.976 down to 2.018×10^{-4}, a ratio of 4834, and follow the Gaussian formula over three decades (Figure 6.39); the last few lie above it because a finite matrix with edges is not exactly a ring. A wave that the detector shrinks to 2.018×10^{-4} of its size must be stretched back by the inverse of that factor, noise included. Averaged over the bins, the standard deviation of the naive inverse is 41200 events for a true content of about 1000.

Key idea: Why unfolding is hard

Smearing multiplies each pattern of the true histogram by a gain λ_k (for Gaussian resolution $\lambda_k = e^{-q_k^2\sigma^2/2}$), small for patterns finer than the resolution. The noise of the data is not shrunk. Inverting the response divides every pattern by its gain, so the fine patterns of the answer are noise amplified by $1/\lambda_k$. The inverse is unbiased and efficient, and useless whenever some gain is smaller than the relative noise.

The analysis also says what helps. Wider bins remove the shortest waves from the problem altogether, so the covariance of the inverse shrinks quickly once the bins are wider than the

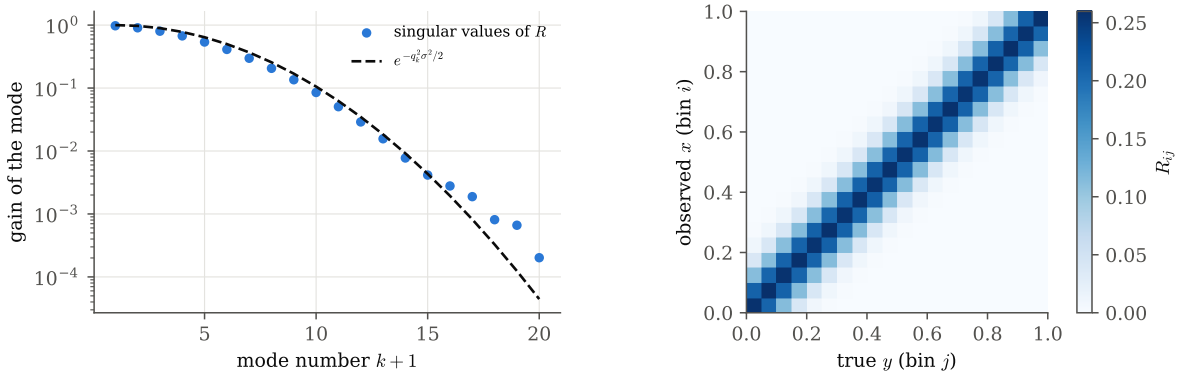

Figure 6.39: Right: the simulated response matrix of the test case; each column spreads the events of one true bin over about five measured bins, and the edge columns lose events. Left: its singular values, the factors by which it shrinks its patterns, from the smoothest to the roughest, against the Gaussian prediction $e^{-q_k^2\sigma^2/2}$ with $q_k = \pi k/L$ (dashed).

resolution [Cowan p. 163]. And if one keeps the naive inverse, it is still an honest result as long as the *full* covariance $\mathbf{U}$ goes with it: a χ^2 comparison with a theory, $(\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_0)^{\mathsf{T}}\mathbf{U}^{-1}(\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_0)$, is valid, whereas the same χ^2 with only the diagonal of $\mathbf{U}$ is meaningless, because the off-diagonal elements are as large as the diagonal ones.

6.14.3 Trading bias for variance: regularisation

The naive inverse is unbiased and has the smallest variance of any unbiased estimator. So any estimator with a smaller variance must be *biased*. That is the whole art of unfolding: accept a bias that is small if some belief about the truth is right (usually, that it is smooth) in exchange for a large cut in variance [Cowan §11.4]. The tool is the mean squared error of Section 3.2.1, MSE = bias^2 + variance, which puts the two on one scale.

Smoothest among the acceptable. Cowan states the strategy in two steps. First, a whole region of true histograms fits the data acceptably: those whose log-likelihood is within some $\Delta \ln L$ of the maximum, $\ln L(\boldsymbol{\mu}) \geq \ln L_{\max} - \Delta \ln L$. The naive inverse is the single best fit, but its wild neighbours fit almost as well, which is exactly what the large $\mathbf{U}$ said. Second, among the acceptable histograms, pick the smoothest, as measured by a **regularisation function** $S(\boldsymbol{\mu})$ that is larger for smoother histograms. Maximising S subject to the likelihood constraint is, with a Lagrange multiplier α, maximising $\alpha \ln L(\boldsymbol{\mu}) + S(\boldsymbol{\mu})$ [Cowan eqs. 11.34–11.37]. A large α gives back the naive inverse; $\alpha \to 0$ ignores the data and returns the smoothest histogram there is.

Tikhonov regularisation. The most common smoothness measure is the mean squared curvature, Tikhonov's choice [Cowan §11.5.1]. For a histogram the second derivative becomes the second difference $\mu_i - 2\mu_{i+1} + \mu_{i+2}$, and

$$S(\boldsymbol{\mu}) = -\sum_{i=1}^{M-2} (\mu_i - 2\mu_{i+1} + \mu_{i+2})^2 = -|\mathbf{C}\boldsymbol{\mu}|^2 = -\boldsymbol{\mu}^{\mathsf{T}}\mathbf{G}\boldsymbol{\mu}, \qquad \mathbf{G} = \mathbf{C}^{\mathsf{T}}\mathbf{C}, \tag{6.70}$$

where row i of the $(M-2) \times M$ matrix $\mathbf{C}$ is $(\ldots, 0, 1, -2, 1, 0, \ldots)$ starting in column i. ($\mathbf{G}$ is Cowan's matrix in [Cowan eq. 11.48]: 6 on most of the diagonal, -4 and 1 beside it.) A straight line has zero second differences, so S does not penalise the overall level or slope at all; those are left entirely to the data, and a truth that is linear is unfolded without bias [Cowan p. 177].

With many events per bin the Poisson log-likelihood is close to the Gaussian $\ln L = -\frac{1}{2}\chi^2(\boldsymbol{\mu})$, $\chi^2 = (\boldsymbol{n} - \mathbf{R}\boldsymbol{\mu})^{\mathsf{T}}\mathbf{V}^{-1}(\boldsymbol{n} - \mathbf{R}\boldsymbol{\mu})$, taking $\boldsymbol{\beta} = 0$ for brevity. Maximising $\alpha \ln L + S$ is then minimising

$$\chi^2(\boldsymbol{\mu}) + \tau\, \boldsymbol{\mu}^{\mathsf{T}}\mathbf{G}\boldsymbol{\mu}, \qquad \tau = 2/\alpha, \tag{6.71}$$

and since this is quadratic in $\boldsymbol{\mu}$, the minimum has a closed form. Set the gradient to zero:

$$\begin{aligned} 0 &\overset{(1)}{=} -2\mathbf{R}^{\mathsf{T}}\mathbf{V}^{-1}(\boldsymbol{n} - \mathbf{R}\hat{\boldsymbol{\mu}}) + 2\tau\mathbf{G}\hat{\boldsymbol{\mu}} \\ \Rightarrow \quad \hat{\boldsymbol{\mu}}_\tau &\overset{(2)}{=} \left(\mathbf{R}^{\mathsf{T}}\mathbf{V}^{-1}\mathbf{R} + \tau\mathbf{G}\right)^{-1}\mathbf{R}^{\mathsf{T}}\mathbf{V}^{-1}\,\boldsymbol{n} \equiv \mathbf{A}_\tau \boldsymbol{n}. \end{aligned} \tag{6.72}$$

(1) The gradient of a quadratic form: $\nabla_\mu(\boldsymbol{a} - \mathbf{R}\boldsymbol{\mu})^{\mathsf{T}}\mathbf{V}^{-1}(\boldsymbol{a} - \mathbf{R}\boldsymbol{\mu}) = -2\mathbf{R}^{\mathsf{T}}\mathbf{V}^{-1}(\boldsymbol{a} - \mathbf{R}\boldsymbol{\mu})$ for symmetric $\mathbf{V}$, and $\nabla_\mu \boldsymbol{\mu}^{\mathsf{T}}\mathbf{G}\boldsymbol{\mu} = 2\mathbf{G}\boldsymbol{\mu}$ for symmetric $\mathbf{G}$.
(2) Collect the terms in $\hat{\boldsymbol{\mu}}$ and multiply by the inverse of the bracket.

At $\tau = 0$ the bracket is $\mathbf{R}^{\mathsf{T}}\mathbf{V}^{-1}\mathbf{R}$ and $\mathbf{A}_0 = \mathbf{R}^{-1}$, the naive inverse. The estimator is linear in the data, so its bias and covariance are exact, by the same two steps as (6.64):

$$\boldsymbol{b}_\tau = \mathbb{E}[\hat{\boldsymbol{\mu}}_\tau] - \boldsymbol{\mu} \overset{(1)}{=} (\mathbf{A}_\tau\mathbf{R} - 1)\,\boldsymbol{\mu}, \qquad \mathbf{U}_\tau \overset{(2)}{=} \mathbf{A}_\tau\mathbf{V}\mathbf{A}_\tau^{\mathsf{T}}. \tag{6.73}$$

(1) $\mathbb{E}[\mathbf{A}_\tau \boldsymbol{n}] = \mathbf{A}_\tau \boldsymbol{\nu} = \mathbf{A}_\tau\mathbf{R}\boldsymbol{\mu}$.
(2) Covariance of a linear map.

The bias vanishes when $\mathbf{A}_\tau\mathbf{R} = \mathbb{1}$, which happens only at $\tau = 0$; but it also vanishes for any truth with $\mathbf{G}\boldsymbol{\mu} = 0$, the straight lines. The bias formula contains the unknown $\boldsymbol{\mu}$, which is why the bias of an unfolding can be estimated but never known [Cowan §11.6].

The two bins again: how regularisation filters. Go back to the two-bin detector of (6.66) and penalise the difference between the bins, $\tau(\mu_1 - \mu_2)^2 = 2\tau d^2$ (with two bins there is no curvature; the first difference plays its role). In the patterns $\boldsymbol{u}_\pm$, with $\mathbf{V} = \bar{\nu}\mathbb{1}$, the objective (6.71) splits into a part for s and a part for d, and only the second is touched:

$$\begin{aligned} \frac{\partial}{\partial d}\left[\frac{(n_d - \epsilon d)^2}{\bar{\nu}} + 2\tau d^2\right] &\overset{(1)}{=} -\frac{2\epsilon(n_d - \epsilon d)}{\bar{\nu}} + 4\tau d = 0 \\ \Rightarrow \quad \hat{d}_\tau &\overset{(2)}{=} \frac{\epsilon\, n_d}{\epsilon^2 + 2\tau\bar{\nu}} \overset{(3)}{=} F \cdot \frac{n_d}{\epsilon}, \qquad F = \frac{\epsilon^2}{\epsilon^2 + 2\tau\bar{\nu}}. \end{aligned} \tag{6.74}$$

(1) The measured difference is $n_d = \epsilon d + \text{noise}$, so its χ^2 term is $(n_d - \epsilon d)^2/\bar{\nu}$.
(2) Solve the linear equation for d.
(3) Multiply and divide by ϵ: the regularised estimate is the naive one, n_d/ϵ, times a factor F between 0 and 1.

So regularisation does not smooth in some vague sense: it multiplies the badly measured pattern by a **filter factor** F, and leaves the well-measured total alone. Hoecker and Kartvelishvili show that this is the general structure [134]: after the data are rescaled to unit errors and $\mathbf{R}$ is decomposed into its patterns (its singular value decomposition), the regularised solution multiplies the k-th pattern of the naive inverse by $s_k^2/(s_k^2 + \tau)$, where s_k is that pattern's gain. Patterns with $s_k^2 \gg \tau$ pass; those with $s_k^2 \ll \tau$ are cut. It is a low-pass filter.

Which F is best? With $E[n_d] = \epsilon d$ and $\mathrm{Var}(n_d) = \bar{\nu}$, the estimate $\hat{d}_\tau$ has bias $(F - 1)d$ and variance $F^2\bar{\nu}/\epsilon^2$, so

$$\mathrm{MSE}(F) \overset{(1)}{=} F^2\frac{\bar{\nu}}{\epsilon^2} + (1 - F)^2 d^2, \qquad F^* \overset{(2)}{=} \frac{d^2}{d^2 + \bar{\nu}/\epsilon^2}, \qquad \mathrm{MSE}(F^*) \overset{(3)}{=} \frac{d^2\,\bar{\nu}/\epsilon^2}{d^2 + \bar{\nu}/\epsilon^2}. \tag{6.75}$$

(1) Variance plus squared bias (Section 3.2.1).
(2) Set $\mathrm{d}\,\mathrm{MSE}/\mathrm{d}F = 2F\bar{v}/\epsilon^2 - 2(1-F)d^2$ to zero.
(3) Insert F^*; both terms share the denominator $(d^2 + \bar{v}/\epsilon^2)^2$, and their numerators add to $d^2(\bar{v}/\epsilon^2)(d^2 + \bar{v}/\epsilon^2)$.

The best filter keeps the pattern in proportion to how much of it is signal: d^2 is the squared size of the true pattern and $\bar{v}/\epsilon^2$ the variance of its naive estimate. With $\bar{v} = 1000$, $\epsilon = 0.1$ and a true difference $\mu_1 - \mu_2 = 200$ ($d^2 = 20\,000$), the naive estimate has MSE $= 10^5$ (an error of 316 in d), setting the difference to zero costs $d^2 = 20\,000$ (an error of 141), and the best filter, $F^* = 1/6$, gets the error down to 129. The optimum strength follows from F^*: $2\tau\bar{v} = \epsilon^2(1/F^* - 1)$ gives $\tau^* = 1/(2d^2)$. It depends on the size of the true structure, which is unknown. This is why choosing τ is the hard part of every unfolding.

Other smoothness measures. The curvature is not the only choice. The entropy of the normalised histogram, $H = -\sum_i p_i \ln p_i$ with $p_i = \mu_i/\mu_{\text{tot}}$, is largest for a flat histogram, and it counts the number of ways $\Omega = \mu_{\text{tot}}!/(\mu_1! \cdots \mu_M!)$ of distributing the events over the bins: with Stirling's $\ln m! \approx m \ln m - m$, $\ln\Omega \approx \mu_{\text{tot}} \ln \mu_{\text{tot}} - \sum_i \mu_i \ln \mu_i = -\sum_i \mu_i \ln(\mu_i/\mu_{\text{tot}}) = \mu_{\text{tot}} H$ [Cowan eqs. 11.51–11.54]. Using $S = H$ is **maximum-entropy** unfolding. It keeps every bin positive, which Tikhonov does not, and it is popular for images with sharp features; read as a Bayesian prior $\pi(\boldsymbol{\mu}) \propto \Omega$ it pulls far too hard towards a flat histogram, so in practice its strength is tuned like τ. A cross-entropy relative to a reference histogram $\boldsymbol{q}$ pulls towards $\boldsymbol{q}$ instead of towards flatness [Cowan §§11.5.2–11.5.4]. Each choice is unbiased for a different kind of truth: curvature for straight lines, entropy for flat histograms, cross-entropy for $\boldsymbol{q}$.

6.14.4 Choosing the strength

In a test case we know the truth, so the exact bias and covariance (6.73) give the exact mean squared error averaged over the bins, $\mathrm{MSE}(\tau) = \frac{1}{M}\sum_i \left(U_{\tau,ii} + b_{\tau,i}^2\right)$ [Cowan eq. 11.79], for every τ. Figure 6.40(b) shows it for our two-peak spectrum. As τ grows the variance falls from the naive inverse's 1.752×10^9 per bin and the squared bias rises; their sum has a minimum at $\tau = 1.413 \times 10^{-5}$, where the root-mean-square error per bin is 72.6 events: a bias of 53.1 and a standard deviation of 49.4. At the optimum the bias and the statistical error are about equal; that is what an optimal trade looks like. For scale, the Poisson error of a single bin with the mean content would be 31.6. Unfolding costs information, and no method gets it back.

Listing 6.16: Tikhonov unfolding as one linear solve (`code/ch06/30_unfolding.py`)

```
C = np.zeros((M - 2, M))
for i in range(M - 2):
    C[i, i:i + 3] = [1.0, -2.0, 1.0]     # second difference mu_i - 2 mu_{i+1} + mu_{i+2}
G = C.T @ C

def tikhonov_matrix(tau, Vdiag):
    """A_tau with mu-hat = A_tau n, for data covariance diag(Vdiag)."""
    W = R.T / Vdiag                       # R^T V^{-1}
    return np.linalg.solve(W @ R + tau * G, W)
```

Lines 119–122 build the second-difference matrix $\mathbf{C}$ of (6.70) and $\mathbf{G} = \mathbf{C}^\mathsf{T}\mathbf{C}$. The function on lines 125–128 returns $\mathbf{A}_\tau$ of (6.72): line 127 forms $\mathbf{R}^\mathsf{T}\mathbf{V}^{-1}$ for a diagonal $\mathbf{V}$, and line 128 solves $(\mathbf{R}^\mathsf{T}\mathbf{V}^{-1}\mathbf{R} + \tau\mathbf{G})\mathbf{A} = \mathbf{R}^\mathsf{T}\mathbf{V}^{-1}$ rather than forming an inverse.

Without the truth. A real analysis does not know $\boldsymbol{\mu}$, so it needs a rule that uses the data only. Three are common. (i) *Estimate the bias.* Replace $\boldsymbol{\mu}$ in (6.73) by the estimate itself, $\hat{\boldsymbol{b}} = (\mathbf{A}_\tau\mathbf{R} - \mathbb{1})\hat{\boldsymbol{\mu}}_\tau$,

and lower τ until the estimated biases are no longer significant compared with their own statistical errors [Cowan eqs. 11.76–11.83]. (ii) *The effective rank.* Hoecker and Kartvelishvili rotate the rescaled data into the patterns of $\mathbf{R}$; the coefficients fall with the pattern number until they reach the noise level, which is one. If that happens at pattern k, they set $\tau = s_k^2$, so that the filter passes exactly the patterns the data can see [134]. They also recommend checking the choice on a test distribution close to, but different from, the simulated one, which is what our toys do. (iii) *The L-curve.* Plot, for each τ, how badly the solution fits the data, $\chi^2(\hat{\boldsymbol{\mu}}_\tau)$, against how rough it is, $|\mathbf{C}\hat{\boldsymbol{\mu}}_\tau|^2$, both on log scales. Small τ gives tiny misfit and huge roughness, large τ the reverse, and in between the curve turns a corner; the corner, the point of largest curvature, is the compromise. For our one data set the corner sits at $\tau = 1.000 \times 10^{-6}$, close to the minimum-MSE value (Figure 6.40c).

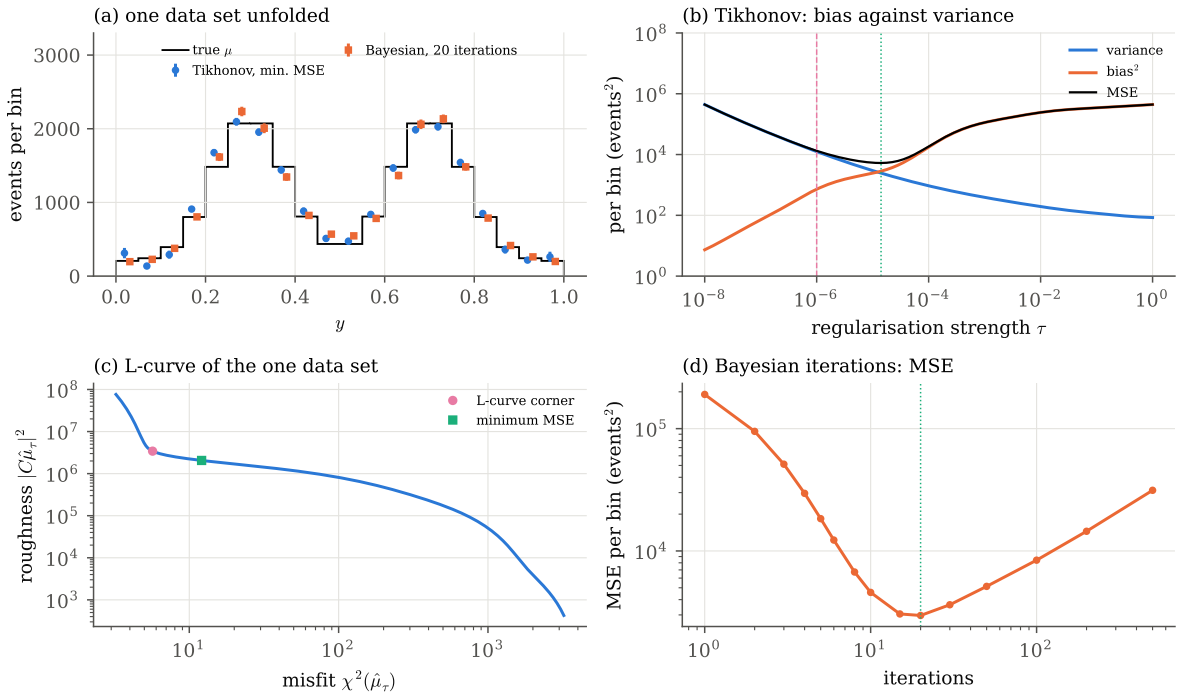

Figure 6.40: (a) The data set of Figure 6.38 unfolded with curvature regularisation at the minimum-MSE strength (blue) and with 20 Bayesian iterations (orange), on the truth (black). (b) Exact variance, squared bias and their sum, the MSE, per bin against τ; the dotted line marks the minimum, the dashed one the L-curve choice. (c) The L-curve of this data set: misfit against roughness as τ runs from small (upper left) to large (lower right). (d) For the Bayesian iterations, the MSE from 1000 toys against the number of iterations.

6.14.5 Unfolding with Bayes' theorem, iterated

D'Agostini's method starts from a different question [135]. *The event.* An event has been recorded in measured bin i. *What could have produced it?* An event created in any of the true bins $j = 1, \dots, M$. These are the hypotheses. *How probable was the event under each hypothesis?* If the event was created in true bin j, the probability that it was recorded and landed in bin i is the response matrix element R_{ij}: that is exactly what (6.61) defined. *Only then the priors.* Before looking at this event, the probability that an event comes from true bin j is the fraction $p_j = \mu_j/\mu_{\text{tot}}$ of the truth in that bin. We do not know it, so we start from a guess $p_j^{(0)}$, flat for instance. *Normalise.* Bayes' theorem (Chapter 5) gives the probability that an event seen in bin i

came from true bin j:

$$\mathrm{P}(j \mid i) = \frac{R_{ij}\, p_j^{(0)}}{\sum_l R_{il}\, p_l^{(0)}}. \tag{6.76}$$

Now share out the data. The n_i events of measured bin i are assigned to the true bins in these proportions, so true bin j receives $\sum_i n_i \,\mathrm{P}(j \mid i)$ recorded events. Recorded events are only the fraction ε_j of those created, so divide by the efficiency:

$$\hat{\mu}_j^{(1)} = \frac{1}{\varepsilon_j} \sum_i n_i \,\mathrm{P}(j \mid i) = \frac{\hat{\mu}_j^{(0)}}{\varepsilon_j} \sum_i R_{ij}\, \frac{n_i}{\hat{\nu}_i^{(0)}}, \qquad \hat{\nu}_i^{(0)} = \sum_l R_{il} \hat{\mu}_l^{(0)}. \tag{6.77}$$

The second form follows by inserting (6.76) with $p_j^{(0)} = \hat{\mu}_j^{(0)} / \hat{\mu}_{\mathrm{tot}}^{(0)}$; the total cancels between numerator and denominator. The result depends on the prior guess, which was the weak point of a Bayesian unfolding. D'Agostini's remedy is to iterate: use $\hat{\boldsymbol{\mu}}^{(1)}$ as the new prior, apply (6.77) again, and so on.

Where do the iterations go? At a fixed point, $\hat{\mu}_j^{(t+1)} = \hat{\mu}_j^{(t)}$, the second form of (6.77) says

$$\frac{1}{\varepsilon_j} \sum_i R_{ij} \frac{n_i}{\hat{\nu}_i} \overset{(1)}{=} 1 \quad \Longleftrightarrow \quad \sum_i R_{ij} \frac{n_i}{\hat{\nu}_i} \overset{(2)}{=} \sum_i R_{ij} \quad \Longleftrightarrow \quad \sum_i R_{ij} \left(\frac{n_i}{\hat{\nu}_i} - 1 \right) = 0, \tag{6.78}$$

(1) Divide the fixed-point condition by $\hat{\mu}_j$ (for a bin with $\hat{\mu}_j \neq 0$).
(2) The efficiency is the column sum, (6.62).

which is the maximum-likelihood condition (6.65). So iterating forever leads towards the maximum-likelihood solution, the naive inverse whenever that is positive, with all its noise. (The iteration is the expectation–maximisation algorithm for Poisson data, known in astronomy as Richardson–Lucy deconvolution.) Stopping early leaves the answer between the prior guess and the maximum-likelihood solution, and the number of iterations plays the role of τ. The smooth patterns, which have large gains, converge in a few iterations; the rough ones, with tiny gains, would take thousands. Stopping early is therefore a filter too.

Listing 6.17: Iterative Bayesian unfolding (`code/ch06/30_unfolding.py`)

```
172 def ibu(n, iters, prior=None):
173     """D'Agostini iterations; n may be (..., M).  Returns the estimate after 'iters'
        steps."""
174     p = np.full(M, 1.0 / M) if prior is None else prior / prior.sum()
175     m_hat = np.broadcast_to(p * n.sum(axis=-1, keepdims=True), n.shape).copy()
176     for _ in range(iters):
177         nu_hat = m_hat @ R.T                                  # sum_j R_ij mu_j
178         m_hat = m_hat / eff * ((n / nu_hat) @ R)              # mu_j/eps_j sum_i R_ij n_i / nu_i
179     return m_hat
```

Line 175 sets the starting guess: the observed total spread flat over the true bins. In each iteration line 177 folds the current guess, $\hat{\nu}_i = \sum_j R_{ij} \hat{\mu}_j$, and line 178 is the second form of (6.77). Written this way it works on a whole stack of toy data sets at once.

Example: how many iterations? With 1000 toy data sets drawn from our $\boldsymbol{\nu}$, the mean squared error per bin falls steeply at first, while the iterations move the flat guess towards the peaks, reaches its minimum of 2969 (an error of 54.5 events per bin) at 20 iterations, and rises again as noise creeps in: after 500 iterations it is 31300 (Figure 6.40d). A small fixed number of iterations, chosen once and for all, would be far from optimal here, because our peaks are narrow and the flat start is far from them. The right number depends on the problem, and has to be chosen

with the same care as τ. The error bars of an iterative unfolding cannot be read off a formula as simply as (6.73); we get them by unfolding 400 Poisson resamplings of the data and taking the spread.

The method of correction factors. The simplest unfolding of all, and perhaps the most widely used, has no matrix: multiply each measured bin by a factor from the simulation, $\hat{\mu}_i = C_i(n_i - \beta_i)$ with $C_i = \mu_i^{\mathrm{MC}}/\nu_i^{\mathrm{MC}}$, the ratio of true to measured content of bin i in the simulation [Cowan §11.3]. Its expectation is $C_i\nu_i^{\mathrm{sig}}$, with $\nu_i^{\mathrm{sig}} = \nu_i - \beta_i$ the expected signal in the bin, so its bias is

$$b_i = \left(\frac{\mu_i^{\mathrm{MC}}}{\nu_i^{\mathrm{MC}}} - \frac{\mu_i}{\nu_i^{\mathrm{sig}}}\right)\nu_i^{\mathrm{sig}},$$

zero only if the simulation has the same ratio of true to measured content as nature. When migrations are large this fails badly. With our flat simulation $C_i \approx 1$ in the interior, so the method returns essentially the smeared histogram: the peak bins come out −23.3% low and the central dip 87.4% high. The estimate is pulled towards the shape of the simulation, which may be the very model the measurement was meant to test.

6.14.6 Do the error bars cover? Toys

An error bar is a promise: in about 68% of repeated experiments, the interval $\hat{\mu}_j \pm \hat{\sigma}_j$ should contain the true μ_j (Section 4.12). For a regularised unfolding the promise is in doubt, because $\hat{\sigma}_j$ describes only the spread of $\hat{\mu}_j$, not its offset from the truth. We check it with toys, the Monte Carlo of everything in this chapter. Draw 2000 data sets $n_i \sim \mathrm{Poisson}(\nu_i)$ from the known truth. Unfold each one exactly as a real analysis would, with error bars computed from that data set alone: for the naive inverse and for Tikhonov from (6.64) and (6.73) with $\mathbf{V} = \mathrm{diag}(\boldsymbol{n})$, for the Bayesian iterations from 100 Poisson resamplings, and for the correction factors as $C_i\sqrt{n_i}$. Then count, bin by bin, the fraction of toys whose interval contains μ_j. The binomial error of each fraction is 1%.

The naive inverse covers 67.9% of the time averaged over the bins, against the nominal 68.3%: its enormous error bars are honest. The regularised methods do not keep the promise (Figure 6.41). Tikhonov at the minimum-MSE strength covers 46.1% on average and only 28.8% in the bin at the top of a peak; the worst bin reaches 19.7%. The Bayesian iterations cover 53.4% on average, down to 14.4% in the central dip, while the peak bin is fine (67.2%). The correction factors almost never cover (0.1%): their error bars are the small Poisson errors of the data, and their bias is tens of per cent.

Why does each method fail where it does? The right panel of Figure 6.41 unfolds the expectation $\boldsymbol{\nu}$ itself, with no noise, so that only the bias is left. Each method is biased towards what it regards as simple. The curvature penalty prefers straight lines, so it cuts the tops of the peaks, where the curvature is largest. The Bayesian iterations remember their flat start, so they leave too many events in the dip between the peaks. The bias is a property of the method and the truth together, which is why it does not average away over toys and why the coverage fails in different bins for different methods.

Watch out: Regularised error bars are not distances to the truth

The covariance $\mathbf{A}_\tau\mathbf{V}\mathbf{A}_\tau^{\mathsf{T}}$ of a regularised unfolding is the spread of the estimate about its own biased mean. Quoting it as the uncertainty on the true spectrum undercovers: in our test case one bin is covered 19.7% of the time instead of 68.3%. Either check the coverage with toys and add the bias as a systematic error, or compare the theory with the data the

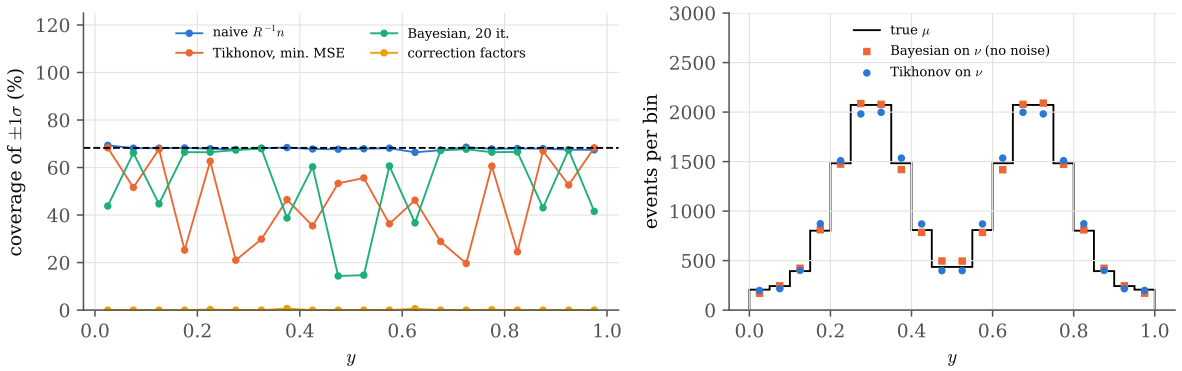

Figure 6.41: Left: the fraction of 2000 toy experiments in which the $\pm 1\sigma$ error bar of each bin contains the true value, for four unfoldings; the dashed line is the nominal 68.3%. Right: the two regularised methods applied to the noise-free expectation $\boldsymbol{\nu}$, which shows their bias alone. Curvature regularisation shaves the peaks; the Bayesian iterations, started flat, leave the dip partly filled.

other way round, by folding the theory through $\mathbf{R}$.

That last option is the one to prefer whenever it is possible. To test a theory, nothing needs to be unfolded: fold the theory's prediction through the response, $\boldsymbol{\nu} = \mathbf{R}\boldsymbol{\mu}_{\text{theory}} + \boldsymbol{\beta}$, and compare it with $\boldsymbol{n}$ using the Poisson likelihood. That comparison is unbiased, has the simple Poisson errors of the data, and is exactly the forward model of Example 1.43. Unfolding earns its cost when the result must be compared with other experiments or with theories not yet written, and then it must be published together with its full covariance and, ideally, the response matrix itself [Cowan pp. 153–154].

How this is used in real research: Unfolding in research

Verification is what our test case does: a known truth, a known detector, toys that check the bias, the variance and the coverage of every method. *Research* use looks the same with the truth unknown. Collider experiments unfold differential cross sections (a jet's transverse momentum, a top quark's rapidity) with a response matrix from an event generator and a GEANT4 detector simulation (Section 6.11.4), using either curvature/SVD regularisation [134] or the iterative Bayesian method [135], with the regularisation strength and the coverage checked on toys built from alternative truths. Cosmology meets the same linear algebra: a partial-sky power spectrum is the true C_ℓ multiplied by a mode-coupling matrix of the mask (Chapter 8), and the pseudo-C_ℓ method inverts that matrix only after binning in ℓ, the "wider bins" cure of Section 6.14.2, because the unbinned matrix is as ill-conditioned as a smearing matrix.

The lesson. Unfolding is the backward, inference direction of a forward chain that simulation lets us write down exactly, and a measurement can only return the patterns its detector did not crush, so every answer beyond those patterns is a choice of bias that has to be shown, checked with toys and reported.

6.15 Shrinking σ: variance reduction

The Monte Carlo error $\sigma/\sqrt{N}$ of Section 6.11.2 has two factors, and only one of them is ours to change. With independent random draws the $1/\sqrt{N}$ is fixed: a hundred times the computing time buys one more digit. The constant σ, the standard deviation of a single term, is not fixed. Importance sampling (Section 6.12) changes it by moving the draws to where the integrand lives. Three other cheap devices change it by arranging the draws more cleverly [HobsonBMC §3.1]. We test each on the same integral,

$$I = \int_0^1 e^x \, \mathrm{d}x = e - 1 = 1.718,$$

where plain Monte Carlo with uniform U has single-term variance $\sigma^2 = \mathbb{E}[e^{2U}] - I^2 = \frac{1}{2}(e^2 - 1) - (e - 1)^2 = 0.242$. Every estimator below uses the same number N of evaluations of e^x, so their variances can be compared directly.

The question. Without changing the integrand or the number of function evaluations, how can we make the average less noisy?

6.15.1 Antithetic pairs

If U is uniform, so is $1 - U$. Evaluate the integrand at both and average the pair. Why should this help? For a monotone integrand, a draw that lands high is paired with one that lands low, so their errors partly cancel. To see how much, compute the variance of one pair,

$$\operatorname{Var}\Big[\tfrac{1}{2}\big(h(U) + h(1-U)\big)\Big] \overset{(1)}{=} \tfrac{1}{4}\big[\operatorname{Var} h(U) + \operatorname{Var} h(1-U) + 2\operatorname{Cov}\big(h(U), h(1-U)\big)\big] \overset{(2)}{=} \tfrac{1}{2}\big(\sigma^2 + \gamma\big), \tag{6.79}$$

(1) The variance of a sum of two correlated terms, with the factor $\frac{1}{2}$ squared.
(2) $h(U)$ and $h(1-U)$ both have variance σ^2; write $\gamma = \operatorname{Cov}\big(h(U), h(1-U)\big)$.

With N evaluations we have $N/2$ pairs, and the average of $N/2$ independent pairs has variance $\frac{1}{2}(\sigma^2 + \gamma)/(N/2) = (\sigma^2 + \gamma)/N$. So the variance per evaluation is $\sigma^2 + \gamma = \sigma^2(1 + \rho)$, where $\rho = \gamma/\sigma^2$ is the correlation between the two members of a pair. A negative ρ helps, and for a monotone h it is always negative, because U and $1 - U$ move in opposite directions. For e^x, $\gamma = \mathbb{E}[e^U e^{1-U}] - I^2 = e - (e - 1)^2 = -0.2342$, almost $-\sigma^2$, so the variance per evaluation drops from 0.242 to 0.007825, a predicted gain of 31. The simulation, 4000 repeats with $N = 1024$, measures a gain of 29.41 in variance.

6.15.2 Control variates

Suppose a second function $c(x)$ is correlated with the integrand and has a mean μ_c we know exactly. Estimate I by averaging $h(X) - \beta\,[c(X) - \mu_c]$ instead of $h(X)$. The added term has mean zero for every β, so the estimator stays unbiased, and its single-term variance is

$$\begin{aligned} \operatorname{Var}\big[h - \beta(c - \mu_c)\big] &\overset{(1)}{=} \sigma_h^2 - 2\beta \operatorname{Cov}(h, c) + \beta^2 \sigma_c^2 \\ &\overset{(2)}{=} \sigma_h^2 - \frac{\operatorname{Cov}(h,c)^2}{\sigma_c^2} \overset{(3)}{=} \sigma_h^2\big(1 - \rho_{hc}^2\big) \quad \text{at} \quad \beta^* = \frac{\operatorname{Cov}(h,c)}{\sigma_c^2}. \end{aligned} \tag{6.80}$$

(1) The variance of a difference; the constant $\beta\mu_c$ does not contribute.

(2) Minimise over β: the derivative $-2\,\mathrm{Cov}(h,c) + 2\beta\sigma_c^2$ vanishes at β^*; substitute it back.
(3) $\rho_{hc} = \mathrm{Cov}(h,c)/(\sigma_h\sigma_c)$ is the correlation coefficient.

In words: we let the draws measure only the *difference* between the integrand and a function whose integral we already know. The better c tracks h, the closer ρ_{hc}^2 is to one and the smaller the variance that is left.

For $h = e^x$ take $c(x) = x$, with $\mu_c = \frac{1}{2}$ and $\sigma_c^2 = \frac{1}{12}$ for x uniform on $[0,1]$. Then $\mathrm{Cov}(e^U, U) = \mathbb{E}[Ue^U] - \frac{1}{2}(e-1) = 1 - \frac{1}{2}(e-1) = \frac{1}{2}(3-e)$, using $\int_0^1 xe^x\mathrm{d}x = \left[(x-1)e^x\right]_0^1 = 1$, so $\beta^* = 6(3-e) = 1.69$ and the residual variance is 0.00394, a predicted gain of 61; the simulation measures 59.7.

In physics the control variate is often a cheap approximation of an expensive simulation: a parametrised detector response averaged against the full GEANT4 simulation, or a leading-order cross section whose integral is known analytically.

6.15.3 Stratified sampling

Random draws clump: by chance, some parts of $[0,1]$ receive more points than others, and this clumping is part of σ. Stratification forbids it. Cut $[0,1]$ into K equal strata, draw N/K points uniformly inside each, and average the K stratum averages. Why does this lower the variance? The law of total variance [total variance = mean of the within-stratum variances + variance of the stratum means] splits σ^2 into two parts, and stratification removes the second one. With μ_k and σ_k^2 the mean and variance of h within stratum k,

$$\sigma^2 \overset{(1)}{=} \frac{1}{K}\sum_{k=1}^{K}\sigma_k^2 + \frac{1}{K}\sum_{k=1}^{K}(\mu_k - I)^2, \qquad \mathrm{Var}[\hat{I}_{\mathrm{strat}}] \overset{(2)}{=} \frac{1}{K^2}\sum_{k=1}^{K}\frac{\sigma_k^2}{N/K} \overset{(3)}{=} \frac{1}{N}\left[\sigma^2 - \frac{1}{K}\sum_{k}(\mu_k - I)^2\right] \le \frac{\sigma^2}{N}. \tag{6.81}$$

(1) The law of total variance, with the stratum chosen uniformly at random (each has probability $1/K$).
(2) $\hat{I}_{\mathrm{strat}} = \frac{1}{K}\sum_k \hat{\mu}_k$, the strata are sampled independently, and each stratum mean $\hat{\mu}_k$ of N/K draws has variance $\sigma_k^2/(N/K)$.
(3) Simplify and substitute the first equation.

The variation *between* strata, which plain sampling pays for through its random clumping, is gone; only the variation within each stratum is left.

How fast does the error then fall? Take one point per stratum ($K = N$) and a smooth integrand. Each stratum has width $1/N$, so h varies across it by about h'/N, and $\sigma_k^2 \approx h'(x_k)^2/(12N^2)$, the variance of a uniform spread over that range. Then $\mathrm{Var}[\hat{I}_{\mathrm{strat}}] \approx \frac{1}{N^2}\sum_k h'(x_k)^2/(12N^2) \approx \int_0^1 h'^2\mathrm{d}x/(12N^3)$, so the error falls as $N^{-3/2}$ instead of $N^{-1/2}$. For e^x, $\int_0^1 e^{2x}\mathrm{d}x = \frac{1}{2}(e^2-1)$, which predicts a standard deviation $0.516\,N^{-3/2} = 1.6\times10^{-5}$ at $N = 1024$; the simulation measures 1.556×10^{-5}, a fitted slope of -1.504, and a gain in variance of 9.486×10^5 over plain sampling. The evenly spread quasi-random (Sobol) points of Section 6.7 push the same idea into many dimensions, where a full grid of strata would again cost n^d points.

Listing 6.18: Four estimators of $\int_0^1 e^x\mathrm{d}x$ with the same number of function evaluations (`code/ch06/29_variance_reduction.py`)

```
29 def plain(n):
30     return np.exp(rng.random((R, n))).mean(axis=1)
31
32
33 def antithetic(n):
```

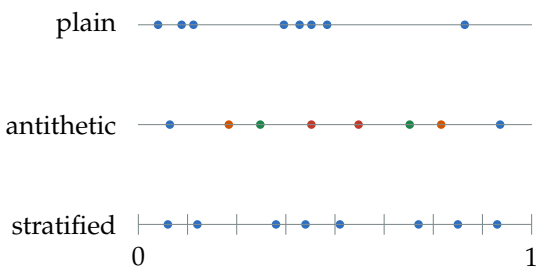

Figure 6.42: Eight evaluation points on $[0, 1]$ three ways. Plain sampling can leave gaps and clumps. Antithetic sampling pairs each u with $1 - u$ (same colour), so a high draw is always balanced by a low one. Stratified sampling puts exactly one point in each of eight equal strata (tick marks), which removes the clumping altogether.

```
34      u = rng.random((R, n // 2))
35      return (0.5 * (np.exp(u) + np.exp(1 - u))).mean(axis=1)
36
37
38  def control(n):
39      u = rng.random((R, n))
40      y = np.exp(u)
41      beta = 6 * (3 - np.e)                          # Cov(e^U, U) / Var(U) = [(3 - e)/2] /
        (1/12), exact
42      return (y - beta * (u - 0.5)).mean(axis=1)
43
44
45  def stratified(n):
46      u = (np.arange(n)[None, :] + rng.random((R, n))) / n
47      return np.exp(u).mean(axis=1)
```

Each function returns 4000 independent estimates, one per row of random numbers, so that the standard deviation of each estimator can be measured directly. Line 34 draws only $n/2$ uniforms and line 35 evaluates e^x at u and $1 - u$. Line 42 subtracts the control variate with the exact β^* of (6.80). Line 46 places one uniform point inside each of the n strata $[k/n, (k + 1)/n)$.

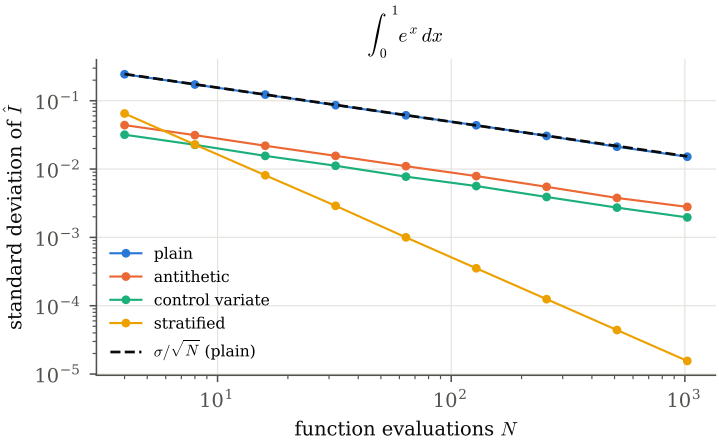

Figure 6.43: Standard deviation of four estimators of $\int_0^1 e^x\,\mathrm{d}x$ against the number of function evaluations, each from 4000 repeats. Plain Monte Carlo follows $\sigma/\sqrt{N}$ (black dashed). Antithetic pairs and the control variate keep the slope $-1/2$ but lower the line by factors of about 5.5 and 8. Stratification with one point per stratum changes the slope to $-3/2$.

Watch out: Error bars for correlated draws

All three devices make the evaluations dependent: pairs are anticorrelated, strata are not exchangeable. The naive error bar $s/\sqrt{N}$ computed from all N values as if they were independent is then wrong. Compute the error from the independent units: the $N/2$ pair averages, the per-stratum variances in (6.81), or, as in the script, from repeated independent runs.

6.16 Which sampler when

The choice of sampler is usually forced by what we know about the density. Every sampler above answers the same question, how to get draws or averages under a density we can describe, but each asks for something different about that density.

Taxonomy: Which sampler when

method	what it needs	cost per draw	fails when
inverse CDF	F^{-1} in closed form or fast to solve; any discrete table	one uniform	F not invertible (Gaussian, most posteriors)
Box–Muller, polar	nothing: Gaussians	two uniforms per two normals	never; beware approximate shortcuts
Cholesky	covariance $\mathbf{C}$ ($n \times n$)	$n^3/3$ once, n^2 per draw	n large: use a diagonalising basis ($a_{\ell m}$, Fourier)
rejection	values of f up to a constant, envelope g, $M = \sup f/g$	M candidates	f/g unbounded; high dimension (M grows exponentially)
plain Monte Carlo integration	draws from f	error $\sigma/\sqrt{N}$ in any dimension	h concentrated where f rarely goes (σ huge)
importance sampling	values of f (up to a constant for the self-normalised form), g like $\lvert h\rvert f$	weights f/g	g thinner-tailed than f (infinite variance)
variance reduction	structure: monotone h, known $\int c$, smoothness	same N, smaller σ	error bars computed as if draws were independent
MCMC (Chapter 9)	values of f up to a constant, nothing else	correlated draws	poor mixing, multimodality

Going down the table, we need to know less and less about f, until Markov chain Monte Carlo needs only the ratio of f at two points, which is the posterior without its evidence (Chapter 5). The price is that the draws become correlated, and the $1/\sqrt{N}$ law then holds with N replaced by an effective number of independent draws [Lambert §12.2].

Recap

- $F(X)$ is uniform for any continuous X; so $X = F^{-1}(U)$ has CDF F. Decay times: $-\tau \ln(1-U)$. Power laws, isotropic directions and discrete tables follow the same way.
- Two uniforms give two exact Gaussians (Box–Muller): $R^2 = -2\ln U_1$ is exponential and the angle is uniform, by the polar Jacobian. $\boldsymbol{\mu} + \mathbf{L}\boldsymbol{z}$ with $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$ gives any Gaussian vector.
- Rejection: points uniform under Mg and kept under f are exact draws from f; acceptance $1/M$, geometric number of trials; needs f/g bounded.
- An integral is an expectation; its Monte Carlo estimate has error $\sigma/\sqrt{N}$ in any dimension, beating grids ($N^{-2/d}$) above about four dimensions. The acceptance of a detector is the verified example; with a dead region the simulation is the answer.
- Importance sampling reweights by f/g; its variance contains $\int h^2 f^2/g$, so g must have thicker tails than f. Self-normalised weights handle unnormalised posteriors.
- A histogram of samples estimates the bin-averaged density with binomial error $\sqrt{Np_k(1-p_k)}/(N\Delta)$; the oscillator at random times reproduces the arcsine density.
- Unfolding: the measured histogram is $\boldsymbol{\nu} = \mathbf{R}\boldsymbol{\mu} + \boldsymbol{\beta}$ with $R_{ij} = \mathrm{P}(\text{observed } i \mid \text{true } j)$ from simulation. The inverse $\mathbf{R}^{-1}\boldsymbol{n}$ is unbiased but divides each pattern by its gain ($e^{-q^2\sigma^2/2}$ for Gaussian smearing), so its variance explodes. Tikhonov curvature and iterated Bayes trade bias for variance; choose the strength by MSE or the L-curve, and check the coverage with toys.
- Antithetic pairs, control variates and stratification shrink σ at fixed N.

Reading the literature

- **The main line.** Wasserman, *All of Statistics*, Chapter 24: basic Monte Carlo integration, importance sampling with the tail rule, and the start of MCMC [Wasserman pp. 403–416]; Section 11.4 on simulating the posterior [Wasserman p. 180].
- **The physicist's chapter.** Cowan, *Statistical Data Analysis*, Chapter 3: uniform generators, the transformation method, acceptance–rejection, the $1/\sqrt{n}$ argument against quadrature, event generators and detector simulation.
- **Derivations.** Casella and Berger, *Statistical Inference*, Section 5.6: the probability integral transform, Box–Muller, discrete generation, the Accept/Reject theorem with its proof and the geometric number of trials.
- **Why sampling.** Lambert, *A Student's Guide to Bayesian Statistics*, Chapter 12 (the intractable denominator, grids, quadrature, independent sampling); Kruschke, *Doing Bayesian Data Analysis*, Section 7.1 (a distribution represented by a representative sample); Hobson et al. (eds.), *Bayesian Methods in Cosmology*, Chapter 3 (Monte Carlo methods for parameter estimation).
- **Generators.** Marsaglia on the lattice structure of congruential generators [122]; L'Ecuyer on combined and well-chosen LCGs [121, 123]; the Mersenne Twister [125]; xorshift [124]; PCG [127]; counter-based generators [128]; the TestU01 battery [126]; Sobol's sequences [129].
- **Sampling methods and physics codes.** Box and Muller [130]; Marsaglia and Bray's polar method [131]; the Pythia 8.3 manual [132] and the Geant4 toolkit paper [133] for sampling at the scale of a collider experiment; Metropolis et al. [36] for where Chapter 9 goes next.

Chapter summary

Turning a probability model into numbers takes three pieces of machinery. First, uniform numbers: a computer is deterministic, so its "random" numbers are the output of a finite machine, and they must be tested like any other null hypothesis. Second, transformations: given good uniform numbers, a few exact transformations turn them into draws from any distribution we can describe. Third, averages: averages over those draws give integrals, with an error $\sigma/\sqrt{N}$ that does not depend on the dimension. In the pipeline from physical model to inference,

$$\text{physical model} \to \text{field or dataset} \to \text{summary } S \to \boxed{P(S \mid \theta)} \to \text{infer physics},$$

Monte Carlo is the arrow into the sampling distribution: whenever the algebra of Chapters 2 and 3 gives out, we simulate the experiment many times and histogram the summary. Chapters 7 and 8 do this for fields and CMB maps, and Chapter 9 adapts it to densities we can only evaluate.

Random numbers on a deterministic machine

concept	operational meaning	used later in
Monty Hall as a test of the generator	The observed event is "Monty opened C". What made him open that door? The possible hypotheses are the three locations of the car, H_A, H_B, H_C. Under each we find the probability that Monty opens C: $\frac{1}{2}$ under H_A (he may open either goat door and tosses a coin), 1 under H_B (he must not open our door A and must not reveal the car), 0 under H_C (the car is there). Only then come the priors ($\frac{1}{3}$ each) and the normalisation, which give posterior probabilities $\frac{1}{3}, \frac{2}{3}, 0$. A simulation reproduces this only if its coin is fair, because a biased coin changes the probability of the event under H_A	every chapter
pseudorandom generator	a finite state, a transition function, an output function and a seed; reproducible, eventually periodic	every simulation
linear congruential generator	$x_{n+1} = (ax_n + c) \bmod m$; period at most m; low bits of a power-of-two modulus are poor	legacy codes
lattice structure, spectral test	t-tuples of an LCG lie on a lattice of parallel planes (RANDU: 15 planes in 3-D); the spectral test measures the largest gap between planes	Chapters 7 and 8
modern generators	bigger state and a nonlinear output function: xorshift, Mersenne Twister, PCG64 (numpy default), counter-based	every chapter
seeds and streams	SeedSequence hashes job identifiers into well-separated states; one stream per parallel job, never "seed = job number" by hand	Chapters 8 and 9
randomness tests	each test is a null hypothesis "the stream is i.i.d. uniform": χ^2 on histograms, serial correlation, runs; batteries such as TestU01	Chapter 4
quasi-random points	Sobol sequences fill the cube evenly; integration error close to $1/N$ instead of $1/\sqrt{N}$ for smooth integrands	Chapter 10

From uniform numbers to any distribution

concept	operational meaning	used later in
probability integral transform	$F(X) \sim \text{Uniform}(0,1)$ for continuous X; $F^{-1}(U)$ has CDF F	Chapters 4 and 8
inverse-CDF sampling	solve $F(x) = u$: decay times $-\tau \ln(1-u)$, power laws, isotropic directions ($\cos\theta = 2u-1$), discrete tables by cumulative sums	every simulation
Box–Muller, polar method	$R = \sqrt{-2\ln U_1}$, $\Theta = 2\pi U_2$ give two exact independent normals; the polar form keeps a fraction $\pi/4$	Chapters 7 to 9
Cholesky colouring	$\boldsymbol{\mu} + \mathbf{L}z$ with $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$ has covariance $\mathbf{C}$; for isotropic fields the factor is $\sqrt{C_\ell}$ per mode	Chapters 7, 8 and 10
rejection sampling	keep $V \sim g$ if $U\,Mg(V) < f(V)$; acceptance $1/M$; trials geometric; needs f/g bounded; hopeless in high dimension	Chapter 9

Integrals, errors and densities from samples

concept	operational meaning	used later in
Monte Carlo integration	write $I = \mathbb{E}_f[h]$, average h over draws from f, report $\hat{I} \pm s/\sqrt{N}$	every chapter
$1/\sqrt{N}$ law	$\text{Var}\,\hat{I} = \sigma^2/N$ from independence, Gaussian by the CLT; the rate is dimension-independent, the constant σ is not; grids lose above $d \approx 4$	Chapters 8 to 10
probability as a mean of an indicator	simulate and count; binomial error $\sqrt{p(1-p)/N}$ (acceptance, $\Phi(2)$, p-values by simulation)	Chapters 4 and 8
verification vs research	detector acceptance: the simulation checks $\Omega/4\pi$, then is the answer with a dead strip; event generators and detector simulation	Chapter 8
importance sampling	average hf/g over draws from g; variance $\int h^2 f^2/g - I^2$; g must have thicker tails than f; effective sample size $(\sum w)^2/\sum w^2$	Chapter 9
self-normalised weights	posterior averages $\sum \theta_j w_j / \sum w_j$ with $w = \mathcal{L}\pi/g$; the evidence cancels; reweighting of simulated events	Chapter 9
histogram as density	$n_k/(N\Delta)$ estimates the bin average p_k/Δ with error $\sqrt{Np_k(1-p_k)}/(N\Delta)$; oscillator position from random times; summaries (mode, HDI) from draws	Chapters 7, 9 and 12
variance reduction	antithetic pairs $\sigma^2(1+\rho)$, control variates $\sigma^2(1-\rho^2)$, stratification removes between-strata variance ($N^{-3/2}$ for smooth h)	Chapter 8

Chapter 7

Random Fields and the Angular Power Spectrum

Where this chapter is going

A cosmological model does not tell us that the microwave sky is hotter in the direction of Orion than in the direction of Leo. It tells us how strongly the temperature at two points a degree apart tends to agree, and how much the temperature fluctuates on each angular scale. The same is true of a turbulent flow, of the thermal ripples on a membrane, and of the noise in a detector: the theory predicts the *statistics* of a field, and nature hands us a single realisation of it. Everything that follows grows out of that one fact.

The object that carries the prediction is a random field: a random variable at every point of space, with a joint distribution for any finite set of points. When the statistics do not care where we stand or which way we look, the relation between two points depends only on their separation, and one function of distance, the correlation function $\xi(r)$, summarises it. For a Gaussian field that function is the whole story. Fourier modes turn the story into arithmetic: in a homogeneous field different wavevectors are uncorrelated, and the variance of each mode is the power spectrum $P(k)$, the Fourier transform of $\xi(r)$. Independent modes are also what make simulation cheap: colour white noise by $\sqrt{P(k)}$ and transform back. Because we live in one universe, the ensemble averages that define ξ and P must be replaced by averages over space, which is legitimate only when distant regions are nearly independent, and which leaves an irreducible scatter of $\sqrt{2/N_{\text{modes}}}$ on every measured power. Real maps are always smoothed by a beam, a pixel or a counting cell, and smoothing multiplies the power spectrum by $|W(k)|^2$. Finally, the power spectrum keeps the amplitude of each Fourier mode and throws away its phase. For a Gaussian field nothing is lost; for any other field the phases hold the shapes, and that is where the topological summaries of Chapter 12 will look.

On the book's pipeline (Chapter 0), where we decide what in a field carries the physics, compress it into a statistic S and work out how S scatters, $P(S \mid \theta)$, the two-point statistics $\xi(r)$, $P(k)$ and, on the sphere, C_ℓ are the first summaries of a field, and their sampling distributions can be derived exactly in the ideal case of a full, noise-free Gaussian field. Chapter 8 adds the mask, the beam and the noise.

7.1 A theory predicts the statistics of a field

Run CAMB with the Planck parameters (Chapter T1) and ask it for the temperature of the microwave sky in the direction of the Galactic north pole. It cannot answer. What it returns is the angular power spectrum C_ℓ: how much the temperature fluctuates, on average, on

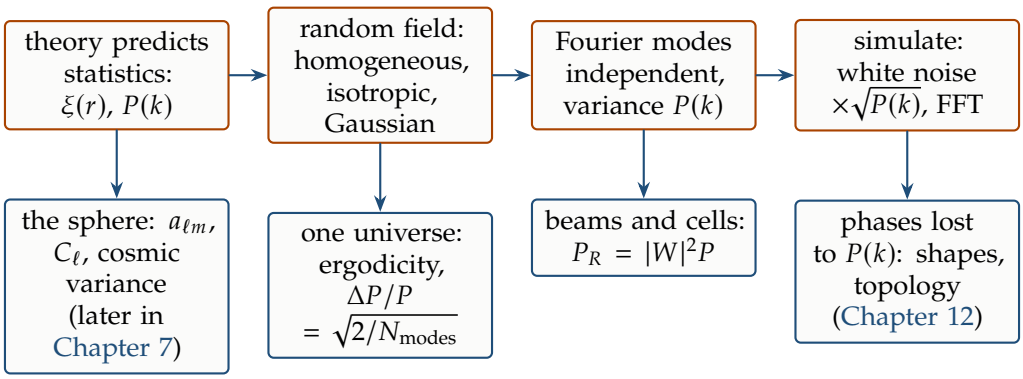

Figure 7.1: How the ideas of the chapter connect. The orange boxes are the backbone: the theory predicts statistics, a homogeneous field has independent Fourier modes, and independent modes make simulation cheap. The blue boxes are what happens when we confront one finite, smoothed realisation, and what the two-point summaries cannot see.

each angular scale. The particular pattern of hot and cold spots that the Planck satellite photographed was set by quantum fluctuations during inflation, and no theory predicts which way those fluctuations happened to fall. The same holds for the matter density of the universe (the theory gives $P(k)$, not the position of the Coma cluster), for the velocity field in a turbulent jet (Kolmogorov gives the spectrum of eddies, not the eddy behind the third bolt), and for the voltage noise in a detector (the noise spectral density, not the next sample). In each case the prediction is a probability distribution over *whole fields*, and the data are one draw from it.

So every inference problem about a field has the same shape. What we observed is one map. The candidate explanations are the possible parameter values, and each one fixes a probability distribution over maps. For each candidate we must be able to say how probable a map like ours would have been. Two things are needed before any of that: a way to write down a probability distribution over functions of position, and a way to compress such a distribution into a few numbers that we can compute from one map.

7.1.1 A random field is a random variable at every point

Think of a temperature map stored on a grid of n pixels. As far as statistics is concerned it is a list of n numbers, so a random map is a random vector $\big(\delta(\boldsymbol{x}_1), \ldots, \delta(\boldsymbol{x}_n)\big)$, exactly the kind of object whose joint density, means and covariance matrix we met in Chapter 1 and whose Gaussian version we built in Chapter 2. A continuous field is the same idea with a random variable attached to every point of space. Any question we actually ask involves finitely many points at a time, so the definition only needs to say what happens at finite sets of points.

Working definition 7.1 (random field)

A **random field** $\delta(\boldsymbol{x})$ on a domain $\mathcal{M}$ (a line, a plane, a box, the sphere) is a collection of random variables, one for each point $\boldsymbol{x} \in \mathcal{M}$, together with the joint density $p\big(\delta(\boldsymbol{x}_1), \ldots, \delta(\boldsymbol{x}_n)\big)$ for every finite set of points $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ [the n-point distributions]. These must be consistent: integrating $\delta(\boldsymbol{x}_n)$ out of the n-point density gives the $(n-1)$-point density of the remaining points. *Operationally:* a random field is a recipe that, run once, produces a whole map, and run many times produces many different maps with the same statistics.

The consistency condition is marginalisation (Chapter 1). To study the field at a few points, we average out the field at every other point, treating it as a nuisance variable; the answer must not depend on how many other points we started with. Throughout, δ is a *fluctuation*. For

matter it is the density contrast $\delta(\boldsymbol{x}) = \rho(\boldsymbol{x})/\bar{\rho} - 1$, the fractional excess of density over its mean $\bar{\rho}$; for the CMB it is $\Delta T/T_0$; for a detector it is the voltage minus its average. A fluctuation has zero mean by construction.

To picture a random field, think of the **ensemble**: an imaginary stack of universes, all made by the same physics but with different random draws (Figure 7.2). "The mean of δ at $\boldsymbol{x}$" means the average down the stack: fix the point $\boldsymbol{x}$ and average over all the universes. It does *not* mean the average over the points of our one map. Whether the two averages agree is a real question, and Section 7.5 answers it.

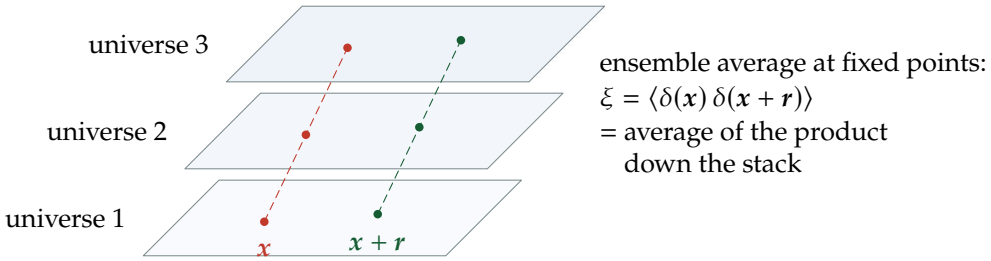

Figure 7.2: The ensemble. Each sheet is one universe, a complete realisation of the field. Statistical statements about the points $\boldsymbol{x}$ (red) and $\boldsymbol{x} + \boldsymbol{r}$ (green) are averages down the stack, along the dashed lines, not across one sheet.

The simplest summaries of a random field are the ones we know for random vectors, now indexed by position. The **mean** is $\mu(\boldsymbol{x}) = \mathbb{E}[\delta(\boldsymbol{x})]$, written $\langle\delta(\boldsymbol{x})\rangle$ in physics, with angle brackets meaning the ensemble average. The **covariance function** is the covariance of the field at two points,

$$C(\boldsymbol{x}, \boldsymbol{y}) = \mathrm{Cov}\big(\delta(\boldsymbol{x}), \delta(\boldsymbol{y})\big) = \langle\delta(\boldsymbol{x})\delta(\boldsymbol{y})\rangle - \mu(\boldsymbol{x})\mu(\boldsymbol{y}), \tag{7.1}$$

the definition of covariance of [Cowan (1.46)] and [Wasserman p. 52, Def. 3.18] with the two random variables being the field at two places. On the diagonal it is the variance, $C(\boldsymbol{x}, \boldsymbol{x}) = \mathrm{Var}\,\delta(\boldsymbol{x})$. On a grid of n pixels, $C(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is simply the $n \times n$ covariance matrix $\mathbf{C}_{ij}$ of the map.

7.1.2 Statistical homogeneity and isotropy

A general covariance function depends on two points, which is far too much to measure from one map. A symmetry usually saves us. The laws that made the field are the same everywhere and in every direction, so the *statistics* of the field should be the same everywhere and in every direction too, even though any one realisation is lumpy.

Working definition 7.2 (statistical homogeneity and isotropy)

A random field is **statistically homogeneous** if all its n-point distributions are unchanged by a common shift of the points, $p\big(\delta(\boldsymbol{x}_1 + \boldsymbol{a}), \ldots, \delta(\boldsymbol{x}_n + \boldsymbol{a})\big) = p\big(\delta(\boldsymbol{x}_1), \ldots, \delta(\boldsymbol{x}_n)\big)$ for every $\boldsymbol{a}$ [the ensemble cannot tell where we are standing]. It is **statistically isotropic** if they are also unchanged by a common rotation of the points about any centre [the ensemble cannot tell which way we are looking]. *Test:* the mean is the same at every point, and the covariance of two points depends only on their separation vector (homogeneity), and only on its length (isotropy).

The test in the definition follows in two lines. Homogeneity applied to the one-point distribution says that $\delta(\boldsymbol{x} + \boldsymbol{a})$ has the same distribution as $\delta(\boldsymbol{x})$, so the mean is a constant, which for a fluctuation is zero. Applied to the two-point distribution with the shift $\boldsymbol{a} = -\boldsymbol{y}$:

$$C(\boldsymbol{x}, \boldsymbol{y}) \overset{(1)}{=} \langle\delta(\boldsymbol{x})\delta(\boldsymbol{y})\rangle \overset{(2)}{=} \langle\delta(\boldsymbol{x} - \boldsymbol{y})\,\delta(\boldsymbol{0})\rangle \overset{(3)}{=} \xi(\boldsymbol{x} - \boldsymbol{y}). \tag{7.2}$$

(1) The mean is zero, so the covariance (7.1) is the average of the product.
(2) Homogeneity: the pair of points $(\boldsymbol{x}, \boldsymbol{y})$ and the pair shifted by $-\boldsymbol{y}$, which is $(\boldsymbol{x}-\boldsymbol{y}, \boldsymbol{0})$, have the same joint distribution, so the average of the product is the same.
(3) The result depends on $\boldsymbol{x}$ and $\boldsymbol{y}$ only through the separation $\boldsymbol{r} = \boldsymbol{x}-\boldsymbol{y}$; we give that function its own name, $\xi(\boldsymbol{r})$.

Isotropy adds that rotating the separation vector does not change the answer, so ξ depends only on the distance $r = |\boldsymbol{r}|$. This is the **two-point correlation function**,

$$\xi(r) = \langle \delta(\boldsymbol{x})\, \delta(\boldsymbol{x}+\boldsymbol{r}) \rangle, \tag{7.3}$$

the same at every $\boldsymbol{x}$ and in every direction of $\boldsymbol{r}$. On the sky the separation is an angle, and (7.3) becomes $\langle \frac{\Delta T}{T_0}(\hat{\boldsymbol{x}}) \frac{\Delta T}{T_0}(\hat{\boldsymbol{y}}) \rangle = C(\arccos \hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{y}})$, with isotropy embodied in the dependence on the angle alone [HobsonBMC p. 230, (10.1)].

The question ξ answers. Pick two points of the field a distance r apart. How strongly is the fluctuation at the first point related to the fluctuation at the second? If the field is above its mean at one point, how much does that tell us about whether it is above its mean at the other? The correlation function answers this with one number for each separation r.

A homogeneous field is not a smooth one. Each realisation in Figure 7.3 below is full of hot and cold patches. Homogeneity says only that a patch is equally likely to sit anywhere, so that, averaged over the ensemble, no place is special.

Properties every correlation function has. Four facts follow straight from (7.3), and they are the checks to run on any ξ someone hands us.

1. $\xi(0) = \langle \delta^2 \rangle = \sigma^2$, the variance of the field at a point.
2. $\xi(-\boldsymbol{r}) = \xi(\boldsymbol{r})$: put $\boldsymbol{x}' = \boldsymbol{x} + \boldsymbol{r}$ in (7.3), so $\langle \delta(\boldsymbol{x})\delta(\boldsymbol{x}+\boldsymbol{r}) \rangle = \langle \delta(\boldsymbol{x}'-\boldsymbol{r})\delta(\boldsymbol{x}') \rangle = \xi(-\boldsymbol{r})$.
3. $|\xi(r)| \le \xi(0)$. The Cauchy–Schwarz inequality for averages, $\langle XY \rangle^2 \le \langle X^2 \rangle \langle Y^2 \rangle$, with $X = \delta(\boldsymbol{x})$, $Y = \delta(\boldsymbol{x}+\boldsymbol{r})$ gives $\xi(r)^2 \le \sigma^2 \cdot \sigma^2$. Equivalently, the **correlation coefficient** $\rho(r) = \xi(r)/\xi(0)$ lies in $[-1, 1]$, as every correlation coefficient must [Wasserman p. 53, Thm. 3.19].
4. ξ is *positive definite*: for any points $\boldsymbol{x}_i$ and real weights a_i,

$$0 \overset{(1)}{\le} \operatorname{Var}\Big(\sum_i a_i\, \delta(\boldsymbol{x}_i) \Big) \overset{(2)}{=} \sum_{i,j} a_i a_j \operatorname{Cov}\big(\delta(\boldsymbol{x}_i), \delta(\boldsymbol{x}_j) \big) \overset{(3)}{=} \sum_{i,j} a_i a_j\, \xi(\boldsymbol{x}_i - \boldsymbol{x}_j). \tag{7.4}$$

   (1) A variance is never negative.
   (2) The variance of a linear combination is the double sum of covariances [Wasserman p. 53, Thm. 3.20].
   (3) Homogeneity, (7.2).

   So the matrix $\xi(\boldsymbol{x}_i - \boldsymbol{x}_j)$ built from any set of points is a valid covariance matrix. Not every even function bounded by $\xi(0)$ passes this test; Section 7.3 turns it into a one-line check in Fourier space.

Example: white noise. A CCD with independent read noise in each pixel, of standard deviation σ_n, is the simplest random field. Different pixels are independent, so $\langle \delta_i \delta_j \rangle = 0$ for $i \ne j$ and σ_n^2 for $i = j$:

$$\xi(\boldsymbol{r}) = \sigma_n^2\, \delta_{\boldsymbol{r},\boldsymbol{0}},$$

a spike at zero separation and nothing elsewhere ($\delta_{r,\mathbf{0}}$ is the Kronecker delta, 1 if $\boldsymbol{r}=\mathbf{0}$ and 0 otherwise). It is homogeneous and isotropic, and knowing one pixel tells us nothing about its neighbour.

Example: a detector that averages. Suppose instead each recorded sample is the average of m consecutive white-noise values, $\delta_i = \frac{1}{m}\sum_{j=0}^{m-1} w_{i+j}$, with w_j independent, mean zero and variance σ_w^2. This is what an integrating amplifier, or a one-dimensional beam of width m pixels, does. For a lag $r \geq 0$,

$$\xi(r) = \langle \delta_i\, \delta_{i+r}\rangle \overset{(1)}{=} \frac{1}{m^2}\sum_{j=0}^{m-1}\sum_{l=0}^{m-1}\langle w_{i+j}\, w_{i+r+l}\rangle \overset{(2)}{=} \frac{\sigma_w^2}{m^2}\,\#\{(j,l):\ j=r+l,\ 0\leq j,l\leq m-1\}$$
$$\overset{(3)}{=} \frac{\sigma_w^2}{m^2}\,(m-r) \quad (0\leq r<m), \qquad \xi(r)=0 \quad (r\geq m). \tag{7.5}$$

(1) Insert the definition of both samples and use linearity of the average.
(2) $\langle w_a w_b\rangle$ is σ_w^2 when $a=b$ and zero otherwise, so the double sum counts the pairs with $i+j=i+r+l$, that is $j=r+l$.
(3) For each $l=0,\ldots,m-1-r$ there is exactly one $j=r+l\leq m-1$, so there are $m-r$ such pairs; when $r\geq m$ there are none.

The correlation function is a triangle: $\xi(0)=\sigma_w^2/m$ (averaging m independent values divides the variance by m), it falls linearly, and it vanishes beyond the averaging length, where two samples share no input. For $m=4$ and $\sigma_w=1$: $\xi = 0.25,\ 0.1875,\ 0.125,\ 0.0625,\ 0$ at $r=0,\ldots,4$. The lesson holds for any smoothing: averaging over a length makes the field correlated over that length (Section 7.6).

Example: when the symmetries fail. Real data can break both symmetries, even when the underlying field has them. Homogeneity first. A galaxy survey observes the sky to different depths in different directions, so the noise added to the density map has a variance $\sigma_n^2(\boldsymbol{x})$ that changes with position. The covariance of the observed map is $\xi(\boldsymbol{x}-\boldsymbol{y})+\sigma_n^2(\boldsymbol{x})\delta_{\boldsymbol{xy}}$, with $\delta_{\boldsymbol{xy}}$ the Kronecker delta (noise in different pixels is independent). This depends on where the pair is, not only on its separation, so the observed field is *not* homogeneous even if the underlying density is. Isotropy fails in a subtler way. Galaxy distances are inferred from redshifts. Galaxies falling into dense regions have extra (peculiar) velocities along our line of sight, and these squash structures along that direction. So ξ measured in redshift space depends on the angle between $\boldsymbol{r}$ and the line of sight [103]. Both effects are real, and both are handled by modelling them on top of a homogeneous, isotropic field.

Seeing the ensemble. The script `code/ch07/01_ensemble_two_points.py` makes $M=3000$ universes: two-dimensional fields on 128×128 unit cells with the Gaussian correlation function $\xi(r)=e^{-r^2/2\ell^2}$, $\ell=4$ cells. (Section 7.4 shows how such fields are made; here we only look at them.) The question is the one ξ answers: does the value at one point tell us about the value a distance r away? At a fixed point $\boldsymbol{x}_0$ the script records $\delta(\boldsymbol{x}_0)$ and $\delta(\boldsymbol{x}_0+\boldsymbol{r})$ in every universe, for $r=2$, 6 and 15 cells, and plots one against the other (Figure 7.3). At $r=2$ the cloud is a narrow ellipse: a hot $\boldsymbol{x}_0$ almost always has a hot neighbour. At $r=6$ the ellipse is fat, and at $r=15$ it is round. The ensemble average of the product is 0.8555, 0.3074 and -0.01811, against $\xi=0.8825$, 0.3247 and ≈ 0.001. Each estimate is within one or two standard errors of the truth. (For two unit-variance Gaussians with correlation ρ, one product has mean ρ and mean square $1+2\rho^2$, by (7.9) below, so its variance is $1+\rho^2$; the average of M products then has standard error $\sqrt{(1+\rho^2)/M}$, between $1/\sqrt{M}\approx0.01826$ and 0.024 here.) Repeating the measurement at a

different point $\boldsymbol{x}_1$ gives 0.8934, 0.3203 and −0.006406: the same function of r, as homogeneity demands.

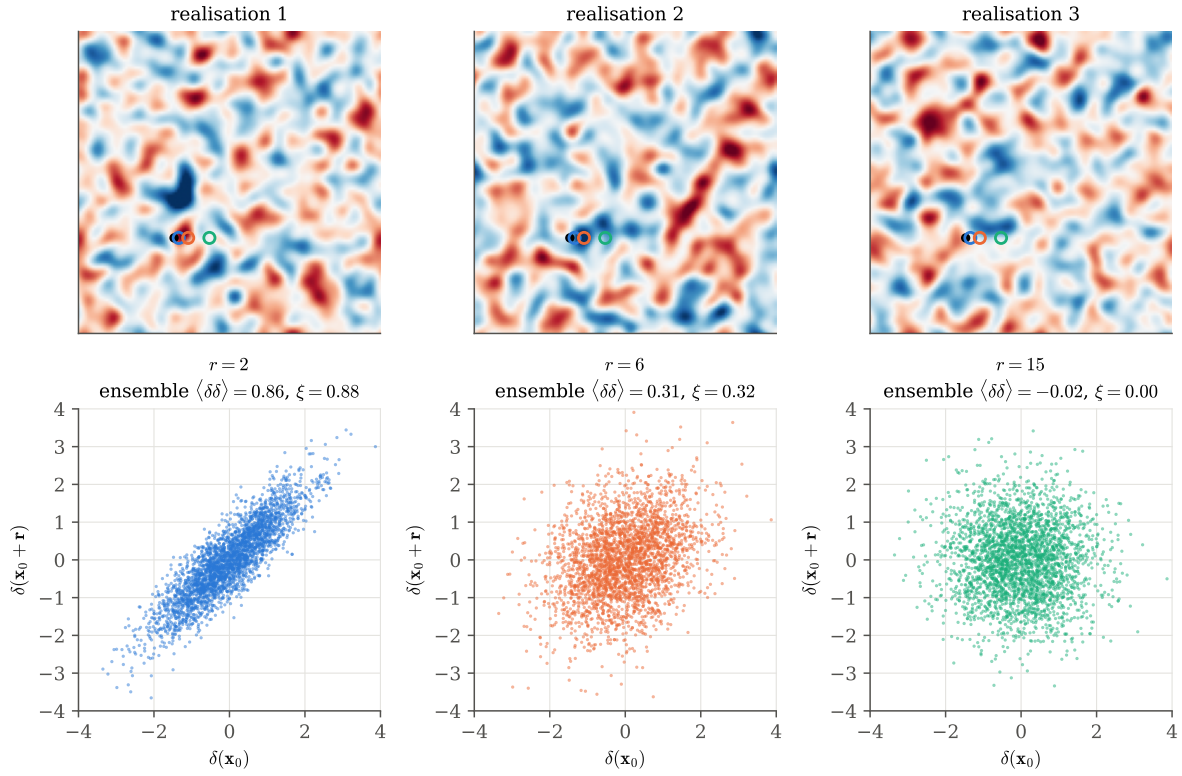

Figure 7.3: Top: three universes drawn from the same Gaussian random field. The black dot is the fixed point $\boldsymbol{x}_0$; the coloured circles are the points 2, 6 and 15 cells to its right. Bottom: the pair $\big(\delta(\boldsymbol{x}_0), \delta(\boldsymbol{x}_0 + \boldsymbol{r})\big)$ collected over 3000 universes. Close points rise and fall together, distant points are unrelated, and the average of the product traces $\xi(r)$.

Watch out: A correlation function is not a property of one map

Each realisation in Figure 7.3 has its own hot and cold spots, and in none of them is the field "homogeneous" in the everyday sense. Homogeneity, isotropy and $\xi(r)$ are properties of the ensemble. Measuring them from one map requires an extra assumption, ergodicity, and carries an irreducible error (Section 7.5).

The correlation function squeezes a whole distribution over maps into one function of one variable. How much of the distribution survives? In general, very little: the n-point distributions can do almost anything that an average over pairs does not see. But there is one large class of fields, and the most important one in physics, for which ξ captures everything.

7.2 Gaussian random fields: when two points tell the whole story

A random field is specified by all of its n-point distributions, for every n and every placement of the points. That is an infinite amount of information, and no experiment will ever pin it down. The microwave background spares us this. To the precision of every test so far, its temperature fluctuations are a *Gaussian* field [HobsonBMC p. 229], and for a Gaussian field the infinite tower collapses to a single function: once we know the mean and $\xi(r)$, we know every n-point distribution. This is why the whole of CMB cosmology can be phrased in terms of a power spectrum.

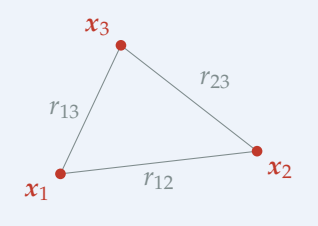
Working definition 7.3 (Gaussian random field)

A random field is **Gaussian** if for every finite set of points $\boldsymbol{x}_1, \dots, \boldsymbol{x}_n$ the vector $\boldsymbol{\delta} = (\delta(\boldsymbol{x}_1), \dots, \delta(\boldsymbol{x}_n))$ has a multivariate Gaussian density [the density of Chapter 2, fixed by a mean vector and a covariance matrix]. For a homogeneous, isotropic, zero-mean Gaussian field the covariance matrix is read off the correlation function, $\mathbf{C}_{ij} = \xi(|\boldsymbol{x}_i - \boldsymbol{x}_j|)$, so

$$p(\boldsymbol{\delta}) = \frac{1}{(2\pi)^{n/2}\sqrt{\det \mathbf{C}}} \exp\!\left(-\tfrac{1}{2}\,\boldsymbol{\delta}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{\delta}\right). \tag{7.6}$$

Consequence: $\xi(r)$ determines every n-point distribution.

Figure 7.4 shows the construction for three points. Write down the three separations, look up ξ at each, fill the symmetric matrix, and (7.6) is the joint density of the three field values. Nothing else about the field enters. Consistency, the marginalisation condition in the definition of a random field, holds automatically: integrating one variable out of a multivariate Gaussian leaves the Gaussian of the remaining ones with the corresponding sub-block of $\mathbf{C}$ (Chapter 2), which is exactly the matrix we would have built for the smaller set of points.



$$\mathbf{C} = \begin{pmatrix} \xi(0) & \xi(r_{12}) & \xi(r_{13}) \\ \xi(r_{12}) & \xi(0) & \xi(r_{23}) \\ \xi(r_{13}) & \xi(r_{23}) & \xi(0) \end{pmatrix}$$

$$\big(\delta(\boldsymbol{x}_1), \delta(\boldsymbol{x}_2), \delta(\boldsymbol{x}_3)\big) \sim \mathcal{N}(\mathbf{0}, \mathbf{C})$$

Figure 7.4: For a Gaussian field the joint distribution at any set of points is built from the separations alone. Three points give three distances; the correlation function at those distances fills the covariance matrix, and the multivariate Gaussian with that matrix is the joint law of the three values.

Why so many physical fields are Gaussian. Three mechanisms recur, one at a time. *Many small causes.* When the value at a point is the sum of many small independent contributions, as the voltage across a resistor sums the kicks of many electrons, the central limit theorem (Chapter 2) makes it Gaussian. The same argument applied to the values at any finite set of points makes them jointly Gaussian. *Quantum vacuum.* Quantum fluctuations of a free field in its vacuum state are Gaussian, and the simplest models of inflation stretch exactly such fluctuations to cosmological size. *Linear evolution.* A linear map $\mathbf{A}$ applied to a Gaussian vector gives another Gaussian vector, with covariance $\mathbf{A}\mathbf{C}\mathbf{A}^{\mathsf{T}}$ (Chapter 1). The CMB fluctuations have amplitude 10^{-5}, so the equations that evolve them are linear, and an initially Gaussian field stays Gaussian [HobsonBMC p. 230]. Gaussianity is lost when evolution is non-linear. Gravitational collapse turns the nearly Gaussian early matter field into a skewed web of halos and filaments; this is the regime where the linear and halofit spectra of Chapter T1 part company.

7.2.1 What Gaussianity predicts

Because the whole distribution is fixed by ξ, a Gaussian field makes sharp predictions that we can check on a map. We need three of them repeatedly.

The pair distribution. For two points a distance r apart, (7.6) with $n = 2$ is a bivariate Gaussian. After dividing each value by σ (so both have unit variance), its correlation coefficient

is $\rho(r) = \xi(r)/\sigma^2$, with $\sigma^2 = \xi(0)$ the variance at a point. Its contours are ellipses along the diagonal, narrow when ρ is near 1 and circular when $\rho = 0$ (Figure 7.5, left). These are the clouds of Figure 7.3, now drawn from the formula.

The field around a hot spot. *What we observed.* A point where the field is high, $\delta(\boldsymbol{x}) = \nu\sigma$: the field sits ν standard deviations above its mean. *The question.* What should we expect a distance r away? *The idea.* Split the second value into a part that the first value predicts and a remainder Z that it says nothing about,

$$\delta(\boldsymbol{x}+\boldsymbol{r}) = \frac{\xi(r)}{\sigma^2}\,\delta(\boldsymbol{x}) + Z.$$

This equation defines Z, and the coefficient $\xi(r)/\sigma^2$ is chosen so that Z is uncorrelated with $\delta(\boldsymbol{x})$: $\operatorname{Cov}(Z, \delta(\boldsymbol{x})) = \xi(r) - \frac{\xi(r)}{\sigma^2}\sigma^2 = 0$. Z is a linear combination of the Gaussian pair, so Z and $\delta(\boldsymbol{x})$ are jointly Gaussian, and for jointly Gaussian variables uncorrelated means independent. Knowing $\delta(\boldsymbol{x})$ therefore tells us nothing about Z, and

$$\begin{aligned}\mathbb{E}\big[\delta(\boldsymbol{x}+\boldsymbol{r}) \,\big|\, \delta(\boldsymbol{x}) = \nu\sigma\big] &\overset{(1)}{=} \frac{\xi(r)}{\sigma^2}\,\nu\sigma + \mathbb{E}[Z] \overset{(2)}{=} \nu\sigma\,\frac{\xi(r)}{\sigma^2}, \\ \operatorname{Var}\big[\delta(\boldsymbol{x}+\boldsymbol{r}) \,\big|\, \delta(\boldsymbol{x}) = \nu\sigma\big] &\overset{(3)}{=} \operatorname{Var} Z \overset{(4)}{=} \sigma^2 - \frac{\xi(r)^2}{\sigma^2}.\end{aligned} \tag{7.7}$$

(1) Conditioning on $\delta(\boldsymbol{x}) = \nu\sigma$ fixes the first term; Z is independent of $\delta(\boldsymbol{x})$, so its distribution is unchanged.
(2) Z is a combination of zero-mean variables.
(3) The first term is fixed by the condition, so only Z fluctuates.
(4) $\operatorname{Var} Z = \operatorname{Var}\delta(\boldsymbol{x}+\boldsymbol{r}) - \frac{\xi^2}{\sigma^4}\operatorname{Var}\delta(\boldsymbol{x}) = \sigma^2 - \xi^2/\sigma^2$, using the independence just shown.

What it means. The mean profile around a point of height $\nu\sigma$ is the correlation function itself, scaled by ν/σ: a hot spot is surrounded by warm field out to the correlation length. This is the seed of the theory of peaks and clusters in [106]. If instead of a single height we select all points above a threshold, $\delta > \nu\sigma$, we average (7.7) over the heights of the selected points (the tower property of expectation). The conditional mean is proportional to the height, so the average simply replaces $\nu\sigma$ by the mean height $\bar{\nu}\sigma$ of the selected points.

The script `code/ch07/02_gaussian_checks.py` tests this on one 512×512 map with $\xi = e^{-r^2/2\ell^2}$, $\ell = 4$. A fraction 0.02405 of the pixels exceed 2σ (the Gaussian tail gives 0.0228), and their mean height is $\bar{\nu} = 2.379$ (the Gaussian value is $\varphi(2)/[1-\Phi(2)] = 2.373$, with φ and Φ the standard normal density and CDF). Four cells to their right the average field is 1.478, against $\bar{\nu}\,\xi(4)/\sigma^2 = 1.443$, and the whole profile follows (7.7) (Figure 7.5, middle). The small excess at large r is noise: the selected pixels belong to a few hundred hot spots, so the average beyond the correlation length scatters by about $1/\sqrt{\text{a few hundred}} \approx 0.05$.

Four-point moments from two-point ones. A Gaussian field carries no new information at higher order: every moment is built from ξ. *The question.* What is the average of a product of four field values? *The tool.* The moment generating function of a zero-mean Gaussian vector (Chapters 1 and 2), $\mathbb{E}\big[e^{\boldsymbol{t}^{\mathsf{T}}\boldsymbol{\delta}}\big] = e^{\frac{1}{2}\boldsymbol{t}^{\mathsf{T}}\mathbf{C}\boldsymbol{t}}$. Expand both sides in powers of $\boldsymbol{t}$: on the left each coefficient is a moment, on the right it is built from $\mathbf{C}$ alone. Matching coefficients gives the answer. For four field values $\delta_1, \dots, \delta_4$ (not necessarily at distinct points) and $C_{ij} = \langle \delta_i \delta_j \rangle$:

$$\begin{aligned}\langle \delta_1\delta_2\delta_3\delta_4 \rangle &\overset{(1)}{=} \Big[\text{coefficient of } t_1t_2t_3t_4 \text{ in } \mathbb{E}\; e^{\boldsymbol{t}^{\mathsf{T}}\boldsymbol{\delta}}\Big] \overset{(2)}{=} \Big[\text{coefficient of } t_1t_2t_3t_4 \text{ in } \tfrac{1}{2!}\big(\tfrac{1}{2}\textstyle\sum_{ij} C_{ij}t_it_j\big)^2\Big] \\ &\overset{(3)}{=} \tfrac{1}{8}\cdot 8\,\big(C_{12}C_{34} + C_{13}C_{24} + C_{14}C_{23}\big) \overset{(4)}{=} C_{12}C_{34} + C_{13}C_{24} + C_{14}C_{23}.\end{aligned} \tag{7.8}$$

(1) Expanding $e^{\boldsymbol{t}^\mathsf{T}\boldsymbol{\delta}}$, the term $t_1t_2t_3t_4$ appears only from $\frac{1}{4!}(\boldsymbol{t}^\mathsf{T}\boldsymbol{\delta})^4$, where it occurs 4! times with coefficient $\delta_1\delta_2\delta_3\delta_4$; so its coefficient in the average is the four-point moment.

(2) In $e^{\frac{1}{2}\boldsymbol{t}^\mathsf{T}\mathbf{C}\boldsymbol{t}} = 1 + \frac{1}{2}\boldsymbol{t}^\mathsf{T}\mathbf{C}\boldsymbol{t} + \frac{1}{2!}(\frac{1}{2}\boldsymbol{t}^\mathsf{T}\mathbf{C}\boldsymbol{t})^2 + \dots$ only the quadratic power of the exponent has terms of fourth order in $\boldsymbol{t}$.

(3) $(\sum_{ij} C_{ij}t_it_j)^2 = \sum_{ijkl} C_{ij}C_{kl}t_it_jt_kt_l$. The term $t_1t_2t_3t_4$ arises when (i,j,k,l) is an ordering of $(1,2,3,4)$: 24 orderings, which split the four indices into one of the three pairings, each pairing reached in $2\times2\times2 = 8$ ways (which pair comes first, and the order inside each pair). The prefactor is $\frac{1}{2}\cdot\frac{1}{4} = \frac{1}{8}$.

(4) Simplify.

This is **Isserlis' theorem**, called Wick's theorem in field theory: the four-point function is the sum over the three ways of pairing the points, and every odd moment vanishes (the exponent is even in $\boldsymbol{t}$). Setting $\delta_3 = \delta_1$ and $\delta_4 = \delta_2$ at two points a distance r apart,

$$\langle \delta(\boldsymbol{x})^2\, \delta(\boldsymbol{x}+\boldsymbol{r})^2 \rangle = \sigma^4 + 2\,\xi(r)^2, \tag{7.9}$$

and at $r = 0$ this is the familiar $\langle\delta^4\rangle = 3\sigma^4$ of a single Gaussian. Equation (7.9) gives a test of Gaussianity that needs nothing but the map: measure both sides and compare. For the Gaussian map the ratio of the two sides is 0.9949 at $r = 0$ and 1.009 at $r = 6$. For a lognormal field, $y = e^{0.8\,\delta}$ standardised to zero mean and unit variance, a common model for the non-linear matter density, the same ratio is 9.061 at $r = 0$ and 2.823 at $r = 6$ (Figure 7.5, right). The lognormal field has a perfectly good two-point function, but that function no longer predicts its four-point function: the lognormal field carries information beyond ξ.

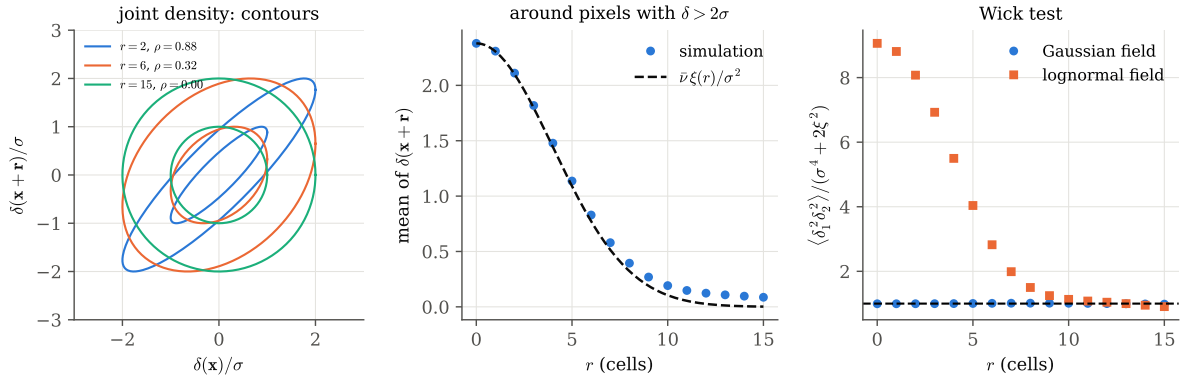


Figure 7.5: Three predictions of Gaussianity. Left: the 1σ and 2σ contours of the joint density of the field at two points, for three separations. Middle: the mean field at distance r from pixels above 2σ (dots) follows the scaled correlation function (dashed). Right: the four-point moment $\langle\delta_1^2\delta_2^2\rangle$ divided by its Gaussian prediction $\sigma^4 + 2\xi^2$ is 1 for a Gaussian map and far from 1 for a lognormal map.

Key idea: For a Gaussian field, $\xi(r)$ is everything

A homogeneous, isotropic Gaussian random field is completely specified by its mean and its correlation function. All n-point distributions follow from (7.6), all higher moments are sums over pairings (7.8), and the conditional field around any feature is a linear function of ξ. A summary that captures ξ (or its Fourier transform) loses nothing. For a non-Gaussian field the same summary is incomplete.

The part of the four-point function that is *not* the sum over pairings, $\langle\delta_1\delta_2\delta_3\delta_4\rangle - (C_{12}C_{34} + C_{13}C_{24} + C_{14}C_{23})$, is called the connected four-point function; its Fourier transform is the trispectrum, and the Fourier transform of the three-point function is the bispectrum. They

are the "higher-order" row of the taxonomy in Section 7.7, and they vanish identically for a Gaussian field.

From here on the working model is a homogeneous, isotropic Gaussian field, whose one free function is $\xi(r)$. In pixel variables its covariance matrix $\mathbf{C}_{ij} = \xi(|\boldsymbol{x}_i - \boldsymbol{x}_j|)$ is full: every pixel is correlated with its neighbours. The natural question is whether some other set of variables makes that matrix diagonal, so that the variables are independent.

7.3 Fourier modes and the power spectrum

A Gaussian map of a million pixels is a Gaussian vector with a million-by-million covariance matrix. To simulate it with the Cholesky factor of Chapter 6 costs about $n^3/3 \approx 3 \times 10^{17}$ operations, and to evaluate its likelihood (7.6) needs the inverse and the determinant of the same matrix. Both are hopeless. Yet the matrix is far from arbitrary: by homogeneity, every entry depends only on the separation of the two pixels. That structure is enough to diagonalise it without computing anything.

The question. In which variables is a homogeneous field a set of *uncorrelated* random numbers, and what are their variances?

The general tool. Any set of correlated random variables x_j with a symmetric covariance matrix V can be rotated into uncorrelated ones, $y_i = \sum_j A_{ij} x_j$: take the rows of A to be the eigenvectors of V. The variances of the y_i are then the eigenvalues of V [Cowan §1.7, (1.61)–(1.65)]. For a general matrix the eigenvectors must be found numerically. *The homogeneous case.* Here we know the eigenvectors in advance: they are plane waves. The reason is the one familiar from physics. A Hamiltonian that is unchanged by translations commutes with the translation operator, so both can be diagonalised together, by momentum eigenstates $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$. For the same reason the normal modes of a uniform chain of masses and springs are waves. A homogeneous covariance is also unchanged by translations, so its eigenvectors are plane waves too.

7.3.1 Four pixels by hand

Take a ring of $n = 4$ pixels, a periodic line so that pixel 4 is pixel 0 again. Homogeneity says the covariance of pixels i and j is ξ of their distance around the ring, so with $\xi_0 = \xi(0)$, $\xi_1 = \xi(1)$ and $\xi_2 = \xi(2)$,

$$\mathbf{C} = \begin{pmatrix} \xi_0 & \xi_1 & \xi_2 & \xi_1 \\ \xi_1 & \xi_0 & \xi_1 & \xi_2 \\ \xi_2 & \xi_1 & \xi_0 & \xi_1 \\ \xi_1 & \xi_2 & \xi_1 & \xi_0 \end{pmatrix}.$$

Each row is the row above shifted one place to the right, with wrap-around: a **circulant** matrix. Try the plane wave $e^{(m)}_j = e^{2\pi i\, jm/4}$, $j = 0, \dots, 3$, for an integer wavenumber m. Its first component after multiplication by $\mathbf{C}$ is

$$(\mathbf{C}e^{(m)})_0 = \xi_0 + \xi_1 e^{2\pi i m/4} + \xi_2 e^{2\pi i\, 2m/4} + \xi_1 e^{2\pi i\, 3m/4} \overset{(1)}{=} \xi_0 + 2\xi_1 \cos\frac{\pi m}{2} + \xi_2 \cos(\pi m),$$

(1) $e^{2\pi i\, 3m/4} = e^{-2\pi i m/4}$, so the two ξ_1 terms add to $2\xi_1 \cos(\pi m/2)$; and $e^{i\pi m} = \cos \pi m$ is real.

and every other row gives the same number times $e^{(m)}_j$, because row j is row 0 shifted by j and the plane wave picks up exactly the factor $e^{2\pi i jm/4}$ under that shift. So $\mathbf{C}e^{(m)} = \lambda_m e^{(m)}$ with

$$\lambda_0 = \xi_0 + 2\xi_1 + \xi_2, \qquad \lambda_1 = \lambda_3 = \xi_0 - \xi_2, \qquad \lambda_2 = \xi_0 - 2\xi_1 + \xi_2.$$

With $\xi_0 = 1$, $\xi_1 = 0.5$, $\xi_2 = 0.2$ the eigenvalues are 2.2, 0.8, 0.2, 0.8. They are the variances of the four Fourier coefficients of the map: large for the smooth mode $m = 0$, small for the zig-zag mode $m = 2$, because neighbouring pixels are positively correlated and the zig-zag fights that correlation.

The eigenvalues also tell us whether a proposed ξ is possible at all. Try $\xi_0 = 1$, $\xi_1 = 0.9$, $\xi_2 = 0$: neighbours very strongly correlated, next-neighbours not at all. It looks harmless, and $|\xi| \le \xi_0$ holds. But $\lambda_2 = 1 - 1.8 = -0.8 < 0$, a negative variance, so no random field has this correlation function. In words: if pixels 0, 1 are correlated at 0.9 and pixels 1, 2 are too, then pixels 0 and 2 cannot be uncorrelated. The eigenvalues are the positivity test (7.4) made explicit.

Figure 7.6 summarises the construction, and `code/ch07/03_fourier_diagonal.py` repeats it on a ring of $n = 64$ pixels with $\xi(r) = e^{-r^2/2\ell^2}$, $\ell = 3$. Rotating the 64×64 covariance matrix into the Fourier basis leaves it diagonal: the largest off-diagonal entry is 2.402×10^{-14}, rounding error. The diagonal agrees with the discrete Fourier transform of the first row of $\mathbf{C}$, and with the eigenvalues of $\mathbf{C}$ from a general-purpose eigensolver, to 6.217×10^{-15}. As a statistical check the script then draws $M = 20000$ rings with the Cholesky factor, a method that knows nothing about Fourier modes, Fourier transforms each one, and estimates the correlation coefficients between different modes. Over the 25 modes that carry appreciable power their r.m.s. is 0.00727, which is the $1/\sqrt{M} = 0.007071$ expected for truly uncorrelated variables (Figure 7.7).

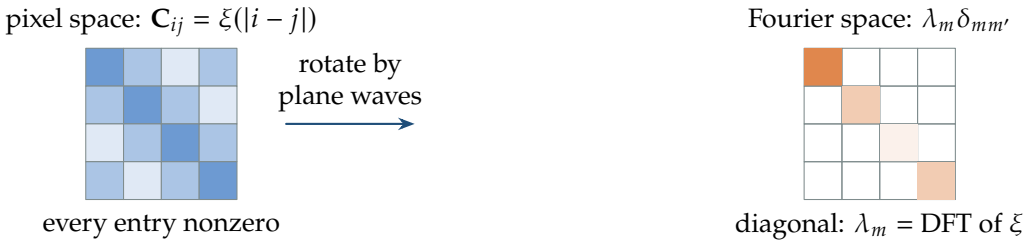

Figure 7.6: A homogeneous covariance on a ring of four pixels. Left: in pixel space every pixel is correlated with every other (darker means larger ξ). Right: in the basis of plane waves the same matrix is diagonal, and the diagonal entries, the variances of the Fourier modes, are the discrete Fourier transform of the correlation function.

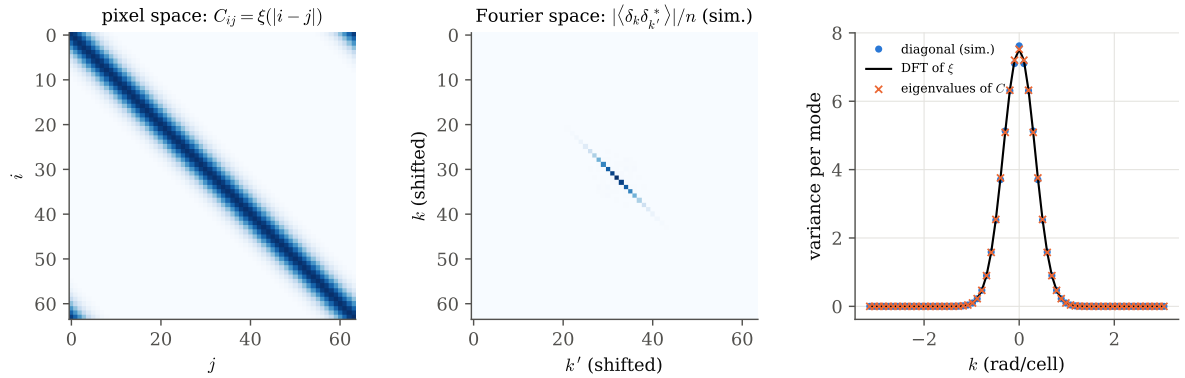

Figure 7.7: The same statement for 64 pixels. Left: the covariance matrix in pixel space, a band of width a few correlation lengths. Middle: the covariance of the Fourier coefficients, estimated from 20 000 simulated rings, is diagonal. Right: the diagonal (dots) equals the discrete Fourier transform of ξ (line), and both equal the eigenvalues of $\mathbf{C}$ (crosses).

7.3.2 The continuum: why Fourier modes are uncorrelated

The same calculation works in any dimension d and in the continuum. We fix a Fourier convention for the whole chapter:

$$\delta_{\boldsymbol{k}} = \int \mathrm{d}^d x\; \delta(\boldsymbol{x})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}}, \qquad \delta(\boldsymbol{x}) = \int \frac{\mathrm{d}^d k}{(2\pi)^d}\; \delta_{\boldsymbol{k}}\, e^{i\boldsymbol{k}\cdot\boldsymbol{x}}, \tag{7.10}$$

with the useful identity $\int \mathrm{d}^d x\, e^{-i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{x}} = (2\pi)^d \delta_D(\boldsymbol{k}-\boldsymbol{k}')$, where δ_D is the Dirac delta. Because $\delta(\boldsymbol{x})$ is real, complex conjugating the first relation gives the **reality condition**

$$\delta^*_{\boldsymbol{k}} = \delta_{-\boldsymbol{k}}, \tag{7.11}$$

so the modes $\boldsymbol{k}$ and $-\boldsymbol{k}$ are not independent numbers: one is the complex conjugate of the other [HobsonBMC p. 132]. Now compute the covariance of two Fourier coefficients of a homogeneous field:

$$\begin{aligned}
\langle \delta_{\boldsymbol{k}}\, \delta^*_{\boldsymbol{k}'} \rangle &\overset{(1)}{=} \int \mathrm{d}^d x \int \mathrm{d}^d y\; \langle \delta(\boldsymbol{x})\delta(\boldsymbol{y})\rangle\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}+i\boldsymbol{k}'\cdot\boldsymbol{y}} \\
&\overset{(2)}{=} \int \mathrm{d}^d x \int \mathrm{d}^d y\; \xi(\boldsymbol{x}-\boldsymbol{y})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}+i\boldsymbol{k}'\cdot\boldsymbol{y}} \\
&\overset{(3)}{=} \int \mathrm{d}^d y\; e^{-i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{y}} \int \mathrm{d}^d r\; \xi(\boldsymbol{r})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{r}} \\
&\overset{(4)}{=} (2\pi)^d\, \delta_D(\boldsymbol{k}-\boldsymbol{k}')\, P(\boldsymbol{k}), \qquad P(\boldsymbol{k}) \equiv \int \mathrm{d}^d r\; \xi(\boldsymbol{r})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{r}}.
\end{aligned} \tag{7.12}$$

(1) Insert (7.10) for $\delta_{\boldsymbol{k}}$ and for $\delta^*_{\boldsymbol{k}'}$ (whose exponent changes sign), and take the ensemble average inside the integrals, where only the fields are random.
(2) Homogeneity: the average of the product depends only on $\boldsymbol{x}-\boldsymbol{y}$, (7.2).
(3) Change variables from $(\boldsymbol{x},\boldsymbol{y})$ to $(\boldsymbol{r}=\boldsymbol{x}-\boldsymbol{y},\boldsymbol{y})$, a shift with unit Jacobian. The exponent becomes $-i\boldsymbol{k}\cdot(\boldsymbol{r}+\boldsymbol{y}) + i\boldsymbol{k}'\cdot\boldsymbol{y} = -i\boldsymbol{k}\cdot\boldsymbol{r} - i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{y}$, which factorises.
(4) The $\boldsymbol{y}$ integral is the Dirac-delta identity; the $\boldsymbol{r}$ integral is a function of $\boldsymbol{k}$ alone, which we name $P(\boldsymbol{k})$.

Two Fourier modes with different wavevectors are uncorrelated. The reason is the $\boldsymbol{y}$ integral, the integral over where the pair of points sits: it averages the phase $e^{-i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{y}}$ to zero unless $\boldsymbol{k}=\boldsymbol{k}'$. Homogeneity is used in exactly one place, step (2); without it the $\boldsymbol{y}$ integral would not split off. The variance of each mode is the **power spectrum** $P(\boldsymbol{k})$, the Fourier transform of ξ. Using the reality condition to replace $\delta^*_{\boldsymbol{k}'}$ by $\delta_{-\boldsymbol{k}'}$, the same result reads $\langle \delta_{\boldsymbol{k}}\delta_{\boldsymbol{k}'}\rangle = (2\pi)^d\delta_D(\boldsymbol{k}+\boldsymbol{k}')P(k)$, the form in which cosmology usually defines the matter power spectrum. Inverting the Fourier transform in (7.12) gives ξ back.

Key idea: Wiener–Khinchin: the power spectrum is the Fourier transform of ξ

For a statistically homogeneous field, different Fourier modes are uncorrelated,

$$\langle \delta_{\boldsymbol{k}}\, \delta^*_{\boldsymbol{k}'} \rangle = (2\pi)^d\, \delta_D(\boldsymbol{k}-\boldsymbol{k}')\, P(\boldsymbol{k}),$$
$$P(\boldsymbol{k}) = \int \mathrm{d}^d r\, \xi(\boldsymbol{r})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{r}}, \qquad \xi(\boldsymbol{r}) = \int \frac{\mathrm{d}^d k}{(2\pi)^d}\, P(\boldsymbol{k})\, e^{i\boldsymbol{k}\cdot\boldsymbol{r}}.$$

Isotropy makes P depend only on $k=|\boldsymbol{k}|$. The power spectrum is the variance per Fourier mode, so $P(k)\geq 0$, and a function is a valid correlation function if and only if its Fourier transform is non-negative.

The last sentence is Bochner's theorem; the four-pixel example above is its smallest case. It has two directions. *Valid ξ implies $P \geq 0$:* this is immediate from (7.12), since P is a variance. *$P \geq 0$ implies a valid ξ:* here the proof is a construction, the simulation recipe of Section 7.4, which takes any $P \geq 0$ and builds a field that has it.

A remark on conventions. Some cosmology texts use the symmetric convention, with $(2\pi)^{-d/2}$ on each side of the transform; then $\langle \delta_{\boldsymbol{k}} \delta^*_{\boldsymbol{k}'} \rangle = \delta_D(\boldsymbol{k} - \boldsymbol{k}')P(k)$ with the *same* $P(k)$, because the relation between P and ξ is unchanged (Chapter T1). This is the $P(k)$ that CAMB returns.

How the variance splits among the modes. Setting $\boldsymbol{r} = 0$ in the inverse transform,

$$\sigma^2 = \xi(0) = \int \frac{\mathrm{d}^d k}{(2\pi)^d} P(k), \tag{7.13}$$

so the variance of the field is the sum of the variances of its modes, and $P(k)\,\mathrm{d}^d k/(2\pi)^d$ is the share of the variance carried by the modes in $\mathrm{d}^d k$. In three dimensions with isotropy, $\mathrm{d}^3 k = 4\pi k^2 \mathrm{d}k$, and

$$\sigma^2 = \int_0^\infty \frac{\mathrm{d}k}{k}\, \Delta^2(k), \qquad \Delta^2(k) \equiv \frac{k^3 P(k)}{2\pi^2},$$

the **dimensionless power spectrum**: the variance per logarithmic interval of k (in two dimensions the same reasoning gives $\Delta^2 = k^2 P/2\pi$). A spectrum with constant Δ^2 puts equal variance in every octave of scale. The primordial curvature perturbation of inflation is close to this "scale-invariant" case.

Isotropic transforms in three and two dimensions. For an isotropic field the angular part of the Fourier integral can be done once and for all. In three dimensions, put the k_z axis along $\boldsymbol{r}$, so $\boldsymbol{k} \cdot \boldsymbol{r} = kr\cos\theta$:

$$\begin{aligned} \xi(r) &\overset{(1)}{=} \int_0^\infty \frac{k^2 \mathrm{d}k}{(2\pi)^3} P(k) \int_0^{2\pi} \mathrm{d}\phi \int_{-1}^{1} \mathrm{d}(\cos\theta)\, e^{ikr\cos\theta} \overset{(2)}{=} \int_0^\infty \frac{k^2 \mathrm{d}k}{(2\pi)^3} P(k)\, 2\pi\, \frac{2\sin kr}{kr} \\ &= \int_0^\infty \frac{k^2 \mathrm{d}k}{2\pi^2} P(k) \frac{\sin kr}{kr}, \end{aligned} \tag{7.14}$$

(1) Spherical coordinates in $\boldsymbol{k}$-space, $\mathrm{d}^3 k = k^2 \mathrm{d}k\, \mathrm{d}\phi\, \mathrm{d}(\cos\theta)$, and P depends only on k.

(2) $\int_{-1}^{1} e^{ikru}\mathrm{d}u = \frac{e^{ikr} - e^{-ikr}}{ikr} = \frac{2\sin kr}{kr}$.

the standard relation between ξ and P in cosmology. In two dimensions, with polar angle ϕ between $\boldsymbol{k}$ and $\boldsymbol{r}$,

$$\xi(r) = \int_0^\infty \frac{k\,\mathrm{d}k}{(2\pi)^2} P(k) \int_0^{2\pi} e^{ikr\cos\phi}\mathrm{d}\phi = \int_0^\infty \frac{k\,\mathrm{d}k}{2\pi} P(k)\, J_0(kr), \tag{7.15}$$

using the integral representation of the Bessel function, $J_0(x) = \frac{1}{2\pi}\int_0^{2\pi} e^{ix\cos\phi}\mathrm{d}\phi$. The inverse relations are the same with the roles of P and ξ exchanged and the factors of 2π moved: $P(k) = 4\pi \int_0^\infty r^2 \mathrm{d}r\, \xi(r) \frac{\sin kr}{kr}$ in 3D and $P(k) = 2\pi \int_0^\infty r\,\mathrm{d}r\, \xi(r) J_0(kr)$ in 2D. On the sphere the analogue is the Legendre series $C(\theta) = \sum_\ell \frac{2\ell+1}{4\pi} C_\ell P_\ell(\cos\theta)$ [HobsonBMC (10.4)], with the multipole ℓ playing the role of k.

Example: the Gaussian pair. Take $\xi(r) = \sigma^2 e^{-r^2/2\ell^2}$ in d dimensions. The Fourier integral factorises over Cartesian components:

$$P(k) \overset{(1)}{=} \sigma^2 \prod_{a=1}^{d} \int_{-\infty}^{\infty} \mathrm{d}r_a\, e^{-r_a^2/2\ell^2 - ik_a r_a} \overset{(2)}{=} \sigma^2 \prod_{a=1}^{d} \sqrt{2\pi\ell^2}\, e^{-k_a^2\ell^2/2} \overset{(3)}{=} \sigma^2 (2\pi\ell^2)^{d/2}\, e^{-k^2\ell^2/2}. \tag{7.16}$$

(1) $r^2 = \sum_a r_a^2$ and $\boldsymbol{k}\cdot\boldsymbol{r} = \sum_a k_a r_a$, so the exponential is a product of one-dimensional factors.
(2) Complete the square: $-\frac{r_a^2}{2\ell^2} - ik_a r_a = -\frac{(r_a + ik_a\ell^2)^2}{2\ell^2} - \frac{k_a^2\ell^2}{2}$, and the shifted Gaussian integral is $\sqrt{2\pi\ell^2}$.
(3) Multiply the d factors; $\sum_a k_a^2 = k^2$.

A Gaussian of width ℓ in real space is a Gaussian of width $1/\ell$ in Fourier space: a field correlated over ℓ has its power at $k \lesssim 1/\ell$. The 2D version, $P = 2\pi\ell^2\sigma^2 e^{-k^2\ell^2/2}$, is the spectrum used in Figures 7.3 and 7.5. As a check of (7.13), $\int \frac{\mathrm{d}^2k}{(2\pi)^2} P = \frac{2\pi\ell^2\sigma^2}{(2\pi)^2}\cdot\frac{2\pi}{\ell^2} = \sigma^2$.

Example: the exponential in two dimensions. For $\xi(r) = \sigma^2 e^{-r/\ell}$ the 2D inverse relation needs $\int_0^\infty r\, e^{-ar} J_0(kr)\,\mathrm{d}r$ with $a = 1/\ell$. Start from the Laplace transform of J_0, $\int_0^\infty e^{-ar} J_0(kr)\,\mathrm{d}r = (a^2 + k^2)^{-1/2}$, and differentiate both sides with respect to a:

$$-\int_0^\infty r\, e^{-ar} J_0(kr)\,\mathrm{d}r = -\frac{a}{(a^2+k^2)^{3/2}} \quad\Rightarrow\quad P(k) = 2\pi\sigma^2\frac{a}{(a^2+k^2)^{3/2}} = \frac{2\pi\ell^2\sigma^2}{(1+k^2\ell^2)^{3/2}}.$$

The kink of $e^{-r/\ell}$ at $r = 0$ shows up as a power-law tail $P \propto k^{-3}$ at large k: a correlation function that is not smooth at the origin means a field with structure on all small scales (Figure 7.8, panel b). The script `code/ch07/04_pk_xi_pairs.py` evaluates (7.15) numerically up to $k_{\max} = 10$. For the Gaussian pair it reproduces the analytic ξ to 8.335×10^{-8}. For the exponential the largest error is 0.02499, at $r = 0$, and it has a clean explanation: the truncated tail carries the variance $\int_{k_{\max}}^\infty \frac{k\,\mathrm{d}k}{2\pi}\frac{2\pi\ell^2}{(k\ell)^3} = \frac{1}{\ell k_{\max}} = 0.025$ for $\ell = 4$ cells and $\sigma = 1$.

Example: a preferred wavelength. If $P(k)$ is a narrow bump around k_0, nearly all the variance sits in waves of wavelength $2\pi/k_0$, and (7.15) gives $\xi(r) \approx \sigma^2 J_0(k_0 r)$ times a slowly decaying envelope. The correlation function oscillates and goes *negative*: a hot spot is surrounded by a cold ring at distance $r \approx 3.83/k_0$, the first minimum of J_0. For $k_0 = 0.5$ the minimum sits at 7.664 cells, and the numerical transform puts it at 7.519 with $\xi = -0.3749$. The field looks like a pattern of cells and stripes, the look of convection rolls or of a Turing pattern (Figure 7.8, panel c). The baryon acoustic oscillations are a weak version of the same thing: wiggles in $P(k)$ become a bump in $\xi(r)$ at the sound horizon (Chapter T1).

Example: power laws. For $P(k) = Ak^n$ the substitution $u = kr$ in (7.14) gives $\xi(r) = \frac{A}{2\pi^2} r^{-(n+3)} \int_0^\infty u^{n+2}\frac{\sin u}{u}\mathrm{d}u$, so $\xi \propto r^{-(n+3)}$, and in d dimensions $\xi \propto r^{-(n+d)}$. The u integral converges only for $-3 < n < -1$ in 3D. Near $u = 0$ the integrand is about u^{n+2}, which needs $n > -3$; at large u it oscillates with amplitude u^{n+1}, which needs $n < -1$. For $n \le -3$ the trouble is at small k, the largest scales; for $n \ge -1$ it is at large k, the smallest scales. Either way the spectrum must be cut off, by the size of the survey or by smoothing. Steep spectra (very negative n) give fields dominated by large waves; shallow ones look like noise (Figure 7.10 below).

7.3.3 A Gaussian field in Fourier space

Different modes. For a Gaussian field each $\delta_{\boldsymbol{k}}$ is a linear combination of Gaussian variables, so the Fourier modes are jointly Gaussian too. Jointly Gaussian variables that are uncorrelated are independent, so different modes are independent.

Inside one mode. Each $\delta_{\boldsymbol{k}} = a + ib$ is complex, so we also ask about its real part a and imaginary part b. Two facts fix them. First, the variance of the mode is $\langle|\delta_{\boldsymbol{k}}|^2\rangle = \langle a^2\rangle + \langle b^2\rangle$, proportional

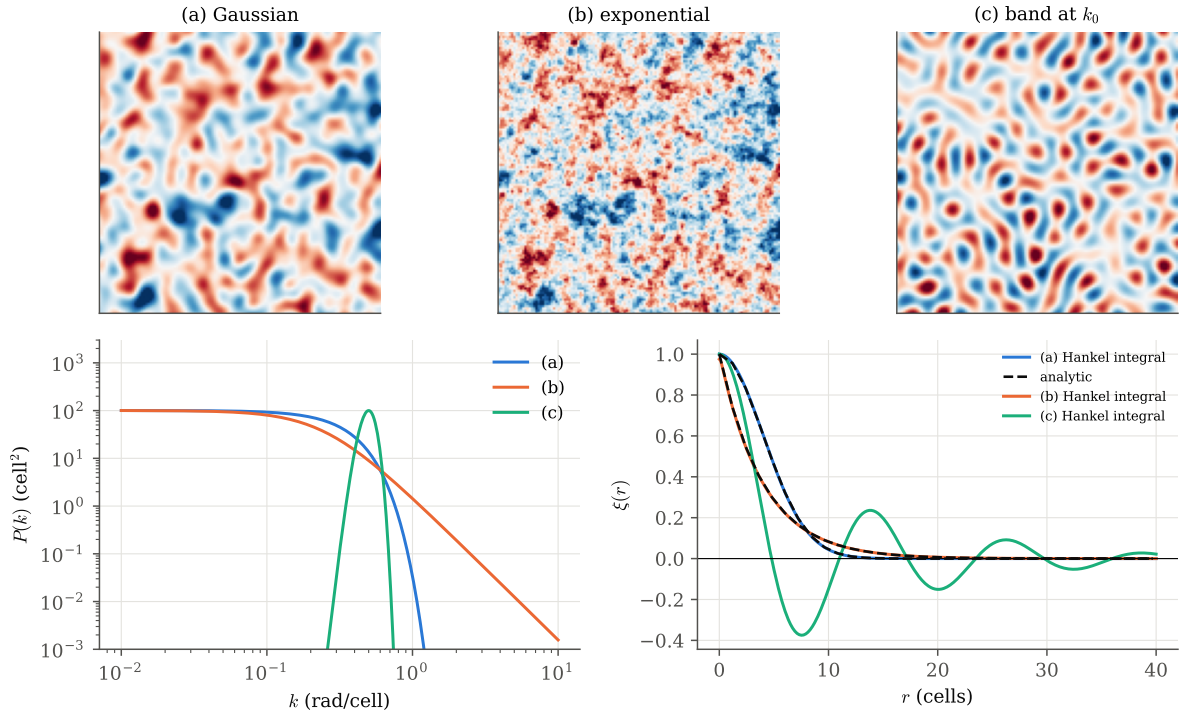

Figure 7.8: Three spectra coloured onto the same white noise. Top: (a) the Gaussian pair, smooth blobs of one size; (b) the exponential, whose k^{-3} tail adds structure on every small scale; (c) a narrow band of wavenumbers, which makes a cellular pattern. Bottom: the spectra and their correlation functions; the analytic ξ (dashed) lies on the numerical Hankel transform, and the band spectrum gives an oscillating ξ with a negative first lobe.

to $P(k)$. Second, for $\boldsymbol{k} \neq \mathbf{0}$ (so that $\boldsymbol{k} \neq -\boldsymbol{k}$) the reality condition gives $\langle \delta_{\boldsymbol{k}} \delta_{\boldsymbol{k}} \rangle = \langle \delta_{\boldsymbol{k}} \delta^*_{-\boldsymbol{k}} \rangle$. That is the covariance of two *different* modes, $\boldsymbol{k}$ and $-\boldsymbol{k}$, so it vanishes by (7.12). Writing it out,

$$0 = \langle (a + ib)^2 \rangle = \langle a^2 \rangle - \langle b^2 \rangle + 2i \langle ab \rangle .$$

The real part says $\langle a^2 \rangle = \langle b^2 \rangle$; the imaginary part says $\langle ab \rangle = 0$. So a and b are independent Gaussians with equal variance, each carrying half of the mode's power.

Amplitude and phase. Then $|\delta_{\boldsymbol{k}}|^2 = a^2 + b^2$ is a sum of two squared Gaussians, a scaled χ^2_2, which is an exponential distribution. In polar form, $\delta_{\boldsymbol{k}} = |\delta_{\boldsymbol{k}}| e^{i\varphi_{\boldsymbol{k}}}$, the amplitude has the Rayleigh distribution and the phase $\varphi_{\boldsymbol{k}}$ is uniform on $[0, 2\pi)$, independent of the amplitude. This is the same polar decomposition of two independent Gaussians that gives the Box–Muller method (Chapter 6).

What it means. A homogeneous Gaussian field is nothing but a sum of plane waves with independent Rayleigh amplitudes, whose mean square is set by $P(k)$, and independent, uniformly random phases. The random amplitudes are why a measured power spectrum scatters about the true one (Section 7.5). The random phases are exactly what $P(k)$ ignores (Section 7.7).

7.4 Simulating a Gaussian random field with the FFT

Every later chapter needs fake universes: hundreds of CMB skies to calibrate an estimator in Chapter 8, mock maps to test a sampler in Chapter 9, Gaussian fields as the null hypothesis for the topological summaries of Chapter 12. *The old way.* The Cholesky factor of Chapter 6 makes a correlated Gaussian vector by colouring white noise: $\boldsymbol{\delta} = \mathbf{L}\boldsymbol{z}$, with $\boldsymbol{z}$ independent standard

normals and $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{C}$. But it costs $n^3/3$ operations for n pixels, so it stops at a few thousand pixels. *The way out.* In the Fourier basis the covariance of a homogeneous field is diagonal (Section 7.3), so its "Cholesky factor" is diagonal too: multiply each Fourier mode of white noise by $\sqrt{P(k)}$. The fast Fourier transform does the change of basis in about $n \log n$ operations.

The question. Given a power spectrum $P(k) \geq 0$, how do we produce, on a grid, a real Gaussian field whose Fourier modes have exactly the variance $P(k)$, and with which normalisation?

7.4.1 The box and the grid

A computer holds a field on a finite grid, and the FFT treats the grid as periodic. So we work in a cubic box of side L in d dimensions, of volume $V = L^d$, with periodic boundary conditions. The box is divided into N cells per side, each of size $\Delta = L/N$; there are N^d cells in all, with centres $\boldsymbol{x}_{\boldsymbol{n}} = \boldsymbol{n}\Delta$ for an integer vector $\boldsymbol{n}$.

The box and the grid each limit which waves exist. Periodicity allows only the wavevectors $\boldsymbol{k} = \frac{2\pi}{L}\boldsymbol{m}$ with integer $\boldsymbol{m}$, so there is one allowed $\boldsymbol{k}$ per cell of volume $(2\pi/L)^d$ in $\boldsymbol{k}$-space. The grid allows only $|k_a| \leq \pi/\Delta$ along each axis a. The two ends of that range have names. The **fundamental mode** $k_f = 2\pi/L$ is the longest wave that fits in the box. The **Nyquist wavenumber** $k_{\mathrm{Ny}} = \pi N/L$ is the shortest wave the grid can represent, one that alternates sign from cell to cell. In a finite box the Fourier series replaces the Fourier integral (7.10):

$$\delta_{\boldsymbol{k}} = \int_V \mathrm{d}^d x\; \delta(\boldsymbol{x})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}}, \qquad \delta(\boldsymbol{x}) = \frac{1}{V}\sum_{\boldsymbol{k}} \delta_{\boldsymbol{k}}\, e^{i\boldsymbol{k}\cdot\boldsymbol{x}}, \tag{7.17}$$

and the calculation (7.12) goes through with one change: the $\boldsymbol{y}$ integral over the box gives $\int_V \mathrm{d}^d y\, e^{-i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{y}} = V\delta_{\boldsymbol{k}\boldsymbol{k}'}$ (the integral of a whole number of periods of a wave vanishes). Hence

$$\langle \delta_{\boldsymbol{k}}\, \delta^*_{\boldsymbol{k}'} \rangle = V\, P(k)\, \delta_{\boldsymbol{k}\boldsymbol{k}'}. \tag{7.18}$$

The Dirac delta $(2\pi)^d\delta_D(\boldsymbol{k}-\boldsymbol{k}')$ of the infinite volume has become the Kronecker delta times the volume, which is how one should read "$(2\pi)^d\delta_D(\boldsymbol{0}) = V$". Every mode has variance $VP(k)$; a bigger box has more modes, each of larger variance, and the variance per unit volume is the same.

On the grid the integral in (7.17) becomes a sum over cells, $\delta_{\boldsymbol{k}} \approx \Delta^d \sum_{\boldsymbol{n}} \delta_{\boldsymbol{n}} e^{-i\boldsymbol{k}\cdot\boldsymbol{x}_{\boldsymbol{n}}} = \Delta^d F_{\boldsymbol{k}}$, where $F_{\boldsymbol{k}}$ is exactly what `numpy.fft.fftn` returns. The inverse is exact: $\delta_{\boldsymbol{n}} = \frac{1}{V}\sum_{\boldsymbol{k}} \Delta^d F_{\boldsymbol{k}} e^{i\boldsymbol{k}\cdot\boldsymbol{x}_{\boldsymbol{n}}} = \frac{1}{N^d}\sum_{\boldsymbol{k}} F_{\boldsymbol{k}} e^{i\boldsymbol{k}\cdot\boldsymbol{x}_{\boldsymbol{n}}}$, which is `numpy.fft.ifftn`, because $V/\Delta^d = N^d$. Since $F_{\boldsymbol{k}} = \delta_{\boldsymbol{k}}/\Delta^d$, the target (7.18) in numpy's units is

$$\langle |F_{\boldsymbol{k}}|^2 \rangle = \frac{V\, P(k)}{\Delta^{2d}} = \frac{N^d\, P(k)}{\Delta^d}. \tag{7.19}$$

7.4.2 The recipe, and why it is right

The recipe has four steps (Figure 7.9). Draw one independent standard normal $w_{\boldsymbol{n}}$ per cell. Fourier transform it, $W_{\boldsymbol{k}} = \sum_{\boldsymbol{n}} w_{\boldsymbol{n}} e^{-i\boldsymbol{k}\cdot\boldsymbol{x}_{\boldsymbol{n}}}$. Multiply each mode by $\sqrt{P(k)/\Delta^d}$. Transform back. To see that the result has the right covariance, first compute the covariance of the transformed white noise:

$$\langle W_{\boldsymbol{k}} W^*_{\boldsymbol{k}'} \rangle \overset{(1)}{=} \sum_{\boldsymbol{n}}\sum_{\boldsymbol{m}} \langle w_{\boldsymbol{n}} w_{\boldsymbol{m}} \rangle\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}_{\boldsymbol{n}} + i\boldsymbol{k}'\cdot\boldsymbol{x}_{\boldsymbol{m}}} \overset{(2)}{=} \sum_{\boldsymbol{n}} e^{-i(\boldsymbol{k}-\boldsymbol{k}')\cdot\boldsymbol{x}_{\boldsymbol{n}}} \overset{(3)}{=} N^d\, \delta_{\boldsymbol{k}\boldsymbol{k}'}. \tag{7.20}$$

(1) Definition of $W_{\boldsymbol{k}}$ and of its complex conjugate; average inside the sums.

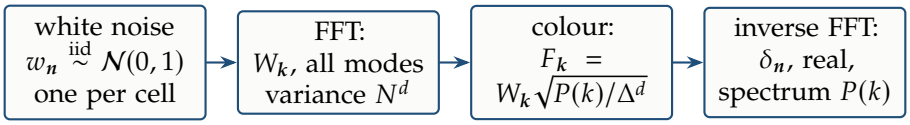

Figure 7.9: The FFT recipe for a Gaussian random field. White noise has the same variance in every Fourier mode; multiplying each mode by the square root of the desired power spectrum, and transforming back, gives a field whose modes have exactly that variance. It is the Cholesky construction of Chapter 6 carried out in the basis where the covariance is diagonal.

(2) The noise is independent with unit variance, $\langle w_n w_m\rangle = \delta_{nm}$, which kills one sum.
(3) For $\boldsymbol{k} = \boldsymbol{k}'$ each of the N^d terms is 1. For $\boldsymbol{k} \neq \boldsymbol{k}'$ the terms are the N-th roots of unity along at least one axis, which sum to zero.

White noise is a field with the same variance, N^d, in every mode and no correlation between modes: a flat power spectrum, which is where the name comes from. The colouring then gives, for $F_k = W_k\sqrt{P(k)/\Delta^d}$,

$$\langle F_k F^*_{k'}\rangle = \sqrt{\tfrac{P(k)}{\Delta^d}}\sqrt{\tfrac{P(k')}{\Delta^d}}\,\langle W_k W^*_{k'}\rangle = \frac{N^d P(k)}{\Delta^d}\,\delta_{kk'},$$

which is the target (7.19). Three more checks complete the argument. *The output is Gaussian,* because it is a linear function of the Gaussian vector $\boldsymbol{w}$. *It is real.* The noise w is real, so $W_{-k} = W^*_k$. Multiplying by $\sqrt{P(|\boldsymbol{k}|)}$, which is real and the same at $\boldsymbol{k}$ and $-\boldsymbol{k}$, keeps $F_{-k} = F^*_k$. That is the reality condition (7.11), so the inverse transform has no imaginary part. *Its variance is right.* By Parseval,

$$\sigma^2 = \langle \delta_n^2\rangle = \frac{1}{V^2}\sum_{\boldsymbol{k}}\langle|\delta_{\boldsymbol{k}}|^2\rangle = \frac{1}{V}\sum_{\boldsymbol{k}} P(k) \;\approx\; \int \frac{\mathrm{d}^d k}{(2\pi)^d} P(k), \tag{7.21}$$

the box version of (7.13): the allowed $\boldsymbol{k}$ have density $V/(2\pi)^d$, so $\frac{1}{V}\sum_{\boldsymbol{k}}$ becomes $\int \mathrm{d}^d k/(2\pi)^d$. Finally, the $\boldsymbol{k} = 0$ mode is the mean of the box. We set it to zero, so every simulated box has mean exactly zero.

Key idea: Colouring white noise in Fourier space

To simulate a homogeneous Gaussian field with power spectrum $P(k)$ on a periodic grid: FFT a map of independent standard normals, multiply mode $\boldsymbol{k}$ by $\sqrt{P(k)/\Delta^d}$, inverse FFT. The cost is $O(N^d \log N^d)$ instead of the $O(N^{3d})$ of a Cholesky factorisation, and the result is exact for the band of wavevectors $k_f \le |k_a| \le k_{\mathrm{Ny}}$ that the box and the grid can hold.

The implementation in the shared library is ten lines.

Listing 7.1: The FFT simulator of a Gaussian random field (`code/ch07/lib_fields.py`)

```
    rng = np.random.default_rng() if rng is None else rng
    D = L / N
    kmag, _ = kgrid(N, L, d)
    with np.errstate(divide="ignore", invalid="ignore"):
        amp = np.sqrt(np.where(kmag > 0, P(np.where(kmag > 0, kmag, 1.0)), 0.0) / D ** d)
    shape = ([nsim] if nsim else []) + [N] * d
    axes = tuple(range(-d, 0))
    w = rng.standard_normal(shape)                      # unit white noise, one number per
    cell
    wk = np.fft.rfftn(w, axes=axes)                     # its FFT: <|wk|^2> = N^d, Hermitian
    return np.fft.irfftn(wk * amp, s=[N] * d, axes=axes)  # colour it, transform back (real)
```

Line 53 is the cell size Δ, line 54 the grid of $|\boldsymbol{k}|$ in the layout of `rfftn`, which stores only the half of $\boldsymbol{k}$-space with $k_d \geq 0$ because the other half is fixed by the reality condition. Line 56 is the colouring factor $\sqrt{P(k)/\Delta^d}$, set to zero at $\boldsymbol{k} = 0$. Lines 59–61 are the recipe: white noise, its FFT, colour, transform back. When `nsim` is given, the first axis counts realisations and the transforms act on the remaining d axes, so a stack of independent fields costs one call. The library also contains the two estimators we use to check the output, and the sphere version of the same recipe.

Estimating $P(k)$ and $\xi(r)$ from a map. Each mode has $\langle|\delta_{\boldsymbol{k}}|^2\rangle = VP(k)$ by (7.18), so $|\delta_{\boldsymbol{k}}|^2/V$ is a one-mode estimate of P. The natural estimate of the power at wavenumber k averages it over the N_{modes} modes in a thin shell $k - \frac{\Delta k}{2} < |\boldsymbol{k}| \leq k + \frac{\Delta k}{2}$,

$$\hat{P}(k) = \frac{1}{N_{\text{modes}}} \sum_{\boldsymbol{k}\in\text{shell}} \frac{|\delta_{\boldsymbol{k}}|^2}{V}, \qquad \langle\hat{P}(k)\rangle = \frac{1}{N_{\text{modes}}} \sum_{\boldsymbol{k}\in\text{shell}} P(|\boldsymbol{k}|), \tag{7.22}$$

so $\hat{P}$ is unbiased for the average of P over the shell. The correlation function could be estimated directly, by averaging $\delta_{\boldsymbol{n}}\delta_{\boldsymbol{n}+\boldsymbol{r}}$ over all cells, but that costs N^d operations for each separation $\boldsymbol{r}$. The Fourier route is faster: it is the discrete form of Wiener–Khinchin. With $\delta_{\boldsymbol{n}}$ real,

$$\begin{aligned}\hat{\xi}(\boldsymbol{r}) \equiv \frac{1}{N^d}\sum_{\boldsymbol{n}} \delta_{\boldsymbol{n}}\delta_{\boldsymbol{n}+\boldsymbol{r}} &\overset{(1)}{=} \frac{1}{N^d}\sum_{\boldsymbol{n}} \frac{1}{N^{2d}} \sum_{\boldsymbol{k},\boldsymbol{k}'} F^*_{\boldsymbol{k}} F_{\boldsymbol{k}'}\, e^{-i\boldsymbol{k}\cdot\boldsymbol{x}_{\boldsymbol{n}} + i\boldsymbol{k}'\cdot(\boldsymbol{x}_{\boldsymbol{n}}+\boldsymbol{r})} \\ &\overset{(2)}{=} \frac{1}{N^{2d}} \sum_{\boldsymbol{k}} |F_{\boldsymbol{k}}|^2 e^{i\boldsymbol{k}\cdot\boldsymbol{r}} \overset{(3)}{=} \frac{1}{N^d}\,\mathrm{IFFT}\big(|F|^2\big)(\boldsymbol{r}),\end{aligned} \tag{7.23}$$

(1) Write $\delta_{\boldsymbol{n}} = \delta^*_{\boldsymbol{n}}$ with the inverse FFT, and $\delta_{\boldsymbol{n}+\boldsymbol{r}}$ with the inverse FFT.
(2) The sum over cells of $e^{i(\boldsymbol{k}'-\boldsymbol{k})\cdot\boldsymbol{x}_{\boldsymbol{n}}}$ is $N^d\delta_{\boldsymbol{k}\boldsymbol{k}'}$, as in (7.20).
(3) The remaining sum is N^d times the inverse FFT of $|F_{\boldsymbol{k}}|^2$.

Its expectation, by (7.19), is $\langle\hat{\xi}(\boldsymbol{r})\rangle = \frac{1}{V}\sum_{\boldsymbol{k}} P(k)e^{i\boldsymbol{k}\cdot\boldsymbol{r}} \equiv \xi_{\text{box}}(\boldsymbol{r})$: the correlation function of the field the box can actually hold, periodic, with no power below k_f or above k_{Ny}. It equals the continuum $\xi(r)$ only for $r \ll L$ and only if P is negligible outside that band. Averaging (7.23) over shells of $|\boldsymbol{r}|$ gives the isotropic $\hat{\xi}(r)$.

7.4.3 Two dimensions: power laws

The script `code/ch07/05_simulate_2d.py` colours one white-noise map of 512×512 unit cells with the power laws $P = Ak^n$, $n = -1, -2, -3$, choosing A so that (7.21) gives $\sigma^2 = 1$ in every case (Figure 7.10). The look of the maps is set by the slope. For $n = -1$ most of the variance is at small scales and the map looks like noise; for $n = -3$, where $\Delta^2 = k^2P/2\pi \propto k^{-1}$ grows towards large scales, a few box-sized waves dominate. In each case the measured $\hat{P}(k)$ follows the input, and averaged over all shells and 20 independent maps the ratio $\hat{P}/\langle\hat{P}\rangle$ is 1.002, 0.9963 and 1.017. The measured $\hat{\xi}(r)$ of the single map scatters about ξ_{box}, and how far it can stray depends on the slope. In this map the variance $\hat{\xi}(0)$ is 1.012, 1.207 and 1.74 for $n = -1, -2, -3$, although each was designed to be 1 on average. The 20 independent maps show how large such strays are: from map to map $\hat{\xi}(0)$ scatters by 0.004822, 0.09247 and 0.3368. Nothing is wrong with the simulation. When the variance lives in the few longest waves, one box contains only a handful of those waves, so it holds only a handful of independent pieces of information about the variance, and the measured variance scatters accordingly. Section 7.5 makes this precise.

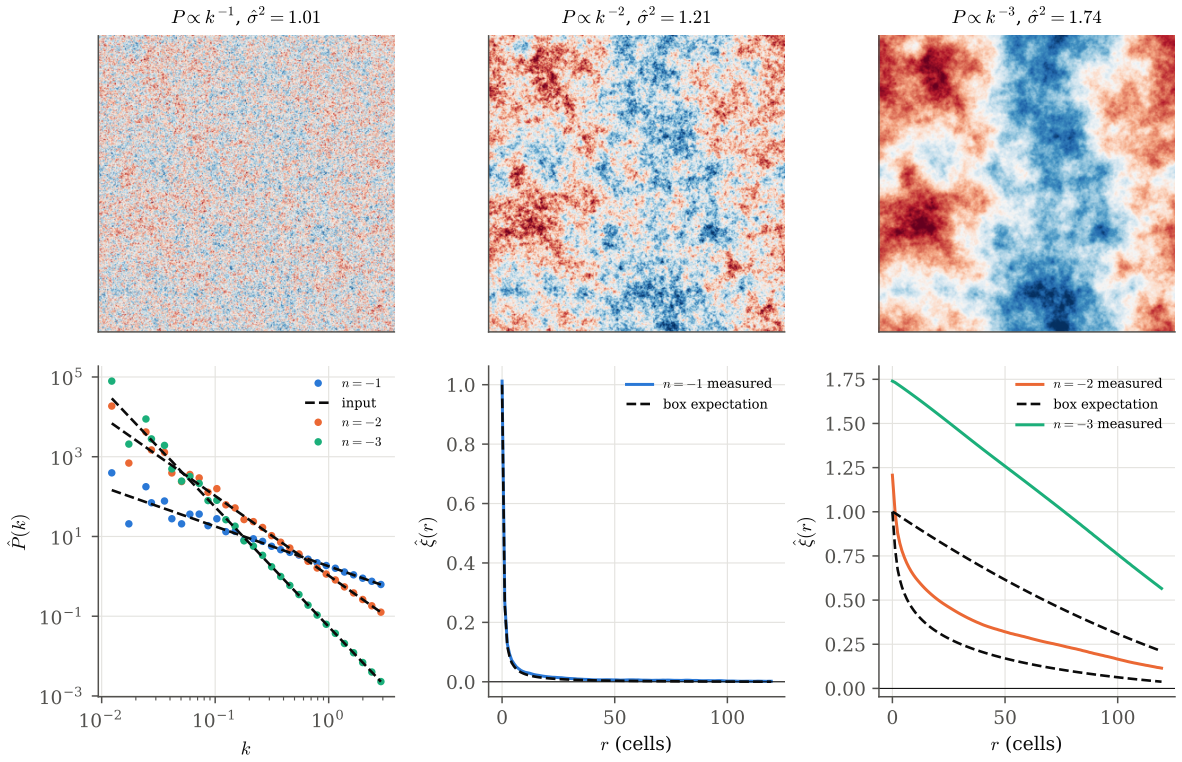

Figure 7.10: Gaussian fields with power-law spectra $P \propto k^n$, coloured from the same white noise. Top: $n = -1, -2, -3$; the steeper the spectrum, the larger the dominant structures. Bottom left: the shell-averaged power of each map (dots) against the input averaged over the same modes (dashed). Bottom middle and right: the measured correlation functions of these maps against their exact box expectations.

7.4.4 Three dimensions: the matter field and the BAO bump

The script `code/ch07/06_simulate_3d_bao.py` takes the linear matter power spectrum of the fiducial Planck 2018 model at $z = 0$ from CAMB (the spectrum of Chapter T1, in $(h^{-1}\text{Mpc})^3$) and fills 4 periodic boxes of side $L = 2000\,h^{-1}\text{Mpc}$ with 256^3 cells of $7.812\,h^{-1}\text{Mpc}$. The box holds the wavenumbers from $k_f = 0.003142$ to $k_{\text{Ny}} = 0.4021\,h\,\text{Mpc}^{-1}$, which covers the turnover of $P(k)$ and the baryon acoustic oscillations. The measured spectra lie on CAMB's, with a mean ratio 0.982 over the shells and visibly larger scatter in the first shells, which contain only 6 modes each (Figure 7.11). In $r^2\hat{\xi}(r)$ every box shows the acoustic bump, which the continuum transform (7.14) puts at $r = 101.3\,h^{-1}\text{Mpc}$; the four boxes scatter about the theory by about $1.301\,(h^{-1}\text{Mpc})^2$ in $r^2\xi$, against a bump height of order ten. A box of $8\,(h^{-1}\text{Gpc})^3$ is larger than any survey yet completed, and a real survey also has a mask, noise and galaxies that are biased tracers of the matter; all of that makes the real measurement harder (Chapter 8).

Watch out: A Gaussian density field can go below -1

The cell-to-cell standard deviation of the simulated matter field is 1.291, so a sizeable fraction of cells have $\delta < -1$, a negative density. The Gaussian model is a statement about the statistics of the linear field on large scales, not a model of the density in $8\,h^{-1}\text{Mpc}$ cells today. Mock catalogues that must be positive use, for example, a lognormal transformation of a Gaussian field, which is non-Gaussian (Figure 7.5) and, for the same $P(k)$, has different higher-order statistics.

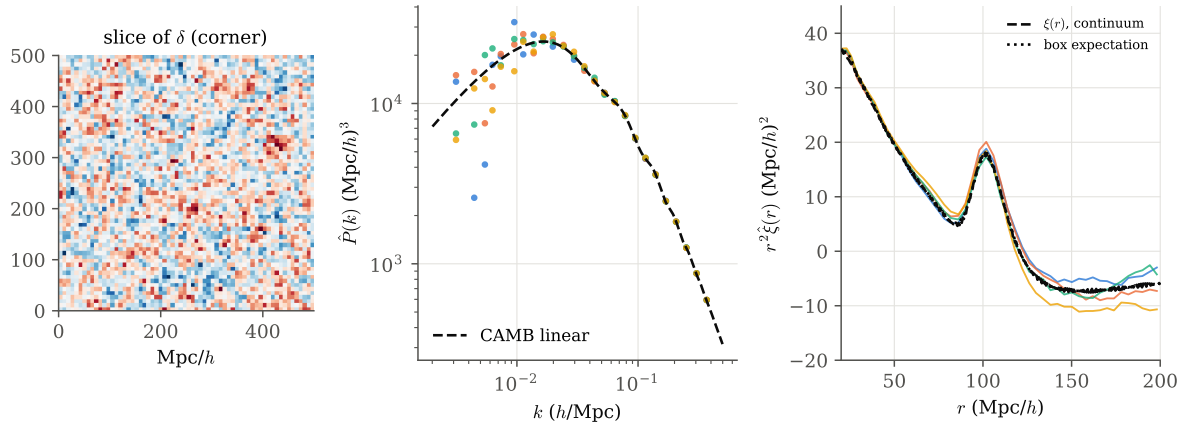

Figure 7.11: A Gaussian matter field with the linear CAMB spectrum. Left: a 500 h^{-1}Mpc corner of one slice. Middle: the shell-averaged power of four independent boxes against the input spectrum; the scatter is largest at small k, where shells contain few modes. Right: $r^2\hat{\xi}(r)$ of the four boxes, the continuum prediction (dashed) and the exact box expectation (dotted); the acoustic bump near 100 h^{-1}Mpc is recovered in every box.

The sphere. On the sky the plane waves are replaced by spherical harmonics and the Fourier coefficients by $a_{\ell m}$, which are independent with variance C_ℓ for a statistically isotropic Gaussian field [HobsonBMC (10.2)–(10.3)]. The library function `gaussian_field_sphere` applies the same recipe: one Gaussian per (ℓ, m), scaled by $\sqrt{C_\ell}$, followed by a spherical-harmonic transform on a HEALPix grid [7], using our own reproducible random stream. The full-sky estimator $\widehat{C}_\ell$ and its cosmic variance, the sphere's version of the scatter just seen in the first k-shells, are derived for the CMB in the second half of Chapter 7.

7.5 One universe: ergodicity and sample variance

Every definition so far is an average down the stack of universes of Figure 7.2: $\xi(r)$ is the ensemble average of $\delta(\boldsymbol{x})\delta(\boldsymbol{x}+\boldsymbol{r})$ at fixed points, $P(k)$ the ensemble variance of a mode. But we have one universe. What we can actually compute is an average *across* our one map: for example the volume average $\hat{\xi}(r) = \frac{1}{V}\int_V \mathrm{d}^d x\, \delta(\boldsymbol{x})\delta(\boldsymbol{x}+\boldsymbol{r})$ over a region of volume V, or the shell average $\hat{P}(k)$ of (7.22). Using the second kind of average in place of the first is the **ergodic hypothesis**. It is an assumption about the field, it can fail, and even when it holds it leaves a finite-volume error that no instrument can remove.

The questions. (1) When does an average over one large volume converge to the ensemble average? (2) For a finite volume, how far from the ensemble value is the spatial average likely to be, for the mean and for the power spectrum?

7.5.1 The variance of a spatial average

Start with the simplest spatial average, the mean of the field over a region of volume V, $\bar{\delta}_V = \frac{1}{V}\int_V \mathrm{d}^d x\, \delta(\boldsymbol{x})$. Its ensemble mean is the ensemble mean of the field, which is zero. The question is how much it scatters from one universe to the next, that is, its variance:

$$\operatorname{Var}\bar{\delta}_V \overset{(1)}{=} \frac{1}{V^2}\int_V \mathrm{d}^d x \int_V \mathrm{d}^d y\, \langle\delta(\boldsymbol{x})\delta(\boldsymbol{y})\rangle \overset{(2)}{=} \frac{1}{V^2}\int_V \mathrm{d}^d x \int_V \mathrm{d}^d y\, \xi(\boldsymbol{x}-\boldsymbol{y})$$

$$\overset{(3)}{\approx} \frac{1}{V^2}\int_V \mathrm{d}^d x \int \mathrm{d}^d r\; \xi(\boldsymbol{r}) \overset{(4)}{=} \frac{1}{V}\int \mathrm{d}^d r\; \xi(\boldsymbol{r}) \overset{(5)}{=} \frac{P(0)}{V}. \tag{7.24}$$

(1) Square the average and take the expectation inside both integrals; it is the continuum version of the variance of a sum, a double sum of covariances [Wasserman p. 53, Thm. 3.20].
(2) Homogeneity, (7.2).
(3) For fixed $\boldsymbol{x}$, substitute $\boldsymbol{r} = \boldsymbol{y} - \boldsymbol{x}$. If the region is much larger than the range of ξ, then for almost every $\boldsymbol{x}$ all the separations where ξ is non-negligible keep $\boldsymbol{y}$ inside the region, and the $\boldsymbol{r}$ integral may be extended over all space. Only a shell of thickness about one correlation length at the edge violates this.
(4) The $\boldsymbol{r}$ integral no longer depends on $\boldsymbol{x}$, and $\int_V \mathrm{d}^d x = V$.
(5) By (7.12) at $\boldsymbol{k} = 0$, $P(0) = \int \mathrm{d}^d r\; \xi(\boldsymbol{r})$.

What it means. A correlated field over a volume V is worth as much as a certain number of independent measurements, one per *correlation volume*. To see this, recall that the mean of n independent measurements of variance σ^2 has variance σ^2/n (Chapter 3), and write (7.24) in the same form:

$$\operatorname{Var}\bar{\delta}_V \approx \frac{\sigma^2}{N_{\mathrm{eff}}}, \qquad N_{\mathrm{eff}} = \frac{V}{V_c}, \qquad V_c \equiv \frac{1}{\sigma^2}\int \mathrm{d}^d r\; \xi(r). \tag{7.25}$$

The volume V acts like N_{eff} independent measurements, one per correlation volume V_c, because neighbouring points repeat each other's information. In words: a survey of volume V contains about V/L^3 statistically independent patches of size L, and the scatter between surveys that this causes is called cosmic variance.

When the average converges: ergodicity. Equation (7.24) answers question (1) for the mean. The spatial average converges to the ensemble mean, in the sense that its variance goes to zero, whenever $\frac{1}{V^2}\int_V \int_V \xi \to 0$ as $V \to \infty$. It is enough that $\xi(r) \to 0$ as $r \to \infty$: then $\int_V \xi$ grows more slowly than V, and dividing by V^2 sends the variance to zero. A field for which spatial averages converge to ensemble averages is called **ergodic**.

For estimating ξ itself, the same argument applies with the field replaced by the products $\delta(\boldsymbol{x})\delta(\boldsymbol{x}+\boldsymbol{r})$. It now needs the covariance of two such products, a four-point function, to die away at large distances. For a Gaussian field Wick's theorem (7.8) writes that four-point function as products of ξ's, so a correlation function that decays fast enough makes $\hat{\xi}$ converge as well [136].

Example: a field that is not ergodic. Add to a Gaussian field $g(\boldsymbol{x})$ a constant $A \sim \mathcal{N}(0, \sigma_A^2)$, drawn once per universe and the same at every point: $\delta(\boldsymbol{x}) = A + g(\boldsymbol{x})$. The result is homogeneous, isotropic and Gaussian, with $\xi_\delta(r) = \sigma_A^2 + \xi_g(r)$. But $\xi_\delta \to \sigma_A^2 \neq 0$ at large r, and (7.24) becomes $\operatorname{Var}\bar{\delta}_V \to \sigma_A^2 + P_g(0)/V \to \sigma_A^2$. However large the volume, the spatial mean converges to A, the offset of *our* universe, and never to the ensemble mean 0. This is not a mathematical curiosity. To a survey, fluctuation modes with wavelengths longer than the survey are exactly such an offset: they shift its mean density, and no measurement inside the survey can tell them apart from a different background.

Checking it on simulated maps. The script `code/ch07/07_sample_variance.py` draws 200 maps of 256×256 cells with the Gaussian $\xi = e^{-r^2/2\ell^2}$, $\ell = 4$, cuts each into square patches of side s, and measures the variance of the patch means (Figure 7.13, right). For this field $P(0) = 2\pi\ell^2 = 100.5$ cells^2, so the correlation area is about 100 cells. At $s = 64$ the measured variance is $0.02169 \pm 6.082 \times 10^{-4}$ (the error from the scatter between the 200 independent maps), the exact expression on the first line of (7.24), evaluated with the box modes, gives 0.02064, and

the large-patch limit $P(0)/s^2$ gives 0.02454. The limit overestimates slightly because it ignores the edge shell of step (3), where pairs straddling the boundary are lost. With the extra offset of standard deviation 0.5 the variance at $s = 64$ is 0.2792, and it flattens at $\sigma_A^2 = 0.25$ instead of falling: the non-ergodic field never averages down.

Watch out: Ergodicity is an assumption about the ensemble

No test on one realisation can prove that a field is ergodic, because the non-ergodic part (the offset A above, or modes larger than the survey) looks like a constant in every map. Ergodicity is part of the model, justified by the physics (here, by the decay of ξ predicted by the theory), and its failure on the largest scales is one reason those scales are the hardest to measure.

7.5.2 The sample variance of the power spectrum

The power spectrum is estimated from one map by averaging $|\delta_{\boldsymbol{k}}|^2/V$ over a shell of wavevectors, (7.22). *The question.* How far from $P(k)$ is that average likely to be? For a Gaussian field the answer is exact, because we know the distribution of every mode (Section 7.3.3). *One mode first.* For a wavevector that is not its own negative, $\delta_{\boldsymbol{k}} = a + ib$ with a and b independent Gaussians, each of variance $VP/2$ (half of the mode variance VP of (7.18)), so

$$x_{\boldsymbol{k}} \equiv \frac{|\delta_{\boldsymbol{k}}|^2}{VP(k)} = \frac{a^2+b^2}{VP} \sim \tfrac{1}{2}\chi_2^2 = \text{Exponential}(1), \qquad \mathbb{E}\,x = 1, \quad \operatorname{Var} x = 1. \tag{7.26}$$

A single mode is a terrible estimate of the power: its standard deviation equals its mean. *Then the shell.* Averaging helps, but only over *independent* modes, and here the reality condition matters. The shell contains N_{modes} wavevectors, but they come in pairs $\pm\boldsymbol{k}$ with $|\delta_{-\boldsymbol{k}}|^2 = |\delta_{\boldsymbol{k}}^*|^2 = |\delta_{\boldsymbol{k}}|^2$, so only $N_{\text{modes}}/2$ of the values are independent (Figure 7.12). Then

$$\operatorname{Var}\hat{P} \overset{(1)}{=} \operatorname{Var}\Big(\frac{2}{N_{\text{modes}}}\sum_{\text{pairs}}\frac{|\delta_{\boldsymbol{k}}|^2}{V}\Big) \overset{(2)}{=} \frac{4}{N_{\text{modes}}^2}\cdot\frac{N_{\text{modes}}}{2}\cdot P^2\operatorname{Var} x \overset{(3)}{=} \frac{2P^2}{N_{\text{modes}}}, \tag{7.27}$$

(1) Group the shell sum into $N_{\text{modes}}/2$ pairs of equal terms; each pair contributes $2|\delta_{\boldsymbol{k}}|^2/V$.
(2) The pairs are independent, so the variance of the sum is the sum of $N_{\text{modes}}/2$ equal variances, each $\operatorname{Var}(|\delta_{\boldsymbol{k}}|^2/V) = P^2\operatorname{Var} x$ (we take P constant across the thin shell).
(3) $\operatorname{Var} x = 1$ by (7.26).

Key idea: Sample variance of the power spectrum

For a Gaussian field measured without noise over a volume V, the shell-averaged power has fractional error

$$\frac{\Delta\hat{P}}{P} = \sqrt{\frac{2}{N_{\text{modes}}}}, \qquad N_{\text{modes}} = \begin{cases} \dfrac{V\,k^2\Delta k}{2\pi^2} & \text{(3D)}, \\[2ex] \dfrac{A\,k\,\Delta k}{2\pi} & \text{(2D, area } A\text{)}. \end{cases}$$

The "2" comes from the reality condition: $\pm\boldsymbol{k}$ carry the same information. In fact $N_{\text{modes}}\hat{P}/P \sim \chi^2_{N_{\text{modes}}}$, a sum of $N_{\text{modes}}/2$ independent χ_2^2 variables.

The mode count is density times volume. The allowed wavevectors sit on a lattice with one point per cell of volume $(2\pi/L)^d$ in $\boldsymbol{k}$-space (Section 7.4.1), a density of $V/(2\pi)^d$ points. A thin shell has volume $4\pi k^2\Delta k$ in 3D and $2\pi k\Delta k$ in 2D. Multiplying gives the two cases of N_{modes}

above. On the sphere the same counting gives $2\ell+1$ real degrees of freedom at multipole ℓ, and the full-sky estimator has $\mathrm{Var}\,\widehat{C}_\ell/C_\ell^2 = 2/(2\ell+1)$, the cosmic variance of the CMB derived later in Chapter 7.

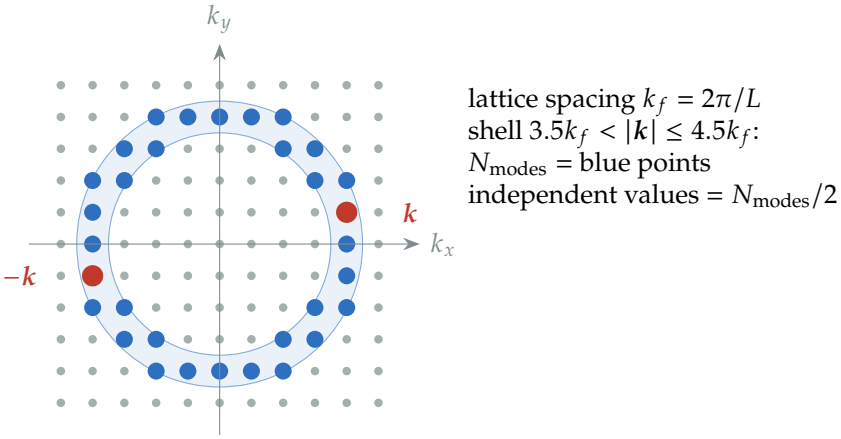

Figure 7.12: Counting modes in two dimensions. The allowed wavevectors form a square lattice of spacing $k_f = 2\pi/L$. The power at $|\boldsymbol{k}| \approx 4k_f$ is estimated from the blue points in the shell. The red pair $\boldsymbol{k}, -\boldsymbol{k}$ carries a single independent value of $|\delta_{\boldsymbol{k}}|^2$, because $\delta_{-\boldsymbol{k}} = \delta_{\boldsymbol{k}}^*$.

Checking it. Figure 7.13 tests both steps on simulated maps. Over 45900 modes of 50 maps, the normalised power $x_{\boldsymbol{k}}$ has mean 1.003 and variance 1.01, and its histogram is the exponential e^{-x} over three decades (left). Over 500 maps of 128×128 cells and 60 shells, the scatter of $\hat{P}$ follows $\sqrt{2/N_{\mathrm{modes}}}$ (middle): the first shell, with 4 modes, scatters by 0.7424 against $\sqrt{2/4} = 0.7071$, the tenth, with 20 modes, by 0.3181 against 0.3162, and averaged over all shells the ratio of measured to predicted scatter is 1.01. The scatter of the steep-spectrum maps in Figure 7.10 and of the first k-shells in Figure 7.11 is this effect: there, most of the variance sat in shells with a handful of modes.

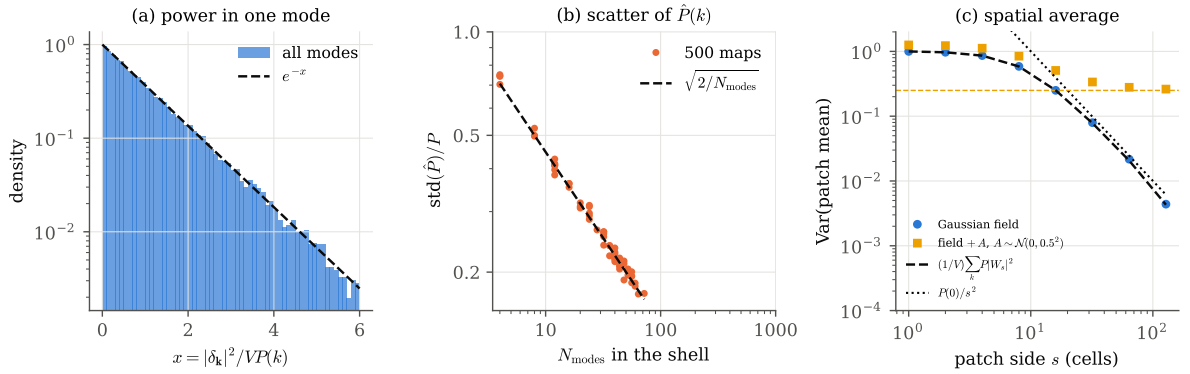

Figure 7.13: One universe, finite volume. Left: the power in a single Fourier mode, in units of its expectation, is exponentially distributed (log scale). Middle: the fractional scatter of the shell-averaged $\hat{P}(k)$ over 500 maps falls as $\sqrt{2/N_{\mathrm{modes}}}$. Right: the variance of the mean over an $s \times s$ patch falls as $P(0)/s^2$ for the Gaussian field (blue), following the exact box prediction (dashed); with a random offset per universe (orange) it stalls at the offset's variance.

Example: how well can a galaxy survey measure $P(k)$? Take an idealised survey of volume $V = 1\,(h^{-1}\mathrm{Gpc})^3 = 10^9\,(h^{-1}\mathrm{Mpc})^3$, no noise, and shells of width $\Delta k = 0.01\,h\,\mathrm{Mpc}^{-1}$ at $k =$

$0.1\,h\,\mathrm{Mpc}^{-1}$:

$$N_{\mathrm{modes}} = \frac{V\,k^2\Delta k}{2\pi^2} = \frac{10^9 \times 10^{-2} \times 10^{-2}}{19.74} = 5066, \qquad \frac{\Delta\hat{P}}{P} = \sqrt{\frac{2}{5066}} = 2.0\%.$$

At $k = 0.01\,h\,\mathrm{Mpc}^{-1}$ with $\Delta k = 0.005\,h\,\mathrm{Mpc}^{-1}$ the same survey has $N_{\mathrm{modes}} = 10^9 \times 10^{-4} \times 0.005/19.74 = 25$ and $\Delta\hat{P}/P = 28\%$. Large scales are always measured worst, because a fixed volume holds few long waves. The only remedy is a bigger volume; a better detector does not help.

Watch out: Sample variance is not noise

The error $\sqrt{2/N_{\mathrm{modes}}}$ is present in a perfect, noise-free measurement of the whole field. It comes from the randomness of the field itself: our universe is one draw. Instrument noise adds to it (white noise of power N multiplies $\sqrt{2/N_{\mathrm{modes}}}$ by $(P+N)/P$), but removing the noise never removes it.

In a periodic box the $\hat{P}$ in different shells are uncorrelated; in a real survey they are not. In the box, different shells contain different modes, and different modes are independent. A survey does not observe a periodic box. It multiplies the field by a window (the survey footprint), and multiplication in real space is convolution in Fourier space. The convolution mixes neighbouring modes and so correlates the shells [HobsonBMC p. 136, (6.5)]. Undoing that mixing on the sphere is the pseudo-C_ℓ problem of Chapter 8.

7.6 Smoothing: beams, pixels and window functions

No instrument records a field at a point. A telescope sees the sky through a beam a few arcminutes wide; a detector pixel integrates over its area; a galaxy survey counts galaxies in cells, or spheres, of finite size. Analysts also smooth on purpose: the amplitude of matter fluctuations is quoted as σ_8, the standard deviation of the density averaged over spheres of radius $8\,h^{-1}$Mpc, and the topological summaries of Chapter 12 are always computed on a field smoothed at a chosen scale. In each case the observed field is a weighted average of the true field over a neighbourhood. The averaging leaves the field homogeneous and Gaussian, and its effect on the power spectrum is a single multiplication.

Working definition 7.4 (window function)

A **window function** $W_R(\boldsymbol{x})$ is a weight centred on the origin with characteristic width R and $\int \mathrm{d}^d x\, W_R(\boldsymbol{x}) = 1$. The field **smoothed** on scale R is the convolution

$$\delta_R(\boldsymbol{x}) = \int \mathrm{d}^d y\; W_R(\boldsymbol{x}-\boldsymbol{y})\,\delta(\boldsymbol{y}) \tag{7.28}$$

[the weighted average of δ around $\boldsymbol{x}$, with weights W_R]. Its Fourier transform $W(\boldsymbol{k})$ is also called the window function; the normalisation means $W(\boldsymbol{0}) = 1$. *Examples:* a Gaussian beam, a top-hat sphere (counts in cells), a square pixel.

The question. If we know the power spectrum $P(k)$ of the true field, what are the power spectrum, the correlation function and the variance of the smoothed field?

7.6.1 The convolution theorem does all the work

Fourier transform (7.28) with the convention (7.10):

$$\delta_{R,\boldsymbol{k}} \overset{(1)}{=} \int \mathrm{d}^d x\; e^{-i\boldsymbol{k}\cdot\boldsymbol{x}} \int \mathrm{d}^d y\; W_R(\boldsymbol{x}-\boldsymbol{y})\,\delta(\boldsymbol{y}) \overset{(2)}{=} \int \mathrm{d}^d y\; \delta(\boldsymbol{y})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{y}} \int \mathrm{d}^d u\; W_R(\boldsymbol{u})\, e^{-i\boldsymbol{k}\cdot\boldsymbol{u}}$$
$$\overset{(3)}{=} W(\boldsymbol{k})\,\delta_{\boldsymbol{k}}. \tag{7.29}$$

(1) Definitions (7.10) and (7.28).
(2) Swap the order of integration and, for fixed $\boldsymbol{y}$, substitute $\boldsymbol{u} = \boldsymbol{x}-\boldsymbol{y}$; then $e^{-i\boldsymbol{k}\cdot\boldsymbol{x}} = e^{-i\boldsymbol{k}\cdot\boldsymbol{y}} e^{-i\boldsymbol{k}\cdot\boldsymbol{u}}$ and the two integrals separate.
(3) Each integral is a Fourier transform.

Smoothing acts mode by mode: each Fourier mode is multiplied by a number, $W(\boldsymbol{k})$. Multiplying each mode by its own number cannot make two different modes correlated, so the covariance of the smoothed modes follows at once from (7.12):

$$\langle \delta_{R,\boldsymbol{k}}\, \delta^*_{R,\boldsymbol{k}'} \rangle = W(\boldsymbol{k}) W^*(\boldsymbol{k}') \langle \delta_{\boldsymbol{k}} \delta^*_{\boldsymbol{k}'} \rangle = (2\pi)^d \delta_D(\boldsymbol{k}-\boldsymbol{k}')\, |W(\boldsymbol{k})|^2 P(k). \tag{7.30}$$

Key idea: Smoothing multiplies the power spectrum by $|W|^2$

A smoothed homogeneous field is homogeneous, with

$$P_R(k) = |W(k)|^2 P(k), \qquad \sigma_R^2 = \langle \delta_R^2 \rangle = \int \frac{\mathrm{d}^d k}{(2\pi)^d}\, |W(k)|^2 P(k).$$

If the field is Gaussian, so is the smoothed field, since (7.28) is linear. Smoothing removes power at $k \gtrsim 1/R$ and leaves larger scales alone.

7.6.2 The common windows

Gaussian. $W_R(\boldsymbol{x}) = (2\pi R^2)^{-d/2} e^{-x^2/2R^2}$. Its transform is (7.16) divided by the normalising constant $(2\pi R^2)^{d/2}$,

$$W(k) = e^{-k^2 R^2/2}. \tag{7.31}$$

It is the standard model of a telescope beam; a beam of full width at half maximum θ_{FWHM} has $R = \theta_{\mathrm{FWHM}}/\sqrt{8\ln 2}$.

Top-hat sphere. In three dimensions, $W_R(\boldsymbol{x}) = \frac{3}{4\pi R^3}$ for $|\boldsymbol{x}| < R$ and zero outside: the average over a ball, which is what counting galaxies in spheres does. It is isotropic, so the 3D radial transform (the inverse of (7.14)) applies:

$$W(k) \overset{(1)}{=} \frac{3}{4\pi R^3} \int_0^R 4\pi r^2\, \frac{\sin kr}{kr}\, \mathrm{d}r \overset{(2)}{=} \frac{3}{R^3 k} \left[\frac{\sin kr}{k^2} - \frac{r\cos kr}{k} \right]_0^R \overset{(3)}{=} \frac{3\,(\sin x - x\cos x)}{x^3}, \quad x = kR. \tag{7.32}$$

(1) $W(k) = 4\pi \int r^2 \mathrm{d}r\, W_R(r) \frac{\sin kr}{kr}$ with the constant weight inside the ball.
(2) Cancel 4π and one power of r, and integrate $r \sin kr$ by parts: $\int r \sin kr\, \mathrm{d}r = \frac{\sin kr}{k^2} - \frac{r\cos kr}{k}$.
(3) Evaluate at $r = R$ (the lower limit gives 0) and write $x = kR$.

For small x, $\sin x - x\cos x = \frac{x^3}{3} - \frac{x^5}{30} + \ldots$, so $W \to 1$ as it must. This is the W in the σ_8 integral, $\sigma_8^2 = \int_0^\infty \frac{k^2 \mathrm{d}k}{2\pi^2} P(k)\, W^2(k \cdot 8\,h^{-1}\mathrm{Mpc})$, evaluated with the CAMB spectrum in Chapter T1.

Disc. In two dimensions the average over a disc of radius R has, by the 2D radial transform and the identity $\frac{\mathrm{d}}{\mathrm{d}x}[xJ_1(x)] = xJ_0(x)$,

$$W(k) = \frac{1}{\pi R^2}\int_0^R 2\pi r\, J_0(kr)\,\mathrm{d}r = \frac{2}{R^2}\cdot\frac{R\,J_1(kR)}{k} = \frac{2J_1(kR)}{kR}. \tag{7.33}$$

Square patch. The patch means of Section 7.5.1 (the field averaged over square patches of side s) are a smoothing too. The average over a square has $W(\boldsymbol{k}) = \prod_a \frac{\sin(k_a s/2)}{k_a s/2}$, the product of the transforms of one-dimensional boxes, one per axis a. So the variance of the patch mean is σ_R^2 with this window. On the grid of the simulation it is the box sum $\frac{1}{V}\sum_{\boldsymbol{k}} P(k)|W(\boldsymbol{k})|^2$, which gave the dashed curve of Figure 7.13. The same formula also explains the large-patch limit $P(0)/V$ of (7.24). For a large patch, $|W|^2$ is a narrow spike around $\boldsymbol{k}=0$, of area $(2\pi)^d/V$ with $V = s^d$ the patch volume. Over so narrow a spike P is nearly constant, equal to $P(0)$, so the integral is $P(0)\cdot\frac{(2\pi)^d}{V}\cdot\frac{1}{(2\pi)^d} = P(0)/V$.

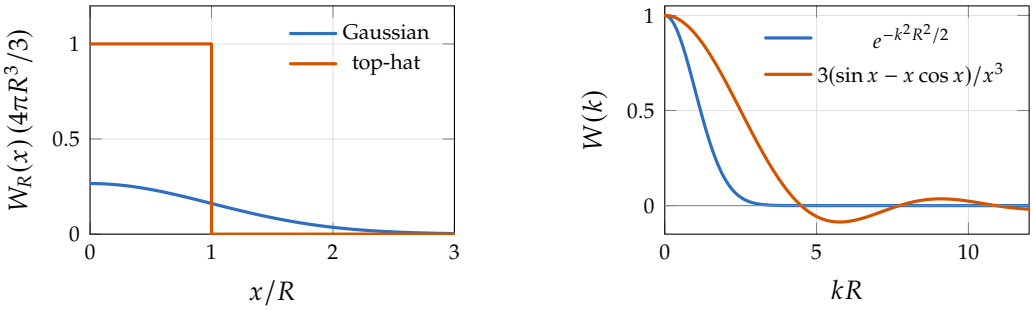

Figure 7.14: The two standard three-dimensional windows. Left: in real space, the Gaussian (scaled to the top-hat's height convention) and the top-hat ball of radius R. Right: their Fourier transforms. Both are 1 at $k = 0$ and cut off near $kR \approx 2$; the sharp edge of the top-hat leaves oscillating side lobes that let through some power at $kR \gg 1$, which the Gaussian suppresses completely.

Example: smoothing white noise. Pixel noise of variance σ_n^2 in cells of area Δ^2 has $\xi = \sigma_n^2\delta_{\boldsymbol{r},\boldsymbol{0}}$, so $P(k) = \sum_{\boldsymbol{r}}\Delta^2\xi(\boldsymbol{r})e^{-i\boldsymbol{k}\cdot\boldsymbol{r}} = \sigma_n^2\Delta^2$, flat. Smooth it with a 2D Gaussian of width $R \gg \Delta$:

$$\sigma_R^2 \overset{(1)}{=} \int\frac{\mathrm{d}^2k}{(2\pi)^2}\,\sigma_n^2\Delta^2\,e^{-k^2R^2} \overset{(2)}{=} \frac{\sigma_n^2\Delta^2}{2\pi}\int_0^\infty k\,e^{-k^2R^2}\,\mathrm{d}k \overset{(3)}{=} \frac{\sigma_n^2\Delta^2}{4\pi R^2}. \tag{7.34}$$

(1) The variance formula for σ_R^2 with $|W|^2 = e^{-k^2R^2}$ from (7.31).
(2) Polar coordinates, $\mathrm{d}^2k = 2\pi k\,\mathrm{d}k$.
(3) $\int_0^\infty k\,e^{-k^2R^2}\mathrm{d}k = \frac{1}{2R^2}$.

The noise variance falls as if we had averaged $4\pi R^2/\Delta^2$ independent pixels: a Gaussian beam of width R has an effective area $4\pi R^2$. For $R = 2$ pixels the noise r.m.s. drops by a factor $\sqrt{4\pi\cdot 2^2} = 2\sqrt{\pi}\times 2 \approx 7.1$. This is the trade-off of every smoothed map: less noise, less resolution.

7.6.3 Gradients and spectral moments

The variance is the first of a family. Because ∇ acting on $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$ brings down $i\boldsymbol{k}$, the gradient of the smoothed field has Fourier modes $i\boldsymbol{k}\,\delta_{R,\boldsymbol{k}}$, and by (7.30)

$$\langle|\nabla\delta_R|^2\rangle = \int\frac{\mathrm{d}^dk}{(2\pi)^d}\,k^2|W(k)|^2P(k) \equiv \sigma_1^2, \qquad \sigma_j^2 \equiv \int\frac{\mathrm{d}^dk}{(2\pi)^d}\,k^{2j}|W(k)|^2P(k), \tag{7.35}$$

the **spectral moments** of [106], with $\sigma_0 = \sigma_R$.

What σ_1/σ_0 measures. The ratio is an inverse length. Its inverse, σ_0/σ_1, is the typical distance over which the field changes by its own r.m.s., and so the typical spacing of its hot and cold spots. *Why it matters.* The expected number of peaks of a Gaussian field, and the expected Euler characteristic of its excursion sets, depend on the power spectrum only through such moments [105, 106]. Those counts are the topological summaries of Chapter 12. For a Gaussian field they carry no information beyond $P(k)$; their value lies in what they reveal when the field is *not* Gaussian.

Without smoothing, the moments of a power law can diverge. With $P = A/k$ in 2D, $\sigma_1^2 \propto \int k^2 \cdot \frac{A}{k} \cdot k\,\mathrm{d}k$, which grows like k_{Ny}^3 as the upper limit k_{Ny} grows. So the unsmoothed field is rough on the scale of the pixel, and its count of hot spots is set by the grid, not by the physics. A Gaussian window cures this:

$$\sigma_0^2 = \frac{A}{2\pi}\int_0^\infty e^{-k^2R^2}\mathrm{d}k = \frac{A}{2\pi}\frac{\sqrt{\pi}}{2R}, \qquad \sigma_1^2 = \frac{A}{2\pi}\int_0^\infty k^2 e^{-k^2R^2}\mathrm{d}k = \frac{A}{2\pi}\frac{\sqrt{\pi}}{4R^3}, \qquad \frac{\sigma_1}{\sigma_0} = \frac{1}{\sqrt{2}\,R},$$

using $\int_0^\infty e^{-k^2R^2}\mathrm{d}k = \frac{\sqrt{\pi}}{2R}$ and $\int_0^\infty k^2 e^{-k^2R^2}\mathrm{d}k = \frac{\sqrt{\pi}}{4R^3}$. Every count of features in a smoothed map must therefore say on which scale R it was smoothed.

Checking it. The script `code/ch07/08_smoothing.py` smooths one 512×512 map with $P = A/k$ and unit raw variance by Gaussian and disc windows (Figure 7.15). The smoothed power spectra lie on $|W|^2P$, including the side lobes of the disc's J_1. At $R = 4$ cells the Gaussian-smoothed map has $\sigma_R = 0.2505$ against the predicted 0.2466, the disc-smoothed one 0.3464 against 0.3439; the disc keeps more variance because it averages over a smaller effective area (πR^2 rather than $4\pi R^2$). Both variances fall as $1/R$, as the integral for σ_0^2 above predicts. The gradient ratio σ_1/σ_0 at $R = 4$, measured by spectral differentiation of the map, is 0.1766, against $1/(\sqrt{2}\cdot 4) = 0.177$ in the continuum and 0.1799 from the box modes.

7.6.4 What a beam does to the acoustic peaks

The temperature spectrum of the microwave sky (Chapter T1) has a flat plateau at the largest angles and then a train of acoustic peaks, the first at $\ell \approx 220$, the next at 536, 813, 1126, 1421 and 1726 in the fiducial model. Here ℓ is the multipole, the sphere's version of a wavenumber: a pattern of multipole ℓ has an angular wavelength of about $2\pi/\ell$ radians, so $\ell = 200$ means spots about a degree across. Its power is C_ℓ, plotted as $D_\ell = \ell(\ell+1)C_\ell/2\pi$ (Chapter T1). Every satellite that mapped this sky saw it through a beam, and the beams differed by a factor of eighty: about 7° for COBE, between 0.9° and 0.2° for the channels of WMAP, and about 5′ for the best Planck channels. *The question.* Which of the peaks can an experiment with a given beam see?

The beam window. On a patch of sky small enough to be flat, ℓ is the length of a two-dimensional wave vector, and C_ℓ plays the role of $P(k)$. A Gaussian beam is the Gaussian window (7.31) with $R = \sigma_b = \mathrm{FWHM}/\sqrt{8\ln 2}$, measured in radians. So each multipole of the sky is multiplied by $B_\ell = e^{-\ell^2\sigma_b^2/2}$, and, since smoothing multiplies the power by $|W|^2$ (Section 7.6.1), the observed spectrum is $B_\ell^2 C_\ell$. On the full sphere the exact form replaces ℓ^2 by $\ell(\ell+1)$, $B_\ell^2 = e^{-\ell(\ell+1)\sigma_b^2}$, which Chapter 8 derives from the Legendre expansion of the beam.

Where does the beam cut? It leaves the large scales alone and removes power above some

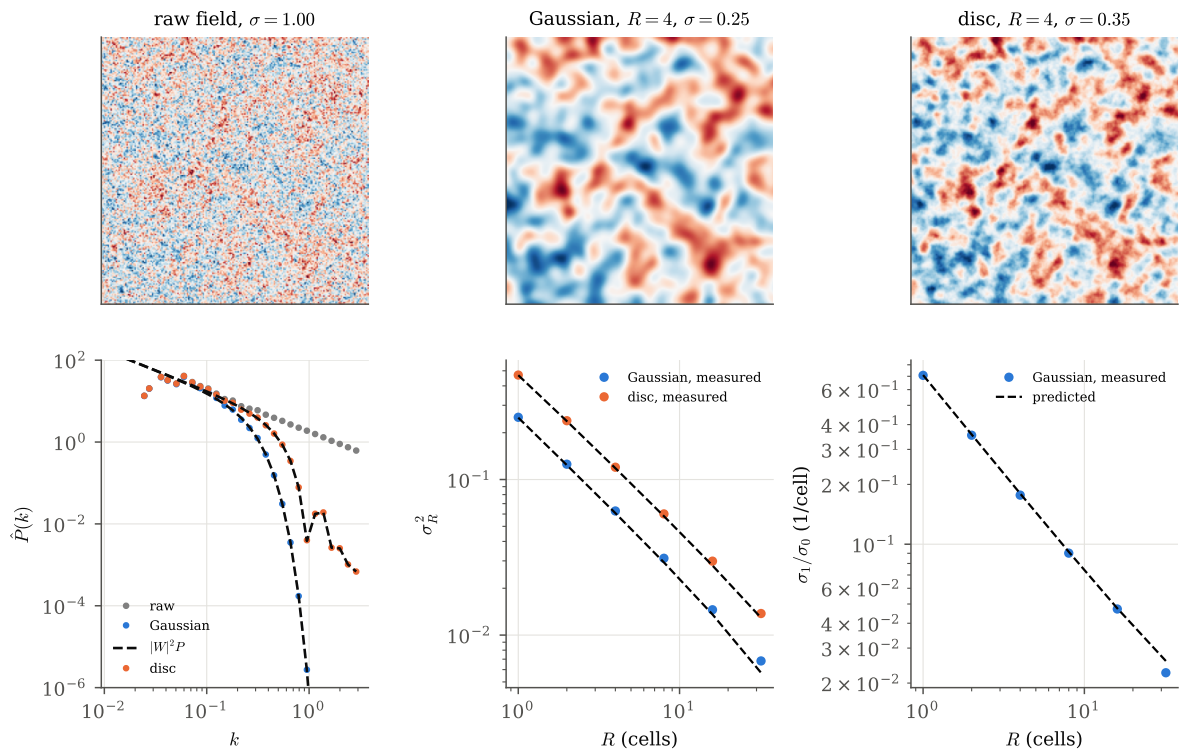

Figure 7.15: Smoothing a field with $P \propto k^{-1}$. Top: a corner of the raw map, and the same map smoothed with a Gaussian and with a disc of radius 4 cells, each shown in units of its own standard deviation. Bottom left: the smoothed spectra follow $|W|^2P$. Bottom middle: σ_R^2 falls as $1/R$ for both windows. Bottom right: the ratio σ_1/σ_0, the inverse feature spacing, falls as $1/(\sqrt{2}R)$.

multipole. A natural marker is the multipole where it has removed half the power:

$$e^{-\ell(\ell+1)\sigma_b^2} = \tfrac{1}{2} \overset{(1)}{=} \ell(\ell+1)\,\sigma_b^2 = \ln 2 \quad \overset{(2)}{\Longrightarrow} \quad \ell_{1/2} \approx \frac{\sqrt{\ln 2}}{\sigma_b}$$
$$\overset{(3)}{=} \frac{\sqrt{8\,\ln 2}}{\mathrm{FWHM}} \approx \frac{1.96}{\mathrm{FWHM\,[rad]}} \overset{(4)}{=} \frac{6740}{\mathrm{FWHM\,[arcmin]}}. \tag{7.36}$$

(1) Take minus the logarithm of both sides.

(2) For $\ell \gg 1$, $\ell(\ell+1) \approx \ell^2$. The exact positive root, $\ell = \left(-1 + \sqrt{1 + 4\ln 2/\sigma_b^2}\right)/2$, is smaller by less than $1/2$.

(3) Insert $\sigma_b = \mathrm{FWHM}/\sqrt{8\ln 2}$: $\sqrt{\ln 2} \cdot \sqrt{8\ln 2} = \sqrt{8}\,\ln 2 = 1.96$.

(4) One arcminute is 2.909×10^{-4} rad.

The amplitude B_ℓ (rather than the power B_ℓ^2) falls to one half at $\sqrt{2}$ times this multipole, $\sqrt{2\ln 2}/\sigma_b$. A beam twice as narrow reaches twice as far in ℓ. For the five beams of Figure 7.16, script `code/ch07/10_beam_peaks.py` gives:

FWHM	7°	1°	30′	10′	5′
σ_b [arcmin]	178	25.5	12.7	4.25	2.12
$\ell_{1/2}$	16	112	224	673	1347
peaks with $B_\ell^2 > 1/2$	0	0	1	2	4
deconvolved noise = sky at ℓ	62	363	654	1479	2014

The exact roots and the approximation (7.36) agree to one unit in every case (1348 against 1347 for the 5′ beam). The left panel of Figure 7.16 shows the beamed spectra $D_\ell B_\ell^2$. The suppression

is exponential in ℓ^2, so a beam always takes the highest peaks first: the 10′ beam keeps the first peak at 93% of its power and the fifth at only 5%.

Undoing the beam, and its price. The beam is known, so it can be divided out: $\widehat{C}_\ell/B_\ell^2$ is again an estimate of the true C_ℓ. The price is noise. The detector noise is added *after* the beam, so dividing by B_ℓ^2 also multiplies the noise power by $1/B_\ell^2 = e^{\ell(\ell+1)\sigma_b^2}$. White noise has a flat spectrum, as in the example of smoothing white noise above: pixel noise of variance σ_n^2 in cells of solid angle Ω has $N_\ell = \sigma_n^2\Omega$ for every ℓ, and $\sqrt{N_\ell}$ is the map depth, quoted in μK arcmin. So the deconvolved spectrum is $C_\ell + N_\ell/B_\ell^2$ on average, and the second term climbs like $e^{\ell^2\sigma_b^2}$. The right panel of Figure 7.16 shows it for the same depth, 30 μK arcmin, in every case: each curve follows the sky until the noise wall rises through it, at the multipole in the last row of the table. Beyond that point no amount of deconvolution recovers the peaks; Chapter 8 turns this into an error bar.

What each experiment could see. A 7° beam, COBE's, keeps half the power only up to $\ell \approx 16$. That is the Sachs–Wolfe plateau, the flat part of D_ℓ at $\ell \lesssim 20$ that carries the amplitude and the tilt of the primordial fluctuations, and nothing of the peaks: at the first peak, $\ell = 220$, the beam leaves $B_\ell^2 = e^{-\ell(\ell+1)\sigma_b^2} \approx 10^{-57}$ of the power. WMAP's sharpest channel had a beam of about 13′, so $\ell_{1/2} \approx 518$: the first peak keeps 88% of its power, the second 48% and the third only 18%. With its noise wall between those of the 10′ and 30′ columns, such a beam measures the first two peaks well and the third at the edge of its reach. A 5′ beam, Planck's, keeps half the power up to $\ell \approx 1347$, so the first four peaks pass almost untouched, and the deconvolved noise of a 30 μK arcmin map overtakes the sky only at $\ell \approx 2014$: all six peaks of the figure, and the start of the damping tail beyond them, are within reach. The beam width and the reach in multipoles are two ways of stating one number: $\ell_{1/2} \approx 6740/\mathrm{FWHM}[']$.

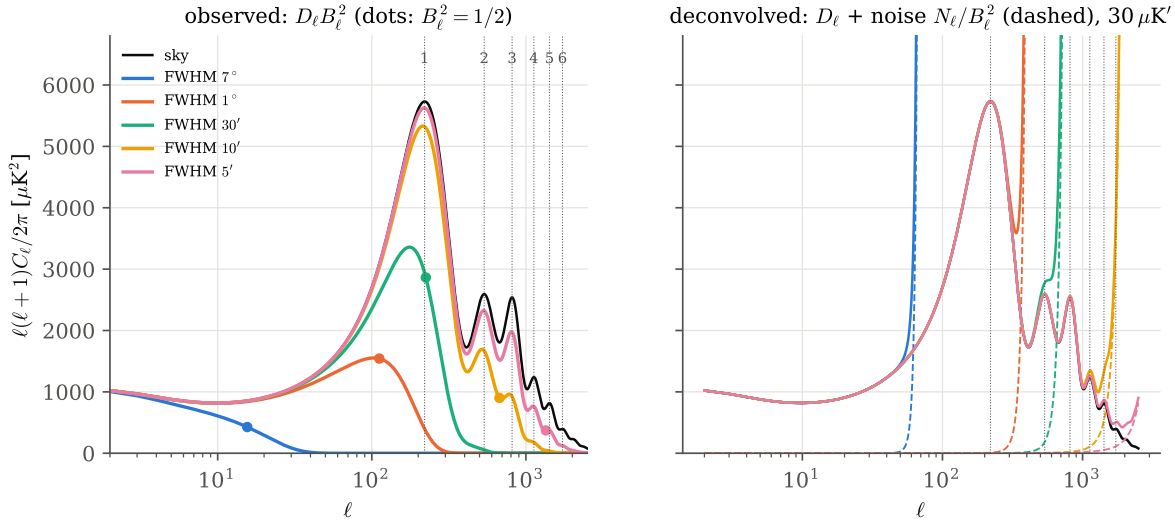

Figure 7.16: What a beam does to the acoustic peaks. Left: the fiducial spectrum D_ℓ (black) seen through Gaussian beams from 7° to 5′; the dotted lines mark the six peaks and each dot the multipole $\ell_{1/2}$ where the beam has removed half the power. The higher peaks go first. Right: the beam divided back out, for white noise of the same depth in every case. The sky is recovered (solid curves lie on the black one) until the deconvolved noise N_ℓ/B_ℓ^2 (dashed) rises through it like a wall.

Smoothing is the first example of an observational effect acting on a summary: the instrument applies a known linear operation to the field, and the power spectrum changes in a known way.

Chapter 8 adds two effects that are harder to undo: noise, which adds power, and the mask, which couples modes.

7.7 What the power spectrum throws away

Imagine a universe in which a first-order phase transition left behind thin shells, the walls of expanding bubbles, scattered at random. Its density map is a field of rings. Now take that map, Fourier transform it, keep the amplitude $|\delta_k|$ of every mode exactly, replace every phase by a random number, and transform back. The result has precisely the same power spectrum as the rings, mode by mode, and it looks like nothing but Gaussian noise (Figure 7.17, panels a and b). Any analysis that measures only $P(k)$ would declare the two universes identical. The physics that made the rings is invisible to it.

The reason is in the definition of the estimator. Write each mode in polar form, $\delta_{\boldsymbol{k}} = |\delta_{\boldsymbol{k}}|e^{i\varphi_{\boldsymbol{k}}}$, with amplitude $|\delta_{\boldsymbol{k}}|$ and phase $\varphi_{\boldsymbol{k}}$. The estimator $\hat{P}(k)$ of (7.22) uses $|\delta_{\boldsymbol{k}}|^2$ and nothing else, so it is unchanged by any change of phases $\varphi_{\boldsymbol{k}} \to \varphi_{\boldsymbol{k}} + \alpha_{\boldsymbol{k}}$ with $\alpha_{-\boldsymbol{k}} = -\alpha_{\boldsymbol{k}}$ (the restriction keeps the reality condition (7.11), so the map stays real). Half of the numbers that describe the map, one phase per independent mode, are discarded.

The question. When is discarding the phases harmless, and what do the phases carry when it is not?

For a Gaussian field the phases are pure noise. In Section 7.3.3 we found that a homogeneous Gaussian field has independent, uniformly distributed phases, independent also of the amplitudes. There is nothing to learn from a uniform random number that the theory already told us was uniform. This is the Fourier-space form of the result of Section 7.2: for a Gaussian field the power spectrum is the whole story.

For a non-Gaussian field the phases carry the shapes. In a non-Gaussian field the phases of different modes are *correlated*. A thin ring is a sum of many plane waves whose crests line up along the ring. That alignment, a relation between the phases of different $\boldsymbol{k}$, is what makes a sharp, connected structure instead of a random interference pattern. The same holds for filaments, walls, clumps and the step-like edges of cosmic strings.

Why random phases look Gaussian. Randomising the phases makes almost any field look Gaussian. Each pixel of the randomised map is a sum over many modes, $\delta(\boldsymbol{x}) = \frac{1}{V}\sum_{\boldsymbol{k}} |\delta_{\boldsymbol{k}}| \cos(\boldsymbol{k}\cdot\boldsymbol{x} + \varphi_{\boldsymbol{k}})$ (pairing $\pm\boldsymbol{k}$), and the phases are now independent random numbers. By the central limit theorem (Chapter 2) a sum of many independent terms is close to Gaussian, whatever the amplitudes. So, as long as the power is spread over many modes, phase randomisation gives an almost Gaussian field with the same power spectrum.

Seeing it. The script `code/ch07/09_phases.py` builds a map of 70 thin rings of random radii on a 256×256 periodic grid, standardised to zero mean and unit variance, and its phase-randomised twin. The phases are taken from the FFT of fresh white noise, which has the Hermitian symmetry built in, so the twin is real automatically:

Listing 7.2: Phase randomisation: keep $|\delta_k|$, draw new phases (`code/ch07/lib_fields.py`)

```
154 def randomise_phases(field, rng=None):
155     """Same |FFT| as field, phases replaced by those of fresh white noise (Hermitian
        symmetry automatic)."""
```

```
156     rng = np.random.default_rng() if rng is None else rng
157     field = np.asarray(field)
158     d = field.ndim
159     N = field.shape[0]
160     fk = np.fft.rfftn(field)
161     wk = np.fft.rfftn(rng.standard_normal(field.shape))
162     u = wk / np.abs(wk)                       # unit complex numbers, uniform phases
163     out = np.abs(fk) * u
164     out.flat[0] = fk.flat[0]                  # keep the mean
165     return np.fft.irfftn(out, s=[N] * d, axes=tuple(range(d)))
```

Lines 160–161 transform the map and a white-noise map of the same size. Line 162 reduces the white-noise modes to unit complex numbers, whose phases are uniform (Section 7.3.3) and already satisfy $u_{-\boldsymbol{k}} = u^*_{\boldsymbol{k}}$. Line 163 attaches them to the old amplitudes, line 164 keeps the $\boldsymbol{k} = 0$ mode (the mean), and line 165 transforms back.

The two maps have the same $\hat{P}(k)$ to 7.772×10^{-16}, rounding error (Figure 7.18, left). Everything else differs. *The one-point distribution.* For the rings it is strongly skewed, with skewness 1.856: most pixels sit on the flat background just below the mean, and a few on the bright rings. The twin has skewness 0.01711 and a Gaussian histogram, as the central-limit argument says. *The excursion sets* differ most of all. Count the connected regions where the field exceeds ν standard deviations (`scipy.ndimage.label` labels the connected clusters of pixels). At $\nu = 1$ the rings give 15 regions, chains of overlapping rings; their Gaussian twin gives 487 small blobs. The ring curve has a sharp spike near $\nu \approx 1.6$, the crest height of a single ring. The grid samples each crest at slightly different heights. So a threshold just below the crest height chops every ring into many short arcs, while a threshold just above it leaves only the places where rings overlap.

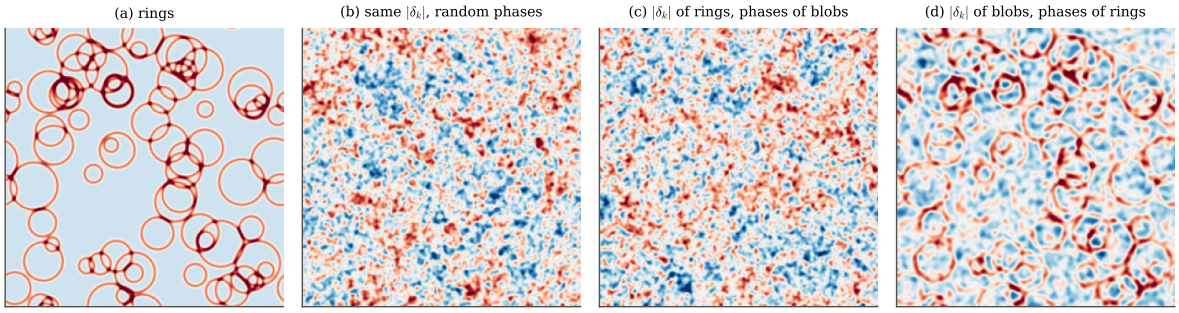

Figure 7.17: Amplitudes and phases. (a) A field of thin rings. (b) The same Fourier amplitudes with random phases: the same power spectrum, and the rings are gone. (c) The amplitudes of the rings with the phases of a Gaussian blob field: the phases are random, and so is the picture. (d) The amplitudes of the blob field with the phases of the rings: the rings come back. Where structures are, and what shape they have, is written in the phases.

The amplitudes say how much of each scale is present; the phases say where it is and how it is arranged. The phase swap in Figure 7.17(c, d) shows this directly. Give the ring map's amplitudes the phases of a Gaussian blob field, and the result is another random-looking Gaussian pattern: the phases of a Gaussian field are random, and they decide what the picture looks like. Give the blob amplitudes the ring phases, and the rings reappear, blurred because the blob amplitudes are weak at high k.

7.7.1 A taxonomy of summaries

The power spectrum is one choice of what to measure. Given a field $\phi : \mathcal{M} \to \mathbb{R}$ on a domain $\mathcal{M}$, the summaries used in physics fall into a few families, each answering a different question

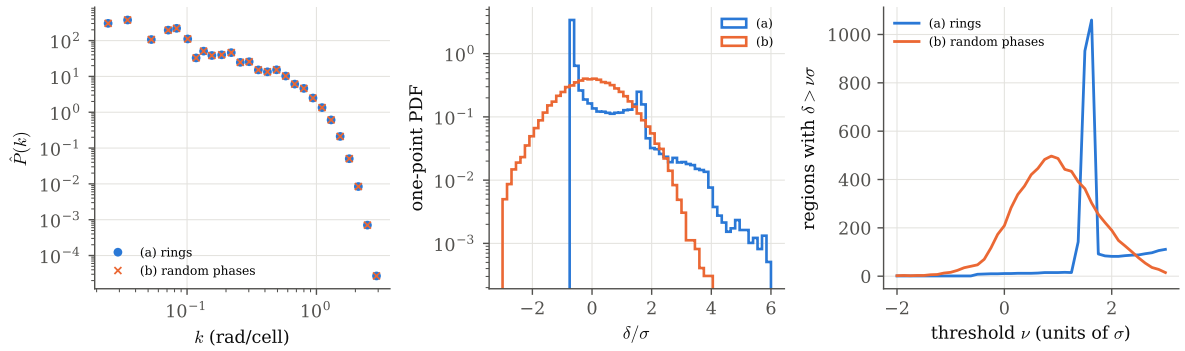

Figure 7.18: Three summaries of the ring map (a) and its phase-randomised twin (b). Left: identical power spectra. Middle: very different one-point distributions, skewed for the rings, Gaussian for the twin. Right: the number of connected regions above a threshold ν, which tells the two apart at all but the lowest and highest thresholds.

about the same data:

$$\phi \longrightarrow \begin{cases} \text{amplitude} & \langle\phi\rangle,\ \mathrm{Var}(\phi),\ P(\phi), \\ \text{correlation} & \xi(r),\ P(k),\ C_\ell, \\ \text{higher-order structure} & B,\ T, \ldots, \\ \text{geometry/morphology} & \text{sizes, shapes, curvature, excursion geometry,} \\ \text{topology} & \beta_i,\ \chi,\ \text{persistence.} \end{cases} \tag{7.37}$$

Each row answers its own question. *Amplitude:* how large is the field typically? It is read from the one-point distribution $P(\phi)$; the skewness above is an amplitude statistic. *Correlation:* how are values at different places related? This is everything for a Gaussian field, and blind to phases. *Higher-order structure:* the three- and four-point functions and their Fourier transforms, the bispectrum B and trispectrum T. The failed Wick test of the lognormal field in Figure 7.5 was a four-point statistic. *Geometry and topology:* what shapes does the field make in real space? An example is the excursion set $\{\boldsymbol{x} : \phi(\boldsymbol{x}) > \nu\}$, whose connected pieces we just counted. In topology β_0 counts connected components, β_1 counts holes, and χ, the Euler characteristic, combines them (Chapter 12).

Each of these summaries S, once chosen, is an ordinary random variable. Repeated universes give it a sampling distribution $P(S \mid \theta)$, with θ the parameters of the theory, and the machinery of the rest of the book applies to it unchanged.

The ring example raises the question behind the last row. Is there physical information in the way the regions of a field are connected that the statistic we are already using, here the power spectrum, does not expose? For the rings the answer is plainly yes, and the region count of Figure 7.18 already sees it. Chapter 12 builds that observation into a method: excursion sets at every threshold, their Betti numbers and Euler characteristic, and persistence, the record of how long each structure survives as the threshold moves. It also turns them into statistics with sampling distributions computed from exactly the Gaussian simulations of Section 7.4, because a Gaussian field with the measured $P(k)$ is the natural null hypothesis: it is the field that contains the two-point information and nothing else.

How this is used in real research: Simulated Gaussian fields: verification and research

Every simulation of a flat Gaussian field above has been a *verification*: we knew the answer analytically (the Wiener–Khinchin theorem, the recipe's normalisation, the exponential distribution of a mode, $\sqrt{2/N_{\mathrm{modes}}}$, $|W|^2P$) and the simulation confirmed it, which is how one tests both the code and one's understanding. In research the same machinery

is the instrument itself, used where no formula exists. Survey analyses estimate the covariance of $\hat{P}(k)$ or $\hat{\xi}(r)$ including the survey window, non-linear evolution and galaxy bias from hundreds to thousands of mock catalogues, typically generated from Gaussian or lognormal fields made exactly as in Section 7.4 or from N-body runs; the finite number of mocks itself biases the inverse covariance, and corrections for it are standard [6, 137]. Searches for non-Gaussianity in the CMB compare the data with large sets of Gaussian simulations that share the measured power spectrum [107]; phase-randomised "surrogate" maps play the same role for any field. On the sphere, the transfer of power by the mask and beam is calibrated on simulated skies (Chapter 8).

The two-point summaries are where the analysis of a field starts and, for a Gaussian field, where it ends. On the sky the plane waves become spherical harmonics, the power spectrum becomes C_ℓ, and the mode counting of Section 7.5.2 becomes cosmic variance; that is the CMB's version of the same story.

Recap

- A theory predicts the statistics of a field, not the field. A random field is a random variable at every point, specified by its n-point distributions; the ensemble is the stack of possible universes.
- Homogeneity and isotropy make the covariance a function of distance only, $\xi(r) = \langle \delta(\boldsymbol{x})\delta(\boldsymbol{x}+\boldsymbol{r})\rangle$, with $\xi(0) = \sigma^2$, $|\xi| \le \xi(0)$, and positive definiteness.
- A Gaussian field is fixed by ξ: the joint law of any set of points is $\mathcal{N}(\mathbf{0}, \mathbf{C})$ with $\mathbf{C}_{ij} = \xi(r_{ij})$; the mean field around a hot spot is $\nu\xi(r)/\sigma$; four-point moments are sums over pairings (Wick).
- Fourier modes of a homogeneous field are uncorrelated, $\langle \delta_{\boldsymbol{k}} \delta^*_{\boldsymbol{k}'}\rangle = (2\pi)^d \delta_D(\boldsymbol{k} - \boldsymbol{k}')P(k)$, with P the Fourier transform of ξ (Wiener–Khinchin) and $P \ge 0$. For a Gaussian field each mode has an exponential power and a uniform phase.
- Simulation: FFT white noise, multiply by $\sqrt{P(k)/\Delta^d}$, inverse FFT; a box holds only $k_f \le k \le k_{\rm Ny}$ and has zero mean.
- One universe: spatial averages replace ensemble averages only for ergodic fields; the mean over a volume has variance $P(0)/V$; a shell-averaged power spectrum has $\Delta\hat{P}/P = \sqrt{2/N_{\rm modes}}$, even without noise.
- Smoothing by a window multiplies the spectrum by $|W(k)|^2$; the spectral moments σ_j set the variance, the gradients and the feature spacing.
- $P(k)$ discards the phases. For a Gaussian field they are noise; for any other field they hold the shapes, which morphology and topology (Chapter 12) measure.

7.8 The Fourier modes of the sphere

Point a radio telescope tuned to millimetre wavelengths at any direction on the sky and it records a temperature of about 2.7255 K. Subtract that average and what remains is a pattern of hot and cold patches, typically about a hundred microkelvin above or below the average (that is the rms). This pattern is the cosmic microwave background (CMB) anisotropy. It is a random field on the sky: one real number $\Theta(\boldsymbol{e})$ for every direction $\boldsymbol{e}$. The number is the temperature

contrast $\delta T/T$. We always quote it multiplied by $T_0 = 2.7255 \times 10^6\ \mu$K, so that Θ and everything built from it are in microkelvin, the units CAMB uses (Chapter T1).

For fields in flat space (Sections 7.3 and 7.3.2) the key step was to expand the field in plane waves $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$. Each plane wave is a pattern of one definite wavelength. Homogeneity made the amplitudes of different plane waves uncorrelated, and the variance of each amplitude was the power spectrum $P(k)$. The sky, however, is a sphere, and a sphere has no plane waves: $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$ has no meaning on a curved, closed surface. So before any statistics we need a piece of geometry.

The question. Which patterns on the sphere play the role that plane waves play in flat space: patterns of a definite angular size, from which any sky can be built, and which a rotation of the sky only shuffles among themselves?

7.8.1 Spherical harmonics: what they are and why they are the right modes

The answer is the spherical harmonics. To see why, ask first what makes a plane wave special. It is an eigenfunction of the Laplacian: $\nabla^2 e^{i\boldsymbol{k}\cdot\boldsymbol{x}} = -k^2 e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$. The eigenvalue $-k^2$ measures how rapidly the pattern wiggles, and $2\pi/k$ is its wavelength. The Laplacian also makes sense on the unit sphere, so the natural replacement for plane waves is the eigenfunctions of the Laplacian on the sphere,

$$\nabla^2_{S^2} Y = \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\Big(\sin\theta\,\frac{\partial Y}{\partial\theta}\Big) + \frac{1}{\sin^2\theta}\frac{\partial^2 Y}{\partial\phi^2} = -\ell(\ell+1)\,Y, \tag{7.38}$$

where $\theta \in [0,\pi]$ is the colatitude (angle from the north pole) and $\phi \in [0, 2\pi)$ the longitude of the direction $\boldsymbol{e}$. We have met these functions before: they are the angular parts of the hydrogen wavefunctions. In quantum mechanics (with $\hbar = 1$) the orbital angular momentum $\boldsymbol{L} = -i\,\boldsymbol{r}\times\boldsymbol{\nabla}$ satisfies $\boldsymbol{L}^2 = -\nabla^2_{S^2}$, and the **spherical harmonics** $Y_{\ell m}(\theta,\phi)$ are the simultaneous eigenfunctions

$$\boldsymbol{L}^2\,Y_{\ell m} = \ell(\ell+1)\,Y_{\ell m}, \qquad L_z\,Y_{\ell m} = m\,Y_{\ell m}, \qquad \ell = 0,1,2,\ldots, \quad m = -\ell,\ldots,\ell, \tag{7.39}$$

with $L_z = -i\,\partial/\partial\phi$. So $Y_{\ell m} \propto e^{im\phi}$, and in general $Y_{\ell m}(\theta,\phi) = N_{\ell m} P_\ell^m(\cos\theta)\,e^{im\phi}$, with P_ℓ^m an associated Legendre function and $N_{\ell m}$ a normalisation constant. We use the standard (Condon–Shortley) phase convention of quantum mechanics, the one healpy and CAMB also use. The first few, written out so that we can compute with them, are

$$\begin{aligned}
&Y_{00} = \frac{1}{\sqrt{4\pi}}, && Y_{10} = \sqrt{\frac{3}{4\pi}}\cos\theta, && Y_{1,\pm1} = \mp\sqrt{\frac{3}{8\pi}}\sin\theta\,e^{\pm i\phi},\\
&Y_{20} = \sqrt{\frac{5}{16\pi}}\,(3\cos^2\theta - 1), && Y_{2,\pm1} = \mp\sqrt{\frac{15}{8\pi}}\sin\theta\cos\theta\,e^{\pm i\phi}, && Y_{2,\pm2} = \sqrt{\frac{15}{32\pi}}\sin^2\theta\,e^{\pm 2i\phi}.
\end{aligned} \tag{7.40}$$

Three properties of the $Y_{\ell m}$ are all we will use.

1. **Orthonormality.** With $\mathrm{d}\Omega = \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi$ the solid-angle element,

$$\int \mathrm{d}\Omega\; Y_{\ell m}(\boldsymbol{e})\,Y^*_{\ell' m'}(\boldsymbol{e}) = \delta_{\ell\ell'}\delta_{mm'}. \tag{7.41}$$

   In quantum mechanics this is $\langle \ell m|\ell' m'\rangle = \delta_{\ell\ell'}\delta_{mm'}$: eigenfunctions of a Hermitian operator with different eigenvalues are orthogonal.

2. **Completeness.** Any square-integrable function on the sphere is a sum of $Y_{\ell m}$'s, just as any periodic function is a Fourier series.

3. **Complex conjugation flips m.** Since $e^{im\phi}$ becomes $e^{-im\phi}$ and the Condon–Shortley phase carries a sign $(-1)^m$,

$$Y_{\ell m}^{*} = (-1)^m \, Y_{\ell,-m}. \tag{7.42}$$

Check it on (7.40): $Y_{11}^{*} = -\sqrt{3/8\pi}\sin\theta\, e^{-i\phi} = -Y_{1,-1}$, which is $(-1)^1 Y_{1,-1}$.

What do ℓ and m mean on the sky? In short, ℓ sets the angular size of the pattern and m sets how its zero lines are oriented. Figure 7.19 shows the real parts of six harmonics in the Mollweide projection, the equal-area map of the whole sky in which the equator is the horizontal midline and the poles are the top and bottom points. The real part of $Y_{\ell m}$ has ℓ nodal lines (lines where it is zero) in total: m of them are great circles through the poles (the factor $\cos m\phi$ vanishes on $2m$ half-meridians) and $\ell - |m|$ are circles of constant latitude (the zeros of P_ℓ^m). The $m = 0$ harmonics depend on latitude only ("zonal"), the $|m| = \ell$ ones on longitude only ("sectoral"), and the rest form a chessboard ("tesseral"). In every case the distance between neighbouring nodal lines is about π/ℓ radians, so

$$\text{multipole } \ell \quad\longleftrightarrow\quad \text{angular scale } \vartheta \approx \frac{\pi}{\ell} = \frac{180^\circ}{\ell}. \tag{7.43}$$

This is the sphere's version of "wavenumber $k \leftrightarrow$ half-wavelength π/k".

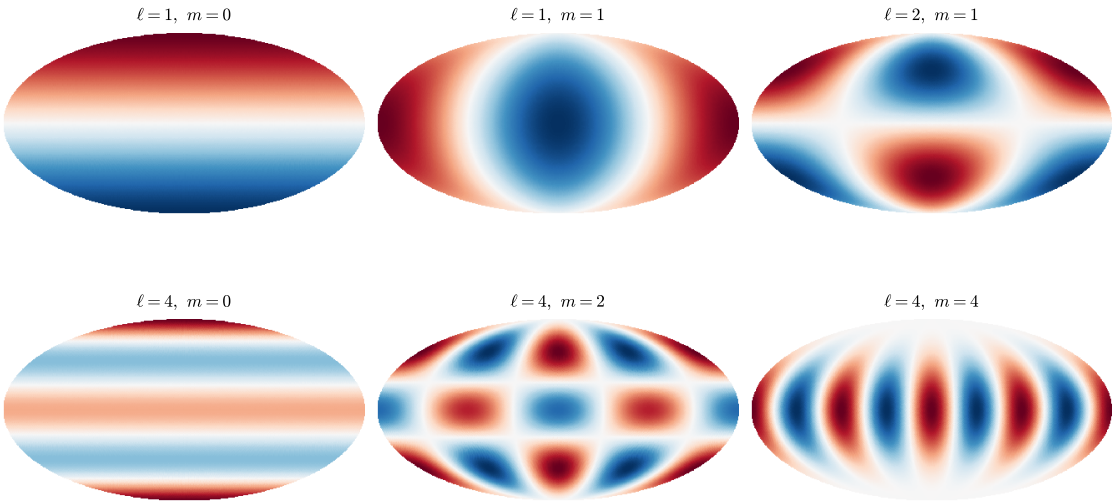

Figure 7.19: Real parts of six spherical harmonics on the whole sky (Mollweide projection, north pole at the top; red positive, blue negative). Top row: the $\ell = 1$ dipole along the pole ($m = 0$) and along the equator ($m = 1$), and a quadrupole with $m = 1$. Bottom row: three $\ell = 4$ harmonics. With $m = 0$ the pattern has four latitude rings of zeros; with $m = 4$ it has eight half-meridians of zeros; $m = 2$ mixes the two. All three bottom patterns have the same angular scale, about $180^\circ/4 = 45^\circ$.

7.8.2 Expanding a sky: the coefficients $a_{\ell m}$

Completeness (property 2 above) lets us write any sky as a sum of harmonics, and orthonormality (property 1) tells us how to find the coefficients. Every CMB analysis starts with this step [HobsonBMC (10.2)], [Hivon (4)–(5)].

Working definition 7.5 (spherical-harmonic coefficients)

A sky $\Theta(\boldsymbol{e})$ is expanded as

$$\Theta(\boldsymbol{e}) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} a_{\ell m}\, Y_{\ell m}(\boldsymbol{e}), \qquad a_{\ell m} = \int \mathrm{d}\Omega\; \Theta(\boldsymbol{e})\, Y^*_{\ell m}(\boldsymbol{e}). \tag{7.44}$$

The coefficient $a_{\ell m}$ [one complex number per (ℓ, m), the overlap of the sky with the pattern $Y_{\ell m}$] measures how much of the pattern $Y_{\ell m}$ the sky contains. *Operationally:* multiply the map pixel by pixel by $Y^*_{\ell m}$, multiply by the pixel area, and add up (Section 7.11.2).

Why is the coefficient given by that integral? Because the harmonics are orthonormal, so projecting the sky onto one harmonic picks out its coefficient and nothing else. In steps: multiply the expansion by $Y^*_{\ell' m'}(\boldsymbol{e})$ and integrate over the sky,

$$\int \mathrm{d}\Omega\; \Theta(\boldsymbol{e})\, Y^*_{\ell' m'}(\boldsymbol{e}) \overset{(1)}{=} \sum_{\ell m} a_{\ell m} \int \mathrm{d}\Omega\; Y_{\ell m}(\boldsymbol{e})\, Y^*_{\ell' m'}(\boldsymbol{e}) \overset{(2)}{=} \sum_{\ell m} a_{\ell m}\, \delta_{\ell \ell'} \delta_{m m'} \overset{(3)}{=} a_{\ell' m'}. \tag{7.45}$$

(1) Insert the expansion and exchange the (convergent) sum with the integral.
(2) Orthonormality (7.41).
(3) The Kronecker deltas keep only the term $\ell = \ell'$, $m = m'$.

Cosmological analyses ignore the first two multipoles and start at $\ell = 2$ [HobsonBMC p. 230]. The reason is that neither carries the primordial pattern. The monopole a_{00} is $\sqrt{4\pi}$ times the sky average (because $Y_{00} = 1/\sqrt{4\pi}$), and we subtracted that average. The dipole $\ell = 1$ is dominated by our own motion through the CMB, which Doppler-shifts the temperature by a few millikelvin.

The sky is real, so half of the coefficients are redundant. The $a_{\ell m}$ are complex, but a temperature is a real number, $\Theta^* = \Theta$. What does that imply for the coefficients? Each negative-m coefficient is fixed by its positive-m partner:

$$a_{\ell,-m} \overset{(1)}{=} \int \mathrm{d}\Omega\; \Theta\, Y^*_{\ell,-m} \overset{(2)}{=} \int \mathrm{d}\Omega\; \Theta\, (-1)^m Y_{\ell m} \overset{(3)}{=} (-1)^m \left(\int \mathrm{d}\Omega\; \Theta\, Y^*_{\ell m} \right)^* \overset{(4)}{=} (-1)^m\, a^*_{\ell m}. \tag{7.46}$$

(1) Definition (7.44) with $m \to -m$.
(2) Conjugate (7.42): $Y^*_{\ell,-m} = (-1)^{-m} Y_{\ell m} = (-1)^m Y_{\ell m}$.
(3) Θ is real, so $\Theta Y_{\ell m} = (\Theta Y^*_{\ell m})^*$, and the conjugate can be taken outside the integral.
(4) Definition (7.44) again.

Two consequences follow. For $m = 0$, (7.46) reads $a_{\ell 0} = a^*_{\ell 0}$, so $a_{\ell 0}$ *is real*. For $m \neq 0$ the negative-m coefficients carry no new information, because the positive-m ones fix them. So at each multipole ℓ the sky is described by

$$\underbrace{1}_{a_{\ell 0}\ \text{real}} + \underbrace{2\ell}_{\mathrm{Re}\, a_{\ell m},\ \mathrm{Im}\, a_{\ell m},\ m=1,\ldots,\ell} = 2\ell + 1 \text{ real numbers}. \tag{7.47}$$

This count becomes the number of degrees of freedom of the power-spectrum estimator in Section 7.10. A second way to reach it: count the independent real patterns at multipole ℓ. They are the real and imaginary parts of the $Y_{\ell m}$ with $m \geq 0$, which is $2(\ell + 1)$ functions, minus $\mathrm{Im}\, Y_{\ell 0}$, which is identically zero. That leaves $2\ell + 1$, the same number. A real sky band-limited to $\ell \leq \ell_{\max}$ is therefore $\sum_{\ell=0}^{\ell_{\max}} (2\ell + 1) = (\ell_{\max} + 1)^2$ real numbers. Libraries store only $m \geq 0$: $(\ell_{\max} + 1)(\ell_{\max} + 2)/2$ complex numbers.

The total power of a sky. How much of a sky's variance sits at each multipole? The mean square of the sky over the sphere is a sum of $|a_{\ell m}|^2$. This is the sphere's version of Parseval's theorem:

$$\frac{1}{4\pi}\int \mathrm{d}\Omega\, \Theta^2(\boldsymbol{e}) \overset{(1)}{=} \frac{1}{4\pi}\sum_{\ell m}\sum_{\ell' m'} a_{\ell m}\, a^*_{\ell' m'} \int \mathrm{d}\Omega\, Y_{\ell m} Y^*_{\ell' m'} \overset{(2)}{=} \frac{1}{4\pi}\sum_{\ell}\sum_{m=-\ell}^{\ell} |a_{\ell m}|^2. \tag{7.48}$$

(1) Write $\Theta^2 = \Theta\,\Theta^*$ and expand the first factor in $Y_{\ell m}$ and the second in $Y^*_{\ell' m'}$ (the conjugate of the expansion, since Θ is real).
(2) Orthonormality collapses the double sum to $\ell = \ell'$, $m = m'$.

So $\sum_m |a_{\ell m}|^2$ (divided by 4π) is the share of the sky's mean square that lives at angular scale π/ℓ. Divided by the number of terms, $2\ell + 1$, it will be our estimator $\widehat{C}_\ell$ of the power spectrum (Section 7.10).

Example: the dipole along the pole. Take $\Theta(\boldsymbol{e}) = A\cos\theta$, hot in the north and cold in the south, with A the temperature at the north pole. The pattern has the shape of $Y_{10} = \sqrt{3/4\pi}\cos\theta$, so we expect only a_{10} to be nonzero. Its value is

$$a_{10} \overset{(1)}{=} \int \mathrm{d}\Omega\, A\cos\theta \sqrt{\frac{3}{4\pi}}\cos\theta \overset{(2)}{=} A\sqrt{\frac{3}{4\pi}}\, 2\pi \int_{-1}^{1} \mu^2\, \mathrm{d}\mu \overset{(3)}{=} A\sqrt{\frac{3}{4\pi}}\,\frac{4\pi}{3} = A\sqrt{\frac{4\pi}{3}}, \tag{7.49}$$

(1) Definition (7.44); Y_{10} is real.
(2) Substitute $\mu = \cos\theta$, $\mathrm{d}\Omega = \mathrm{d}\mu\,\mathrm{d}\phi$; the ϕ integral gives 2π.
(3) $\int_{-1}^{1} \mu^2 \mathrm{d}\mu = 2/3$.

and every other $a_{\ell m}$ vanishes, because $\cos\theta$ is proportional to Y_{10} and Y_{10} is orthogonal to all the other $Y_{\ell m}$. The script `code/ch07/21_spherical_harmonics.py` builds this map with $A = 3\,\mu$K on a HEALPix grid (Section 7.11.2) and computes the coefficients numerically: $a_{10} = 6.139960\,\mu$K against $A\sqrt{4\pi/3} = 6.139960\,\mu$K, and the largest of all the other coefficients up to $\ell = 4$ is $1.009 \times 10^{-15}\,\mu$K, zero to machine precision.

Example: the same dipole along the equator. Now turn the dipole on its side: $\Theta = B\sin\theta\cos\phi$, hottest at $\phi = 0$ on the equator. The question is how its coefficients compare with those of the polar dipole. Write $\cos\phi = (e^{i\phi} + e^{-i\phi})/2$ and read $\sin\theta\, e^{\pm i\phi}$ off (7.40):

$$B\sin\theta\cos\phi \overset{(1)}{=} \frac{B}{2}\left(\sin\theta\, e^{i\phi} + \sin\theta\, e^{-i\phi}\right) \overset{(2)}{=} \frac{B}{2}\sqrt{\frac{8\pi}{3}}\left(-Y_{11} + Y_{1,-1}\right) = B\sqrt{\frac{2\pi}{3}}\left(-Y_{11} + Y_{1,-1}\right). \tag{7.50}$$

(1) Euler's formula.
(2) From (7.40): $\sin\theta\, e^{i\phi} = -\sqrt{8\pi/3}\, Y_{11}$ and $\sin\theta\, e^{-i\phi} = +\sqrt{8\pi/3}\, Y_{1,-1}$.

So $a_{11} = -B\sqrt{2\pi/3}$ and $a_{1,-1} = +B\sqrt{2\pi/3}$, with $a_{10} = 0$. The reality condition checks out: $(-1)^1 a^*_{11} = +B\sqrt{2\pi/3} = a_{1,-1}$.

Now compare the two dipoles (take $B = A$). They are the same pattern, rotated by 90°. Their coefficients are completely different: one sits in $m = 0$, the other in $m = \pm 1$. But the sum of $|a_{\ell m}|^2$ over m is the same: $|a_{10}|^2 = 4\pi A^2/3$ for the first and $|a_{11}|^2 + |a_{1,-1}|^2 = 2 \times 2\pi B^2/3 = 4\pi B^2/3$ for the second. A rotation reshuffles the $a_{\ell m}$ within one ℓ and leaves $\sum_m |a_{\ell m}|^2$ alone. This is the seed of everything in Section 7.9.

Example: how many numbers is a sky? By the count (7.47), a sky band-limited to $\ell_{\max}$ needs about $\ell_{\max}^2$ real numbers, and $\ell_{\max}$ is set by the telescope's resolution through (7.43). The Planck satellite resolves features of about 5′, which is $\ell \approx 180°/5' \approx 2000$. A sky band-limited to $\ell_{\max} = 600$, roughly the resolution of the earlier WMAP satellite, already has $(601)^2 - 4 = 361197$ real numbers in $2 \le \ell \le 600$, stored by healpy as 180901 complex numbers with $m \ge 0$ (the storage includes $\ell = 0, 1$ and the zero imaginary parts of the $m = 0$ entries). Figure 7.20 shows one random sky drawn from the fiducial cosmological model (Section 7.11.1) and built up from its harmonics: with $\ell \le 4$ we see a few continent-sized blobs; each factor of four in $\ell_{\max}$ shrinks the smallest features by a factor of four.

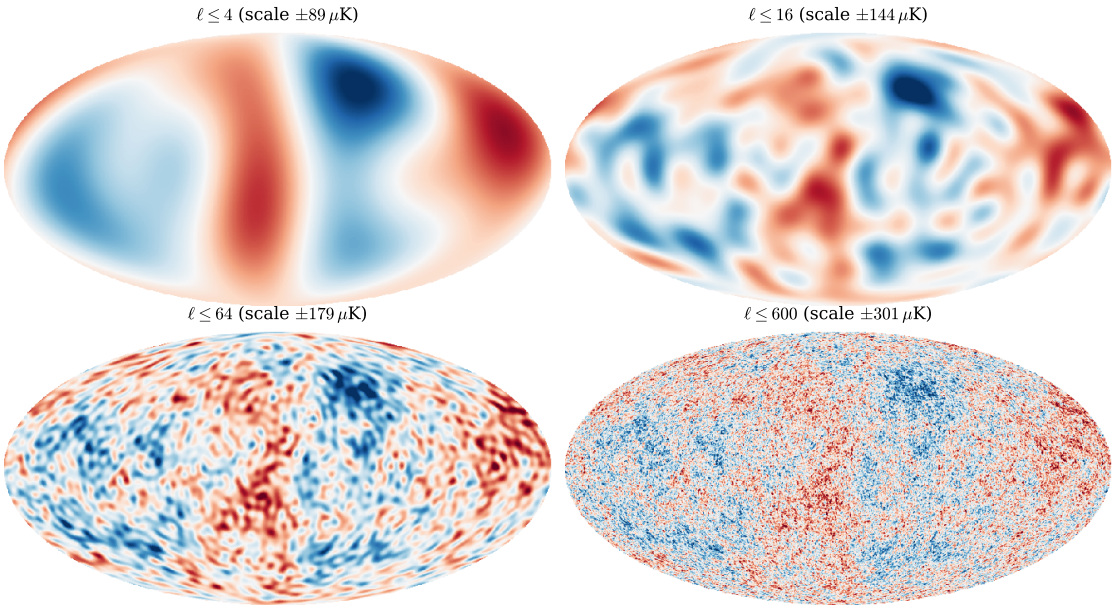

Figure 7.20: One simulated CMB sky (fiducial ΛCDM spectrum) summed up to $\ell_{\max} = 4$, 16, 64 and 600. The coefficients are the same in all four panels; each panel simply keeps more of them. The colour scale is set separately in each panel, because adding multipoles adds variance. The large-scale pattern of the first panel is still visible underneath the fine structure of the last.

7.9 No preferred direction: why the $a_{\ell m}$ are uncorrelated

A cosmological model does not predict our sky. Inflation predicts the statistics of the primordial fluctuations, and linear physics carries those statistics forward to the last scattering surface; the particular pattern of hot and cold spots we see is one draw from that ensemble of possible skies (Chapter T1). The property of the ensemble that we rely on most is that it has no preferred direction: turn the whole sky through any rotation, and the collection of possible skies, with their probabilities, is unchanged. This does not say that our sky looks the same in every direction. Our sky may well have a striking feature somewhere; the statement is that the feature was equally likely to point anywhere.

In flat space the matching symmetry was homogeneity (invariance under shifts), and it made the Fourier amplitudes of different wavevectors uncorrelated, $\langle \delta_{\boldsymbol{k}} \delta^*_{\boldsymbol{k}'} \rangle \propto \delta(\boldsymbol{k} - \boldsymbol{k}') P(k)$ (Section 7.3.2). The reason was simple: shifting a plane wave only changes its phase. Rotations of the sphere are harder, because rotations about different axes do not commute and a general rotation mixes harmonics with different m. The tool that handles this is one we already know, the angular-momentum algebra of quantum mechanics.

The question. If no direction on the sky is special, which pairs of coefficients $a_{\ell m}$, $a_{\ell' m'}$ can be correlated, and can the variance of $a_{\ell m}$ depend on m?

Working definition 7.6 (statistical isotropy)

A random sky $\Theta(\boldsymbol{e})$ is **statistically isotropic** if for every rotation R the rotated sky $\Theta(R^{-1}\boldsymbol{e})$ has the same joint distribution as $\Theta(\boldsymbol{e})$ [same probabilities for the temperatures at any finite set of directions]. For the mean and the two-point function this means

$$\langle \Theta(\boldsymbol{e}) \rangle = 0, \qquad \langle \Theta(\boldsymbol{e})\Theta(\boldsymbol{e}') \rangle = C(\boldsymbol{e}\cdot\boldsymbol{e}'), \tag{7.51}$$

where C is the **angular correlation function** [the average product of the temperatures at two directions, a function of the angle ϑ between them only, with $\cos\vartheta = \boldsymbol{e}\cdot\boldsymbol{e}'$] [HobsonBMC (10.1)]. Angle brackets are averages over the ensemble of skies, never over our one sky.

The mean is zero because we subtracted the average temperature; the correlation depends on the angle alone because a rotation can carry any pair of directions to any other pair with the same separation.

7.9.1 The covariance of two coefficients is a double integral

Start from the definition of the coefficients (7.44) and average:

$$\begin{aligned} \langle a_{\ell m}\, a^*_{\ell' m'} \rangle &\overset{(1)}{=} \left\langle \int \mathrm{d}\Omega\, \Theta(\boldsymbol{e}) Y^*_{\ell m}(\boldsymbol{e}) \int \mathrm{d}\Omega'\, \Theta(\boldsymbol{e}') Y_{\ell' m'}(\boldsymbol{e}') \right\rangle \\ &\overset{(2)}{=} \int \mathrm{d}\Omega \int \mathrm{d}\Omega'\, \langle \Theta(\boldsymbol{e})\Theta(\boldsymbol{e}') \rangle\, Y^*_{\ell m}(\boldsymbol{e})\, Y_{\ell' m'}(\boldsymbol{e}') \\ &\overset{(3)}{=} \int \mathrm{d}\Omega \int \mathrm{d}\Omega'\, C(\boldsymbol{e}\cdot\boldsymbol{e}')\, Y^*_{\ell m}(\boldsymbol{e})\, Y_{\ell' m'}(\boldsymbol{e}'). \end{aligned} \tag{7.52}$$

(1) Definition (7.44) for both coefficients; conjugating $a_{\ell' m'}$ conjugates the harmonic but not the real sky.

(2) The average of a sum (an integral) is the sum of the averages, and the harmonics are fixed functions, not random.

(3) Isotropy (7.51).

Since $\langle a_{\ell m} \rangle = \int \mathrm{d}\Omega\, \langle \Theta \rangle Y^*_{\ell m} = 0$, this average is the covariance of the two coefficients. The question has become: what does this double integral give, given that its kernel $C(\boldsymbol{e}\cdot\boldsymbol{e}')$ depends only on the angle between the two directions? We answer it in two steps. First we use only the rotations about the pole, which need nothing but the factor $e^{im\phi}$ in each harmonic. Then we use all rotations, which need the angular-momentum algebra.

7.9.2 Rotations about the pole: m must equal m'

The question. What does a rotation about the pole do to the coefficients? Rotate the sky by an angle α about the z-axis. The new sky has, at longitude ϕ, the temperature the old sky had at $\phi - \alpha$: $\Theta_\alpha(\theta,\phi) = \Theta(\theta, \phi - \alpha)$. Its coefficients are

$$a^{(\alpha)}_{\ell m} \overset{(1)}{=} \int \mathrm{d}\Omega\, \Theta(\theta, \phi-\alpha)\, Y^*_{\ell m}(\theta,\phi) \overset{(2)}{=} \int \mathrm{d}\Omega'\, \Theta(\theta,\phi')\, Y^*_{\ell m}(\theta, \phi'+\alpha) \overset{(3)}{=} e^{-im\alpha}\, a_{\ell m}. \tag{7.53}$$

(1) Definition (7.44) applied to the rotated sky.

(2) Substitute $\phi' = \phi - \alpha$; the solid-angle element and the range of a full turn are unchanged.
(3) $Y_{\ell m} \propto e^{im\phi}$, so $Y^*_{\ell m}(\theta, \phi' + \alpha) = e^{-im\alpha} Y^*_{\ell m}(\theta, \phi')$.

So a rotation about the pole only changes the phase of each coefficient, by an angle proportional to m.

Now use isotropy. The rotated sky is a draw from the same ensemble, so its coefficients have the same covariances as the original ones. Hence, for every angle α,

$$\langle a_{\ell m} a^*_{\ell' m'} \rangle = \langle a^{(\alpha)}_{\ell m} a^{(\alpha)*}_{\ell' m'} \rangle = e^{-i(m-m')\alpha} \langle a_{\ell m} a^*_{\ell' m'} \rangle. \tag{7.54}$$

If $m \neq m'$ we can pick α with $e^{-i(m-m')\alpha} \neq 1$ (for example $\alpha = \pi/|m - m'|$, which gives -1). Then the covariance equals -1 times itself, and the only such number is zero. So coefficients with different m are uncorrelated. This is the same logic as momentum conservation: a symmetry under shifts of ϕ forbids correlations between different eigenvalues of the generator of those shifts, $L_z = -i\partial_\phi$.

Example: turning the equatorial dipole. The dipole $B \sin\theta \cos\phi$ of Section 7.8.2 had $a_{11} = -B\sqrt{2\pi/3}$. Rotate it by $\alpha = 90°$ about the pole: the hot spot moves from $\phi = 0$ to $\phi = 90°$, and the sky becomes $B \sin\theta \sin\phi$. Equation (7.53) predicts $a_{11} \to e^{-i\pi/2} a_{11} = iB\sqrt{2\pi/3}$. Directly, with $\sin\phi = (e^{i\phi} - e^{-i\phi})/2i$ and the same table (7.40),

$$B \sin\theta \sin\phi \overset{(1)}{=} \frac{B}{2i}\left(\sin\theta e^{i\phi} - \sin\theta e^{-i\phi}\right) \overset{(2)}{=} \frac{B}{2i}\sqrt{\frac{8\pi}{3}}\left(-Y_{11} - Y_{1,-1}\right) \overset{(3)}{=} iB\sqrt{\frac{2\pi}{3}}\, Y_{11} + iB\sqrt{\frac{2\pi}{3}}\, Y_{1,-1}, \tag{7.55}$$

(1) Euler's formula for $\sin\phi$.
(2) $\sin\theta e^{i\phi} = -\sqrt{8\pi/3}\, Y_{11}$ and $\sin\theta e^{-i\phi} = \sqrt{8\pi/3}\, Y_{1,-1}$.
(3) $-1/(2i) = i/2$, and $\frac{1}{2}\sqrt{8\pi/3} = \sqrt{2\pi/3}$.

so $a_{11} = iB\sqrt{2\pi/3}$, as predicted. Only the phase moved; $|a_{11}|$ did not.

7.9.3 All rotations: one ℓ at a time, and no dependence on m

Rotations about other axes mix different m, so the phase argument no longer works on its own. The idea instead is to write the covariance as a matrix element of an operator, and then use what quantum mechanics tells us about operators that commute with rotations. Define the **covariance operator** $\hat{C}$, which acts on a function f on the sphere by smoothing it with the correlation function,

$$(\hat{C} f)(\boldsymbol{e}) = \int \mathrm{d}\Omega'\; C(\boldsymbol{e} \cdot \boldsymbol{e}')\, f(\boldsymbol{e}'), \tag{7.56}$$

and use the inner product $\langle f | g \rangle = \int \mathrm{d}\Omega\, f^* g$ of wavefunctions on the sphere, with $|\ell m\rangle$ standing for $Y_{\ell m}$. Then (7.52) reads

$$\langle a_{\ell m}\, a^*_{\ell' m'} \rangle = \int \mathrm{d}\Omega\; Y^*_{\ell m}(\boldsymbol{e})\, (\hat{C} Y_{\ell' m'})(\boldsymbol{e}) = \langle \ell m | \hat{C} | \ell' m' \rangle. \tag{7.57}$$

The covariance matrix of the coefficients is the matrix of $\hat{C}$ in the basis of spherical harmonics, exactly as the matrix of a Hamiltonian in the $|\ell m\rangle$ basis.

The covariance operator commutes with every rotation. Let U_R rotate a function, $(U_R f)(\boldsymbol{e}) = f(R^{-1}\boldsymbol{e})$. Then

$$(U_R \hat{C} f)(\boldsymbol{e}) \overset{(1)}{=} \int \mathrm{d}\Omega'\, C\big((R^{-1}\boldsymbol{e})\cdot\boldsymbol{e}'\big)\, f(\boldsymbol{e}') \overset{(2)}{=} \int \mathrm{d}\Omega''\, C\big((R^{-1}\boldsymbol{e})\cdot(R^{-1}\boldsymbol{e}'')\big)\, f(R^{-1}\boldsymbol{e}'')$$
$$\overset{(3)}{=} \int \mathrm{d}\Omega''\, C(\boldsymbol{e}\cdot\boldsymbol{e}'')\,(U_R f)(\boldsymbol{e}'') \overset{(4)}{=} (\hat{C} U_R f)(\boldsymbol{e}). \tag{7.58}$$

(1) Definition of U_R applied to the function $\hat{C}f$.
(2) Change variables $\boldsymbol{e}' = R^{-1}\boldsymbol{e}''$; a rotation preserves solid angle, so $\mathrm{d}\Omega' = \mathrm{d}\Omega''$.
(3) A rotation preserves dot products, $(R^{-1}\boldsymbol{a})\cdot(R^{-1}\boldsymbol{b}) = \boldsymbol{a}\cdot\boldsymbol{b}$; and $f(R^{-1}\boldsymbol{e}'') = (U_R f)(\boldsymbol{e}'')$.
(4) Definition (7.56).

So $U_R\hat{C} = \hat{C}U_R$ for every rotation. Now take a rotation by a small angle ε about a unit axis $\boldsymbol{n}$. In quantum mechanics the angular momentum is the generator of rotations, $U_R = 1 - i\varepsilon\, \boldsymbol{n}\cdot\boldsymbol{L} + O(\varepsilon^2)$. Insert this into $U_R\hat{C} = \hat{C}U_R$: the terms $\hat{C}$ cancel, and the terms of order ε give $(\boldsymbol{n}\cdot\boldsymbol{L})\hat{C} = \hat{C}(\boldsymbol{n}\cdot\boldsymbol{L})$. Taking $\boldsymbol{n}$ along x, y and z in turn, and then noting that $\boldsymbol{L}^2$ and $L_\pm$ are built from L_x, L_y, L_z, we get

$$[\hat{C}, L_x] = [\hat{C}, L_y] = [\hat{C}, L_z] = 0 \quad\Longrightarrow\quad [\hat{C}, \boldsymbol{L}^2] = 0, \qquad [\hat{C}, L_\pm] = 0, \tag{7.59}$$

with the ladder operators $L_\pm = L_x \pm i L_y$. These commutators answer the question in three short steps.

Step 1: different ℓ are uncorrelated. Sandwich $\hat{C}\boldsymbol{L}^2 = \boldsymbol{L}^2\hat{C}$ between $\langle \ell m|$ and $|\ell' m'\rangle$:

$$\ell'(\ell'+1)\langle \ell m|\hat{C}|\ell' m'\rangle \overset{(1)}{=} \langle \ell m|\hat{C}\boldsymbol{L}^2|\ell' m'\rangle \overset{(2)}{=} \langle \ell m|\boldsymbol{L}^2\hat{C}|\ell' m'\rangle \overset{(3)}{=} \ell(\ell+1)\langle \ell m|\hat{C}|\ell' m'\rangle. \tag{7.60}$$

(1) $\boldsymbol{L}^2|\ell' m'\rangle = \ell'(\ell'+1)|\ell' m'\rangle$ from (7.39).
(2) $\hat{C}$ commutes with $\boldsymbol{L}^2$ (7.59).
(3) $\boldsymbol{L}^2$ is Hermitian, so it acts to the left on $\langle \ell m|$ with its real eigenvalue.

If $\ell \neq \ell'$ then $\ell(\ell+1) \neq \ell'(\ell'+1)$ and the matrix element vanishes.

Step 2: different m are uncorrelated. The same sandwich with L_z gives $(m - m')\langle \ell m|\hat{C}|\ell m'\rangle = 0$. This is the infinitesimal version of (7.54).

Step 3: the variance does not depend on m. After steps 1 and 2, only the diagonal elements $c_m \equiv \langle \ell m|\hat{C}|\ell m\rangle = \langle |a_{\ell m}|^2\rangle$ survive. The question is whether they can differ from one m to the next. The ladder operators move between neighbouring m with the real, positive coefficients of quantum mechanics, $L_+|\ell m\rangle = \lambda_m|\ell, m+1\rangle$ and $L_-|\ell, m+1\rangle = \lambda_m|\ell m\rangle$, where $\lambda_m = \sqrt{\ell(\ell+1) - m(m+1)}$. Compute one matrix element in two ways:

$$\lambda_m\, c_{m+1} \overset{(1)}{=} \langle \ell, m+1|\hat{C}\, L_+|\ell m\rangle \overset{(2)}{=} \langle \ell, m+1|L_+\hat{C}|\ell m\rangle \overset{(3)}{=} \big(L_-|\ell, m+1\rangle\big)^\dagger \hat{C}|\ell m\rangle \overset{(4)}{=} \lambda_m\, c_m. \tag{7.61}$$

(1) $L_+|\ell m\rangle = \lambda_m|\ell, m+1\rangle$, and the definition of c_{m+1}.
(2) $\hat{C}$ commutes with L_+ (7.59).
(3) The adjoint of L_+ is L_- (because L_x and L_y are Hermitian), so L_+ acting to the left is L_- acting on the bra's ket.
(4) $L_-|\ell, m+1\rangle = \lambda_m|\ell m\rangle$ with λ_m real, and the definition of c_m.

For $m = -\ell, \ldots, \ell - 1$ the factor λ_m is strictly positive (it vanishes only at $m = \ell$), so we may divide by it: $c_{m+1} = c_m$. Walking from $m = -\ell$ up to $m = \ell$, all $2\ell + 1$ diagonal elements are equal. Call their common value C_ℓ.

Key idea: Isotropy diagonalises the sky

For a statistically isotropic sky,

$$\langle a_{\ell m}\rangle = 0, \qquad \langle a_{\ell m}\, a^*_{\ell' m'}\rangle = C_\ell\, \delta_{\ell\ell'}\, \delta_{mm'}. \tag{7.62}$$

The **angular power spectrum** C_ℓ is the variance of each coefficient at multipole ℓ, the same for all $2\ell+1$ values of m [HobsonBMC (10.3)], [Hivon (7)].

In group-theory language this is Schur's lemma: the harmonics with a given ℓ carry an irreducible representation of the rotation group, and an operator that commutes with an irreducible representation is a multiple of the identity on it. The ladder-operator argument above is the proof of that lemma in the one case we need. The result also shows that C_ℓ is *all* an isotropic two-point function can contain: one number per ℓ.

The result also fixes the average of a product without a conjugate. The reality condition (7.46), read with $m \to -m'$, says $a_{\ell' m'} = (-1)^{m'} a^*_{\ell', -m'}$. Insert this and use (7.62): $\langle a_{\ell m} a_{\ell' m'}\rangle = (-1)^{m'}\langle a_{\ell m} a^*_{\ell', -m'}\rangle = (-1)^m C_\ell\, \delta_{\ell\ell'}\delta_{m,-m'}$. In particular $\langle a^2_{\ell m}\rangle = 0$ whenever $m \neq 0$, a fact that fixes the distribution of the real and imaginary parts in Section 7.10.

Watch out: Isotropy is a property of the ensemble, not of our sky

Every single sky has directions that stand out: the $\ell \le 4$ panel of Figure 7.20 has a hot band and two cold blobs. Isotropy says that a rotated version of that sky was exactly as likely, not that the sky looks the same in all directions. The $a_{\ell m}$ of one sky are what they are; the statement (7.62) is about their averages over many hypothetical skies.

7.9.4 From C_ℓ back to the correlation function

The correlation function $C(\vartheta)$ of (7.51) and the power spectrum C_ℓ carry the same information: each is a Legendre series of the other. To show it we need the **addition theorem** for spherical harmonics, the sphere's version of $\sum_k e^{i\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{x}')}$ depending only on $\boldsymbol{x}-\boldsymbol{x}'$:

$$\sum_{m=-\ell}^{\ell} Y_{\ell m}(\boldsymbol{e})\, Y^*_{\ell m}(\boldsymbol{e}') = \frac{2\ell+1}{4\pi}\, P_\ell(\boldsymbol{e}\cdot\boldsymbol{e}'), \tag{7.63}$$

with P_ℓ the Legendre polynomial ($P_0 = 1$, $P_1(x) = x$, $P_2(x) = (3x^2-1)/2$). Check it for $\ell = 1$ with both directions at the north pole: only $m = 0$ survives at $\theta = 0$, and $|Y_{10}|^2 = 3/4\pi = (3/4\pi)P_1(1)$. Then

$$\begin{aligned} C(\boldsymbol{e}\cdot\boldsymbol{e}') = \langle \Theta(\boldsymbol{e})\Theta(\boldsymbol{e}')\rangle &\overset{(1)}{=} \sum_{\ell m}\sum_{\ell' m'} \langle a_{\ell m} a^*_{\ell' m'}\rangle\, Y_{\ell m}(\boldsymbol{e})\, Y^*_{\ell' m'}(\boldsymbol{e}') \\ &\overset{(2)}{=} \sum_{\ell} C_\ell \sum_{m=-\ell}^{\ell} Y_{\ell m}(\boldsymbol{e})\, Y^*_{\ell m}(\boldsymbol{e}') \overset{(3)}{=} \sum_{\ell} \frac{2\ell+1}{4\pi}\, C_\ell\, P_\ell(\cos\vartheta). \end{aligned} \tag{7.64}$$

(1) Expand $\Theta(\boldsymbol{e})$ in $Y_{\ell m}$ and the real $\Theta(\boldsymbol{e}') = \Theta^*(\boldsymbol{e}')$ in $Y^*_{\ell' m'}$, and average term by term.
(2) Equation (7.62) keeps $\ell = \ell'$, $m = m'$.
(3) Addition theorem (7.63), with $\cos\vartheta = \boldsymbol{e}\cdot\boldsymbol{e}'$.

This is [HobsonBMC (10.4)]. To invert it, multiply by $P_{\ell'}(\cos\vartheta)$ and integrate over $x = \cos\vartheta$, using $\int_{-1}^{1} P_\ell P_{\ell'}\, \mathrm{d}x = 2\delta_{\ell\ell'}/(2\ell+1)$:

$$C_\ell = 2\pi \int_{-1}^{1} \mathrm{d}(\cos\vartheta)\; P_\ell(\cos\vartheta)\, C(\vartheta). \tag{7.65}$$

(Hobson et al. print the prefactor as 4π [HobsonBMC (10.5)]; the orthogonality integral above gives 2π.)[1]

How much does each multipole add to the temperature variance at one point? At zero separation, $P_\ell(1) = 1$, and the correlation function is that variance,

$$\sigma_\Theta^2 = C(0) = \sum_\ell \frac{2\ell+1}{4\pi} C_\ell . \tag{7.66}$$

Each multipole contributes $(2\ell+1)C_\ell/4\pi$: the factor $2\ell+1$ counts the patterns at that ℓ and C_ℓ is the variance of each. Per logarithmic interval of ℓ the contribution is $\ell(2\ell+1)C_\ell/4\pi \approx \ell(\ell+1)C_\ell/2\pi = D_\ell$, which is why D_ℓ is the quantity that is plotted (Chapter T1).

The covariance of a map. In pixels the covariance is a full matrix; in harmonics it is diagonal. A map is the sky sampled at pixel centres $\boldsymbol{e}_p$, usually smoothed by the telescope beam. A circular beam multiplies each $a_{\ell m}$ by a number B_ℓ (its harmonic transform), so $C_\ell \to C_\ell B_\ell^2$; this is the sphere's version of smoothing in flat space (Section 7.6). The signal in two pixels p and p' then has the covariance

$$\boldsymbol{C}^S_{pp'} = \sum_\ell \frac{2\ell+1}{4\pi} C_\ell B_\ell^2 \, P_\ell(\cos\vartheta_{pp'}), \tag{7.67}$$

which is (7.64) with the beam included and $\vartheta_{pp'}$ the angle between the two pixel centres [HobsonBMC (10.18)]. This $N_{\rm pix} \times N_{\rm pix}$ matrix is the signal covariance of a Gaussian likelihood written in pixels. Every entry is nonzero, since any two pixels are correlated. In harmonic space the same covariance (7.62) is diagonal. That is why we work with the $a_{\ell m}$.

Example: the rms of the CMB. For the fiducial spectrum (Section 7.11.1), `code/ch07/22_isotropy.py` evaluates (7.66) up to $\ell = 2000$: $\sigma_\Theta^2 = 12635\,\mu\mathrm{K}^2$, an rms of $112.4\,\mu$K, the "hundred microkelvin" of the opening paragraph. The multipoles $\ell \le 30$ supply 19.9% of this variance, although they are only about 10^3 of the four million coefficients up to $\ell = 2000$. Figure 7.21(a) shows how fast the correlation falls: by a separation of one degree, $C(\vartheta)$ has dropped to about a quarter of its value at zero, which is the statement that most of the variance sits in features smaller than about a degree, the scale of the first acoustic peak.

Figure 7.21(b) makes a point that matters for statistics: the correlation function measured on one sky can differ from the ensemble prediction by as much as the prediction itself, at large separations. What we measure on one sky is the average of $\Theta(\boldsymbol{e})\Theta(\boldsymbol{e}')$ over all pairs of directions at separation ϑ. This equals the same Legendre series (7.64) with C_ℓ replaced by that sky's own average over m, $\widehat{C}_\ell = \sum_m |a_{\ell m}|^2/(2\ell+1)$. (Averaging the pair over all orientations does to the product of harmonics what the ensemble average did in step (2) of (7.64).) Five simulated skies give five visibly different curves at large separations. They scatter around the ensemble prediction by 80 to $180\,\mu\mathrm{K}^2$ at 30° to 90°, which is as large as the signal itself there ($|C| \approx 160$ to $230\,\mu\mathrm{K}^2$). This is cosmic variance seen in real space. It is large at large ϑ because large separations are controlled by the few low multipoles, and a low multipole has few coefficients to average over. We quantify it in Section 7.10.

7.9.5 Seeing isotropy, and its violation, in simulated skies

The argument of Section 7.9.3 makes two predictions we can test: within one ℓ, the average power $\langle |a_{\ell m}|^2 \rangle$ is the same for every m; and different ℓ are uncorrelated. A test is convincing only if it can fail, so we also build a sky that is *not* isotropic and check that both predictions break.

[1] Insert (7.64) into the right-hand side: $2\pi \sum_{\ell'} \frac{2\ell'+1}{4\pi} C_{\ell'} \cdot \frac{2\delta_{\ell\ell'}}{2\ell+1} = C_\ell$. With 4π the right-hand side would be $2C_\ell$.

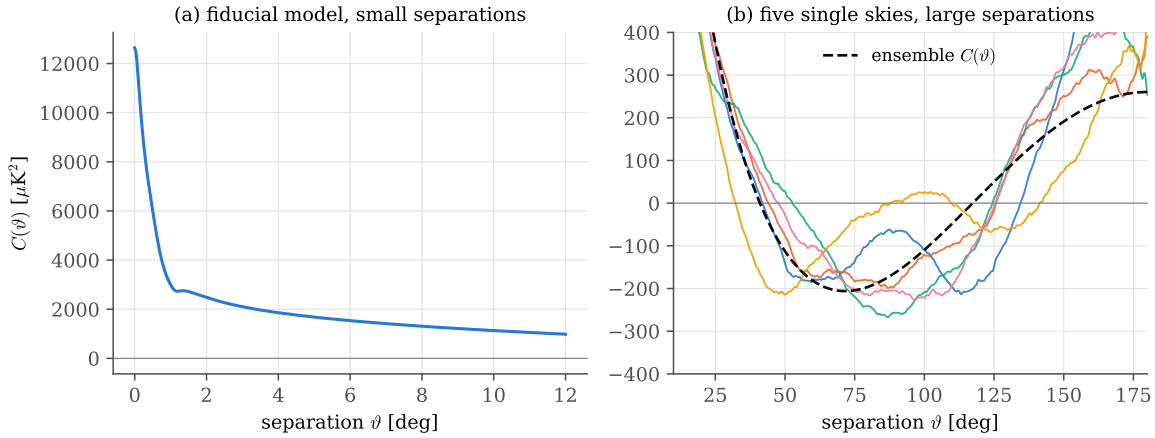

Figure 7.21: (a) The angular correlation function of the fiducial model for separations up to 12°. It falls from the point variance $C(0) \approx 1.3\times10^4\,\mu\mathrm{K}^2$ to a quarter of that within one degree, then decays slowly. (b) Large separations: the ensemble $C(\vartheta)$ (black dashed) and the full-sky pair average for five single simulated skies (coloured). The five skies are drawn from the same model; their differences are cosmic variance.

Example: a sky with a preferred axis. Multiply an isotropic sky by $1 + A\cos\theta$. Fluctuations are then amplified by a factor $1 + A$ at the north pole and damped by $1 - A$ at the south pole: the z-axis is special. (A small effect of this kind, a "hemispherical power asymmetry", is one of the anomalies that the Planck collaboration tests for [109].) What does the modulation do to the coefficients? In harmonic space, multiplying by $\cos\theta$ is simple, because $\cos\theta \propto Y_{10}$ carries one unit of angular momentum along z. It changes ℓ by ±1 and keeps m, the dipole selection rule of atomic physics:

$$\cos\theta\, Y_{\ell m} = c_{\ell+1,m}\, Y_{\ell+1,m} + c_{\ell m}\, Y_{\ell-1,m}, \qquad c_{\ell m} = \sqrt{\frac{\ell^2 - m^2}{(2\ell+1)(2\ell-1)}}. \tag{7.68}$$

Check it on $\ell = 0$: $\cos\theta\, Y_{00} = \cos\theta/\sqrt{4\pi} = \sqrt{1/3}\, Y_{10}$, and $c_{10} = \sqrt{1/3}$. The coefficients of the modulated sky $\Theta' = (1 + A\cos\theta)\Theta$ are

$$a'_{LM} \overset{(1)}{=} a_{LM} + A\sum_{\ell m} a_{\ell m} \int \mathrm{d}\Omega\, \cos\theta\, Y_{\ell m} Y^*_{LM} \overset{(2)}{=} a_{LM} + A\big(c_{LM}\, a_{L-1,M} + c_{L+1,M}\, a_{L+1,M}\big). \tag{7.69}$$

(1) Definition (7.44) for Θ', with Θ expanded in harmonics.
(2) Equation (7.68) and orthonormality: the term $Y_{\ell+1,m}$ contributes when $\ell + 1 = L$, the term $Y_{\ell-1,m}$ when $\ell - 1 = L$, and only for $m = M$.

Each new coefficient is a mix of three old ones, which are independent. Averaging products with (7.62) for the old sky gives

$$\langle a'_{\ell+1,m}\, a'^*_{\ell m}\rangle = A\, c_{\ell+1,m}\,(C_\ell + C_{\ell+1}), \tag{7.70}$$

$$\langle |a'_{\ell m}|^2\rangle = C_\ell + A^2\big(c^2_{\ell m}\, C_{\ell-1} + c^2_{\ell+1,m}\, C_{\ell+1}\big). \tag{7.71}$$

Both predictions of isotropy now fail. By (7.70), neighbouring multipoles are correlated. By (7.71), the power depends on m through $c^2_{\ell m}$ and $c^2_{\ell+1,m}$, which are both largest at $m = 0$ and shrink towards $|m| = \ell$ (where $c_{\ell m}$ vanishes). Both violations come from the preferred axis.

The script `code/ch07/22_isotropy.py` draws 6000 isotropic skies up to $\ell = 42$ from the fiducial spectrum, modulates each one with $A = 0.5$ using (7.69), and averages. The modulation is done exactly in harmonic space by the function `modulate_dipole` of the small library `code/ch07/lib_harmonic.py`:

Listing 7.3: Multiplying a sky by $1+A\cos\theta$, coefficient by coefficient (`code/ch07/lib_harmonic.py`)

```
84 def modulate_dipole(alm, lmax: int, A: float):
85     """a_lm of (1 + A cos theta) * map, computed exactly in harmonic space (result
       truncated at lmax-1).
86
87     a'_LM = a_LM + A [ c_{L,M} a_{L-1,M} + c_{L+1,M} a_{L+1,M} ].
88     """
89     ell, m = getlm(lmax)
90     out = alm.copy()
91     down = ell - 1 >= m                    # a_{L-1,M} exists
92     up = ell + 1 <= lmax                   # a_{L+1,M} exists
93     i = np.arange(ell.size)
94     out[down] += A * ccoef(ell[down], m[down]) * alm[i[down] - 1]
95     out[up] += A * ccoef(ell[up] + 1, m[up]) * alm[i[up] + 1]
96     return out
```

Lines 91–92 find which neighbours $a_{L\mp1,M}$ exist (the stored list starts at $\ell = m$ and stops at $\ell_{\max}$); lines 94–95 add the two terms of (7.69). In the storage order of healpy, which the library uses (Section 7.11.2), $a_{L-1,M}$ and $a_{L+1,M}$ sit just before and just after a_{LM}.

Figure 7.22 shows the result at $\ell = 20$. For the isotropic skies the power is the same in every m: the largest deviation of $\langle|a_{20,m}|^2\rangle/C_{20}$ from 1 among $m = 1,\dots,20$ is 0.02503, about two standard errors of 0.01291 (since $|a_{\ell m}|^2/C_\ell$ has standard deviation 1 for $m > 0$, as we will see), which is what the largest of twenty independent deviations typically is. The correlation between $\ell = 20$ and $\ell = 21$ is zero within 0.01502. For the modulated skies both predictions fail exactly as (7.70) and (7.71) say: the power rises to $1.126\,C_{20}$ at $m = 0$, and the neighbour correlation reaches $0.5005\,C_{20}$ at $m = 0$ and falls towards $|m| = \ell$.

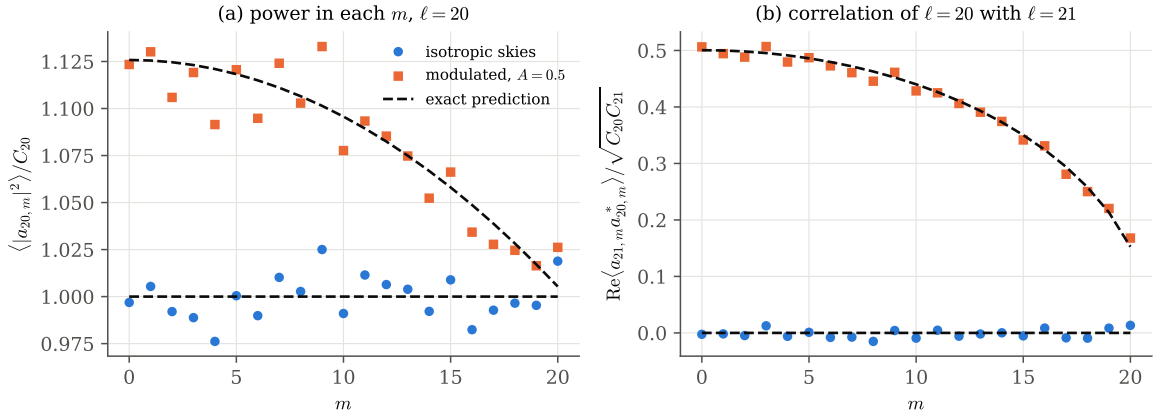

Figure 7.22: Two predictions of isotropy, tested on 6000 simulated skies at $\ell = 20$. (a) Average power in each m, in units of C_{20}: flat for isotropic skies (blue), tilted for skies modulated by $1 + 0.5\cos\theta$ (orange). (b) Average product of the coefficients at $\ell = 21$ and $\ell = 20$ with the same m: zero for isotropic skies, large for modulated ones. Black dashed lines are the exact predictions (7.70) and (7.71) (and 1, 0 for the isotropic case).

Gaussianity turns "uncorrelated" into "independent". So far isotropy has told us which coefficients are uncorrelated. For a Gaussian sky that is enough to make them independent. The coefficients are integrals of the sky with fixed weights, so they are linear combinations of the field values. If the field is Gaussian (as linear evolution of Gaussian initial conditions guarantees, [HobsonBMC p. 230]), the coefficients are jointly Gaussian, and for jointly Gaussian variables zero correlation means independence (Chapter 2). For complex coefficients we must be careful about what "zero correlation" means, since a complex number is two real numbers; Section 7.10 does

that bookkeeping and turns (7.62) into the exact distribution of the power-spectrum estimator.

7.10 One sky, $2\ell+1$ numbers: the estimator $\widehat{C}_\ell$ and cosmic variance

The model predicts $C_\ell = \langle |a_{\ell m}|^2 \rangle$, an average over an ensemble of skies we will never see. We have one sky. What saves us is the result of Section 7.9: in an isotropic sky the coefficients at one multipole are uncorrelated and all have the same variance C_ℓ (7.62). So at each multipole the sky hands us $2\ell+1$ real numbers (the count (7.47)) with a common variance. That is the situation of a laboratory physicist who has measured the same noisy quantity $2\ell+1$ times and wants its variance: average the squares (the mean is known to be zero). Replacing the ensemble average by this average over the sphere is called the ergodic replacement. Its weakness is at low ℓ, where there are very few numbers to average. That limit comes from the Universe, not from the instrument.

The question. If we estimate C_ℓ by averaging $|a_{\ell m}|^2$ over the $2\ell+1$ values of m, is the estimate right on average, how is it distributed, and how large is its scatter around the truth?

Working definition 7.7 (full-sky power-spectrum estimator)

For a full, noiseless sky,

$$\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_{m=-\ell}^{\ell} |a_{\ell m}|^2 = \frac{1}{2\ell+1}\left(a_{\ell 0}^2 + 2\sum_{m=1}^{\ell} |a_{\ell m}|^2\right) \tag{7.72}$$

[the mean square of the $2\ell+1$ coefficients at one ℓ, each $m>0$ counted twice because $|a_{\ell,-m}| = |a_{\ell m}|$] [Hivon (8)], [HobsonBMC (10.25)]. healpy's `alm2cl` computes exactly this from the stored $m \geq 0$ coefficients.

The second form uses the reality condition (7.46), $|a_{\ell,-m}| = |a_{\ell m}|$. Its expectation follows in one line from (7.62):

$$\mathbb{E}\,\widehat{C}_\ell = \frac{1}{2\ell+1}\sum_{m=-\ell}^{\ell} \langle |a_{\ell m}|^2 \rangle = \frac{1}{2\ell+1}\,(2\ell+1)\,C_\ell = C_\ell. \tag{7.73}$$

So $\widehat{C}_\ell$ is unbiased. Here is the estimator written out from scratch, as every simulation script in this chapter uses it:

Listing 7.4: The full-sky estimator (7.72) from the stored coefficients (`code/ch07/lib_harmonic.py`)

```
48 def alm2cl(alm, lmax: int):
49     """Full-sky estimator C_hat_l = (1/(2l+1)) sum_{m=-l}^{l} |a_lm|^2.
50
51     The sum over negative m is folded in: |a_{l,-m}| = |a_lm|, so each m > 0 counts twice.
52     """
53     ell, m = getlm(lmax)
54     w = np.where(m == 0, 1.0, 2.0)
55     s = np.bincount(ell, weights=w * np.abs(alm) ** 2, minlength=lmax + 1)
56     return s / (2 * np.arange(lmax + 1) + 1)
```

Line 54 gives weight 1 to $m=0$ and weight 2 to $m>0$, which folds in the negative m that are not stored. Line 55 adds up the weighted $|a_{\ell m}|^2$ for each ℓ with `np.bincount`, and line 56 divides by $2\ell+1$. Applied to the same coefficients, it agrees with healpy's `alm2cl` to a relative 6.474×10^{-16}, rounding error.

7.10.1 Counting real degrees of freedom

$\widehat{C}_\ell$ is a sum of squares. To find its distribution we need the distribution of the real numbers being squared, the real and imaginary parts of the $a_{\ell m}$. Fix ℓ and write $a_{\ell m} = x_m + iy_m$ for $m = 1, \dots, \ell$, with x_m and y_m real. Section 7.9 gave us two averages: $\langle a_{\ell m} a^*_{\ell m} \rangle = C_\ell$, and $\langle a^2_{\ell m} \rangle = 0$ for $m \neq 0$. Expand both in real and imaginary parts:

$$C_\ell \overset{(1)}{=} \langle |a_{\ell m}|^2 \rangle = \langle x_m^2 \rangle + \langle y_m^2 \rangle,$$
$$0 \overset{(2)}{=} \langle a^2_{\ell m} \rangle = \langle x_m^2 \rangle - \langle y_m^2 \rangle + 2i \langle x_m y_m \rangle \quad \Longrightarrow \quad \langle x_m^2 \rangle = \langle y_m^2 \rangle = \frac{C_\ell}{2}, \qquad \langle x_m y_m \rangle = 0. \tag{7.74}$$

(1) Equation (7.62) with $\ell' = \ell$, $m' = m$, and $|x + iy|^2 = x^2 + y^2$.

(2) $\langle a_{\ell m} a_{\ell' m'} \rangle = (-1)^m C_\ell \delta_{\ell \ell'} \delta_{m,-m'}$ vanishes for $m' = m \neq 0$. The real part of the zero gives $\langle x^2 \rangle = \langle y^2 \rangle$, the imaginary part gives $\langle xy \rangle = 0$; with the first line, each is $C_\ell/2$.

What about two different coefficients, $m \neq m'$ with both positive? Both averages vanish: $\langle a_{\ell m} a^*_{\ell m'} \rangle = 0$ because $m \neq m'$, and $\langle a_{\ell m} a_{\ell m'} \rangle = 0$ because $m' \neq -m$. Taking the real and imaginary parts of these two zeros makes all four products $\langle x_m x_{m'} \rangle$, $\langle y_m y_{m'} \rangle$, $\langle x_m y_{m'} \rangle$, $\langle y_m x_{m'} \rangle$ zero. The same argument with $m' = 0$ shows that $a_{\ell 0}$ is uncorrelated with every x_m and y_m. Finally, $a_{\ell 0}$ is real with $\langle a^2_{\ell 0} \rangle = C_\ell$. In summary, at each ℓ:

real number	how many	variance
$a_{\ell 0}$	1	C_ℓ
$x_m = \mathrm{Re}\, a_{\ell m}$, $m = 1, \dots, \ell$	ℓ	$C_\ell/2$
$y_m = \mathrm{Im}\, a_{\ell m}$, $m = 1, \dots, \ell$	ℓ	$C_\ell/2$
$a_{\ell m}$ with $m < 0$	–	fixed by $a_{\ell,-m} = (-1)^m a^*_{\ell m}$

For a Gaussian sky these $2\ell + 1$ real numbers are jointly Gaussian and uncorrelated, hence independent (Chapter 2). Figure 7.23 draws the bookkeeping for $\ell = 3$.

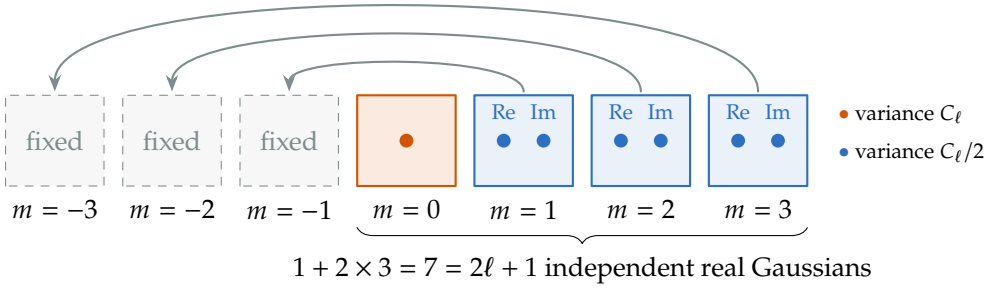

Figure 7.23: The real degrees of freedom at $\ell = 3$. The coefficient with $m = 0$ is one real number of variance C_ℓ (orange). Each $m > 0$ coefficient is two real numbers, its real and imaginary parts, each of variance $C_\ell/2$ (blue). The grey arcs send each $m > 0$ cell to its partner $-m$, which the reality condition fixes completely, so the negative-m cells add nothing new.

Now standardise each real number to unit variance, $z_0 = a_{\ell 0}/\sqrt{C_\ell}$, $z^{\mathrm{R}}_m = x_m/\sqrt{C_\ell/2}$, $z^{\mathrm{I}}_m = y_m/\sqrt{C_\ell/2}$, all independent $\mathcal{N}(0,1)$, and rewrite the estimator:

$$\frac{(2\ell+1)\widehat{C}_\ell}{C_\ell} \overset{(1)}{=} \frac{1}{C_\ell}\left(a^2_{\ell 0} + 2\sum_{m=1}^{\ell}(x_m^2 + y_m^2)\right) \overset{(2)}{=} z_0^2 + \frac{2}{C_\ell}\frac{C_\ell}{2}\sum_{m=1}^{\ell}\left[(z^{\mathrm{R}}_m)^2 + (z^{\mathrm{I}}_m)^2\right]$$
$$\overset{(3)}{=} z_0^2 + \sum_{m=1}^{\ell}\left[(z^{\mathrm{R}}_m)^2 + (z^{\mathrm{I}}_m)^2\right] \;\sim\; \chi^2_{2\ell+1}. \tag{7.75}$$

(1) Equation (7.72) multiplied by $(2\ell+1)/C_\ell$, with $|a_{\ell m}|^2 = x_m^2 + y_m^2$.
(2) Substitute $a_{\ell 0} = \sqrt{C_\ell}\, z_0$, $x_m = \sqrt{C_\ell/2}\, z_m^{\mathrm{R}}$, $y_m = \sqrt{C_\ell/2}\, z_m^{\mathrm{I}}$.
(3) The factor 2 from the folded negative m cancels the $1/2$ in the variance. What remains is a sum of $1 + 2\ell$ squares of independent standard normals, which is the definition of a χ^2 variable with $2\ell+1$ degrees of freedom (Chapter 2).

Step (3) is why the careful count matters: the factor 2 from folding and the halved variance cancel exactly, so every real degree of freedom enters with weight one.

Watch out: Two ways to get the count wrong

(i) Treating all $2\ell+1$ coefficients as independent complex Gaussians gives $2(2\ell+1)$ real degrees of freedom and a cosmic variance half the true value: it forgets that $a_{\ell,-m}$ is a copy of $a_{\ell m}$. (ii) Giving the real and imaginary parts of an $m > 0$ coefficient the variance C_ℓ each doubles $\langle |a_{\ell m}|^2 \rangle$. The one-point density $p(a_{\ell m}) = e^{-a_{\ell m}^2/2C_\ell}/\sqrt{2\pi C_\ell}$ of and [HobsonBMC (10.17)] is the density of a *real* variable of variance C_ℓ: exact for $a_{\ell 0}$; for $m > 0$ it has to be read as the joint density of x_m and y_m, each of variance $C_\ell/2$. Either way the count is $2\ell+1$, and so is the χ^2.

7.10.2 The distribution of $\widehat{C}_\ell$ and cosmic variance

We now know that $\widehat{C}_\ell$ is a rescaled χ^2 variable. Its density and its scatter follow from those of χ^2. Write $\nu = 2\ell+1$ and $V = \nu\widehat{C}_\ell/C_\ell \sim \chi^2_\nu$, whose density is $f_\nu(v) = v^{\nu/2-1}e^{-v/2}/\left(2^{\nu/2}\Gamma(\nu/2)\right)$ for $v > 0$. Since $\widehat{C}_\ell = C_\ell V/\nu$ is a rescaling, the change-of-variables rule gives the density of the estimator,

$$p\left(\widehat{C}_\ell \,|\, C_\ell\right) = \frac{\nu}{C_\ell} f_\nu\left(\frac{\nu\widehat{C}_\ell}{C_\ell}\right), \tag{7.76}$$

a *scaled* χ^2_ν. Its first two moments follow from those of χ^2_ν, which is a Gamma$(\nu/2, 2)$ variable with mean ν and variance 2ν (Chapter 2):

$$\operatorname{Var}\widehat{C}_\ell \overset{(1)}{=} \left(\frac{C_\ell}{\nu}\right)^2 \operatorname{Var} V \overset{(2)}{=} \frac{C_\ell^2}{\nu^2}\, 2\nu = \frac{2C_\ell^2}{2\ell+1}. \tag{7.77}$$

(1) $\operatorname{Var}(cV) = c^2 \operatorname{Var} V$ with $c = C_\ell/\nu$.
(2) $\operatorname{Var}\chi^2_\nu = 2\nu$.

Key idea: Cosmic variance

From one full, noiseless sky the power spectrum is measured with

$$\frac{\Delta C_\ell}{C_\ell} \equiv \frac{\sqrt{\operatorname{Var}\widehat{C}_\ell}}{C_\ell} = \sqrt{\frac{2}{2\ell+1}}, \tag{7.78}$$

the sampling error of a variance estimated from $2\ell+1$ Gaussian numbers. No instrument can reduce it; only more independent modes can. Chapter 3 showed (in the section that finds an estimator from a model) that $\widehat{C}_\ell$ is sufficient for C_ℓ, is its maximum-likelihood estimator, and attains the Cramér–Rao bound, which equals (7.77): no unbiased estimator built from one sky does better.

Hivon et al. state the result in one sentence, "C_ℓ-s are χ^2_ν-distributed with the mean equal to

$C_\ell^{\rm th}$, $\nu = 2\ell + 1$ degrees of freedom, and a variance of $2C_\ell^{\rm th\,2}/\nu$" [Hivon p. 3].[2] Knox gives the same number as the noiseless limit of his error formula [138, eq. 4], with the same reading: for each ℓ there are $2\ell + 1$ "samples" from a Gaussian of variance C_ℓ, and the sampling variance of a variance is twice its square divided by the number of samples. On the full sky this sampling variance is called **cosmic variance**.

The shape matters as much as the width. A χ^2_ν has skewness $\sqrt{8/\nu}$ and its mode sits at $\nu - 2$, below the mean ν. So at low ℓ the estimator is more often below C_ℓ than above it, and occasionally far above. Figure 7.24(a) shows the density (7.76) in units of C_ℓ for $\ell = 2, 5, 20$ and 100. At $\ell = 2$ the density starts at zero, peaks at $0.6\,C_\ell$, and has a long tail; by $\ell = 100$ it is a narrow, nearly symmetric bell, close to the Gaussian of the same mean and variance (dotted lines, shown for $\ell = 5$ and $\ell = 100$).

Example: the quadrupole. At $\ell = 2$, $\nu = 5$, and (7.78) gives a fractional error of 0.6325: one sky determines the quadrupole only to 63%. The distribution is skewed (skewness 1.265), and the script `code/ch07/23_cl_distribution.py` evaluates $\mathrm{P}(\widehat{C}_2 < C_2) = \mathrm{P}(\chi^2_5 < 5) = 0.5841$: a low quadrupole is more likely than a high one. Suppose the measured quadrupole were a fifth of the model's. In the language of Chapter 4: if the model were true, would getting a quadrupole this low, or even lower, be something we'd reasonably expect? The probability is $\mathrm{P}(\widehat{C}_2 < 0.2\,C_2) = \mathrm{P}(\chi^2_5 < 1) = 0.03743$: small but not negligible. It is even less alarming than it looks, because the quadrupole was singled out for testing only after the sky had been seen; with many multipoles to look at, one of them is likely to look odd. A low quadrupole in the real sky is one of the large-angle features examined in the Planck isotropy analysis [109], and this χ^2_5 tail is the first thing any such test computes.

Example: $\ell = 30$ and $\ell = 1000$. At $\ell = 30$, $\nu = 61$ and the fractional error is 0.1811; still, a 20% low fluctuation, $\mathrm{P}(\widehat{C}_{30} < 0.8\,C_{30}) = 0.1299$, happens in one sky in eight. At $\ell = 1000$ the error is 0.03161, about 3%. Since different multipoles are independent on the full sky (Section 7.12.4), averaging $\Delta\ell$ neighbouring multipoles with nearly equal C_ℓ divides the variance by $\Delta\ell$:

$$\mathrm{Var}\Big(\frac{1}{\Delta\ell}\sum_{\ell'\in\mathrm{bin}}\widehat{C}_{\ell'}\Big) = \frac{1}{\Delta\ell^2}\sum_{\ell'\in\mathrm{bin}}\frac{2C_{\ell'}^2}{2\ell'+1} \approx \frac{2C_\ell^2}{(2\ell+1)\,\Delta\ell}. \tag{7.79}$$

A bin of $\Delta\ell = 50$ at $\ell = 1000$ is measured to 0.4471%. Real experiments see only part of the sky, with noise N_ℓ and a beam B_ℓ, and the rule of thumb becomes $\Delta C_\ell \approx (C_\ell + N_\ell/B_\ell^2)\sqrt{2/[(2\ell+1)\Delta\ell\, f_{\rm sky}]}$ [138, eq. 4], [Hivon (16)–(17)]: noise adds to the signal inside the bracket, and observing a fraction $f_{\rm sky}$ of the sky leaves about a fraction $f_{\rm sky}$ of the modes. Chapter 8 derives this and shows where it fails.

7.10.3 Reading the distribution backwards: which C_ℓ made our sky?

Everything so far was prediction: given C_ℓ, what values of $\widehat{C}_\ell$ come out, and how often. The physicist's problem runs the other way. We observe one sky; what does it tell us about C_ℓ?

What we observed. Our sky's estimate at multipole ℓ, $\widehat{C}_\ell = \hat{c}$, a single number in $\mu\mathrm{K}^2$. *What could have produced it?* Any value of the true C_ℓ, each one a different cosmological model at that multipole; cosmic variance lets every one of them give $\hat{c}$, some far more readily than others. *How probable was $\hat{c}$ under each candidate?* That is the density (7.76) evaluated at the observed $\hat{c}$, once for each candidate C_ℓ. *Only then the prior.* The update multiplies these numbers by prior

[2] Read literally, a χ^2_ν variable has mean ν and variance 2ν. What is meant is the scaled χ^2 of (7.76): $\nu\widehat{C}_\ell/C_\ell \sim \chi^2_\nu$.

weights and normalises (Chapter 5). *Only then the numbers.* The third step is the likelihood. Read (7.76) as a function of C_ℓ with $\hat{c}$ held fixed:

$$\mathcal{L}(C_\ell) = p(\hat{c} \mid C_\ell) \overset{(1)}{=} \frac{\nu}{C_\ell} \frac{(\nu\hat{c}/C_\ell)^{\nu/2-1} e^{-\nu\hat{c}/2C_\ell}}{2^{\nu/2}\Gamma(\nu/2)} \overset{(2)}{=} \text{const} \times C_\ell^{-\nu/2} \exp\!\left(-\frac{\nu\hat{c}}{2C_\ell}\right). \tag{7.80}$$

(1) Insert the χ^2_ν density into (7.76) at $\widehat{C}_\ell = \hat{c}$.

(2) Collect the powers of C_ℓ: $C_\ell^{-1} \cdot C_\ell^{-(\nu/2-1)} = C_\ell^{-\nu/2}$; the factors that depend only on $\hat{c}$ and ν do not distinguish hypotheses and go into the constant.

This is the full-sky CMB likelihood of Chapter 3; its maximum is at $C_\ell = \hat{c}$, the estimator itself. Figure 7.24(b) plots it against the candidate C_ℓ in units of the observed $\hat{c}$. At $\ell = 2$ it is very broad and lopsided: candidate spectra up to $2.03\,\hat{c}$ and down to $0.56\,\hat{c}$ lie within $\Delta(-2\ln\mathcal{L}) = 1$ of the peak. The interval extends much further upwards because a large true C_ℓ produces a low estimate fairly often (the long left part of the χ^2_5 density), while a small true C_ℓ almost never produces a high one. At $\ell = 100$ the interval $[0.91, 1.11]\,\hat{c}$ is narrow and nearly symmetric. Chapter 9 runs the same reasoning over six cosmological parameters at once, with $C_\ell(\boldsymbol{\theta})$ supplied by CAMB.

Example: adding white noise. A detector adds its own noise to the sky: $\hat{a}_{\ell m} = a_{\ell m} + n_{\ell m}$, with $n_{\ell m}$ the coefficients of a map of uniform white noise of pixel variance σ^2 and pixel area Ω_{pix}. The question is what this does to the estimator and the likelihood. First, the noise coefficients. They are uncorrelated with each other and with the signal, and each has the variance $N_\ell = \sigma^2\Omega_{\text{pix}}$. The reason: $n_{\ell m} = \sum_p n_p Y^*_{\ell m}(p)\,\Omega_{\text{pix}}$ is a sum of independent pixel noises, so its variance is $\sigma^2\Omega^2_{\text{pix}} \sum_p |Y_{\ell m}(p)|^2$, and $\sum_p |Y_{\ell m}(p)|^2 \Omega_{\text{pix}} \approx \int \mathrm{d}\Omega\, |Y_{\ell m}|^2 = 1$. Second, signal plus noise is a sum of two independent Gaussians, so it has the covariance (7.62) with $C_\ell + N_\ell$ in place of C_ℓ. The whole argument of this section therefore holds with that replacement: $(2\ell+1)\hat{C}^{\text{obs}}_\ell/(C_\ell + N_\ell) \sim \chi^2_{2\ell+1}$, where $\hat{C}^{\text{obs}}_\ell$ is (7.72) computed from the $\hat{a}_{\ell m}$. The likelihood (7.80) becomes

$$\mathcal{L}(C_\ell) \propto (C_\ell + N_\ell)^{-(2\ell+1)/2} \exp\!\left[-\frac{(2\ell+1)\,\hat{C}^{\text{obs}}_\ell}{2(C_\ell + N_\ell)}\right], \tag{7.81}$$

which, by the same argument as before, is largest when $C_\ell + N_\ell = \hat{C}^{\text{obs}}_\ell$:

$$\hat{C}^{\text{ML}}_\ell = \hat{C}^{\text{obs}}_\ell - N_\ell \tag{7.82}$$

[HobsonBMC (10.24)–(10.25)]. The noise is subtracted on average, but the scatter is that of $C_\ell + N_\ell$, which is why N_ℓ enters the bracket of the error formula of Section 7.10.2.

7.11 Where C_ℓ and the skies come from: CAMB and HEALPix

Up to now C_ℓ has been a given function and a sky has been a given set of $a_{\ell m}$. In a real analysis both have to be produced. The spectrum comes from physics: six cosmological numbers go into a Boltzmann code, and C_ℓ comes out (Chapter T1). The skies come from geometry: we cut the sphere into pixels and use fast spherical-harmonic transforms to turn coefficients into maps and maps back into coefficients. Think of the chain physical model → field or dataset → summary → sampling distribution → inference. CAMB supplies the first arrow. HEALPix lets us make the second arrow on a computer, as many times as we like.

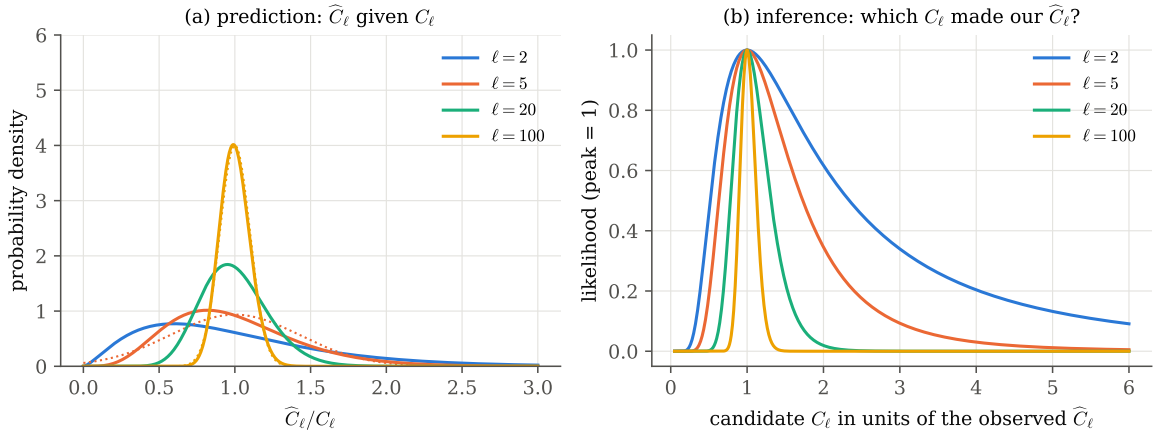

Figure 7.24: The two directions of the same formula. (a) Prediction: the density of $\widehat{C}_\ell/C_\ell$ for $\ell = 2, 5, 20, 100$, a scaled $\chi^2_{2\ell+1}$; dotted curves are Gaussians with the same mean and variance, for $\ell = 5$ and $\ell = 100$. At low ℓ the estimator is skewed, with its mode below the truth. (b) Inference: the likelihood of the true C_ℓ given an observed $\widehat{C}_\ell$, normalised to peak 1. All curves peak at the observed value; at low ℓ the likelihood has a long tail towards large C_ℓ.

7.11.1 What CAMB computes

The input. Follow one Fourier mode $\boldsymbol{k}$ of the primordial curvature perturbation ζ, the seed set up by inflation. Through gravity it perturbs every component of the Universe: photons, baryons, cold dark matter, neutrinos and the metric.

What is followed. The photon temperature perturbation in that mode depends on the direction in which the photon travels, measured relative to $\boldsymbol{k}$. It is therefore expanded in Legendre multipoles $\Theta_\ell(k, \eta)$, with η the conformal time. The equations for these multipoles form the **Boltzmann hierarchy**. For free-streaming particles it reads

$$\Theta'_\ell = \frac{k}{2\ell+1}\left[\ell\,\Theta_{\ell-1} - (\ell+1)\,\Theta_{\ell+1}\right] \qquad (\ell \geq 2), \tag{7.83}$$

where the prime is $\partial/\partial\eta$. In words: streaming moves anisotropy from each multipole into its neighbours, and so from large angles to small. Photons obey the same equation plus two extra terms: a Thomson scattering term, which damps every $\ell \geq 2$ multipole while the plasma is ionised, and gravitational source terms at $\ell \leq 2$.

What the code does. A Boltzmann code integrates these coupled linear ODEs, together with the fluid equations for baryons and dark matter and the linearised Einstein equations, from deep in the radiation era to today, for a few thousand values of k. Integrating the hierarchy directly up to $\ell \sim 3000$ would be slow. The trick that made the codes fast is to write today's multipoles as an integral along the line of sight, $\Theta_\ell(k, \eta_0) = \int_0^{\eta_0} \mathrm{d}\eta\, S(k, \eta)\, j_\ell\big(k(\eta_0 - \eta)\big)$, where the source S needs only the first few multipoles and the spherical Bessel function j_ℓ is pure geometry, independent of the cosmology [139]. CAMB implements this method [8]; so do CMBFAST and CLASS, and all of them compute the linear CMB spectra by integrating the sources along the photon line of sight [Padilla §7.1.1].

For statistics, what matters is the structure of the answer, and it is simple. The equations are linear, so each $\boldsymbol{k}$ mode evolves on its own, and today's temperature in that mode is a fixed number times its primordial amplitude $\zeta_{\boldsymbol{k}}$. That number, for multipole ℓ, is the radiation **transfer function** $g_{T\ell}(k)$ [the temperature anisotropy at multipole ℓ produced by one unit of ζ

at wavenumber k, computed once per cosmology]. Projected on the sky [139],

$$a_{\ell m} = 4\pi\, i^\ell \int \frac{\mathrm{d}^3k}{(2\pi)^3}\; g_{T\ell}(k)\, Y^*_{\ell m}(\hat{\boldsymbol{k}})\, \zeta_{\boldsymbol{k}}. \tag{7.84}$$

With isotropic primordial statistics, $\langle \zeta_{\boldsymbol{k}} \zeta^*_{\boldsymbol{k}'} \rangle = (2\pi)^3 \delta^{(3)}(\boldsymbol{k} - \boldsymbol{k}') P_\zeta(k)$, the covariance of the coefficients is

$$\begin{aligned}
\langle a_{\ell m} a^*_{\ell' m'} \rangle &\overset{(1)}{=} (4\pi)^2\, i^{\ell-\ell'} \int \frac{\mathrm{d}^3k}{(2\pi)^3}\; g_{T\ell}(k)\, g_{T\ell'}(k)\, P_\zeta(k)\, Y^*_{\ell m}(\hat{\boldsymbol{k}})\, Y_{\ell' m'}(\hat{\boldsymbol{k}}) \\
&\overset{(2)}{=} \frac{16\pi^2}{8\pi^3} \int_0^\infty k^2 \mathrm{d}k\; g_{T\ell}\, g_{T\ell'}\, P_\zeta(k) \int \mathrm{d}\Omega_{\hat{\boldsymbol{k}}}\; Y^*_{\ell m} Y_{\ell' m'} \\
&\overset{(3)}{=} \underbrace{\frac{2}{\pi} \int_0^\infty k^2 \mathrm{d}k\; P_\zeta(k)\, g_{T\ell}(k)^2}_{C_\ell}\; \delta_{\ell\ell'} \delta_{mm'}.
\end{aligned} \tag{7.85}$$

(1) Multiply (7.84) by the conjugate of its primed copy, average, and do the $\boldsymbol{k}'$ integral with the delta function; $(i^{\ell'})^* = i^{-\ell'}$.
(2) Split $\mathrm{d}^3k = k^2 \mathrm{d}k\, \mathrm{d}\Omega_{\hat{\boldsymbol{k}}}$: the transfer functions and P_ζ depend only on $k = |\boldsymbol{k}|$, the harmonics only on the direction $\hat{\boldsymbol{k}}$.
(3) Orthonormality (7.41) over the directions of $\boldsymbol{k}$ sets $\ell = \ell'$, $m = m'$, which also makes $i^{\ell-\ell'} = 1$.

This is the formula for C_ℓ in Chapter T1. It is also the isotropy result (7.62), reached this time from the physics side. The Kronecker deltas came from integrating the harmonics over the directions of $\boldsymbol{k}$, which was possible only because P_ζ depends on $k = |\boldsymbol{k}|$ and not on the direction: that is where isotropy enters. The formula carries three lessons. First, $a_{\ell m}$ is a linear combination of Gaussian $\zeta_{\boldsymbol{k}}$, hence Gaussian. Second, the whole cosmology sits in P_ζ (the amplitude A_s and tilt n_s) and in $g_{T\ell}$ (the other four parameters). Third, CAMB returns C_ℓ, an expectation value. It never returns a sky; to get one we must draw the $a_{\ell m}$ ourselves.

How to call it. The fiducial spectra are computed once, in `code/camb_fiducial.py`:

Listing 7.5: The CAMB call behind every fiducial spectrum (`code/camb_fiducial.py`)

```
13 FIDUCIAL = dict(H0=67.36, ombh2=0.02237, omch2=0.1200, tau=0.0544, As=2.100e-9, ns=0.9649,
       mnu=0.06)
14
15
16 def compute(params=FIDUCIAL, lmax=LMAX):
17     import camb
18     p = camb.set_params(**params, lmax=lmax + 200, lens_potential_accuracy=1)
19     r = camb.get_results(p)
20     cls = r.get_cmb_power_spectra(p, CMB_unit="muK", raw_cl=True)
21     tot = cls["total"][: lmax + 1]
22     return np.arange(lmax + 1), tot  # columns TT, EE, BB, TE
```

Line 13 is the Planck 2018 best fit [25] in CAMB's keywords (the dictionary of Chapter T1). Line 18 builds a parameter object; computing to $\ell_{\max} + 200$ and setting `lens_potential_accuracy=1` keep the lensed spectra accurate up to $\ell_{\max} = 3000$. Line 19 solves the Boltzmann equations. Line 20 asks for the *raw* C_ℓ in $\mu\mathrm{K}^2$ (without `raw_cl=True` CAMB returns D_ℓ, a factor $\ell(\ell+1)/2\pi$ larger). Line 21 keeps the lensed total, with columns TT, EE, BB, TE. The result is cached in `data/camb_fiducial.npz`, and every script loads it with `load_fiducial()`, which returns ℓ and C_ℓ^{TT} with $C_0 = C_1 = 0$. Rerunning CAMB takes seconds, and is needed only when a script varies the parameters.

Example: the spectrum and its irreducible error bar. Figure 7.25 shows the fiducial $D_\ell = \ell(\ell+1)C_\ell/2\pi$ with the band $D_\ell[1 \pm \sqrt{2/(2\ell+1)}]$ of (7.78), and the $\widehat{D}_\ell$ of one simulated sky (`code/ch07/24_camb_healpix.py`). The first acoustic peak is at $\ell = 220$ with $D_\ell = 5732\,\mu\mathrm{K}^2$; there the band is $\pm\sqrt{2/441} = \pm 6.7\%$. At $\ell = 2$ the band is ±63% wide and the one sky wanders through it; above $\ell \sim 500$ the band is too thin to see and the simulated points trace the curve. Large scales are known poorly from one sky, and nothing can be done about it.

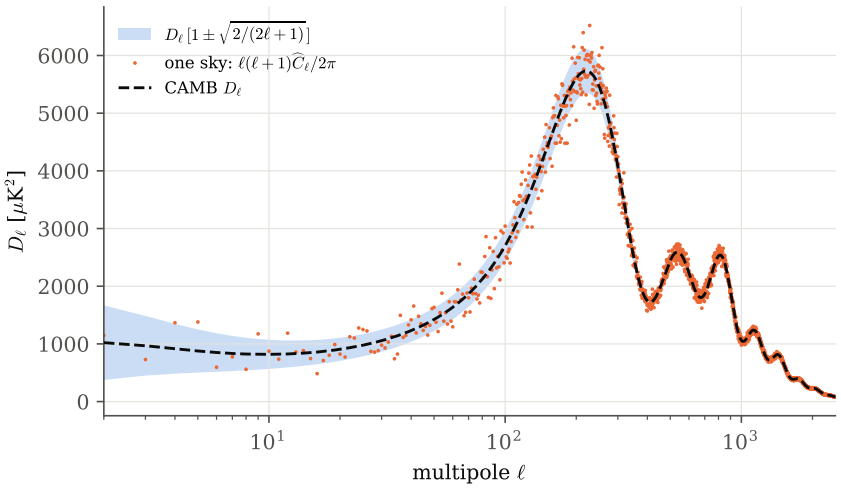

Figure 7.25: The fiducial CAMB spectrum D_ℓ (black dashed), its cosmic-variance band $\pm\sqrt{2/(2\ell+1)}$ (blue), and the estimate $\ell(\ell+1)\widehat{C}_\ell/2\pi$ from one simulated full sky up to $\ell = 2500$ (orange points). The logarithmic ℓ axis stretches the few low multipoles, where the band is wide, over a large part of the plot.

7.11.2 HEALPix: cutting the sphere into equal pixels

A computer stores a map as a list of numbers, one per pixel, so we must cut the sphere into pixels. Latitude–longitude grids are a poor choice. Their pixels shrink towards the poles. Noise averaged over a small polar pixel then has a different variance from noise averaged over a large equatorial one, so the map's noise changes with latitude. Górski et al. list three properties a good pixelisation needs [7]:

1. *Equal areas*, so that white noise in time stays white noise in the map and every pixel samples the sky with the same weight;
2. *Pixel centres on rings of constant latitude*, so that spherical-harmonic transforms are fast: $Y_{\ell m} \propto P_\ell^m(\cos\theta)e^{im\phi}$, the expensive Legendre functions need to be evaluated once per ring rather than once per pixel, and the $e^{im\phi}$ sum along each ring is an FFT;
3. *A hierarchy*: each pixel splits into four at the next resolution, so that nearby pixels are nearby in memory.

Working definition 7.8 (HEALPix grid)

The **HEALPix** grid starts from 12 equal-area base pixels and divides each into $N_{\mathrm{side}} \times N_{\mathrm{side}}$ sub-pixels [N_{side} is a power of 2 that sets the resolution]. It has

$$N_{\mathrm{pix}} = 12\,N_{\mathrm{side}}^2 \text{ pixels}, \qquad \Omega_{\mathrm{pix}} = \frac{4\pi}{N_{\mathrm{pix}}} = \frac{\pi}{3N_{\mathrm{side}}^2}, \qquad 4N_{\mathrm{side}} - 1 \text{ rings of constant latitude}, \tag{7.86}$$

and a full spherical-harmonic transform costs of order $N_{\text{pix}}^{3/2}$ operations instead of N_{pix}^2 [7], [Hivon p. 4].

Figure 7.26 shows the first three levels. The pixels are not squares (they are curvilinear quadrilaterals, and near the poles they are visibly distorted), but they all have exactly the same area.

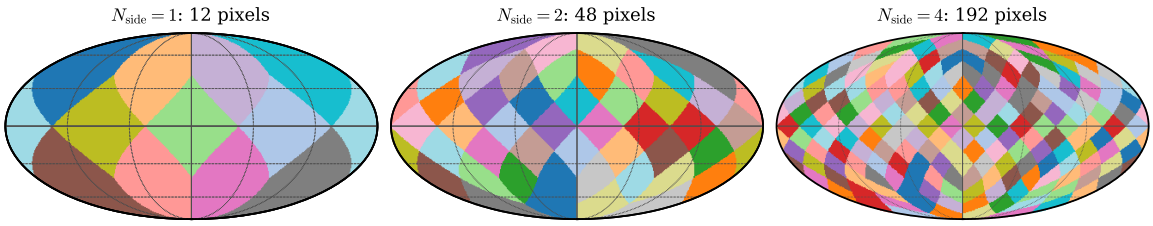

Figure 7.26: HEALPix tilings with $N_{\text{side}} = 1, 2, 4$, each pixel painted a random colour, with lines of latitude and longitude every 30° and 60°. The twelve base pixels form three rings of four; each step in N_{side} splits every pixel into four of equal area.

Where the pixel edges come from. The edges in Figure 7.26 look like arbitrary curves, but every one of them follows from the demand for equal areas and an observation of Archimedes. Wrap the unit sphere in a cylinder that touches it along the equator, and push each point of the sphere straight out, away from the axis and at constant height, onto the cylinder (Figure 7.27a). The point at polar angle θ and longitude ϕ lands at the same ϕ and at height $z = \cos\theta$. This map keeps areas. Take the small patch between θ and $\theta + \Delta\theta$ and between ϕ and $\phi + \Delta\phi$:

$$\Delta\Omega \overset{(1)}{=} (\sin\theta\,\Delta\phi)\,(\Delta\theta) \overset{(2)}{=} \Delta\phi\;|\Delta z|\,. \tag{7.87}$$

(1) The patch is nearly a rectangle. Its width runs along the circle of latitude, whose radius is $\sin\theta$, so the width is $\sin\theta\,\Delta\phi$; its height runs along the meridian and is $\Delta\theta$.

(2) On the cylinder, of radius 1, the same patch has width $\Delta\phi$ and height $|\Delta z|$, and $z = \cos\theta$ gives $|\Delta z| = \sin\theta\,\Delta\theta$.

The image on the cylinder is wider than the patch by $1/\sin\theta$ and shorter by $\sin\theta$, and the two factors cancel. Now cut the cylinder open along $\phi = 0$ and lay it flat: a rectangle $0 \le \phi < 2\pi$, $-1 \le z \le 1$, of area 4π (Figure 7.27b). A region of the sphere has the same area as its image in this rectangle, so *equal-area pixels on the sphere are the same thing as equal-area tiles in the flat* (ϕ, z) *rectangle*. We design the tiles there.

The equatorial belt. Here the pixels are laid out in rings of constant z, and every ring holds the same number of pixels, $4N_{\text{side}}$: the equator crosses four base pixels, each N_{side} pixels across. Two numbers then fix everything, the width $\Delta\phi$ of a pixel along its ring and the spacing Δz between neighbouring rings (Figure 7.27b):

$$\Delta\phi \overset{(1)}{=} \frac{2\pi}{4N_{\text{side}}} = \frac{\pi}{2N_{\text{side}}}, \qquad \Delta z \overset{(2)}{=} \frac{\Omega_{\text{pix}}}{\Delta\phi} \overset{(3)}{=} \frac{\pi/(3N_{\text{side}}^2)}{\pi/(2N_{\text{side}})} = \frac{2}{3N_{\text{side}}}. \tag{7.88}$$

(1) A ring goes once round, 2π, and holds $4N_{\text{side}}$ pixels.

(2) In the flat picture area is $\Delta\phi\,\Delta z$, and each pixel must have area Ω_{pix}.

(3) $\Omega_{\text{pix}} = \pi/(3N_{\text{side}}^2)$ from (7.86).

The rings of pixel centres in the belt are therefore at

$$z_j = j\,\Delta z = \frac{2j}{3N_{\text{side}}}, \qquad \cos\theta_j = \frac{2j}{3N_{\text{side}}}, \qquad j = -N_{\text{side}}, \ldots, N_{\text{side}}, \tag{7.89}$$

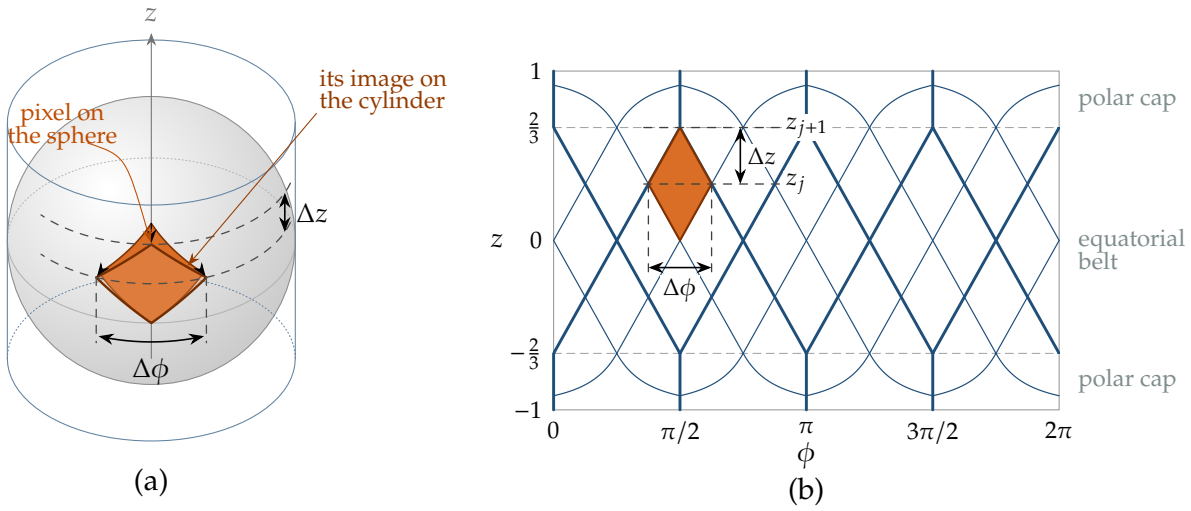

Figure 7.27: Archimedes' map and the HEALPix edges. (a) Each point of the sphere is pushed straight out, at constant height, onto the cylinder that touches the sphere along the equator. One pixel for $N_{\text{side}} = 2$ is shown on the sphere (solid) and as its image on the cylinder (see-through); the dashed rings z_j and z_{j+1} and the dashed lines below its side corners mark Δz and $\Delta\phi$ on the cylinder. (b) The cylinder cut open along $\phi = 0$ and laid flat. The thick lines are the boundaries of the twelve base pixels, the thin ones those for $N_{\text{side}} = 2$: straight (7.91) in the belt $|z| \le \frac{2}{3}$, curved (7.94) in the two polar caps. The same pixel is shaded: its width along its ring is $\Delta\phi = \pi/(2N_{\text{side}})$, and the rings z_j and z_{j+1} of pixel centres are $\Delta z = 2/(3N_{\text{side}})$ apart (7.88), so its area is $\Delta\phi\,\Delta z = \Omega_{\text{pix}}$.

and the belt ends at $j = \pm N_{\text{side}}$, $z = \pm\frac{2}{3}$, which is where the number $\frac{2}{3}$ in HEALPix comes from. If the pixels of neighbouring rings sat directly above one another, they would be rectangles $\Delta\phi \times \Delta z$. HEALPix instead shifts each ring by half a pixel, $\Delta\phi/2$, against its neighbours, so a pixel centre sits directly above the gap between two pixels of the ring below. The pixel around the centre (ϕ_c, z_j) is then the diamond with corners at $(\phi_c \pm \frac{1}{2}\Delta\phi,\ z_j)$ on its own ring and at $(\phi_c,\ z_j \pm \Delta z)$, the centres' height of the rings above and below. Its area is half the product of its diagonals, $\frac{1}{2}\,\Delta\phi \cdot 2\Delta z = \Delta\phi\,\Delta z = \Omega_{\text{pix}}$, as required, and its edges are straight lines of slope

$$\pm\frac{\Delta z}{\Delta\phi/2} = \pm\frac{2/(3N_{\text{side}})}{\pi/(4N_{\text{side}})} = \pm\frac{8}{3\pi}, \tag{7.90}$$

the same for every N_{side}. Edges of the same slope pass through corners that are $\Delta\phi$ apart along a ring, so their values at $\phi = 0$ differ by $\frac{8}{3\pi}\Delta\phi = \frac{4}{3N_{\text{side}}}$, and one of them passes through the corner at $(0, \frac{2}{3})$. The pixel edges in the belt are thus

$$z = \frac{2}{3} - \frac{4k}{3N_{\text{side}}} \pm \frac{8\phi}{3\pi}, \qquad k \text{ an integer}, \quad |z| \le \frac{2}{3}, \tag{7.91}$$

straight lines on the flat rectangle and curves with $\cos\theta$ linear in ϕ on the sphere. For $N_{\text{side}} = 1$ the same construction gives the twelve base pixels: four diamonds $\Delta\phi = \frac{\pi}{2}$ wide and $2\Delta z = \frac{4}{3}$ tall around the equator, with the four northern and four southern base pixels filling the triangles between them.

The polar caps. Above $z = \frac{2}{3}$ the flat picture has a strip of height $\frac{1}{3}$ and area $2\pi/3$. It belongs to the four northern base pixels. The lower part of each, a triangle between two equatorial diamonds, has area $\frac{1}{2} \cdot \frac{\pi}{2} \cdot \frac{2}{3} = \frac{\pi}{6}$, so the remaining $\frac{\pi}{6}$ of each is a quarter of the strip, a rectangle $\phi_t \in [0, \frac{\pi}{2}]$, $z \in [\frac{2}{3}, 1]$, where ϕ_t is ϕ measured from the start of its quarter. Diamonds cannot tile it, because its top edge $z = 1$ is not a line on the sphere but a single point, the pole: on the sphere the rectangle is a triangle with one corner at the pole. We need coordinates in which it

is drawn as a triangle and areas are still uniform. Near the pole $1 - z = 1 - \cos\theta \approx \theta^2/2$, so $\sqrt{1-z}$ measures distance from the pole. Set

$$\rho = \sqrt{3(1-z)}, \qquad u = \frac{2\phi_t}{\pi}\,\rho, \qquad v = \Big(1 - \frac{2\phi_t}{\pi}\Big)\rho. \tag{7.92}$$

The pole, $\rho = 0$, becomes the single point $u = v = 0$. The edge $\phi_t = 0$ becomes $u = 0$, the edge $\phi_t = \frac{\pi}{2}$ becomes $v = 0$, and the bottom edge $z = \frac{2}{3}$, where $\rho = 1$, becomes the line $u + v = 1$. The quarter-cap is the triangle $u, v \geq 0$, $u + v \leq 1$, half of a unit square. Its areas are uniform:

$$\Delta\Omega \overset{(1)}{=} |\Delta z|\;\Delta\phi_t \overset{(2)}{=} \frac{2\rho}{3}\,\Delta\rho\,\Delta\phi_t \overset{(3)}{=} \frac{\pi}{3}\,\Delta u\,\Delta v. \tag{7.93}$$

(1) Archimedes' rule (7.87).

(2) $z = 1 - \rho^2/3$, so $|\Delta z| = \frac{2\rho}{3}\Delta\rho$.

(3) The area of a small cell in the (u, v) plane is the Jacobian times $\Delta\rho\,\Delta\phi_t$: with $\partial u/\partial\rho = 2\phi_t/\pi$, $\partial u/\partial\phi_t = 2\rho/\pi$, $\partial v/\partial\rho = 1 - 2\phi_t/\pi$ and $\partial v/\partial\phi_t = -2\rho/\pi$, the determinant is $-\frac{2\phi_t}{\pi}\frac{2\rho}{\pi} - \frac{2\rho}{\pi}\big(1 - \frac{2\phi_t}{\pi}\big) = -\frac{2\rho}{\pi}$, so $\Delta u\,\Delta v = \frac{2\rho}{\pi}\Delta\rho\,\Delta\phi_t$; replace $\frac{2\rho}{3}\Delta\rho\,\Delta\phi_t$ by $\frac{\pi}{3}\Delta u\,\Delta v$.

The factor $\pi/3$ is the same everywhere, so equal areas in the (u, v) triangle are equal areas on the sphere (the whole triangle, of area $\frac{1}{2}$, is $\frac{\pi}{6}$, as it should be). In the triangle we can again cut with straight lines, $u = k/N_{\text{side}}$ and $v = k/N_{\text{side}}$, into squares of area $1/N_{\text{side}}^2$, each a pixel of area $\frac{\pi}{3N_{\text{side}}^2} = \Omega_{\text{pix}}$; the squares cut in half by $u + v = 1$ are completed by the half-diamonds just below $z = \frac{2}{3}$, since at $\rho = 1$ the line $u = k/N_{\text{side}}$ sits at $\phi_t = k\pi/(2N_{\text{side}})$, exactly where the belt edge (7.91) with the same k reaches $z = \frac{2}{3}$. Turning the straight lines back into (ϕ, z) with (7.92): $u = k/N_{\text{side}}$ means $\frac{2\phi_t}{\pi}\sqrt{3(1-z)} = \frac{k}{N_{\text{side}}}$; square both sides and solve for z, and do the same for v:

$$z = 1 - \frac{k^2}{3N_{\text{side}}^2}\Big(\frac{\pi}{2\phi_t}\Big)^2, \qquad z = 1 - \frac{k^2}{3N_{\text{side}}^2}\Big(\frac{\pi}{\pi - 2\phi_t}\Big)^2, \qquad z \geq \frac{2}{3}, \tag{7.94}$$

and the same with $z \to -z$ in the south. These are the curved edges near the top and bottom of Figure 7.27b, and (7.91) and (7.94) are the pixel boundaries of [7]. The corners again sit on rings: where $u = k/N_{\text{side}}$ meets $v = j/N_{\text{side}}$, $\rho = u + v = (k + j)/N_{\text{side}}$ and $z = 1 - (k + j)^2/(3N_{\text{side}}^2)$.

Example: pixel sizes and band limits. The side of a pixel is about the square root of its area,

$$\theta_{\text{pix}} \approx \sqrt{\Omega_{\text{pix}}} = \sqrt{\frac{\pi}{3}}\,\frac{1}{N_{\text{side}}}\ \text{rad} = \frac{58.6^\circ}{N_{\text{side}}}. \tag{7.95}$$

For $N_{\text{side}} = 256$ that is 13.74′ with 786432 pixels; $N_{\text{side}} = 512$ gives 6.871′ and 3145728 pixels; Planck's high-frequency maps use $N_{\text{side}} = 2048$, 1.718′ and 50,331,648 pixels. How high in ℓ can a map of N_{pix} numbers go? A sky band-limited to $\ell_{\max}$ has $(\ell_{\max} + 1)^2$ real degrees of freedom (Section 7.8.2), and N_{pix} numbers cannot determine more than N_{pix} unknowns:

$$(\ell_{\max} + 1)^2 \leq 12N_{\text{side}}^2 \quad\Longrightarrow\quad \ell_{\max} \lesssim \sqrt{12}\,N_{\text{side}} \approx 3.5\,N_{\text{side}}. \tag{7.96}$$

In practice healpy never goes beyond $\ell_{\max} = 3N_{\text{side}} - 1$, and analyses that need accurate coefficients stay below about $2N_{\text{side}}$, as the next example shows.

7.11.3 healpy: four operations and their from-scratch versions

The Python package healpy wraps the HEALPix library. Four functions do everything in this chapter, and two more are shorthands (Figure 7.28):

- `synalm(cl, lmax)`: draw one set of Gaussian $a_{\ell m}$ with spectrum C_ℓ;
- `alm2map(alm, nside)`: sum the series (7.44) at every pixel centre;
- `map2alm(map, lmax, iter)`: compute the coefficients of a map;
- `alm2cl(alm)`: the estimator $\widehat{C}_\ell$ of (7.72);
- `synfast` = `synalm` then `alm2map`, and `anafast` = `map2alm` then `alm2cl`.

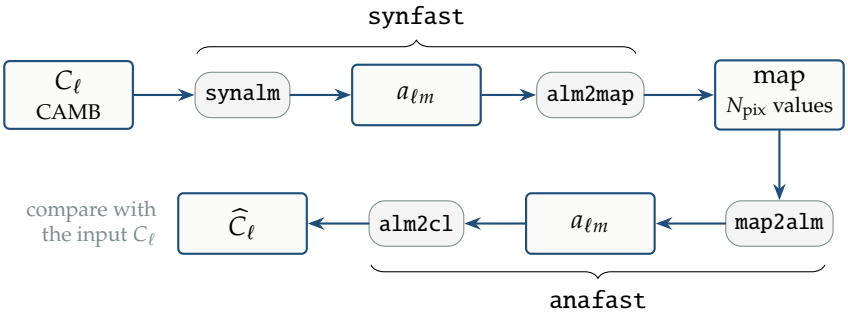

Figure 7.28: The healpy pipeline. Objects are in blue boxes, functions in grey. `synfast` draws coefficients from a spectrum and turns them into a map; `anafast` turns a map back into coefficients and squares them into $\widehat{C}_\ell$. Comparing the output $\widehat{C}_\ell$ with the input C_ℓ, over many skies, is the Monte Carlo study of Section 7.12.

Storage. healpy stores only the coefficients with $m \geq 0$, since the others follow from the reality condition (7.46). They are ordered by m first: all ℓ for $m = 0$, then all $\ell \geq 1$ for $m = 1$, and so on, so that $a_{\ell m}$ sits at position $m(2\ell_{\max} + 1 - m)/2 + \ell$. For $\ell_{\max} = 20$, the coefficient $a_{5,3}$ is at $3 \times 38/2 + 5 = 62$, which is what `healpy.Alm.getidx(20, 5, 3)` returns. Neighbouring ℓ at fixed m are neighbours in memory, which is what made the modulation code of Section 7.9.5 so short.

Drawing a sky by hand. To see the mechanism we first write `synalm` ourselves, straight from the table of real degrees of freedom in Section 7.10.1:

Listing 7.6: Isotropic Gaussian coefficients from a spectrum (`code/ch07/lib_harmonic.py`)

```
34 def synalm(cl, lmax: int, rng: np.random.Generator):
35     """One isotropic Gaussian realisation of the a_lm (m >= 0) with spectrum cl.
36
37     m = 0 : a_l0 is real,        a_l0 ~ N(0, C_l)
38     m > 0 : Re a_lm, Im a_lm are independent N(0, C_l / 2), so <|a_lm|^2> = C_l
39     """
40     cl = np.asarray(cl, dtype=float)
41     ell, m = getlm(lmax)
42     sig = np.sqrt(cl[ell])
43     re = rng.standard_normal(ell.size)
44     im = rng.standard_normal(ell.size)
45     return np.where(m == 0, sig * re, sig * (re + 1j * im) / np.sqrt(2.0)).astype(complex)
```

Line 42 gives every stored coefficient the standard deviation $\sqrt{C_\ell}$ of its multipole. Lines 43–44 draw two standard normals per coefficient. Line 45 is the table: for $m = 0$ the coefficient is real with variance C_ℓ (the imaginary draw is discarded); for $m > 0$ the real and imaginary parts are each $\sqrt{C_\ell/2}$ times a standard normal. Nothing else is needed for an isotropic Gaussian sky, because the coefficients are independent: this is the diagonal Cholesky factor of Chapter 6, one $\sqrt{C_\ell}$ per mode. The library function `healpy.synalm` does the same with numpy's global random stream; in Section 7.12 we check that the two produce statistically identical skies.

From a map back to coefficients. The integral (7.44) becomes a sum over pixels, $a_{\ell m} \approx \Omega_{\mathrm{pix}} \sum_p \Theta(p)\, Y^*_{\ell m}(p)$ [Hivon (12)], with Ω_{pix} the pixel area of (7.86). That sum is a quadrature rule, and it is not exact. healpy improves it by iteration (`iter`): synthesise a map from the current coefficients, analyse the difference between that map and the input map, and add the correction.

How accurate is the round trip $a_{\ell m} \to \text{map} \to a_{\ell m}$? We test it at $N_{\mathrm{side}} = 256$ (Figure 7.29) with the script `code/ch07/24_camb_healpix.py`. For a sky band-limited to $\ell \le 2N_{\mathrm{side}} = 512$, the recovered $\widehat{C}_\ell$ agrees with that of the input coefficients to a median relative error of 2.272×10^{-5} without iteration, and 1.116×10^{-8} with three iterations (the worst multipole is off by 3.973×10^{-7}). Now let the sky contain power up to $3N_{\mathrm{side}} - 1 = 767$. The pixels can no longer tell the highest multipoles apart from lower ones, so power leaks downwards (**aliasing**). The error below $\ell = 512$ rises to a median of 2.213×10^{-6}, and near $\ell = 3N_{\mathrm{side}}$ it reaches ten percent.

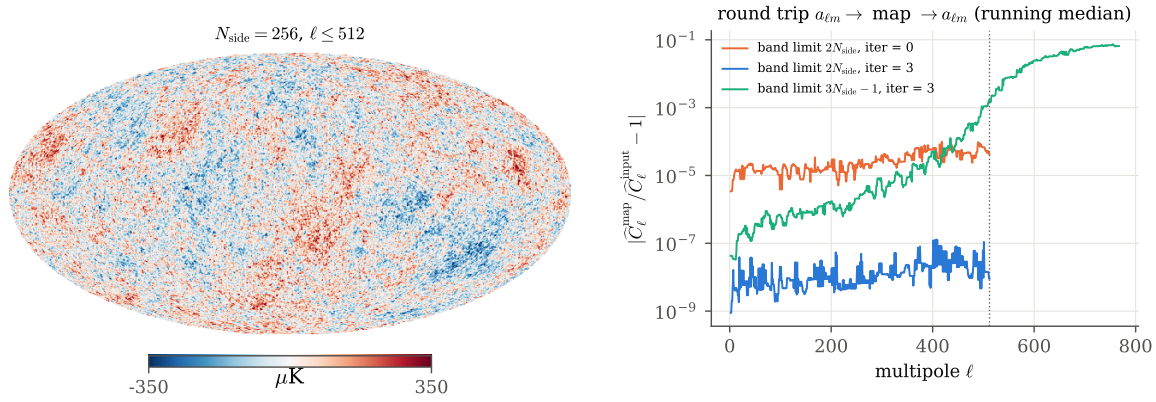

Figure 7.29: Left: a simulated sky at $N_{\mathrm{side}} = 256$ with $\ell \le 512$. Right: relative difference between $\widehat{C}_\ell$ measured on the map (`anafast`) and $\widehat{C}_\ell$ of the coefficients the map was made from, smoothed with a running median over 9 multipoles. Iterating the quadrature (blue) gains three orders of magnitude over a single pass (orange). With power up to $3N_{\mathrm{side}} - 1$ (green), aliasing spoils the high multipoles. The dotted line marks $\ell = 2N_{\mathrm{side}}$.

Watch out: A map is not a band-limited sky

The real sky has power at every ℓ, and a pixel averages the sky over its area. Both effects change the measured spectrum: power above the band limit aliases into lower multipoles, and the pixel average multiplies C_ℓ by the square of a *pixel window function* (healpy's `pixwin`), just as a beam multiplies it by B_ℓ^2 [Hivon (15)]. A simulation that draws $a_{\ell m}$ only up to ℓ_{max} and analyses at the same ℓ_{max} sees neither effect. Choose N_{side} so that the beam has already killed the signal well below $2N_{\mathrm{side}}$, and include the pixel window when comparing with data (Chapter 8).

7.12 Cosmic variance by Monte Carlo

We now have two independent routes to the same numbers. Algebra gave the exact sampling distribution of $\widehat{C}_\ell$ (Section 7.10.2): a scaled $\chi^2_{2\ell+1}$ with variance $2C_\ell^2/(2\ell+1)$. The tools of Section 7.11 let us make as many skies as we like from the CAMB spectrum. If we draw many skies, measure $\widehat{C}_\ell$ on each, and histogram the results, the histogram must reproduce the algebra. The comparison does two jobs. It checks every step of the derivation: the reality condition, the counting, the factor of two. And it builds, where the right answer is known, the same machine that Chapter 8 will use where no answer is known.

The questions. With N simulated full skies from the fiducial C_ℓ:

1. Does the histogram of $\widehat{C}_\ell$ at a given ℓ follow the scaled $\chi^2_{2\ell+1}$?
2. Does the Monte Carlo variance of $\widehat{C}_\ell$ converge to $2C_\ell^2/(2\ell+1)$, and how fast: how large is the Monte Carlo error on a Monte Carlo variance?
3. Is the covariance between different multipoles zero, and what does "zero" look like when it is estimated from N skies?

7.12.1 The simulation

The script `code/ch07/25_mc_cosmic_variance.py` simulates $N = 20{,}000$ full skies for $2 \le \ell \le 300$. It does not build maps. On the full sky a map is a lossless re-encoding of the coefficients: Figure 7.29 showed that the round trip returns them to a part in 10^8. So drawing the coefficients and applying (7.72) is the same experiment, thousands of times faster. For each multipole the script draws the $2\ell+1$ real numbers of the table in Section 7.10.1 directly:

Listing 7.7: $\widehat{C}_\ell$ for many independent skies, one multipole at a time (`code/ch07/lib_harmonic.py`)

```
59 def chat_sims(cl, ells, nsim: int, rng: np.random.Generator):
60     """C_hat_l for nsim independent full skies, multipole by multipole (memory-light).
61
62     For each l we draw the 2l+1 real numbers that make up the a_lm of one sky:
63     a_l0, and Re/Im of a_lm for m = 1..l.  Returns an array of shape (nsim, len(ells)).
64     """
65     out = np.empty((nsim, len(ells)))
66     for j, l in enumerate(ells):
67         z = rng.standard_normal((nsim, 2 * l + 1))
68         a0 = np.sqrt(cl[l]) * z[:, 0]                        # real, variance C_l
69         reim = np.sqrt(cl[l] / 2.0) * z[:, 1:]               # l real parts + l imaginary
       parts
70         out[:, j] = (a0 ** 2 + 2.0 * np.sum(reim ** 2, axis=1)) / (2 * l + 1)
71     return out
```

Line 67 draws a block of standard normals, one row per sky and $2\ell+1$ columns. Line 68 turns the first column into $a_{\ell 0}$, with variance C_ℓ; line 69 turns the other 2ℓ columns into the real and imaginary parts of $a_{\ell 1}, \dots, a_{\ell\ell}$, each with variance $C_\ell/2$. Line 70 is the estimator (7.72) with the factor 2 for the negative m. Nowhere does the code use the χ^2 result; it only uses the covariance (7.62) and the reality condition. The driver is short:

Listing 7.8: The Monte Carlo run (`code/ch07/25_mc_cosmic_variance.py`)

```
27 N_SIM, LMAX = 20000, 300
28 ELLS = np.arange(2, LMAX + 1)
29 rng = rng_for("ch07", "25_mc_cosmic_variance", stream=0)
30
31 # ------------------------------------------------------------------ the simulation
32 chat = lh.chat_sims(cl, ELLS, N_SIM, rng)          # shape (N_SIM, 299): one row per
       simulated sky
33 y = chat / cl[ELLS]                                 # C_hat_l / C_l, mean 1, variance
       2/(2l+1)
34 nu = 2 * ELLS + 1
```

Line 32 returns an array with one row per sky and one column per multipole; line 33 divides by the input spectrum, so that every column of `y` should have mean 1 and variance $2/(2\ell+1)$. The run draws about 1.8×10^9 Gaussian numbers and takes under a minute.

7.12.2 The sampling distribution of $\widehat{C}_\ell$

The first question has a clear answer: yes. Figure 7.30 compares the histograms of $\widehat{C}_\ell/C_\ell$ at $\ell = 2$, 10, 50 and 300 with the scaled $\chi^2_{2\ell+1}$ density (7.76). The agreement is visible by eye, including the strong skew at $\ell = 2$. There the Gaussian of the same mean and variance (dotted) is plainly wrong: it puts probability on negative power and misses the peak. For a quantitative check we use the Kolmogorov–Smirnov test of Chapter 4, with the null hypothesis "$(2\ell+1)\widehat{C}_\ell/C_\ell$ is $\chi^2_{2\ell+1}$". The p-values are 0.2452, 0.8436, 0.3608 and 0.6115: with 20,000 skies per multipole, nothing distinguishes the simulation from the scaled χ^2. The mean is right too: the average of $\widehat{C}_\ell/C_\ell$ over all skies is 1 at every one of the 299 multipoles. The largest deviation, in units of its standard error $\sqrt{2/[(2\ell+1)N]}$, is 3.081, which is the typical size of the largest of 299 independent standard normal deviations. The estimator is unbiased.

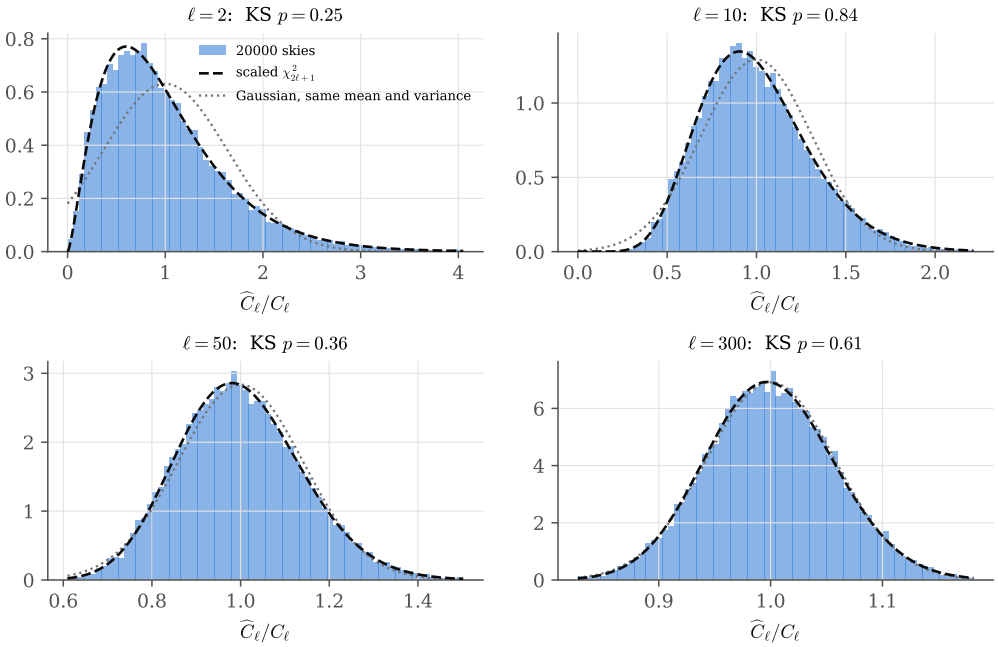

Figure 7.30: Histograms of $\widehat{C}_\ell/C_\ell$ from 20,000 simulated full skies at four multipoles (blue), the scaled $\chi^2_{2\ell+1}$ density (black dashed) and a Gaussian with the same mean and variance (grey dotted). The quadrupole is strongly skewed; by $\ell = 300$ all three agree. Each title gives the Kolmogorov–Smirnov p-value of the simulation against the χ^2.

7.12.3 How fast does the Monte Carlo variance converge?

From N simulated values $X_1, \dots, X_N$ of $\widehat{C}_\ell$ we estimate its variance with the sample variance $S^2 = \frac{1}{N-1}\sum_i (X_i - \bar{X})^2$ (Chapter 3), and compare with $2C_\ell^2/(2\ell+1)$. S^2 is itself a random quantity: run the simulation again with other seeds and it changes. To know whether a 2% discrepancy is a bug or bad luck we need the standard deviation of S^2.

For Gaussian X. If the X_i are independent $\mathcal{N}(\mu, \sigma^2)$, then $(N-1)S^2/\sigma^2 \sim \chi^2_{N-1}$ (Chapter 2), so

$$\operatorname{Var} S^2 = \left(\frac{\sigma^2}{N-1}\right)^2 2(N-1) = \frac{2\sigma^4}{N-1}, \qquad \frac{\sqrt{\operatorname{Var} S^2}}{\sigma^2} = \sqrt{\frac{2}{N-1}}. \tag{7.97}$$

This is cosmic variance again, one level up: the Monte Carlo variance is a variance estimated from N numbers, just as $\widehat{C}_\ell$ is a variance estimated from $2\ell+1$ numbers. But $\widehat{C}_\ell$ is not Gaussian,

and at low ℓ it is far from Gaussian, so we need a formula that holds for any distribution.

For any X: the fourth moment. Let the X_i be independent with mean μ, variance σ^2 and fourth central moment μ_4. Shift to $\mu = 0$ (the sample variance does not change). Expand $(N-1)S^2 = \sum_i X_i^2 - N\bar{X}^2$ into a diagonal part $A = \sum_i X_i^2$ and an off-diagonal part $B = \sum_{i\neq j} X_i X_j$:

$$
\begin{aligned}
(N-1)S^2 &\overset{(1)}{=} \sum_i X_i^2 - \frac{1}{N}\sum_{i,j} X_i X_j \overset{(2)}{=} \Big(1-\frac{1}{N}\Big)A - \frac{1}{N}\,B, \\
\operatorname{Var}\big[(N-1)S^2\big] &\overset{(3)}{=} \Big(1-\frac{1}{N}\Big)^2 N(\mu_4-\sigma^4) + \frac{1}{N^2}\,2N(N-1)\sigma^4, \\
\operatorname{Var} S^2 &\overset{(4)}{=} \frac{\mu_4-\sigma^4}{N} + \frac{2\sigma^4}{N(N-1)} \overset{(5)}{=} \frac{1}{N}\Big[\mu_4 - \frac{N-3}{N-1}\,\sigma^4\Big].
\end{aligned}
\tag{7.98}
$$

(1) $N\bar{X}^2 = \frac{1}{N}(\sum_i X_i)^2 = \frac{1}{N}\sum_{i,j} X_i X_j$.
(2) Split the double sum into $i = j$ (which is A) and $i \neq j$ (which is B).
(3) $\operatorname{Var} A = N \operatorname{Var}(X^2) = N(\mu_4 - \sigma^4)$. $\mathbb{E}\,B = 0$, and in $\mathbb{E}\,B^2 = \sum_{i\neq j}\sum_{k\neq l}\mathbb{E}[X_iX_jX_kX_l]$ only the terms with $\{k,l\} = \{i,j\}$ survive, two for each of the $N(N-1)$ ordered pairs, each equal to σ^4. $\operatorname{Cov}(A,B) = \sum_k \sum_{i\neq j}\mathbb{E}[X_k^2 X_i X_j] = 0$, because at least one of X_i, X_j appears exactly once and has mean zero.
(4) Divide by $(N-1)^2$: $(1-1/N)^2/(N-1)^2 = 1/N^2$ times N gives $1/N$, and $2N(N-1)/[N^2(N-1)^2] = 2/[N(N-1)]$.
(5) Combine over the common factor $1/N$: $-\sigma^4 + 2\sigma^4/(N-1) = -\sigma^4(N-3)/(N-1)$.

This is the variance of the sample variance derived in Chapter 3. Divide by σ^4 and write $\mu_4/\sigma^4 = 3 + \gamma_2$, with γ_2 the **excess kurtosis** [the fourth moment in excess of a Gaussian's, zero for a Gaussian]:

$$
\frac{\operatorname{Var} S^2}{\sigma^4} = \frac{1}{N}\Big[3 + \gamma_2 - \frac{N-3}{N-1}\Big] = \frac{2}{N-1} + \frac{\gamma_2}{N}. \tag{7.99}
$$

For $\gamma_2 = 0$ this is (7.97). Heavy tails ($\gamma_2 > 0$) make the Monte Carlo variance converge more slowly, but only by a constant factor; the rate $N^{-1/2}$ is unchanged.

The kurtosis of $\widehat{C}_\ell$. To use (7.99) we need γ_2 for $\widehat{C}_\ell$. Since $\widehat{C}_\ell$ is a rescaled χ^2_ν, and rescaling does not change γ_2, we need the excess kurtosis of χ^2_ν. Its moment generating function is $M(t) = (1-2t)^{-\nu/2}$ (Chapter 2), so its cumulant generating function is

$$
K(t) = \ln M(t) \overset{(1)}{=} -\frac{\nu}{2}\ln(1-2t) \overset{(2)}{=} \frac{\nu}{2}\sum_{n\geq 1}\frac{(2t)^n}{n} \overset{(3)}{=} \sum_{n\geq 1}\underbrace{\nu\,2^{n-1}(n-1)!}_{\kappa_n}\,\frac{t^n}{n!}, \tag{7.100}
$$

(1) Logarithm of M.
(2) $-\ln(1-x) = \sum_{n\geq 1} x^n/n$ with $x = 2t$.
(3) Rewrite $\frac{\nu}{2}\,2^n/n = \nu 2^{n-1}(n-1)!/n!$; the coefficient of $t^n/n!$ is the n-th cumulant κ_n.

so $\kappa_2 = 2\nu$ (the variance) and $\kappa_4 = 48\nu$. The fourth cumulant is the fourth central moment minus its Gaussian value, $\kappa_4 = \mu_4 - 3\kappa_2^2$, so $\gamma_2 = \kappa_4/\kappa_2^2 = 48\nu/4\nu^2 = 12/\nu$. With $\nu = 2\ell + 1$, (7.99) becomes the prediction we test:

Key idea: The Monte Carlo error on a Monte Carlo variance

Estimating $\mathrm{Var}\,\widehat{C}_\ell$ from N simulated skies gives a fractional error

$$\frac{\sqrt{\mathrm{Var}\,S^2}}{2C_\ell^2/(2\ell+1)} = \sqrt{\frac{2}{N-1}+\frac{12}{(2\ell+1)\,N}} \approx \frac{1}{\sqrt{N}}\sqrt{2+\frac{12}{2\ell+1}}. \tag{7.101}$$

It falls as $N^{-1/2}$. At high ℓ the coefficient is the Gaussian $\sqrt{2}$; at the quadrupole it is $\sqrt{2+12/5}=2.098$, half as large again, because the skewed χ^2_5 has heavy tails.

Example: how many simulations did Knox need? Knox estimated parameter errors by simulating data sets and reported that "typically we perform 100 simulations which is sufficient to determine the standard deviation to better than 10%" [138]. Is that right? A standard deviation is the square root of a variance, so a small fractional error on S^2 becomes half as large on S ($\delta S/S \approx \frac{1}{2}\,\delta S^2/S^2$, the error propagation of Chapter 3). For roughly Gaussian estimates, (7.97) with $N=100$ gives $\frac{1}{2}\sqrt{2/99}=7.1\%$. The claim is right, with little room to spare.

What the simulation shows. Figure 7.31(a) follows the Monte Carlo variance, in units of $2C_\ell^2/(2\ell+1)$, as the number of skies grows, for $\ell=2$, 10 and 100, with the $\pm1\sigma$ band of (7.101) shaded. Early on the estimates wander by tens of percent (most visibly at $\ell=2$, whose band is the widest); as N grows they narrow with their bands and settle onto 1. At $N=20{,}000$ the ratios at $\ell=2$, 10, 50 and 300 are 1.021, 1.000, 1.015 and 0.998, against predicted errors of 0.01483 at $\ell=2$ and 0.01005 at $\ell=300$: all within 1.5 standard deviations.

Panel (a) shows one run. To test the *rate* $N^{-1/2}$ we need the scatter of the Monte Carlo variance over many runs, which Figure 7.31(b) measures directly. We cut a long run into many independent batches of N skies, compute S^2 in each batch, and take the rms of S^2/σ^2-1 over batches. For $\ell=2$ and $\ell=10$ the script draws an extra 10^6 skies (cheap, since these multipoles need only 5 and 21 numbers per sky); for $100\le\ell\le300$ it pools the 201 independent multipoles of the main run. On logarithmic axes the points fall on straight lines of slope -0.5011 ($\ell=2$) and -0.5133 (high ℓ), on top of (7.101). The quadrupole points lie above the Gaussian line $\sqrt{2/(N-1)}$ by the predicted factor $2.098/\sqrt{2}\approx1.5$; the high-ℓ points lie on it.

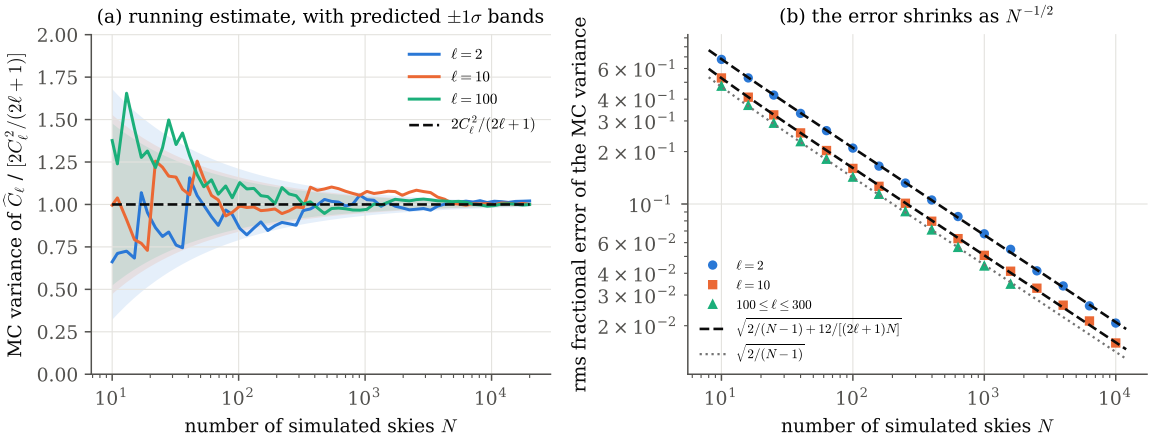

Figure 7.31: (a) Running Monte Carlo estimate of $\mathrm{Var}\,\widehat{C}_\ell$ divided by the cosmic variance $2C_\ell^2/(2\ell+1)$, for $\ell=2$, 10, 100, with the predicted $\pm1\sigma$ bands of (7.101). (b) Measured rms fractional error of the Monte Carlo variance against the number of skies N per batch. Black dashed: (7.101) for $\ell=2$ (upper) and $\ell=10$ (lower); grey dotted: the Gaussian $\sqrt{2/(N-1)}$. All lines have slope $-1/2$.

7.12.4 Different multipoles are independent

The third question is about pairs of multipoles. On the full sky, $\widehat{C}_\ell$ is a function of the $2\ell+1$ real numbers at multipole ℓ only, and $\widehat{C}_{\ell'}$ of those at ℓ' only. By (7.62) and Gaussianity, the two sets are independent, so $\widehat{C}_\ell$ and $\widehat{C}_{\ell'}$ are independent for $\ell \neq \ell'$ and their covariance matrix is diagonal,

$$\operatorname{Cov}\big(\widehat{C}_\ell, \widehat{C}_{\ell'}\big) = \frac{2C_\ell^2}{2\ell+1}\,\delta_{\ell\ell'}. \tag{7.102}$$

This is what made the binning of (7.79) legitimate, and it is the property that a mask destroys (Section 7.13).

A covariance estimated from N skies is never exactly diagonal, so we need to know what "zero" looks like. The answer: the estimated correlation of two independent quantities scatters around zero with standard deviation $1/\sqrt{N}$. To see why, take two independent variables, standardise them to $u = (\widehat{C}_\ell - C_\ell)/\sigma_\ell$ and $v = (\widehat{C}_{\ell'} - C_{\ell'})/\sigma_{\ell'}$, and look at the sample correlation coefficient. For large N the corrections from estimating the means and standard deviations are of relative order $1/N$, so $r \approx \frac{1}{N}\sum_i u_i v_i$, and

$$\operatorname{Var} r \overset{(1)}{=} \frac{1}{N^2}\sum_i \mathbb{E}\big[u_i^2 v_i^2\big] \overset{(2)}{=} \frac{1}{N^2}\,N\;\mathbb{E}[u^2]\;\mathbb{E}[v^2] \overset{(3)}{=} \frac{1}{N}. \tag{7.103}$$

(1) The skies are independent and $\mathbb{E}[uv] = 0$, so the cross terms $i \neq j$ vanish.
(2) u and v are independent, so the mean of the product is the product of the means.
(3) Both are standardised.

No step used Gaussianity: the skewed χ^2_5 of the quadrupole gives the same $1/\sqrt{N}$ as anything else. So an estimated correlation matrix of truly independent quantities should look like the identity plus noise of standard deviation $1/\sqrt{N}$ off the diagonal.

Figure 7.32(a) shows the correlation matrix of $\widehat{C}_\ell$ for $2 \le \ell \le 41$ estimated from the first 500 skies. It is the identity plus a speckle of positive and negative values. Their standard deviation is 0.04741, against $1/\sqrt{500} = 0.04472$. (The 780 distinct pairs share variables, so their spread is itself uncertain by a few percent.) With all 20,000 skies the spread is 0.007064 against $1/\sqrt{N} = 0.007071$, and Figure 7.32(b) shows the $N^{-1/2}$ law over two and a half decades. Over all 44551 pairs with $2 \le \ell < \ell' \le 300$ the largest correlation is 0.02929, about $4.1/\sqrt{N}$, the size one expects for the largest of so many Gaussian deviates. The script computes the matrix with `np.corrcoef`:

Listing 7.9: Off-diagonal correlations of $\widehat{C}_\ell$ from the first N skies (`code/ch07/25_mc_cosmic_variance.py`)

```
130 def corr_offdiag(N):
131     R = np.corrcoef(y[:N, jc], rowvar=False)
132     off = R[~np.eye(len(LC), dtype=bool)]
133     return R, off
134 
135 R500, off500 = corr_offdiag(500)
136 Rall, offall = corr_offdiag(N_SIM)
137 Nc = np.unique(np.round(np.geomspace(50, N_SIM, 14)).astype(int))
138 sd_off = np.array([corr_offdiag(N)[1].std() for N in Nc])
139 # all multipoles l=2..300 with the full run: the largest off-diagonal element
140 Rbig = np.corrcoef(y, rowvar=False)
141 off_big = Rbig[~np.eye(len(ELLS), dtype=bool)]
```

Line 131 estimates the 40×40 correlation matrix from the first N rows; line 132 keeps the off-diagonal elements; lines 140–141 repeat it for all 299 multipoles with every sky.

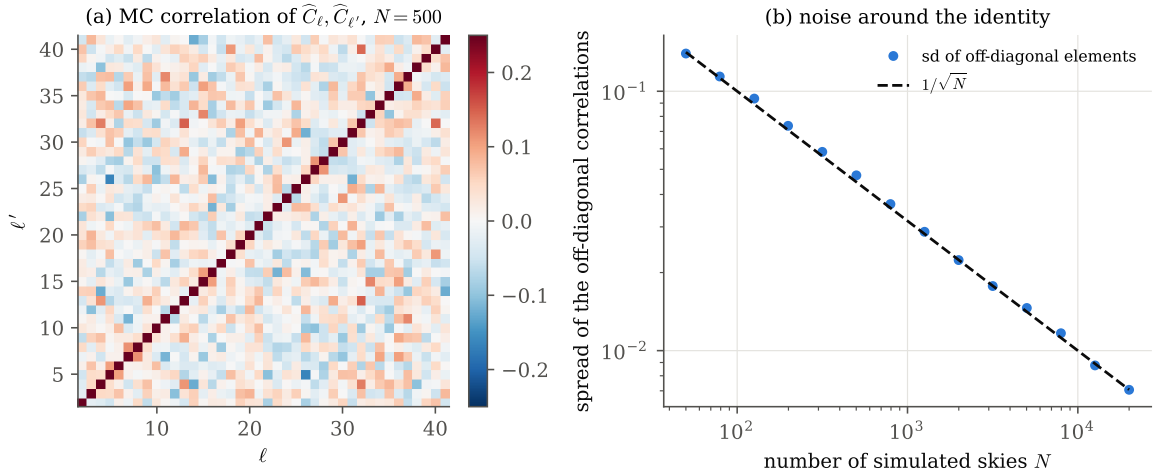

Figure 7.32: (a) Correlation matrix of $\widehat{C}_\ell$ and $\widehat{C}_{\ell'}$ for $2 \le \ell, \ell' \le 41$, estimated from 500 simulated skies (the colour scale saturates at ±0.25, so the diagonal 1 appears as the darkest red). Off the diagonal there is only noise. (b) Standard deviation of the off-diagonal elements against the number of skies, with the prediction $1/\sqrt{N}$ of (7.103) (black dashed).

Cross-check with healpy. Does the library's generator give the same skies as our from-scratch one? The script draws 3000 skies up to $\ell = 50$ with `healpy.synalm` and measures them with `healpy.alm2cl`. Two-sample Kolmogorov–Smirnov tests against our own skies give $p = 0.5166$, 0.998 and 0.9504 at $\ell = 2$, 10 and 50, and the healpy variances in units of the cosmic variance are 0.973 ($\ell = 2$) and 0.996 ($\ell = 50$), within the $\pm\sqrt{4.4/3000} \approx 4\%$ and ±2.6% that (7.101) allows for 3000 skies. The two generators produce the same skies, statistically.

How this is used in real research: Verification here, research instrument next

These simulations *verify* a result we already had in closed form: the $\chi^2_{2\ell+1}$ distribution, cosmic variance $2C_\ell^2/(2\ell+1)$, and a diagonal covariance. They test the code and our understanding where the answer is known, and they tell us how many simulations buy how much precision (7.101). In research the same loop (draw skies with `synfast`, push them through the real pipeline, measure with `anafast`) is the instrument itself. A real sky is masked, noisy, beamed and filtered; the pseudo-spectrum is then biased by mode coupling, its covariance is not diagonal, and no formula gives either exactly. MASTER calibrates the transfer function of the pipeline and the covariance of the estimate with exactly such simulations [Hivon §2–3], [140]; Planck's likelihoods are validated on thousands of simulated skies. With (7.101) we know in advance that 1000 simulations determine a variance to about 4.5% and a standard deviation to about 2.2%. Chapter 8 builds that pipeline.

7.13 What C_ℓ does not see

The estimator $\widehat{C}_\ell$ keeps one number per multipole, the mean of $|a_{\ell m}|^2$ over m. It throws away the phase of every $a_{\ell m}$ and the way the power is shared among the m. Is anything lost? For a Gaussian, isotropic sky, no. The covariance (7.62) is then the whole distribution, the phases are uniformly random, and Chapter 3 showed that $\widehat{C}_\ell$ is sufficient for C_ℓ. For any other sky, yes: the phases carry the shapes. In flat space (Section 7.7), randomising the Fourier phases of a non-Gaussian field left $P(k)$ untouched and erased every structure in it. The same experiment

on the sphere takes a few lines.

Example: hot spots and their phase-scrambled twin. Can two skies with the same $\widehat{C}_\ell$ look completely different? Paint 40 Gaussian hot spots of width 4° at random positions on a sky and compute its coefficients. Then build a second sky with the same $|a_{\ell m}|$ but new phases. For $m > 0$ each $a_{\ell m}$ is multiplied by a random unit complex number, and each real $a_{\ell 0}$ by a random sign (the only phase a real number can have). The reality condition (7.46) is respected automatically, because only $m \geq 0$ is stored and the negative m are rebuilt from it. By construction both skies have the same $\widehat{C}_\ell$ at every ℓ; numerically they agree to 5.322×10^{-16}. Figure 7.33 shows how different they look: isolated spots on a flat background, against a featureless Gaussian-looking pattern. The pixel histograms in Figure 7.34(b) put a number on the difference: the spot sky has skewness 2.903, its twin 0.01184. A test based on $\widehat{C}_\ell$ alone could never tell them apart. (The experiment is `code/ch07/26_phases_sphere.py`.)

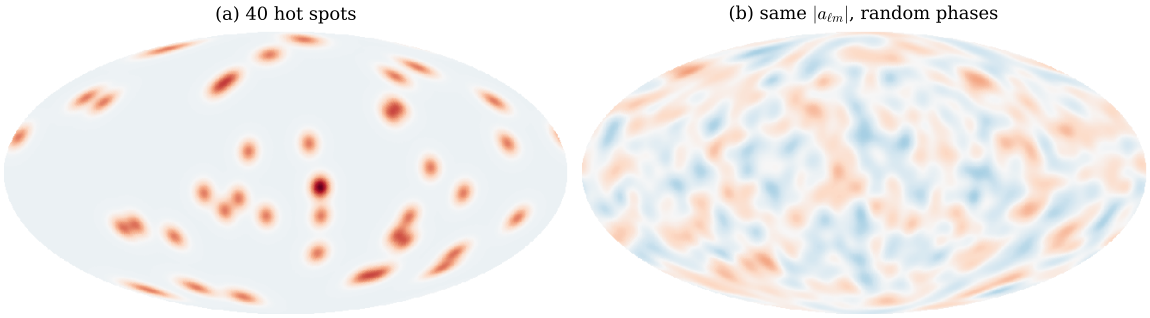

Figure 7.33: (a) A sky made of 40 hot spots, band-limited to $\ell \leq 255$. (b) The same $|a_{\ell m}|$ with random phases. Same colour scale in both panels. The two skies have identical $\widehat{C}_\ell$ at every multipole.

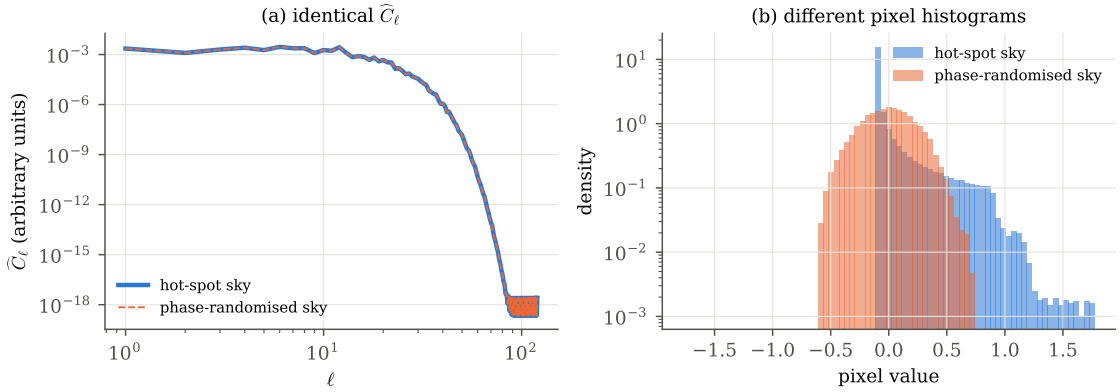

Figure 7.34: (a) $\widehat{C}_\ell$ of the two skies of Figure 7.33 up to $\ell = 120$ (the 4° spots have essentially no power beyond): the curves lie on top of each other. (b) Histograms of their pixel values (logarithmic vertical axis): the spot sky has a long positive tail, the phase-randomised sky is symmetric and close to Gaussian.

Two things break the clean full-sky picture of this chapter. The first is the sky itself. Primordial non-Gaussianity (f_{NL}, Chapter T1), lensing and foregrounds put information into the phases, where C_ℓ cannot see it; Chapter 12 builds summaries that can, from the shapes of hot and cold regions. The second is the observation: a real map covers only part of the sky. Let $W(\boldsymbol{e})$ be the mask, 1 where we observe and 0 elsewhere. The coefficients of the masked sky are $\tilde{a}_{\ell m} = \int \mathrm{d}\Omega\, \Theta\, W\, Y^*_{\ell m}$ [Hivon (11)]. Because the mask multiplies the sky, these coefficients

mix neighbouring multipoles, just as multiplying by $1 + A\cos\theta$ did in Section 7.9.5. Their mean square is then a weighted sum of the true spectrum, $\langle \widetilde{C}_\ell \rangle = \sum_{\ell'} M_{\ell\ell'} C_{\ell'}$ [Hivon (14)]. The covariance (7.102) is no longer diagonal, the $\chi^2_{2\ell+1}$ law is gone, and the Monte Carlo loop of Section 7.12 becomes the only way to get the sampling distribution. That is where Chapter 8 begins.

Recap

- The spherical harmonics $Y_{\ell m}$ (eigenfunctions of $\boldsymbol{L}^2$ and L_z) are the Fourier modes of the sphere; multipole ℓ is an angular scale of about $180^\circ/\ell$. A sky is $\Theta = \sum a_{\ell m} Y_{\ell m}$ with $a_{\ell m} = \int \mathrm{d}\Omega\, \Theta Y^*_{\ell m}$.
- A real sky has $a_{\ell,-m} = (-1)^m a^*_{\ell m}$: $a_{\ell 0}$ is real, and there are $2\ell + 1$ real numbers per ℓ.
- Statistical isotropy makes $\hat{C}$ commute with all rotations; with $\boldsymbol{L}^2$, L_z and $L_\pm$ this gives $\langle a_{\ell m} a^*_{\ell' m'} \rangle = C_\ell \delta_{\ell\ell'} \delta_{mm'}$. $C(\vartheta) = \sum (2\ell+1) C_\ell P_\ell(\cos\vartheta)/4\pi$. A preferred axis breaks both the diagonality and the m-independence.
- $\widehat{C}_\ell = \sum_m |a_{\ell m}|^2/(2\ell+1)$ is unbiased; $(2\ell+1)\widehat{C}_\ell/C_\ell \sim \chi^2_{2\ell+1}$ because $a_{\ell 0}$ has variance C_ℓ and $\mathrm{Re}, \mathrm{Im}\, a_{\ell m}$ have $C_\ell/2$. Cosmic variance: $\mathrm{Var}\, \widehat{C}_\ell = 2C_\ell^2/(2\ell+1)$, 63% at the quadrupole. Read backwards, the same density is the likelihood $\mathcal{L}(C_\ell) \propto C_\ell^{-(2\ell+1)/2} e^{-(2\ell+1)\widehat{C}_\ell/2C_\ell}$.
- CAMB solves the linear Boltzmann hierarchy and returns $C_\ell = \frac{2}{\pi}\int k^2 \mathrm{d}k\, P_\zeta g^2_{T\ell}$, an expectation, never a sky. HEALPix has $12N^2_{\mathrm{side}}$ equal-area pixels on rings; healpy's `synfast`/`anafast` go between C_ℓ, $a_{\ell m}$, maps and $\widehat{C}_\ell$, accurately below $\ell \approx 2N_{\mathrm{side}}$.
- Monte Carlo with N skies reproduces the χ^2, converges to the cosmic variance with fractional error $\sqrt{2/(N-1) + 12/[(2\ell+1)N]}$, and gives a correlation matrix equal to the identity plus $1/\sqrt{N}$ noise. This verifies a known result; Chapter 8 uses the same loop where no formula exists.
- $\widehat{C}_\ell$ ignores the phases of the $a_{\ell m}$: skies with the same $\widehat{C}_\ell$ can look nothing alike.

Reading the literature

- **Random fields and their two-point statistics.** Hobson et al. (eds.), *Bayesian Methods in Cosmology*: the pages on parameterising a field by pixels or by Fourier modes, where homogeneity makes the Fourier covariance diagonal and a window couples the modes, and Chapter 10 (Jaffe) on the CMB as a hierarchical model, with the harmonic expansion, the power spectrum, the Wiener filter and the full-sky likelihood [HobsonBMC pp. 229–238]. Cowan, *Statistical Data Analysis*, Chapter 1, for covariance matrices and their diagonalisation by an orthogonal transformation; Wasserman, *All of Statistics*, Chapter 3, for covariance and correlation.
- **Gaussian random fields in cosmology.** Bardeen, Bond, Kaiser and Szalay on the statistics of peaks of Gaussian fields [106]; Peacock's *Cosmological Physics* [136] for power spectra, correlation functions and windows; Kaiser on clustering in redshift space [103].
- **The CMB power spectrum and cosmic variance.** Knox on the errors of C_ℓ from noise, beam, sky coverage and cosmic variance [138]; Hivon et al., MASTER, Section 2 for the harmonic expansion, the full-sky estimator and its χ^2, and the pseudo-spectrum of a masked sky [140].
- **Computing C_ℓ.** Seljak and Zaldarriaga on line-of-sight integration [139]; Lewis, Challinor and Lasenby, the CAMB paper [8]; Padilla et al. for a survey of Boltzmann and sampling

codes [40]; the Planck 2018 parameters that define the fiducial model [25], and the Planck tests of isotropy [109]. For the physics behind C_ℓ (the Boltzmann hierarchy, transfer functions, acoustic peaks), see the cosmology notes and Chapter T1.

- **Pixelising the sphere.** Górski et al. on HEALPix [7].

Chapter summary

A physical theory of fluctuations predicts the statistics of a field, never the field itself, and we observe one realisation. Homogeneity and isotropy make the natural modes of the field uncorrelated: plane waves in flat space, spherical harmonics on the sky. Their variances are $P(k)$ or C_ℓ, and for a Gaussian field those variances are everything. One realisation offers only a finite number of independent modes at each scale: $N_{\rm modes}$ in a k-shell, or $2\ell+1$ at a multipole. That number sets an error $\sqrt{2/N_{\rm modes}}$ on every measured power, and no instrument can reduce it. In the pipeline

$$\text{physical model} \longrightarrow \text{field or dataset} \longrightarrow \text{summary } S \longrightarrow \boxed{P(S \mid \theta)} \longrightarrow \text{infer physics},$$

random-field theory supplies the first summaries of a field, $\xi(r)$, $P(k)$ and C_ℓ, and their exact sampling distributions in the ideal case of a complete, noiseless field; Monte Carlo confirms them. Chapter 8 adds the mask, the beam and the noise, Chapters 9 and 10 turn the sampling distribution into parameter constraints, and Chapter 12 looks at what the two-point summaries throw away.

Random fields in flat space

concept	operational meaning	used later in
random field	a random variable at every point, with a joint distribution for any finite set of points; theory predicts its statistics, we see one draw	Chapters 8 and 12
homogeneity, isotropy	all joint distributions unchanged by translations (rotations); the two-point function depends only on the separation	Chapters 8 and 12
correlation function $\xi(r)$	$\langle\delta(\boldsymbol{x})\delta(\boldsymbol{x}+\boldsymbol{r})\rangle$: how strongly the field at two points a distance r apart is related	Chapters 10 and 12
Gaussian random field	all joint distributions Gaussian; mean and $\xi(r)$ determine everything	Chapters 8, 9 and 12
power spectrum $P(k)$	variance of each Fourier mode; Fourier modes of a homogeneous field are uncorrelated; P is the Fourier transform of ξ (Wiener–Khinchin)	Chapters 8 and 10
simulating a field	colour white noise by $\sqrt{P(k)}$ in Fourier space and transform back (FFT)	Chapters 8 and 12
ergodicity, sample variance	a spatial average replaces the ensemble average when distant regions are nearly independent; a k-shell with $N_{\rm modes}$ modes gives $\Delta P/P = \sqrt{2/N_{\rm modes}}$	Chapters 8 and 10
smoothing	a beam, pixel or counting cell multiplies $P(k)$ by $\lvert W(k)\rvert^2$	Chapters 8 and 12
spectral moments σ_j	integrals of $k^{2j}P(k)$ (with the window): the variance of the field, of its gradient and the typical spacing of its features	Chapter 12
phases	$P(k)$ keeps the amplitudes and discards the phases; phases hold the shapes of non-Gaussian fields	Chapter 12

Fields on the sphere

concept	operational meaning	used later in
spherical harmonics, $a_{\ell m}$	eigenfunctions of $\boldsymbol{L}^2$, L_z; $a_{\ell m} = \int \mathrm{d}\Omega\, \Theta Y^*_{\ell m}$; multipole $\ell \leftrightarrow$ angle $180°/\ell$	Chapters 8 and 12
reality condition	$a_{\ell,-m} = (-1)^m a^*_{\ell m}$; $a_{\ell 0}$ real; $2\ell+1$ real numbers per ℓ, $(\ell_{\max}+1)^2$ in all; store $m \geq 0$ only	Chapter 8
isotropy in harmonic space	$\langle a_{\ell m} a^*_{\ell' m'} \rangle = C_\ell \delta_{\ell\ell'} \delta_{mm'}$, from $[\hat{C}, \boldsymbol{L}] = 0$ and the ladder operators; a preferred axis couples ℓ to $\ell \pm 1$	Chapters 8 and 9
$C(\vartheta)$ and C_ℓ	$C(\vartheta) = \sum_\ell \frac{2\ell+1}{4\pi} C_\ell P_\ell(\cos\vartheta)$, $C_\ell = 2\pi \int \mathrm{d}\cos\vartheta\, P_\ell C$; point variance $\sum(2\ell+1)C_\ell/4\pi$	Chapters 8 and 12
full-sky estimator $\widehat{C}_\ell$	mean of $\lvert a_{\ell m}\rvert^2$ over m; unbiased, sufficient, maximum likelihood	Chapters 8 to 10
$\chi^2_{2\ell+1}$ law	$(2\ell+1)\widehat{C}_\ell/C_\ell \sim \chi^2_{2\ell+1}$: one real $a_{\ell 0}$ of variance C_ℓ, 2ℓ real and imaginary parts of variance $C_\ell/2$; skewed at low ℓ	Chapters 8 and 9
cosmic variance	$\mathrm{Var}\,\widehat{C}_\ell = 2C_\ell^2/(2\ell+1)$ (the Cramér–Rao bound); binned: divide by $\Delta\ell$; with noise and sky fraction, $(C_\ell + N_\ell/B_\ell^2)\sqrt{2/[(2\ell+1)\Delta\ell f_{\mathrm{sky}}]}$	Chapters 8 and 10
likelihood of C_ℓ	$\mathcal{L} \propto C_\ell^{-(2\ell+1)/2} \exp[-(2\ell+1)\widehat{C}_\ell/2C_\ell]$: broad and lopsided at low ℓ	Chapters 9 and 10
CAMB	solves the linear Boltzmann hierarchy, line of sight; $C_\ell = \frac{2}{\pi}\int k^2 \mathrm{d}k\, P_\zeta \mathcal{G}^2_{T\ell}$; call with `raw_cl=True`, $\mu\mathrm{K}^2$	Chapters 8 to 10
HEALPix and healpy	$N_{\mathrm{pix}} = 12N^2_{\mathrm{side}}$ equal areas on rings, pixel $58.6°/N_{\mathrm{side}}$; `synalm`, `alm2map`, `map2alm`, `alm2cl`; trust $\ell \lesssim 2N_{\mathrm{side}}$; pixel window	Chapters 8 and 12
Monte Carlo of $\widehat{C}_\ell$	simulate skies, histogram $\widehat{C}_\ell$; MC variance error $\sqrt{2/(N-1) + 12/[(2\ell+1)N]}$; off-diagonal correlations $\pm 1/\sqrt{N}$	Chapters 8 and 9
verification vs research	here the simulation checks a closed-form answer; with a mask, noise and a beam it is the only way to the sampling distribution	Chapter 8
what C_ℓ misses	the phases of the $a_{\ell m}$: equal $\widehat{C}_\ell$, different shapes and pixel histograms	Chapter 12

Chapter 8

Monte Carlo as a Research Instrument: Observing the CMB

Where this chapter is going

A Boltzmann code such as CAMB turns six cosmological numbers into an angular power spectrum C_ℓ (Chapter T1). That spectrum describes the *ensemble* of skies the theory could have produced. A telescope gives us one of those skies, and not even all of it: it sees the sky through a beam that blurs it, stores it in pixels that average it, adds detector noise to every pixel, and, once the Galaxy is cut away, sees only part of it. Each of these steps changes the numbers we compute from the map. In Chapter 7 the spectrum estimator $\widehat{C}_\ell$ was computed on perfect, complete skies, and everything about its sampling distribution was known in closed form: it is unbiased, it is a scaled $\chi^2_{2\ell+1}$ variable, and its variance is the cosmic variance $2C_\ell^2/(2\ell+1)$. What survives of those statements when the sky is observed by a real instrument? Monte Carlo simulation answers it.

In the pipeline of the book (physical model → field → what matters → summary → sampling distribution → inference) the problem sits on one arrow: finding the sampling distribution of the summary $\widehat{C}_\ell$ under realistic observation. The beam and the noise come first, on the full sky, where every answer can still be derived by hand. There the simulations *verify* known formulas, and the same machine is tested and trusted. The mask comes next: it couples multipoles, correlates their errors and bends the distribution of $\widehat{C}_\ell$ away from any formula, and the simulations become the research instrument (Figure 8.1). The output, a mean, a covariance and a distribution shape for $\widehat{C}_\ell$, is exactly what the likelihood of Chapter 9, the Fisher forecast of Chapter 10 and the topological summaries of Chapter 12 need.

8.1 The research problem

Picture the data as they arrive. A detector sweeps across the sky and records a voltage many times per second. Every sample is the temperature of a small patch of sky, averaged over the response pattern of the telescope, plus noise from the detector and its electronics. Months of samples are binned into a map of a few million pixels. A theorist, meanwhile, has run CAMB and holds a curve C_ℓ. The question is how to put the map and the curve on the same plot, and how big the error bars on that plot really are. Answering it for the cosmic microwave background (CMB) is the research problem that organises everything below:

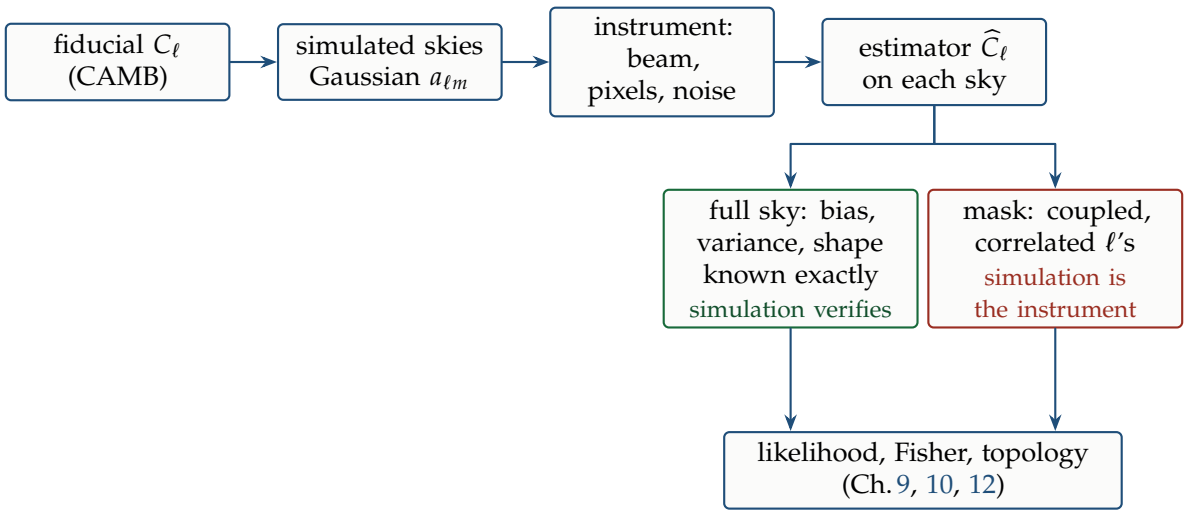

Figure 8.1: The research problem. A fiducial spectrum is turned into many simulated skies, each is observed by a model of the instrument, and the spectrum is estimated on each. On the full sky (green) the statistics of the estimator follow from a short derivation, and the simulations check it. Once the sky is masked (red) no formula is exact, and the simulations are the only way to the mean, the covariance and the shape of the distribution that the later chapters feed into a likelihood.

The central framing: The research problem

A theoretical CMB power spectrum C_ℓ, obtained from a fiducial cosmological model, describes the ensemble-averaged statistics of the CMB sky. In practice, however, CMB observations provide only a finite and potentially incomplete realization of this random field. Sky masks, instrumental noise, beam effects, and other observational limitations modify the statistical properties of the quantities extracted from the map.

The problem is to use Monte Carlo simulations of CMB skies generated from a fiducial theoretical power spectrum to investigate how these observational effects influence the statistical properties of CMB power-spectrum estimators. In particular, we seek to determine the sampling distribution, bias, variance, and covariance of the recovered spectrum and to assess the validity of commonly used analytical approximations for these quantities.

The study will begin with the full-sky Gaussian case, for which the statistical properties of $\widehat{C}_\ell$ are known analytically, and then introduce partial-sky coverage through realistic or controlled masks. The simulated realizations will be used to quantify the resulting mode coupling and correlations between multipoles, and to determine how these effects depend on the sky fraction, mask geometry, and multipole range.

The central computational question is therefore:

> **How does incomplete and imperfect observation of the CMB alter the statistical information contained in the measured angular power spectrum, and how accurately can these effects be characterized using Monte Carlo simulations?**

The statement mixes several questions, and each needs a different tool. Before any equation it helps to say them one at a time, in words, in the order in which they depend on each other. The first is physical: what exactly does the instrument do to the sky? Only when that is written down as a model can we ask what it does to the *average* of the estimator (does $\widehat{C}_\ell$ still centre on C_ℓ?), then to its *scatter* (how wide is the spread over skies, and are neighbouring multipoles correlated?), and then to the *shape* of its distribution (is it still a scaled χ^2, or close enough to a Gaussian?). The last two questions are about the method itself: do the quick formulas that

everyone uses survive the comparison with simulations, and how many simulations does it take to know?

In order, the questions are:

1. What does the instrument do to the sky? (A beam, a pixel window, noise, a mask: the observation model.)

2. Does the estimator still average to the true C_ℓ? If not, by how much is it off, and can the offset be removed? (Bias.)

3. How much does it scatter from sky to sky, and do the errors at different multipoles move together? (Variance and covariance.)

4. What is the full shape of its distribution? (The sampling distribution: the likelihood of Chapter 9 needs it, not just its width.)

5. Are the standard analytic shortcuts, such as the Knox formula with a sky fraction $f_{\rm sky}$, accurate, and where do they fail?

6. How many simulated skies are needed to answer 2–5 to a given precision?

On the full sky with a beam and noise, questions 1–4 have exact answers, which we derive below. That makes the full sky the place to build the simulation machine and to check, number by number, that it reproduces what we already know. A machine that has passed that test can then be trusted where the answers are not known.

8.1.1 Why we do not simply maximise the likelihood

The procedure of Chapter 3 for finding an estimator starts from the likelihood: write the probability of the data given the parameter, maximise it, read the error bar off its curvature. For a CMB map the data model is

$$\boldsymbol{d} = \mathsf{A}\,\boldsymbol{s} + \boldsymbol{n}, \tag{8.1}$$

where $\boldsymbol{s}$ is the sky in pixels, the matrix A applies the beam and the pointing, and $\boldsymbol{n}$ is Gaussian noise with covariance matrix N [HobsonBMC (10.8)–(10.9)]. Here the observed outcome is the whole map and the hypotheses are the possible spectra C_ℓ; each spectrum is judged by how plausible the random sky-plus-noise fluctuation it would need to produce this particular map is, the reading set out for a single multipole in Section 8.3.1. The sky is a Gaussian random field whose pixel covariance $\mathsf{S}(C_\ell)$ is fixed by the spectrum, and the noise is independent of it, so the map is Gaussian with covariance $\mathsf{S}+\mathsf{N}$, the sum of the two covariances. Its density is the multivariate Gaussian of Chapter 2, $(2\pi)^{-N_{\rm pix}/2}\det(\mathsf{S}+\mathsf{N})^{-1/2}\exp[-\frac{1}{2}\boldsymbol{d}^{\mathsf{T}}(\mathsf{S}+\mathsf{N})^{-1}\boldsymbol{d}]$, and minus twice its logarithm, read as a function of C_ℓ, is

$$-2\ln\mathcal{L}(C_\ell) = \boldsymbol{d}^{\mathsf{T}}(\mathsf{S}+\mathsf{N})^{-1}\boldsymbol{d} + \ln\det(\mathsf{S}+\mathsf{N}) + \text{const} \tag{8.2}$$

[HobsonBMC (10.23)], [141].

What does maximising this over C_ℓ give? Write $\mathsf{C} \equiv \mathsf{S}+\mathsf{N}$ for the total covariance. The covariance of the sky between two pixels is a sum over ℓ of C_ℓ times a fixed angular pattern (Chapter 7), so S is linear in the spectrum, $\mathsf{S} = \sum_\ell C_\ell\,\mathsf{S}_\ell$, where $\mathsf{S}_\ell \equiv \partial\mathsf{S}/\partial C_\ell$ is the pixel covariance that one unit of C_ℓ produces. Two matrix rules do the differentiation: the derivative of an inverse, $\partial\mathsf{C}^{-1} = -\mathsf{C}^{-1}(\partial\mathsf{C})\,\mathsf{C}^{-1}$, and the derivative of a log-determinant,

$\partial \ln\det \mathsf{C} = \mathrm{tr}\big(\mathsf{C}^{-1}\partial\mathsf{C}\big)$. With $\partial\mathsf{C}/\partial C_\ell = \mathsf{S}_\ell$ and the shorthand $\mathsf{E}_\ell \equiv \mathsf{C}^{-1}\mathsf{S}_\ell\,\mathsf{C}^{-1}$,

$$\frac{\partial \ln \mathcal{L}}{\partial C_\ell} \overset{(1)}{=} \frac{1}{2}\Big[\boldsymbol{d}^{\mathsf{T}}\mathsf{E}_\ell\,\boldsymbol{d} - \mathrm{tr}\big(\mathsf{C}^{-1}\mathsf{S}_\ell\big)\Big] \overset{(2)}{=} \frac{1}{2}\Big[\boldsymbol{d}^{\mathsf{T}}\mathsf{E}_\ell\,\boldsymbol{d} - \mathrm{tr}\big(\mathsf{E}_\ell\mathsf{N}\big)\Big] - \sum_{\ell'} F_{\ell\ell'}C_{\ell'},$$

$$\widehat{C}_\ell^{\,\mathrm{QML}} \overset{(3)}{=} \frac{1}{2}\sum_{\ell'}\big(F^{-1}\big)_{\ell\ell'}\Big[\boldsymbol{d}^{\mathsf{T}}\mathsf{E}_{\ell'}\,\boldsymbol{d} - \mathrm{tr}\big(\mathsf{E}_{\ell'}\mathsf{N}\big)\Big]. \tag{8.3}$$

(1) Differentiate (8.2) with the two rules and multiply by $-\tfrac{1}{2}$.
(2) Insert $\mathsf{C}\,\mathsf{C}^{-1}$ into the trace, $\mathrm{tr}(\mathsf{C}^{-1}\mathsf{S}_\ell) = \mathrm{tr}(\mathsf{E}_\ell\mathsf{C})$, and split $\mathsf{C} = \sum_{\ell'} C_{\ell'}\mathsf{S}_{\ell'} + \mathsf{N}$. The sky part gives $\sum_{\ell'} C_{\ell'}\,\mathrm{tr}(\mathsf{E}_\ell\mathsf{S}_{\ell'}) = 2\sum_{\ell'} F_{\ell\ell'}C_{\ell'}$, with $F_{\ell\ell'} = \tfrac{1}{2}\,\mathrm{tr}(\mathsf{C}^{-1}\mathsf{S}_\ell\mathsf{C}^{-1}\mathsf{S}_{\ell'})$ the Fisher matrix of the spectrum (Chapter 3).
(3) Set the slope to zero and solve for the $C_{\ell'}$. The matrices E_ℓ and F still contain C_ℓ, so they are evaluated at a fiducial spectrum, and the solution is one Newton step from it; repeating the step with the result as the new fiducial converges to the maximum.

The estimator (8.3) is *quadratic in the data*, because the data enter only through $\boldsymbol{d}^{\mathsf{T}}\mathsf{E}_\ell\boldsymbol{d}$. Read from the inside out, it weights the map by the inverse covariance, correlates it with the pattern S_ℓ that a change in one C_ℓ would produce, subtracts the part of that correlation the noise alone would give, $\mathrm{tr}(\mathsf{E}_\ell\mathsf{N})$, and normalises by the Fisher matrix. This is the **quadratic maximum-likelihood** (QML) estimator [141]. On a complete sky with uniform noise every matrix is diagonal in the harmonic coordinates (the real numbers u_k of (8.21)): C has $V_\ell = T_\ell^2 C_\ell + N_\ell$ on the $\nu = 2\ell+1$ modes of each ℓ, and S_ℓ has T_ℓ^2 on them. Then $\boldsymbol{d}^{\mathsf{T}}\mathsf{E}_\ell\boldsymbol{d} = T_\ell^2\nu\,\widehat{C}_\ell^{\,\mathrm{obs}}/V_\ell^2$, $\mathrm{tr}(\mathsf{E}_\ell\mathsf{N}) = T_\ell^2\nu N_\ell/V_\ell^2$ and $F_{\ell\ell} = \nu T_\ell^4/2V_\ell^2$, and (8.3) collapses to $(\widehat{C}_\ell^{\,\mathrm{obs}} - N_\ell)/T_\ell^2$, with the fiducial V_ℓ cancelling: the average of $|a_{\ell m}|^2$ over m with the noise subtracted, which Section 8.3.1 obtains directly.

The trouble is the size of the matrices. Every evaluation of (8.2) needs the inverse and the determinant of an $N_{\mathrm{pix}} \times N_{\mathrm{pix}}$ matrix, which costs of order N_{pix}^3 operations and $8N_{\mathrm{pix}}^2$ bytes of memory [HobsonBMC p. 238], [Hivon §1].

Example: how long is one likelihood evaluation? On an ordinary desktop computer, the Cholesky factor of a 6000×6000 covariance takes 0.80 s (Figure 8.2). The cost grows as N^3, so for the $N_{\mathrm{pix}} = 786432$ pixels of a HEALPix map at $N_{\mathrm{side}} = 256$ the same operation takes about 21 days, and the matrix alone occupies 4.9 TB. At $N_{\mathrm{side}} = 512$ it is about 4 years. At $N_{\mathrm{side}} = 2048$, the resolution of the Planck maps, it is 1.5×10^4 years for a single evaluation, and a parameter fit needs tens of thousands of them. A spherical-harmonic transform of the same Planck-size map, which is all the simple estimator needs, takes about 9 s, because on the iso-latitude HEALPix grid its cost grows only as $N_{\mathrm{pix}}^{3/2}$ [Hivon §2.2], [7].

Example: when is the cheap estimator as good as the expensive one? Two limits are known exactly [141]. When the signal dominates the noise, the cheap estimator with equal weight on every pixel is statistically equivalent to the maximum-likelihood one. When the noise dominates and is uncorrelated between pixels, the cheap estimator with each pixel weighted by its inverse noise variance is mathematically identical to it. Between the two limits, and with a mask, it loses some information, and the loss has to be measured.

So the field took a different road, and the recipe of Chapter 3 already contains it: its step 5, for problems whose likelihood cannot be evaluated. Choose a statistic that is cheap and sensitive to C_ℓ: the average of $|a_{\ell m}|^2$ over m, computed directly on the observed map, which on a cut sky is called the **pseudo-C_ℓ** [Hivon (13)]. Then simulate many skies, pass each through the same instrument and the same analysis, and read off the mean, the scatter and the shape of the statistic from the simulations. The statistic is suboptimal, but its bias is calibrated out and

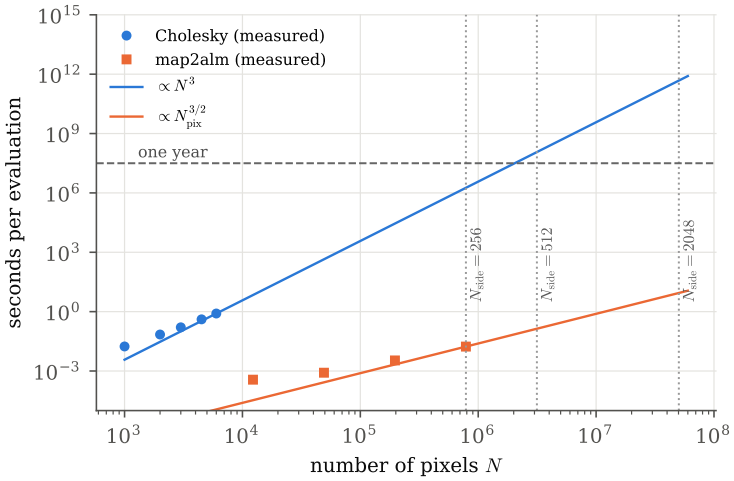

Figure 8.2: Time for one evaluation of the exact pixel likelihood (blue: a Cholesky factorisation, which grows as N^3) and for one spherical-harmonic transform (orange, growing as $N_{\rm pix}^{3/2}$). Points are measured, lines are extrapolations from the largest measured size. The dotted verticals mark three HEALPix resolutions, the dashed horizontal one year.

its error bar is honest. Hivon and collaborators named the method after this calibration step: MASTER, the Monte Carlo Apodised Spherical Transform EstimatoR [Hivon §1].

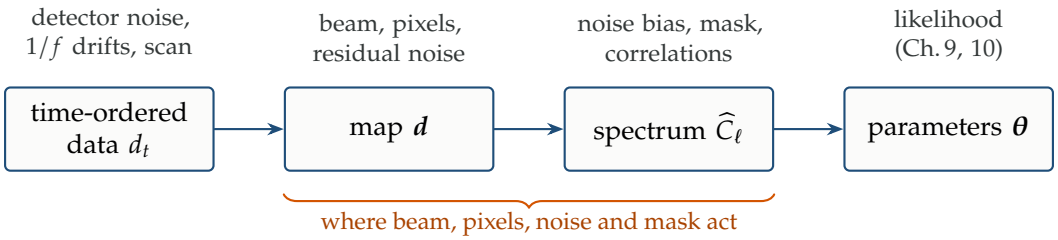

Figure 8.3: The CMB analysis as a chain of compressions [HobsonBMC §10.2]. Each step keeps the information the next one needs, and each adds its own complications (grey). The bracket marks the middle link: how the beam, the pixels and the noise of the map, and the mask, change the statistics of the spectrum computed from it.

The chain of Figure 8.3 is called a hierarchical model [HobsonBMC §10.2]: the timestream is compressed into a map, the map into a spectrum, the spectrum into parameters, and each step only needs the output of the one before. Making the map from the timestream is a least-squares problem of its own; for white noise it reduces to averaging the samples that fall in each pixel, which divides the noise variance by the number of hits [HobsonBMC (10.14)–(10.15)]. Real detector noise has extra power at low frequencies ($1/f$ noise), which leaves stripes along the scan and has to be filtered out [Hivon §2.1], [HobsonBMC p. 234]. We start from the map and assume the noise left in it is Gaussian and uncorrelated between pixels, with a variance that may change from pixel to pixel. Everything that this simplification leaves out (filtering, correlated noise, asymmetric beams) is exactly the kind of effect that real pipelines handle by putting it into the simulations [Hivon §3.2–3.3].

8.2 What the instrument does to the sky

A radio telescope pointed in direction $\hat{\boldsymbol{n}}$ does not measure the temperature at the single point $\hat{\boldsymbol{n}}$. Its optics collect radiation from a small cone around $\hat{\boldsymbol{n}}$, weighted by the **beam**: the response

pattern of the telescope, the same object an astronomer calls the point-spread function. What it records is therefore a weighted average of the sky. The recorded averages are then binned into pixels, which averages them a second time over the area of each pixel. Finally every pixel carries noise from the detector. The three steps act at different places, and the order matters: the beam and the pixels act on the sky, while the noise is added afterwards and is blurred by neither.

Working definition 8.1 (observation model of a temperature map)

The **observed map** is

$$d_p = \int_{S^2} b\big(\hat{\boldsymbol{n}}_p \cdot \hat{\boldsymbol{n}}'\big)\, s(\hat{\boldsymbol{n}}')\, \mathrm{d}\Omega' + n_p \equiv (B \circledast s)(\hat{\boldsymbol{n}}_p) + n_p, \tag{8.4}$$

where $s(\hat{\boldsymbol{n}})$ is the sky temperature fluctuation in μK, $\hat{\boldsymbol{n}}_p$ is the centre of pixel p, b is the beam [the weight given to the sky at angle γ from the pointing, a function of $\cos\gamma = \hat{\boldsymbol{n}}_p \cdot \hat{\boldsymbol{n}}'$ only for a circular beam], normalised as $\int b\,\mathrm{d}\Omega = 1$, and n_p is the noise of pixel p [Gaussian, mean zero, variance σ_p^2, independent of the sky and of the noise in every other pixel]. The pixel average is included as one more smoothing of s. *Operationally:* to simulate an observation, smooth the simulated sky with the beam and the pixel, then add one independent Gaussian number to each pixel.

This is the model (8.1) written out for a single detector with a circular beam, after the timestream has been turned into a map [HobsonBMC (10.6)–(10.7)]. The same structure, data equal smoothed model plus noise, appears in the cosmology notes as $\boldsymbol{d} = \boldsymbol{s}(\boldsymbol{\theta}) + \boldsymbol{n}$ with the beam inside $\boldsymbol{s}$ (see the cosmology notes).

8.2.1 A beam multiplies each multipole by a number

Smoothing is a convolution, and on a line a convolution becomes a multiplication in Fourier space. The sphere has the same property, with spherical harmonics in place of Fourier modes and with one condition: the smoothing kernel must depend only on the angle between the two directions. To see it, expand the beam, a function of $x = \cos\gamma$ on $[-1, 1]$, in Legendre polynomials,

$$b(x) = \sum_{\ell=0}^{\infty} \frac{2\ell+1}{4\pi} B_\ell\, P_\ell(x), \qquad B_\ell = 2\pi \int_{-1}^{1} b(x)\, P_\ell(x)\, \mathrm{d}x. \tag{8.5}$$

The formula for B_ℓ follows by multiplying the expansion by $P_{\ell'}$ and integrating, using $\int_{-1}^{1} P_\ell P_{\ell'}\,\mathrm{d}x = 2\delta_{\ell\ell'}/(2\ell+1)$. The coefficient $B_0 = 2\pi\int b\,\mathrm{d}x = \int b\,\mathrm{d}\Omega = 1$ is the normalisation: the beam does not change the mean of the sky. Now smooth a sky $s = \sum_{\ell m} a_{\ell m} Y_{\ell m}$ (Chapter 7):

$$\begin{aligned}
(B \circledast s)(\hat{\boldsymbol{n}}) &\overset{(1)}{=} \int \sum_{\ell} \frac{2\ell+1}{4\pi} B_\ell\, P_\ell(\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{n}}')\, s(\hat{\boldsymbol{n}}')\, \mathrm{d}\Omega' \\
&\overset{(2)}{=} \sum_{\ell} B_\ell \sum_{m=-\ell}^{\ell} Y_{\ell m}(\hat{\boldsymbol{n}}) \int Y^*_{\ell m}(\hat{\boldsymbol{n}}')\, s(\hat{\boldsymbol{n}}')\, \mathrm{d}\Omega' \\
&\overset{(3)}{=} \sum_{\ell m} \big(B_\ell\, a_{\ell m}\big)\, Y_{\ell m}(\hat{\boldsymbol{n}}).
\end{aligned} \tag{8.6}$$

(1) Insert the Legendre expansion (8.5) of the beam.
(2) The addition theorem $P_\ell(\hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{n}}') = \frac{4\pi}{2\ell+1}\sum_m Y_{\ell m}(\hat{\boldsymbol{n}}) Y^*_{\ell m}(\hat{\boldsymbol{n}}')$ (Chapter 7); the factors $(2\ell+1)/4\pi$ cancel.

(3) The remaining integral is the definition of the harmonic coefficient $a_{\ell m}$ of s.

Key idea: The convolution theorem on the sphere

A circular beam multiplies every harmonic coefficient of the sky by a number that depends on ℓ only: $a_{\ell m} \to B_\ell\, a_{\ell m}$. The beam does not mix different (ℓ, m), so the smoothed sky is still statistically isotropic, with power spectrum $B_\ell^2\, C_\ell$.

The last statement follows from $\langle |B_\ell a_{\ell m}|^2 \rangle = B_\ell^2 \langle |a_{\ell m}|^2 \rangle = B_\ell^2 C_\ell$. In the cosmology notes the same factor is called the window function, $W_\ell = B_\ell^2$ (see the cosmology notes); we keep B_ℓ because it is the factor that multiplies $a_{\ell m}$. A beam that is not circular has a kernel that depends on more than the angle between the two directions, and then it does mix the m's [HobsonBMC p. 232], [Hivon §3.6].

The Gaussian beam. Most telescope main lobes are close to a two-dimensional Gaussian of width σ_b,

$$b(\theta) = \frac{1}{2\pi\sigma_b^2}\, e^{-\theta^2/2\sigma_b^2}, \qquad \sigma_b = \frac{\mathrm{FWHM}}{\sqrt{8\ln 2}} \approx \frac{\mathrm{FWHM}}{2.355}, \tag{8.7}$$

where θ is the angle from the pointing and FWHM is the full width at half maximum [the angular diameter of the circle on which the beam has fallen to half its peak]. The relation between FWHM and σ_b comes from setting $e^{-\theta^2/2\sigma_b^2} = 1/2$ at $\theta = \mathrm{FWHM}/2$, which gives $\mathrm{FWHM}^2/(8\sigma_b^2) = \ln 2$. Since the beam is small, $\sin\theta \approx \theta$ and the normalisation is that of a flat two-dimensional Gaussian. Its B_ℓ follows from (8.5) with $x = \cos\theta$. For the low multipoles, where $\ell\sigma_b \ll 1$, expand P_ℓ around $x = 1$:

$$\begin{aligned} B_\ell &\overset{(1)}{=} 2\pi \int_0^\pi b(\theta)\, P_\ell(\cos\theta)\, \sin\theta\, \mathrm{d}\theta \\ &\overset{(2)}{=} 2\pi \int_0^\infty b(\theta) \Big[1 - \frac{\ell(\ell+1)}{2}\,\frac{\theta^2}{2}\Big]\theta\, \mathrm{d}\theta \\ &\overset{(3)}{=} 1 - \frac{\ell(\ell+1)}{4}\,\langle\theta^2\rangle_b \\ &\overset{(4)}{=} 1 - \frac{\ell(\ell+1)\,\sigma_b^2}{2}. \end{aligned} \tag{8.8}$$

(1) Change variable $x = \cos\theta$, $\mathrm{d}x = -\sin\theta\,\mathrm{d}\theta$.

(2) Taylor expansion $P_\ell(\cos\theta) \approx P_\ell(1) + P_\ell'(1)(\cos\theta - 1)$ with $P_\ell(1) = 1$, $\cos\theta - 1 \approx -\theta^2/2$, and $P_\ell'(1) = \ell(\ell+1)/2$. The last value follows from Legendre's equation $(1-x^2)P_\ell'' - 2xP_\ell' + \ell(\ell+1)P_\ell = 0$ evaluated at $x = 1$, where the first term vanishes. Also $\sin\theta \approx \theta$, and the upper limit can be moved to ∞ because the beam is negligible far from its centre.

(3) The first term is the normalisation $2\pi \int b\,\theta\,\mathrm{d}\theta = 1$. The second is the mean of θ^2 over the beam, $\langle\theta^2\rangle_b \equiv 2\pi \int \theta^2 b\,\theta\,\mathrm{d}\theta$.

(4) For a two-dimensional Gaussian, $\theta^2 = x^2 + y^2$ with x and y independent, each of variance σ_b^2, so $\langle\theta^2\rangle_b = 2\sigma_b^2$.

Equation (8.8) is the first-order expansion of $e^{-\ell(\ell+1)\sigma_b^2/2}$, and the cosmology notes reach the same expansion for the window function, $W_\ell \approx 1 - \sigma_b^2\ell(\ell+1)$. At high ℓ the flat-sky limit fixes the full shape: on a small patch, ℓ becomes the length of a two-dimensional wave vector, and the Fourier transform of a two-dimensional Gaussian is a Gaussian,

$$\tilde{b}(\boldsymbol{\ell}) = \int \frac{e^{-(x^2+y^2)/2\sigma_b^2}}{2\pi\sigma_b^2}\, e^{-i(\ell_x x + \ell_y y)}\, \mathrm{d}x\, \mathrm{d}y = e^{-\ell_x^2\sigma_b^2/2}\, e^{-\ell_y^2\sigma_b^2/2} = e^{-\ell^2\sigma_b^2/2}, \tag{8.9}$$

each factor being the familiar one-dimensional result obtained by completing the square. The formula that joins both limits is the one used everywhere,

$$B_\ell = \exp\!\left[-\frac{\ell(\ell+1)\,\sigma_b^2}{2}\right] \tag{8.10}$$

[138], and it is what `healpy.gauss_beam` returns. Is it exact? The function `gaussian_beam_exact` in `code/ch08/lib_cmbsim.py` evaluates the Legendre integral (8.5) numerically, with P_ℓ from Bonnet's recursion $(\ell+1)P_{\ell+1} = (2\ell+1)xP_\ell - \ell P_{\ell-1}$. For a 30′ beam the two agree to 8×10^{-7} at every $\ell \le 767$; even for beams of 5° and 10° they differ by at most 0.2% and 0.6% wherever $B_\ell > 10^{-3}$ (Figure 8.4, script `code/ch08/02_beam_window.py`).

Example: where the beam halves the power. Take the beam of our toy experiment, FWHM = 30′, so $\sigma_b = 12.7' = 3.71\times10^{-3}$ rad. The observed power $B_\ell^2 C_\ell$ is half the true power where $\ell(\ell+1)\sigma_b^2 = \ln 2$, that is at $\ell \approx \sqrt{\ln 2}/\sigma_b \approx 225$ (the numerical B_ℓ gives 224). For a 5′ beam, typical of the best Planck channels, $\sigma_b = 2.12' = 6.18\times10^{-4}$ rad and the power is halved only at $\ell \approx 1350$. The beam sets the multipole range an experiment can reach: angular resolution in degrees and multipole reach are two descriptions of the same number.

Example: the beam at the edge of the analysed range. At $\ell = 512$ our beam gives $B_\ell = 0.165$, so the sky power there is multiplied by $B_\ell^2 \approx 0.027$, a suppression by a factor of about 37. The sky is still there; it has been turned down, and it can be turned back up by dividing by B_ℓ^2. What that costs is the subject of Section 8.4.

The pixel window. Storing the smoothed sky in pixels averages it once more, over the area of each pixel. If every pixel had the same shape, this would be one more convolution, with a kernel equal to $1/\Omega_{\rm pix}$ inside the pixel and zero outside. HEALPix pixels have equal areas $\Omega_{\rm pix} = 4\pi/N_{\rm pix}$ but slightly different shapes [7], so the averaging is only approximately a convolution. Averaged over the sky, its effect on the spectrum is a multiplication by p_ℓ^2, where p_ℓ, the **pixel window function**, is tabulated by `healpy.pixwin` [Hivon (15)]. Its low-ℓ form follows from the same expansion as (8.8), with the beam replaced by a square of side $a = \sqrt{\Omega_{\rm pix}}$: the mean of x^2+y^2 over a square is $2\cdot a^2/12$, so

$$p_\ell \approx 1 - \frac{\ell(\ell+1)}{4}\cdot\frac{a^2}{6} = 1 - \frac{\ell(\ell+1)\,\Omega_{\rm pix}}{24}. \tag{8.11}$$

Example: the pixel window of $N_{\rm side} = 256$. The pixels have $\Omega_{\rm pix} = 1.598\times10^{-5}$ sr, sides of 13.7′. At $\ell = 256$, (8.11) gives $1 - 65792\times1.598\times10^{-5}/24 = 0.956$, against the tabulated 0.954. At $\ell = 512$ it gives 0.825, against 0.827. A 17% suppression of the amplitude at $\ell = 512$ is a 32% suppression of the power. Forgetting it is not a small error (Section 8.6).

The beam and the pixel act on the same sky one after the other, so their factors multiply. We call the product the **transfer function** of the instrument,

$$T_\ell \equiv B_\ell\, p_\ell, \qquad a_{\ell m} \;\to\; T_\ell\, a_{\ell m}, \qquad C_\ell \;\to\; T_\ell^2\, C_\ell. \tag{8.12}$$

Real pipelines add further factors to T_ℓ, for example a filter applied to the timestream, and measure them with simulations [Hivon (15), (18)].

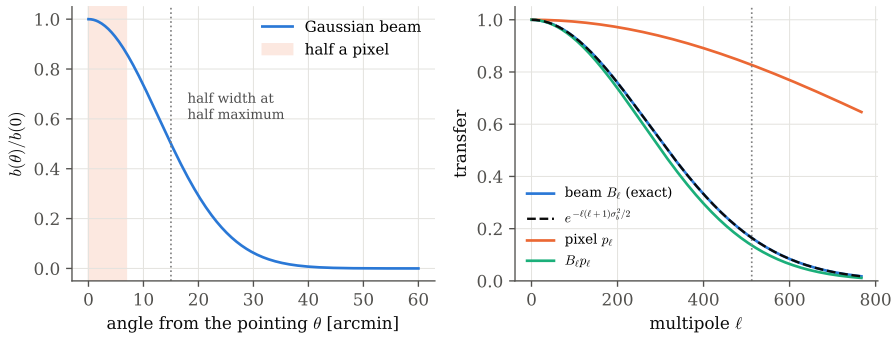

Figure 8.4: Left: the Gaussian beam of the toy experiment as a function of the angle from the pointing; the shaded band is half a pixel. Right: in harmonic space the beam becomes the transfer function B_ℓ. The exact Legendre transform (blue) and the formula $e^{-\ell(\ell+1)\sigma_b^2/2}$ (dashed) are indistinguishable. The pixel window p_ℓ (orange) is a milder suppression; the product $B_\ell p_\ell$ (green) is what multiplies each $a_{\ell m}$. The dotted line marks the analysed range $\ell \le 512$.

8.2.2 Pixel noise in harmonic space

The noise n_p enters (8.4) after the smoothing. To see what it does to the spectrum we need its harmonic coefficients, which a map transform computes as a sum over pixels, the quadrature version of $\int \mathrm{d}\Omega$:

$$n_{\ell m} = \Omega_{\mathrm{pix}} \sum_p n_p \, Y^*_{\ell m}(\hat{\boldsymbol{n}}_p). \tag{8.13}$$

Each $n_{\ell m}$ is a sum of independent Gaussian numbers, so it is Gaussian with mean zero. Its covariance is

$$\begin{aligned} \langle n_{\ell m}\, n^*_{\ell' m'} \rangle &\overset{(1)}{=} \Omega^2_{\mathrm{pix}} \sum_{p,q} \langle n_p n_q \rangle \, Y^*_{\ell m}(\hat{\boldsymbol{n}}_p)\, Y_{\ell' m'}(\hat{\boldsymbol{n}}_q) \\ &\overset{(2)}{=} \Omega^2_{\mathrm{pix}} \sum_p \sigma_p^2 \, Y^*_{\ell m}(\hat{\boldsymbol{n}}_p)\, Y_{\ell' m'}(\hat{\boldsymbol{n}}_p) \qquad (8.14) \\ &\overset{(3)}{=} \sigma^2 \, \Omega_{\mathrm{pix}} \sum_p \Omega_{\mathrm{pix}} \, Y^*_{\ell m}(\hat{\boldsymbol{n}}_p)\, Y_{\ell' m'}(\hat{\boldsymbol{n}}_p) \\ &\overset{(4)}{=} \sigma^2 \, \Omega_{\mathrm{pix}} \, \delta_{\ell\ell'} \delta_{mm'}. \qquad (8.15) \end{aligned}$$

(1) Insert (8.13) twice; the noise is real, $n^*_p = n_p$, and the average acts only on the noise.

(2) Different pixels are independent, $\langle n_p n_q \rangle = \sigma_p^2 \delta_{pq}$.

(3) For uniform noise, $\sigma_p = \sigma$ in every pixel; split Ω^2_{pix} into two factors.

(4) The remaining sum is the pixel approximation of $\int Y^*_{\ell m} Y_{\ell' m'} \mathrm{d}\Omega = \delta_{\ell\ell'}\delta_{mm'}$, accurate for $\ell \lesssim 2N_{\mathrm{side}}$ (Chapter 7).

Uniform, uncorrelated pixel noise is therefore **white** in harmonic space: every (ℓ, m) gets an independent Gaussian of the same variance,

$$N_\ell = \sigma^2 \, \Omega_{\mathrm{pix}} \equiv \Delta_T^2, \tag{8.16}$$

the **noise power spectrum** [Hivon §3.3], [138]. The cosmology notes write it as w^{-1}, where $w \equiv (\Omega_{\mathrm{pix}}\sigma^2)^{-1}$ is the weight per solid angle (see the cosmology notes).[1] The square root

[1] In [HobsonBMC (10.24)–(10.25)] the symbol σ^2 is the variance of the harmonic noise coefficients, $\sigma^2_{\mathrm{pix}}\Omega_{\mathrm{pix}}$ in the notation here, not the variance of a pixel; the two differ by a factor of order 10^{-5} for our pixels.

$\Delta_T = \sigma\sqrt{\Omega_{\rm pix}}$ is called the **map depth**, quoted in μK arcmin [the noise of a pixel one arcminute on a side]. It is the natural label of an experiment because it does not depend on how the map was pixelised: at a fixed total observing time, a pixel half as large in area gets half the samples, so σ^2 doubles and $\sigma^2\Omega_{\rm pix}$ stays the same.

Example: the toy experiment. Our experiment has depth $\Delta_T = 200\,\mu$K arcmin on $N_{\rm side} = 256$ pixels of side 13.7′. The noise per pixel is $\sigma = \Delta_T/13.7' = 14.6\,\mu$K, and $N_\ell = (200 \times 2.909 \times 10^{-4})^2\,\mu{\rm K}^2 = 3.38 \times 10^{-3}\,\mu{\rm K}^2$, using $1' = 2.909 \times 10^{-4}$ rad. On the map (Figure 8.5) the sky has an rms of 108 μK, the beam brings it down to 86 μK, and the noise adds 14.6 μK per pixel. By eye the noise is a faint grain on the large spots. In harmonic space it dominates the beamed sky above $\ell \approx 436$ (Section 8.3).

Example: Knox's experiment. Knox [138] considered a year of observation with $\sigma = 22\,\mu$K in $20' \times 20'$ pixels. Its depth is $\Delta_T = 22 \times 20 = 440\,\mu$K arcmin, or 7.3 μK deg. He quotes the weight per solid angle $w = (7.5\,\mu{\rm K})^{-2}\,{\rm deg}^{-2}$, which is the same number to the rounding in his σ. The same experiment pixelised into $10' \times 10'$ pixels would show $\sigma = 44\,\mu$K per pixel and exactly the same N_ℓ.

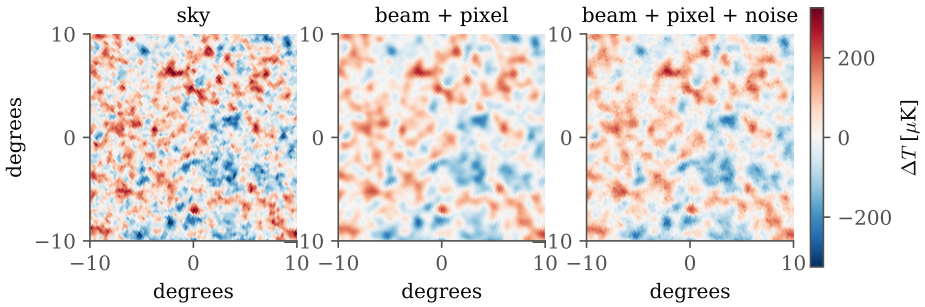

Figure 8.5: One simulated sky, 20° on a side, before and after the instrument. Left: the sky drawn from the fiducial C_ℓ. Middle: after the 30′ beam and the 13.7′ pixels; the smallest spots are gone. Right: with 200 μK arcmin of white noise added, which shows up as a fine grain. The colour scale is the same in all three panels.

Watch out: The beam acts on the sky, not on the noise

In (8.4) the noise is added after the smoothing, so the observed coefficients are $d_{\ell m} = T_\ell a_{\ell m} + n_{\ell m}$ and not $T_\ell(a_{\ell m} + n_{\ell m})$. The beam turns the sky down at high ℓ but leaves the noise at its full, flat level [138]. Dividing the observed coefficients by T_ℓ to undo the beam therefore turns the noise up by $1/T_\ell$: the effective noise on the sky is N_ℓ/T_ℓ^2, which grows like $e^{\ell(\ell+1)\sigma_b^2}$. A simulation that smooths the noise along with the sky gets every error bar at high ℓ wrong.

When the noise is not uniform. A scanning telescope does not visit every pixel equally often, and the noise variance of a pixel falls as one over its number of hits [HobsonBMC (10.15)]. Then σ_p changes across the sky and step (3) of (8.15) is no longer allowed. Line (8.14) is still exact, and it says that the harmonic noise is no longer diagonal: a pattern in σ_p^2 couples different (ℓ, m). One combination survives untouched. Average the diagonal over the $2\ell + 1$ values of m:

$$\bar{N}_\ell \equiv \frac{1}{2\ell+1}\sum_{m=-\ell}^{\ell}\langle|n_{\ell m}|^2\rangle \overset{(1)}{=} \frac{\Omega_{\rm pix}^2}{2\ell+1}\sum_p \sigma_p^2 \sum_m |Y_{\ell m}(\hat{\boldsymbol{n}}_p)|^2$$

$$\overset{(2)}{=} \frac{\Omega_{\text{pix}}^2}{4\pi} \sum_p \sigma_p^2$$

$$\overset{(3)}{=} \Omega_{\text{pix}} \langle \sigma^2 \rangle. \tag{8.17}$$

(1) Line (8.14) with $\ell' = \ell$, $m' = m$, summed over m.
(2) The addition theorem at coincident points, $\sum_m |Y_{\ell m}(\hat{\boldsymbol{n}})|^2 = (2\ell+1)/4\pi$, the same for every direction.
(3) $N_{\text{pix}}\Omega_{\text{pix}} = 4\pi$, and $\langle \sigma^2 \rangle \equiv \sum_p \sigma_p^2 / N_{\text{pix}}$ is the sky-averaged pixel variance.

However the noise is distributed over the sky, the average noise power at every ℓ is the pixel area times the mean pixel variance [141, eq. 48]. This number fixes the noise *bias* of the next section. The noise *scatter* depends on the full pattern, and Section 8.6 measures it.

8.3 The noise bias and how to remove it

Take the observed map of the toy experiment (Figure 8.5, right), transform it, and average $|d_{\ell m}|^2$ over m at $\ell = 500$, exactly as Chapter 7 did for a perfect sky. The answer comes out about four times larger than the beamed sky power $T_\ell^2 C_\ell$ at that multipole. Nothing went wrong in the transform. The noise in each $d_{\ell m}$ averages to zero, but its square does not: squaring a fluctuation turns it into power, and power from the detector adds to power from the sky. Every spectrum computed from a noisy map is biased upward, and the first task is to say by exactly how much.

Write the observed harmonic coefficients, using the transfer function $T_\ell = B_\ell p_\ell$ of (8.12) and the harmonic noise $n_{\ell m}$ of (8.13), as $d_{\ell m} = T_\ell a_{\ell m} + n_{\ell m}$, and define the **observed spectrum** as the same average that gave $\widehat{C}_\ell$ on a perfect sky:

$$\widehat{C}_\ell^{\text{obs}} \equiv \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} |d_{\ell m}|^2. \tag{8.18}$$

Its average over skies and noise realisations is

$$\begin{aligned} \langle \widehat{C}_\ell^{\text{obs}} \rangle &\overset{(1)}{=} \frac{1}{2\ell+1} \sum_m \Big[T_\ell^2 \langle |a_{\ell m}|^2 \rangle + T_\ell \langle a_{\ell m} n_{\ell m}^* \rangle + T_\ell \langle a_{\ell m}^* n_{\ell m} \rangle + \langle |n_{\ell m}|^2 \rangle \Big] \\ &\overset{(2)}{=} \frac{1}{2\ell+1} \sum_m \Big[T_\ell^2 C_\ell + \langle |n_{\ell m}|^2 \rangle \Big] \\ &\overset{(3)}{=} T_\ell^2 \, C_\ell + \bar{N}_\ell. \end{aligned} \tag{8.19}$$

(1) Expand $|T_\ell a_{\ell m} + n_{\ell m}|^2$; T_ℓ is real.
(2) The sky and the noise are independent and both have mean zero, so $\langle a_{\ell m} n_{\ell m}^* \rangle = \langle a_{\ell m} \rangle \langle n_{\ell m}^* \rangle = 0$; statistical isotropy gives $\langle |a_{\ell m}|^2 \rangle = C_\ell$ for every m (Chapter 7).
(3) The definition (8.17) of the mean noise power; for uniform noise $\bar{N}_\ell = N_\ell = \sigma^2 \Omega_{\text{pix}}$.

The observed spectrum measures the beamed sky plus the noise. The excess $\bar{N}_\ell$ is the **noise bias** [Hivon (15)], [138]. Because it is known, it can be subtracted, and because T_ℓ is known, the beam can be divided out.

Working definition 8.2 (debiased, deconvolved estimator)

For a full-sky map with transfer function T_ℓ and noise power N_ℓ,

$$\widehat{C}_\ell = \frac{\widehat{C}_\ell^{\,\mathrm{obs}} - N_\ell}{T_\ell^2} \tag{8.20}$$

[subtract the power the noise alone would give, then undo the suppression by the beam and the pixel]. By (8.19) it is unbiased, $\langle \widehat{C}_\ell \rangle = C_\ell$, for every ℓ. *Operationally:* compute `alm2cl(map2alm(d))`, subtract N_ℓ (from (8.16), or from noise-only simulations when no formula exists), divide by $B_\ell^2 p_\ell^2$.

How large is the correction? The left panel of Figure 8.6 plots the three spectra of (8.19) for the toy experiment. The beamed sky $T_\ell^2 C_\ell$ falls steeply past $\ell \approx 300$, while the noise N_ℓ is flat, and the two cross at $\ell_{\mathrm{eq}} = 436$. Below ℓ_{eq} the measurement is limited by the sky itself; above it, by the detector.

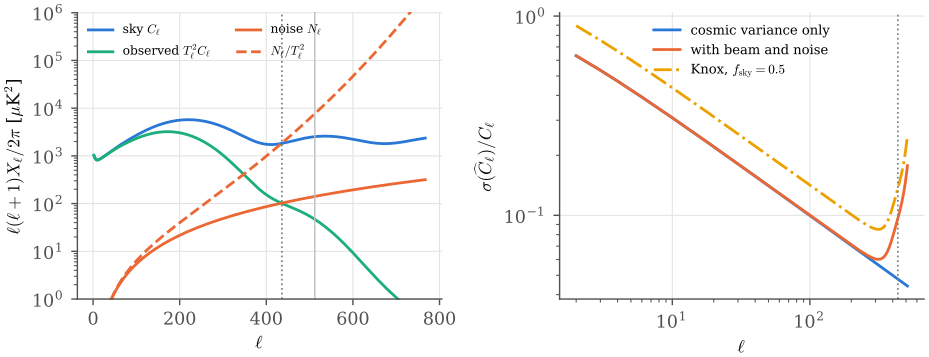

Figure 8.6: The signal and noise budget of the toy experiment, plotted as $\ell(\ell+1)X_\ell/2\pi$ for each spectrum X_ℓ. Left: the sky spectrum (blue) is turned down by the beam and pixel (green), while the white noise (orange, solid), flat in N_ℓ, rises only as ℓ^2 in these units; the two cross at ℓ_{eq} (dotted line). After dividing by T_ℓ^2 the noise (orange, dashed) climbs exponentially. The grey line marks the analysed range $\ell \le 512$. Right: the fractional error on C_ℓ at a single multipole, from cosmic variance alone (blue), with the beam and the noise (orange), and with Knox's sky-fraction factor for half the sky (yellow); the dotted line is again ℓ_{eq}.

Example: forgetting the subtraction. Without the subtraction the estimator $\widehat{C}_\ell^{\,\mathrm{obs}}/T_\ell^2$ is off by $N_\ell/(T_\ell^2 C_\ell)$. For the toy experiment this is 0.05 at $\ell = 300$, a 5% excess, close to the cosmic-variance error of a single multipole there (5.8%). At $\ell = 512$ it is 3.0: the uncorrected spectrum is four times too high.

8.3.1 Is this the best we can do?

The estimator (8.20) was built by matching an average. The procedure of Chapter 3 asks a different question: which value of C_ℓ makes the data we observed most probable? Say it in words first, in four moves.

The observed outcome is what the map gives us at one ℓ: the coefficients $d_{\ell m}$. They are complex, but only $2\ell+1$ real numbers are free, because the map is real and $d_{\ell,-m} = (-1)^m d_{\ell m}^*$ (Chapter 7). To make these numbers all alike, rescale the ones that come in pairs. The real $d_{\ell 0}$ has variance V_ℓ; for $m > 0$ the variance $V_\ell = \langle |d_{\ell m}|^2 \rangle$ is shared equally between the real and

imaginary parts, so each of them has $V_\ell/2$. Define

$$u_1 \equiv d_{\ell 0}, \qquad u_{2m} \equiv \sqrt{2}\,\mathrm{Re}\, d_{\ell m}, \qquad u_{2m+1} \equiv \sqrt{2}\,\mathrm{Im}\, d_{\ell m} \qquad (m = 1, \dots, \ell), \tag{8.21}$$

$$\sum_{k=1}^{\nu} u_k^2 \overset{(1)}{=} d_{\ell 0}^2 + 2\sum_{m=1}^{\ell} |d_{\ell m}|^2 \overset{(2)}{=} \sum_{m=-\ell}^{\ell} |d_{\ell m}|^2 \overset{(3)}{=} \nu\, \widehat{C}_\ell^{\,\mathrm{obs}}, \qquad \nu = 2\ell + 1.$$

(1) $(\sqrt{2}\,\mathrm{Re}\, d)^2 + (\sqrt{2}\,\mathrm{Im}\, d)^2 = 2|d|^2$.
(2) $|d_{\ell,-m}| = |d_{\ell m}|$, so the terms with $m < 0$ repeat those with $m > 0$.
(3) The definition (8.18) of the observed spectrum.

Each u_k now has the same variance V_ℓ and mean zero, and the ν of them are independent. Every later count of "$2\ell + 1$ independent numbers" at one ℓ refers to these u_k.

The hypotheses are the possible values of C_ℓ. Under one of them, the model predicts mean zero for every u_k; what turns that prediction into the numbers actually observed is a random fluctuation, made of an independent sky part and an independent noise part. Variances of independent Gaussians add, so under the hypothesis C_ℓ the fluctuation is Gaussian with variance $V_\ell = T_\ell^2 C_\ell + N_\ell$. The likelihood of C_ℓ asks how plausible it is that a fluctuation of that size produced exactly these $u_1, \dots, u_\nu$: too small a C_ℓ makes the observed values improbably large, too large a C_ℓ makes them improbably small. Read as a function of C_ℓ with the data held fixed, that probability ranks the hypotheses; maximising it, or combining it with a prior by Bayes' theorem, picks among them. Then

$$-2\ln \mathcal{L}(C_\ell) \overset{(1)}{=} \sum_{k=1}^{\nu} \left[\frac{u_k^2}{V_\ell} + \ln(2\pi V_\ell) \right]$$

$$\overset{(2)}{=} \nu \left[\frac{\widehat{C}_\ell^{\,\mathrm{obs}}}{T_\ell^2 C_\ell + N_\ell} + \ln\left(T_\ell^2 C_\ell + N_\ell\right) \right] + \text{const}, \tag{8.22}$$

$$\frac{\partial(-2\ln\mathcal{L})}{\partial C_\ell} \overset{(3)}{=} \nu\, T_\ell^2 \left[-\frac{\widehat{C}_\ell^{\,\mathrm{obs}}}{(T_\ell^2 C_\ell + N_\ell)^2} + \frac{1}{T_\ell^2 C_\ell + N_\ell} \right] = 0 \implies \hat{C}_\ell^{\mathrm{ML}} = \frac{\widehat{C}_\ell^{\,\mathrm{obs}} - N_\ell}{T_\ell^2}. \tag{8.23}$$

(1) Each u_k is $\mathcal{N}(0, V_\ell)$, with density $(2\pi V_\ell)^{-1/2} e^{-u_k^2/2V_\ell}$; independent densities multiply, so minus twice their logarithms add.
(2) $\sum_k u_k^2 = \nu \widehat{C}_\ell^{\,\mathrm{obs}}$, and $V_\ell = T_\ell^2 C_\ell + N_\ell$; the $\ln 2\pi$ terms do not depend on C_ℓ.
(3) Differentiate with the chain rule, $\partial V_\ell / \partial C_\ell = T_\ell^2$; the bracket vanishes when $V_\ell = \widehat{C}_\ell^{\,\mathrm{obs}}$.

The maximum-likelihood estimator is the debiased, deconvolved estimator [HobsonBMC (10.24)–(10.25)]. On the full sky with uniform white noise, the cheap estimator is not an approximation to the best one; it *is* the best one, the quadratic maximum-likelihood estimator of Section 8.1.1 with every matrix diagonal. Section 8.4 confirms that its variance reaches the Cramér–Rao bound.

One detail of (8.23) matters in practice. If the noise happens to fluctuate low, $\widehat{C}_\ell^{\,\mathrm{obs}} < N_\ell$ and the estimate is negative, although C_ℓ cannot be. Restricting the maximum to $C_\ell \geq 0$ would replace those estimates by zero and bias the average upward. We keep the unrestricted estimator, which is unbiased and can be negative, and leave the constraint $C_\ell \geq 0$ to the likelihood in which $\widehat{C}_\ell$ is later used (Chapter 9).

8.3.2 When the noise level is not known exactly

The subtraction in (8.20) needs N_ℓ. For white, uniform noise (8.16) gives it. Real noise is coloured, varies across the sky, and is filtered during map-making; then N_ℓ has no formula and

is estimated by simulating noise-only timestreams, making maps from them in the same way, and averaging their spectra, $\langle \tilde{N}_\ell \rangle_{\mathrm{MC}}$ [Hivon §3.3]. Two questions follow: how much bias does an error in N_ℓ cause, and how many noise simulations keep that error small?

Example: a 2% error in the noise level. Subtract $(1+\varepsilon)N_\ell$ instead of N_ℓ. By (8.19) the average of the estimator becomes $C_\ell - \varepsilon N_\ell / T_\ell^2$, a fractional bias

$$\frac{\langle \widehat{C}_\ell \rangle - C_\ell}{C_\ell} = -\varepsilon \, \frac{N_\ell}{T_\ell^2 C_\ell}. \tag{8.24}$$

At $\ell = 512$, $N_\ell/(T_\ell^2 C_\ell) = 3.0$, so $\varepsilon = 0.02$ gives -6%. The statistical error of one multipole there is 18% (Section 8.4), and of a bin of 25 multipoles about $18\%/\sqrt{25} \approx 3.6\%$. A 2% error in the noise model produces a bias of almost two standard deviations per bin.

Watch out: A small noise error is a large spectrum error at high ℓ

The bias (8.24) is the noise error ε times the noise-to-signal ratio $N_\ell/(T_\ell^2 C_\ell)$, which grows like $e^{\ell(\ell+1)\sigma_b^2}$. However well the noise is known, there is a multipole beyond which the auto-spectrum is dominated by the uncertainty in the noise model rather than by the sky.

Example: how many noise simulations? If N_ℓ is estimated as the average of the spectra of N_n independent noise-only maps, each of which scatters by $\sqrt{2/(2\ell+1)}\, N_\ell$ (the noise coefficients are Gaussian, so their spectrum is a scaled χ^2 like the sky's, Chapter 7), the estimate scatters by $\sqrt{2/(2\ell+1)}\, N_\ell/\sqrt{N_n}$. Compare it with the statistical error of $\widehat{C}_\ell^{\,\mathrm{obs}}$, which is $\sqrt{2/(2\ell+1)}\,(T_\ell^2 C_\ell + N_\ell)$ (Section 8.4):

$$\frac{\text{error from the noise estimate}}{\text{statistical error}} = \frac{N_\ell}{T_\ell^2 C_\ell + N_\ell} \, \frac{1}{\sqrt{N_n}} \;\le\; \frac{1}{\sqrt{N_n}}. \tag{8.25}$$

With 100 noise simulations the extra error is at most 10% of the statistical one. Errors from independent sources add in quadrature, so the total error bar is at most $\sqrt{1+0.1^2} = 1.005$ times the statistical one: it grows by at most 0.5%. This is the number Hivon et al. found for the Boomerang analysis [Hivon (42)].

8.3.3 Cross-spectra: no noise bias at all

There is a way to avoid the noise model entirely. Split the data in two: the first and second halves of the mission, or two sets of detectors. Each half sees the same sky through the same beam, $d_{\ell m}^{(i)} = T_\ell a_{\ell m} + n_{\ell m}^{(i)}$ for $i = 1, 2$, but the two noise realisations are independent. Instead of squaring one map, multiply the two:

$$\widehat{C}_\ell^{\,12} \equiv \frac{1}{2\ell+1} \sum_m \mathrm{Re}\big(d_{\ell m}^{(1)} d_{\ell m}^{(2)*}\big), \qquad \big\langle \widehat{C}_\ell^{\,12} \big\rangle = T_\ell^2 C_\ell + \big\langle \mathrm{Re}\, n_{\ell m}^{(1)} n_{\ell m}^{(2)*} \big\rangle = T_\ell^2 C_\ell. \tag{8.26}$$

The cross terms between sky and noise vanish as in (8.19), and the noise–noise term vanishes because the two noises are independent. The **cross-spectrum** has no noise bias, and it needs no noise model [16]. The Planck high-ℓ likelihood is built from cross-spectra between half-mission maps for exactly this reason [70] (Figure 8.7).

The price is paid in scatter. Each half has twice the noise variance of the full map, $N_\ell^{(1)} = N_\ell^{(2)} = 2N_\ell$, because it has half the observing time. To find the variance of (8.26),

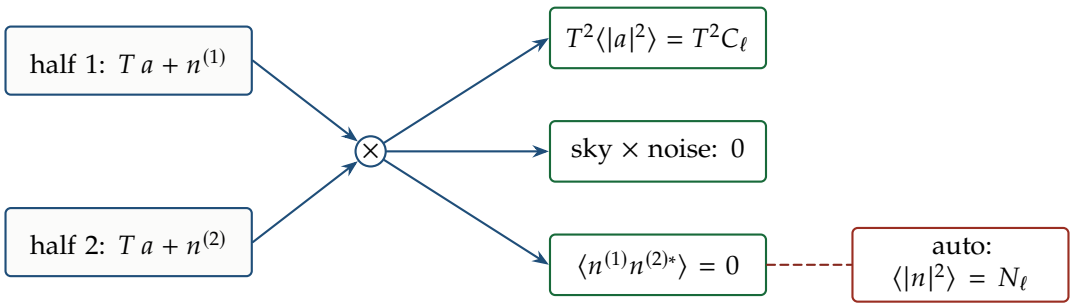

Figure 8.7: Why the cross-spectrum has no noise bias. Multiplying two maps of the same sky with independent noise leaves three kinds of terms on average: the sky power survives, sky times noise averages to zero, and noise times the *other* noise averages to zero. In the auto-spectrum (red) the last term is a noise times itself, whose average is the noise power.

write it, as for the likelihood above, as a sum over the $\nu = 2\ell + 1$ real degrees of freedom, $\nu \widehat{C}_\ell^{12} = \sum_k u_k v_k$, where u_k and v_k are the corresponding real components of the two maps. The pairs are independent for different k; within a pair u and v are zero-mean Gaussians with variances $S + 2N$ each (writing $S = T_\ell^2 C_\ell$, $N = N_\ell$) and covariance $\langle uv\rangle = S$, since only the sky is shared. Then

$$\begin{aligned}\mathrm{Var}(uv) &\overset{(1)}{=} \langle u^2 v^2\rangle - \langle uv\rangle^2 \\ &\overset{(2)}{=} \langle u^2\rangle\langle v^2\rangle + 2\langle uv\rangle^2 - \langle uv\rangle^2 \\ &\overset{(3)}{=} (S+2N)^2 + S^2, \end{aligned} \tag{8.27}$$

$$\mathrm{Var}\big(\widehat{C}_\ell^{12}\big) \overset{(4)}{=} \frac{(S+2N)^2 + S^2}{2\ell+1} \quad \text{versus} \quad \mathrm{Var}\big(\widehat{C}_\ell^{\mathrm{obs}}\big) = \frac{2(S+N)^2}{2\ell+1}. \tag{8.28}$$

(1) Definition of the variance.
(2) Isserlis' theorem for zero-mean Gaussians (Chapter 7): $\langle uuvv\rangle$ is the sum over the three ways of pairing the four factors.
(3) Insert the variances and the covariance.
(4) The ν terms are independent, so their variances add, and dividing the sum by ν divides the variance by ν^2. The auto-spectrum line is the case $u = v$ with variance $S + N$, derived in Section 8.4.

When the sky dominates ($N \ll S$) both variances are $2S^2/\nu$: nothing is lost. When the noise dominates ($S \ll N$) the cross-spectrum variance is $4N^2/\nu$ against $2N^2/\nu$, so its error bar is $\sqrt{2}$ times larger. At $\ell = 512$ the predicted ratio of error bars is 1.25; the simulations of Section 8.6 find 1.24. The cross-spectrum trades a little precision for immunity to the noise model, a trade that real analyses usually accept.

8.4 How much the estimate scatters

The debiased, deconvolved estimator $\widehat{C}_\ell = (\widehat{C}_\ell^{\mathrm{obs}} - N_\ell)/T_\ell^2$ of (8.20) centres on the true spectrum. Here $\widehat{C}_\ell^{\mathrm{obs}}$ is the average of $|d_{\ell m}|^2$ over m on the observed map, N_ℓ the noise power and $T_\ell = B_\ell p_\ell$ the beam times the pixel window (Section 8.2). Centring on the truth is a statement about the average over many skies. We have one sky, and on it a single estimate at $\ell = 512$ typically lands about a fifth away from C_ℓ. On a perfect sky the same estimate would land only about 4% away. Something in the observation has made the scatter four times larger, and we want to know what, by how much at every ℓ, and whether any other estimator could do better.

Said in words, there are four questions. How wide is the spread of $\widehat{C}_\ell$ over skies and noise realisations? How much of it comes from the sky and how much from the detector? Is it the smallest spread any estimator could achieve with these data? And what is the full shape of the distribution, not just its width?

The width. The answer comes from the same bookkeeping that gave the likelihood in Section 8.3.1. At one ℓ the observed map supplies $\nu = 2\ell + 1$ real numbers $u_1, \dots, u_\nu$, the coefficients $d_{\ell m}$ rescaled so that all have the same variance, (8.21). Each is a sky part plus an independent noise part, so each is a zero-mean Gaussian with variance $V_\ell = T_\ell^2 C_\ell + N_\ell$, they are independent of one another, and $\sum_k u_k^2 = \nu\, \widehat{C}_\ell^{\,\mathrm{obs}}$. A sum of ν squared independent standard Gaussians is a χ^2_ν variable, whose variance is 2ν (Chapter 7). Then

$$\begin{aligned}\operatorname{Var}\big(\widehat{C}_\ell\big) &\overset{(1)}{=} \frac{1}{T_\ell^4}\operatorname{Var}\big(\widehat{C}_\ell^{\,\mathrm{obs}}\big) \overset{(2)}{=} \frac{1}{T_\ell^4}\frac{V_\ell^2}{\nu^2}\operatorname{Var}\Big(\sum_{k=1}^{\nu}\frac{u_k^2}{V_\ell}\Big)\\ &\overset{(3)}{=} \frac{1}{T_\ell^4}\frac{V_\ell^2}{\nu^2}\,2\nu \overset{(4)}{=} \frac{2}{2\ell+1}\Big(C_\ell + \frac{N_\ell}{T_\ell^2}\Big)^2. \end{aligned} \tag{8.29}$$

(1) N_ℓ and T_ℓ are fixed numbers: subtracting a constant does not change a variance, and dividing by T_ℓ^2 divides it by T_ℓ^4.
(2) $\widehat{C}_\ell^{\,\mathrm{obs}} = \frac{1}{\nu}\sum_k u_k^2 = \frac{V_\ell}{\nu}\sum_k (u_k^2/V_\ell)$, and a constant factor comes out of a variance squared.
(3) Each $u_k/\sqrt{V_\ell}$ is a standard Gaussian, so the sum is χ^2_ν, with variance 2ν.
(4) $V_\ell/T_\ell^2 = C_\ell + N_\ell/T_\ell^2$ and $\nu = 2\ell + 1$.

Key idea: The error bar of a full-sky, beamed, noisy spectrum

$$\sigma\big(\widehat{C}_\ell\big) = \sqrt{\frac{2}{2\ell+1}}\,\Big(C_\ell + \frac{N_\ell}{T_\ell^2}\Big).$$

The sky and the noise enter added, inside the bracket, and the noise enters as it looks *after* the beam has been divided out, N_ℓ/T_ℓ^2.

This is the formula of Knox [138, eq. 4], written there with the weight per solid angle $w^{-1} = N_\ell$ and a Gaussian beam, $T_\ell^2 \to e^{-\ell^2\sigma_b^2}$. The cosmology notes reach it as the inverse square root of the Fisher information of C_ℓ, with the window $W_\ell = B_\ell^2$ (see the cosmology notes). With no noise it is the cosmic variance of Chapter 7. Knox also explained the factor $2/(2\ell+1)$ in words: the error on a variance measured from n Gaussian samples is $2\sigma^4/n$, however precisely each sample is measured, and the sky offers $2\ell + 1$ samples at each ℓ [Knox1995 p. 8].

Where the variance comes from. Squaring the bracket in (8.29) splits the variance into three terms,

$$\operatorname{Var}\big(\widehat{C}_\ell\big) = \frac{1}{2\ell+1}\Big[\underbrace{2C_\ell^2}_{\text{sky}} + \underbrace{4\,C_\ell\,\frac{N_\ell}{T_\ell^2}}_{\text{sky}\times\text{noise}} + \underbrace{2\Big(\frac{N_\ell}{T_\ell^2}\Big)^2}_{\text{noise}}\Big]. \tag{8.30}$$

The first is the cosmic variance, which no instrument can remove. The last is the scatter of the noise power itself, which would be there with no sky at all. The middle one is easy to overlook. Each observed coefficient is a sum of a sky part and a noise part, so $|d_{\ell m}|^2$ contains the product of the two. That product averages to zero, which is why it did not appear in the bias (8.19), but it fluctuates, and its fluctuation is the cross term.

Example: when does the noise supply half the variance? Write $r = N_\ell/(T_\ell^2 C_\ell)$ for the noise-to-signal ratio on the sky. The two terms of (8.30) that involve the noise make up half of the total when

$$4r + 2r^2 = \tfrac{1}{2}\big(2 + 4r + 2r^2\big) \overset{(1)}{=} r^2 + 2r - 1 = 0 \overset{(2)}{=} r = \sqrt{2} - 1 \approx 0.41.$$

(1) Divide (8.30) by $C_\ell^2/(2\ell+1)$, multiply out and collect terms.
(2) The positive root of the quadratic.

The noise already supplies half the variance when its power on the sky is 41% of the signal, well before the two powers are equal. At equality, $r = 1$, the noise terms are $6/8 = 75\%$ of the variance. In the toy experiment of Section 8.2.2 (a 30′ beam and 200 μK arcmin of white noise on $N_{\rm side} = 256$ pixels) the two powers cross at $\ell_{\rm eq} = 436$, but the noise supplies half the variance from $\ell = 386$ onward.

Example: the error bar at three multipoles. At $\ell = 300$ the cosmic variance alone gives a fractional error $\sqrt{2/601} = 5.8\%$, and the noise, with $r = 0.05$, raises it to 6.0%. At $\ell = 512$ the cosmic variance gives $\sqrt{2/1025} = 4.4\%$, but $r = 3.0$ multiplies it by $1 + r$, to 18%: the factor of four of the opening paragraph. At $\ell = 700$, beyond the analysed band, $r = 246$ and the fractional error is 9.33, nearly a thousand per cent. The right panel of Figure 8.6 plots the whole curve.

The smallest possible width. Is there a better estimator? The Cramér–Rao bound of Chapter 3 says no unbiased estimator can have a variance below one over the Fisher information, $I(C_\ell) = \big\langle \partial^2(-\ln \mathcal{L})/\partial C_\ell^2 \big\rangle$. With $-\ln\mathcal{L} = \frac{\nu}{2}\big[\widehat{C}_\ell^{\,\rm obs}/V_\ell + \ln V_\ell\big]$ + const from (8.22), and $\partial V_\ell/\partial C_\ell = T_\ell^2$,

$$\frac{\partial(-\ln\mathcal{L})}{\partial C_\ell} \overset{(1)}{=} \frac{\nu}{2}\,T_\ell^2\Big[-\frac{\widehat{C}_\ell^{\,\rm obs}}{V_\ell^2} + \frac{1}{V_\ell}\Big],$$

$$I(C_\ell) \overset{(2)}{=} \frac{\nu}{2}\,T_\ell^4\Big[\frac{2\langle\widehat{C}_\ell^{\,\rm obs}\rangle}{V_\ell^3} - \frac{1}{V_\ell^2}\Big] \overset{(3)}{=} \frac{\nu\,T_\ell^4}{2V_\ell^2} \overset{(4)}{=} \frac{2\ell+1}{2\,(C_\ell + N_\ell/T_\ell^2)^2}. \tag{8.31}$$

(1) Chain rule on both terms.
(2) Differentiate once more (again $\partial V_\ell/\partial C_\ell = T_\ell^2$) and average over the data.
(3) $\langle\widehat{C}_\ell^{\,\rm obs}\rangle = V_\ell$ by (8.19), so the bracket is $1/V_\ell^2$.
(4) $V_\ell/T_\ell^2 = C_\ell + N_\ell/T_\ell^2$.

One over (8.31) is exactly (8.29). The debiased estimator reaches the bound: on the full sky with uniform white noise it extracts every bit of information about C_ℓ that the map contains. Whatever an estimator on a masked sky loses is measured against this number.

8.4.1 The shape of the distribution

The width is not the whole story; the likelihood of Chapter 9 needs the full distribution. It follows from the same bookkeeping that gave the width (8.29) and the bound (8.31). There, the $\nu = 2\ell + 1$ real numbers u_k at one ℓ were independent Gaussians of variance $V_\ell = T_\ell^2 C_\ell + N_\ell$, so $X \equiv \sum_k u_k^2/V_\ell = \nu\,\widehat{C}_\ell^{\,\rm obs}/V_\ell$ is a χ^2_ν variable. Solve for $\widehat{C}_\ell^{\,\rm obs} = V_\ell X/\nu$ and insert it in the estimator

(8.20), with the noise-to-signal ratio $r_\ell \equiv N_\ell/(T_\ell^2 C_\ell)$ of Section 8.4:

$$\frac{\widehat{C}_\ell}{C_\ell} \overset{(1)}{=} \frac{\widehat{C}_\ell^{\,\mathrm{obs}} - N_\ell}{T_\ell^2 C_\ell} \overset{(2)}{=} \frac{V_\ell}{\nu\, T_\ell^2 C_\ell}\, X - \frac{N_\ell}{T_\ell^2 C_\ell}$$
$$\overset{(3)}{=} A_\ell\, X - r_\ell, \qquad X \sim \chi^2_{2\ell+1}, \qquad A_\ell = \frac{1+r_\ell}{2\ell+1}. \tag{8.32}$$

(1) The definition (8.20), divided by C_ℓ.
(2) $\widehat{C}_\ell^{\,\mathrm{obs}} = V_\ell X/\nu$.
(3) $V_\ell/(T_\ell^2 C_\ell) = 1 + N_\ell/(T_\ell^2 C_\ell) = 1 + r_\ell$, and $\nu = 2\ell + 1$.

The debiased estimator is a scaled and shifted χ^2. Its variance closes the loop with the previous subsection: $\mathrm{Var}(\widehat{C}_\ell/C_\ell) = A_\ell^2\,\mathrm{Var}(X) = A_\ell^2\, 2\nu = 2(1+r_\ell)^2/(2\ell+1)$, so $\mathrm{Var}(\widehat{C}_\ell) = 2(C_\ell + N_\ell/T_\ell^2)^2/(2\ell+1)$, which is (8.29) and one over the Fisher information (8.31). The distribution (8.32) is the full shape whose width sits exactly on the Cramér–Rao bound. The appendix of Knox [138] derives the same density (his eqs. 31–33). Two features follow at once. At low ℓ, ν is small and the χ^2 is visibly skewed. How skewed follows from its cumulants. A χ^2_ν is a sum of ν independent squared standard Gaussians, cumulants of independent terms add, and each square contributes $\kappa_k = 2^{k-1}(k-1)!$; so $\kappa_k = 2^{k-1}(k-1)!\,\nu$ for the sum, as derived in (7.100). The skewness is the third cumulant over the variance to the power $3/2$,

$$\frac{\kappa_3}{\kappa_2^{3/2}} = \frac{8\nu}{(2\nu)^{3/2}} = \sqrt{\frac{8}{\nu}}, \qquad \text{and likewise the excess kurtosis is} \qquad \frac{\kappa_4}{\kappa_2^2} = \frac{48\nu}{(2\nu)^2} = \frac{12}{\nu}. \tag{8.33}$$

Scaling and shifting the variable, as in (8.32), changes neither ratio. The skewness is 1.07 at $\ell = 3$. And the shift $-r_\ell$ moves part of the distribution below zero. The estimate is negative whenever the observed power happens to fall below the noise power, $X < \nu\, r_\ell/(1+r_\ell)$, which becomes likely once r_ℓ is large.

Example: how often is the estimate negative? At $\ell_{\mathrm{eq}} = 436$, where $r_\ell = 1$, a negative estimate needs $X < \nu/2$, a χ^2_{873} variable more than ten standard deviations below its mean: the probability is 4×10^{-38}. At $\ell = 700$, $r_\ell = 246$ and the threshold $\nu r_\ell/(1+r_\ell)$ sits within a fraction of a standard deviation of the mean ν. The probability of a negative estimate is then 46% (Figure 8.8, right). A negative $\widehat{C}_\ell$ there is not a sign of a bug. The measurement simply contains almost no signal, and the unbiased estimator has to straddle zero.

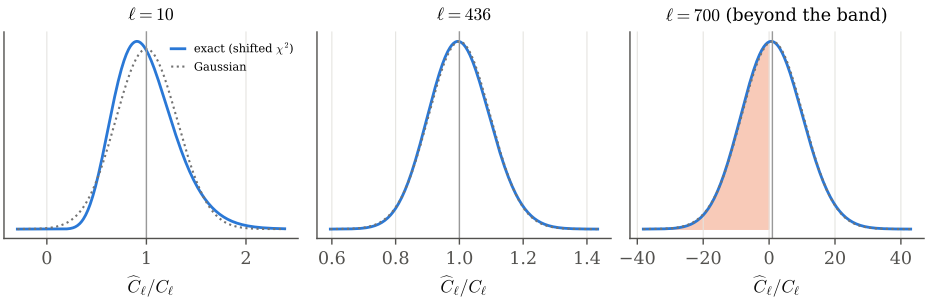

Figure 8.8: The exact distribution of $\widehat{C}_\ell/C_\ell$ for the toy experiment at three multipoles (blue), with the Gaussian of the same mean and width (dotted). At $\ell = 10$ the χ^2 is skewed, with its peak below the mean. At $\ell = 436$ it is close to Gaussian and safely positive. At $\ell = 700$, outside the analysed band, it is a broad Gaussian centred on 1, almost half of which (orange) lies below zero.

8.4.2 Knox's formula on part of the sky

Knox's formula was derived for a complete sky. Every real temperature analysis cuts away the Galaxy, and every ground or balloon experiment sees a patch. The approximation used everywhere for that case divides the variance by the observed sky fraction f_{sky} and, when $\Delta\ell$ neighbouring multipoles are averaged into one bin, by $\Delta\ell$ as well:

$$\sigma\big(\widehat{C}_b\big) \approx \sqrt{\frac{2}{(2\ell+1)\,\Delta\ell\, f_{\mathrm{sky}}}}\left(C_\ell + \frac{N_\ell}{T_\ell^2}\right) \tag{8.34}$$

[Hivon (16)–(17)], [141, eq. 33] (see also the cosmology notes). Each of its two new factors comes from one move applied to the full-sky error (8.29).

- *The bin.* The binned estimate $\widehat{C}_b$ is the plain average of the $\Delta\ell$ values $\widehat{C}_\ell$ in the bin. On the full sky they are independent, so their variances add, and the $1/\Delta\ell$ of the average comes out squared: $\mathrm{Var}(\widehat{C}_b) = \Delta\ell^{-2}\sum_{\ell\in b}\mathrm{Var}(\widehat{C}_\ell)$. If the spectrum changes little across the bin, the $\Delta\ell$ terms are all about equal, the sum is $\Delta\ell$ times one of them, and $2/(2\ell+1)$ becomes $2/[(2\ell+1)\Delta\ell]$.
- *The sky fraction.* The factor $2/(2\ell+1)$ is $2/\nu$, with ν the number of independent modes. A patch covering a fraction f_{sky} of the sky is taken to carry that fraction of the modes, $\nu \to \nu\, f_{\mathrm{sky}}$, which divides the variance by f_{sky}.

The same two moves are written out as labelled chains where we reproduce the papers that use the formula: (8.41) for the bin, (8.40) for the sky fraction. Hivon et al. [140] add a factor w_2^2/w_4 to f_{sky} for a weighted mask, where w_i is the sky average of the i-th power of the mask over the observed region [Hivon (17)].

The plain claim is: *observing half the sky doubles the variance*. The everyday question behind it is, how many independent numbers does a patch of sky provide at multipole ℓ? On the full sky the answer is $2\ell+1$, one per m, and they are independent, which is why the error is $\sqrt{2/(2\ell+1)}$. The formula assumes that a fraction f_{sky} of the sky provides the same fraction of independent numbers, $(2\ell+1)f_{\mathrm{sky}}$, and that each still belongs to a single ℓ. That is the hidden assumption: the modes on the patch are taken to be as clean as on the full sky, only fewer.

It cannot be literally true, and three short moves show why. First, the observed map is the sky times the mask, $s(\hat{\boldsymbol{n}})M(\hat{\boldsymbol{n}})$, with $M = 1$ inside the patch and 0 outside. Second, expand both factors in spherical harmonics. A product $Y_{\ell'm'}Y_{LM}$ is again a sum of spherical harmonics, but of every degree from $|\ell' - L|$ to $\ell' + L$ (the rule for adding angular momenta), so a coefficient of degree ℓ of the cut map collects sky coefficients $a_{\ell'm'}$ from every ℓ' that differs from ℓ by a degree L present in the mask. A patch of angular size θ_{p} has its harmonic content concentrated at $L \lesssim \pi/\theta_{\mathrm{p}}$, so each ℓ of the cut map mixes the sky over a width $\Delta\ell_c \sim \pi/\theta_{\mathrm{p}}$ around it. Third, two neighbouring multipoles of the cut map then share sky modes and are correlated; the power of one ℓ is spread over its neighbours. This is called **mode coupling** [Hivon (14)]. The modes on a patch are shared between multipoles, so the counting is right only on average over a bin wider than $\Delta\ell_c$, which is why the formula comes with a bin width $\Delta\ell$. The coupling is computed exactly for the masked sky in Section 8.10.1.

Example: the counting fails where there is less than one mode. Hivon et al.'s test region covers $f_{\mathrm{sky}} = 1.82\%$ of the sky [Hivon §4.1]. For the quadrupole, $(2\ell+1)f_{\mathrm{sky}} = 0.09$: the formula claims a tenth of one mode and an error bar $\sqrt{2/0.09} \approx 4.7$ times the signal. A patch $40^\circ \times 24^\circ$ cannot contain a single wavelength of the quadrupole, so it cannot tell a quadrupole from a

dipole or from an $\ell = 3$ pattern. The question "how well is C_2 measured?" has no separate answer there, and no counting rule can supply one. Efstathiou [141] shows by comparing with the exact maximum-likelihood Fisher matrix that the $f_{\rm sky}$ formula fails at low ℓ even for large sky fractions.

Example: the counting works where there are many. In the same region, take a bin of $\Delta\ell = 50$ around $\ell = 200$. The number of modes is $(2 \cdot 200 + 1) \times 50 \times 0.0182 = 365$, and (8.34) gives a fractional error of $\sqrt{2/365} = 7.4\%$ on the signal-dominated bin. With the cosine-apodised weighting of their Table 1, $w_2^2/w_4 = 0.514$, the count drops to 188 and the error rises to 10.3%. Hivon et al. found that their simulated error bars match this rule of thumb almost exactly [Hivon (36), §4.2].

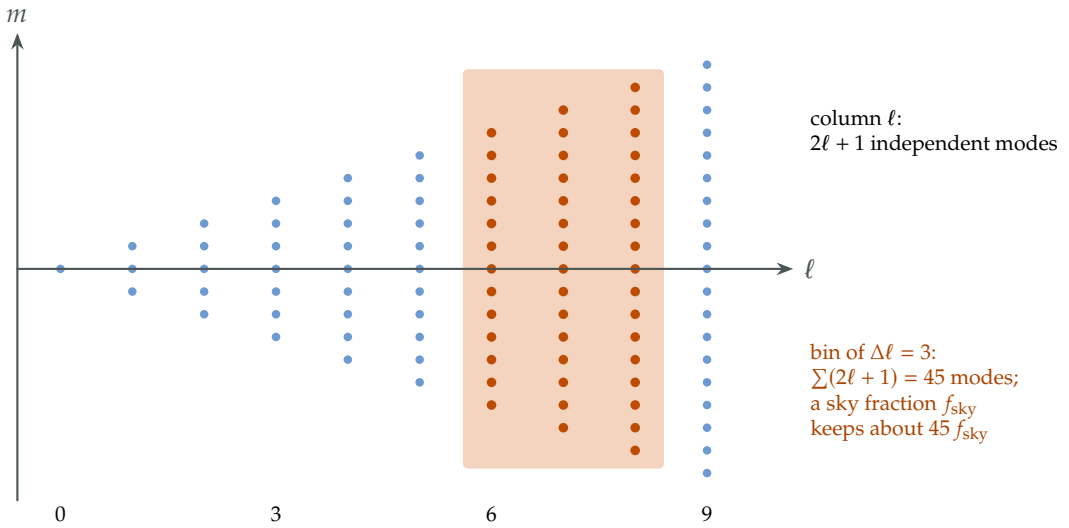

Figure 8.9: Counting modes. Each dot is one independent number on the full sky, one per (ℓ, m); column ℓ has $2\ell + 1$ of them. A bin of $\Delta\ell$ multipoles (orange) contains about $(2\ell + 1)\Delta\ell$. The $f_{\rm sky}$ rule assumes that a patch of sky keeps the fraction $f_{\rm sky}$ of these dots, each still in its own column. A mask actually smears every dot over neighbouring columns, so the rule can hold only for bins wider than the smearing.

Watch out: The $f_{\rm sky}$ formula is a count, not a theorem

Equation (8.34) counts modes. It is reliable only for bins that contain many modes and are wider than the coupling a mask induces between multipoles. At low ℓ, for small patches, and for the correlations between neighbouring bins, it says nothing; there the covariance must come from simulations or from the exact mode-coupling matrix of the masked sky [Hivon §3.1].

8.4.3 Signal-to-noise, per multipole and in total

How well does each multipole measure the spectrum? The natural number is the **signal-to-noise per multipole**, the spectrum divided by its own error bar, from (8.29):

$$\mathrm{SNR}_\ell \equiv \frac{C_\ell}{\sigma(\widehat{C}_\ell)} = \sqrt{\frac{2\ell+1}{2}}\,\frac{C_\ell}{C_\ell + N_\ell/T_\ell^2} = \sqrt{\frac{2\ell+1}{2}}\,\frac{1}{1+r_\ell}. \tag{8.35}$$

With no noise it grows as $\sqrt{\ell}$, because higher multipoles have more modes. The noise cuts it by the factor $1/(1 + r_\ell)$, which falls exponentially once the beam has turned the sky down.

Between these two behaviours there is a best multipole. For the toy experiment it is $\ell = 314$, with $\mathrm{SNR}_\ell = 16.6$; at ℓ_{eq} the value has fallen to 10.4 (Figure 8.10, left).

A second question is how well all multipoles together measure the spectrum. Since one number per ℓ is too much to summarise, ask about the simplest possible change of the spectrum: an overall amplitude, $C_\ell = A\, C_\ell^{\mathrm{fid}}$ with $A = 1$ for the true sky. Each multipole gives an independent unbiased estimate of A, namely $\widehat{C}_\ell / C_\ell^{\mathrm{fid}}$, with variance $1/\mathrm{SNR}_\ell^2$. Independent estimates of one number are best combined with weights proportional to their inverse variances (Chapter 3):

$$\hat{A} = \frac{\sum_\ell \mathrm{SNR}_\ell^2 \, \widehat{C}_\ell / C_\ell^{\mathrm{fid}}}{\sum_\ell \mathrm{SNR}_\ell^2},$$

$$\mathrm{Var}(\hat{A}) \overset{(1)}{=} \frac{\sum_\ell \mathrm{SNR}_\ell^4 \, \mathrm{Var}(\widehat{C}_\ell / C_\ell^{\mathrm{fid}})}{\left(\sum_\ell \mathrm{SNR}_\ell^2\right)^2} \overset{(2)}{=} \frac{\sum_\ell \mathrm{SNR}_\ell^2}{\left(\sum_\ell \mathrm{SNR}_\ell^2\right)^2} = \frac{1}{\sum_\ell \mathrm{SNR}_\ell^2}. \tag{8.36}$$

(1) The terms are independent (different ℓ on the full sky), so variances add, each multiplied by the square of its weight.

(2) $\mathrm{Var}(\widehat{C}_\ell / C_\ell^{\mathrm{fid}}) = 1/\mathrm{SNR}_\ell^2$ by the definition (8.35).

Working definition 8.3 (cumulative signal-to-noise)

$$\mathrm{SNR}(\leq \ell_{\mathrm{max}}) \equiv \left[\sum_{\ell=2}^{\ell_{\mathrm{max}}} \mathrm{SNR}_\ell^2\right]^{1/2} = \left[\sum_{\ell=2}^{\ell_{\mathrm{max}}} \frac{2\ell+1}{2} \frac{1}{(1+r_\ell)^2}\right]^{1/2}$$

[the number of standard deviations by which the spectrum up to ℓ_{max} is detected, if only its overall amplitude is fitted]. *Operationally:* one over the error of the amplitude $\hat{A}$ of (8.36).

The same sum appears in Hamimeche and Lewis [16, eq. 21] as the measure of how much information a noisy spectrum carries. It is a sum of squares, so each multipole adds its SNR_ℓ^2, and a multipole whose SNR_ℓ has dropped below one adds almost nothing.

Example: where adding multipoles stops helping. With no noise, $\mathrm{SNR}(\leq \ell_{\mathrm{max}})^2 = \sum_{\ell=2}^{\ell_{\mathrm{max}}} (2\ell+1)/2 = [(\ell_{\mathrm{max}}+1)^2 - 4]/2$, so that $\mathrm{SNR}(\leq 512) = 363$, and the square keeps growing like ℓ_{max}^2. With the beam and the noise of the toy experiment, the sum reaches 280 at $\ell = 512$, and 281 at $\ell = 767$, the largest multipole the $N_{\mathrm{side}} = 256$ maps can hold, where the cosmic-variance limit would be 543. The last 255 multipoles add one unit. Ninety per cent of the final value is already reached at $\ell = 378$ (Figure 8.10, right). This is the sense in which the beam sets the reach of an experiment: beyond a few ℓ_{eq} there is nothing left to measure, whatever the number of pixels.

8.5 The Monte Carlo machine

Three formulas now describe the full-sky estimator: its mean (8.19), its variance (8.29) and its distribution (8.32). Each was derived under assumptions: a Gaussian sky, a circular beam, white noise, transforms that are exact on the pixel grid. A simulation makes none of these assumptions on our behalf. It does to fake skies exactly what the instrument and the analysis do to the real one, thousands of times, and reads the statistics off the results. On the full sky the outcome must reproduce the three formulas, and a disagreement means a mistake in a formula or in the code. Once the two agree, the same machine can be pointed at the masked sky, where

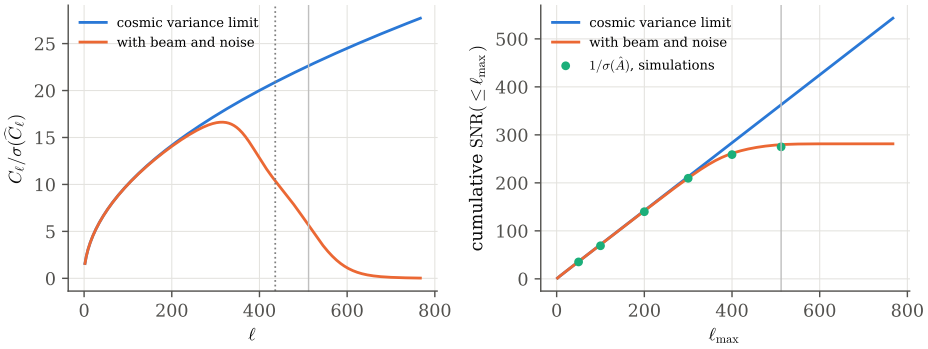

Figure 8.10: Signal-to-noise of the toy experiment. Left: per multipole, against the cosmic-variance limit $\sqrt{(2\ell+1)/2}$ (blue). The noise turns the curve over at $\ell = 314$, before the power equality $\ell_{\rm eq}$ (dotted); the grey line, in both panels, marks the analysed limit $\ell = 512$. Right: cumulative, up to $\ell_{\rm max}$. Without noise it would keep rising; with the beam and the noise it saturates. The green dots are $1/\sigma(\hat{A})$ measured on the simulated skies of Section 8.6.

no formula is exact. This is step 5 of the estimator recipe of Chapter 3, carried out with the Monte Carlo tools of Chapter 6.

The question to answer before writing any code is: what must be simulated for the simulated $\widehat{C}_\ell$ to have the same distribution as the $\widehat{C}_\ell$ we would compute from the real map? Two kinds of ingredient enter the real $\widehat{C}_\ell$. The random ones, the sky and the noise, must be drawn afresh from their distributions for every simulated sky. The deterministic ones, the beam, the pixels, the transforms, the noise subtraction and the deconvolution, must be applied exactly as they would be to the data, with the same code. Anything left out of the simulation is assumed to have no effect on $\widehat{C}_\ell$.

Working definition 8.4 (Monte Carlo of an observed spectrum)

For $i = 1, \ldots, N_{\rm sim}$, with independent random numbers each time:

1. draw a Gaussian sky $a_{\ell m}$ from the fiducial C_ℓ, up to $\ell = 3N_{\rm side} - 1$;
2. multiply by the transfer function, $a_{\ell m} \to T_\ell a_{\ell m}$, and synthesise the map;
3. add an independent Gaussian number of variance σ_p^2 to every pixel;
4. analyse the map exactly as the data: transform, average $|d_{\ell m}|^2$ over m, subtract N_ℓ, divide by T_ℓ^2;
5. store the spectrum $\widehat{C}_\ell^{(i)}$, not the map.

Operationally: the sample mean, sample variance and histogram of $\{\widehat{C}_\ell^{(i)}\}$ estimate the mean, variance and distribution of $\widehat{C}_\ell$ [to a precision set by $N_{\rm sim}$, which is itself computed, Section 8.6].

Figure 8.11 draws the loop. Each step deserves the question: why is it legitimate?

Step 1: the sky. A statistically isotropic Gaussian sky is completely specified by its spectrum (Chapter 7): the $a_{\ell m}$ are independent, $a_{\ell 0} \sim \mathcal{N}(0, C_\ell)$ is real, and for $m > 0$ the real and imaginary parts are independent $\mathcal{N}(0, C_\ell/2)$, with $a_{\ell,-m} = (-1)^m a_{\ell m}^*$ fixing the negative m; after the rescaling of (8.21) these are $2\ell + 1$ independent $\mathcal{N}(0, C_\ell)$ numbers. Drawing those numbers

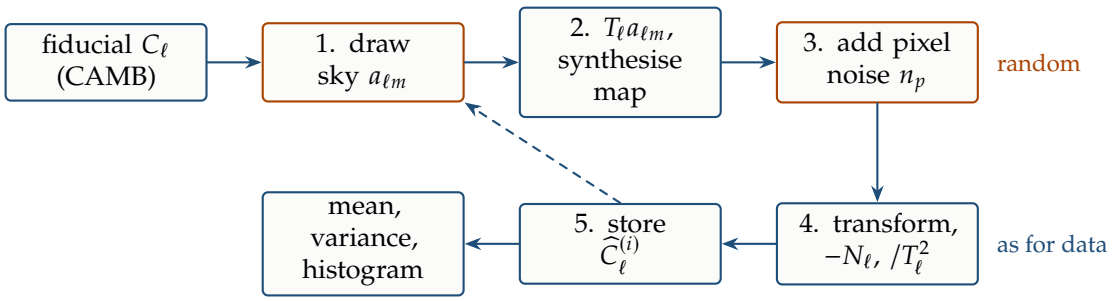

Figure 8.11: The Monte Carlo loop. The two orange steps draw random numbers, the sky and the noise, afresh for every simulated sky. The blue steps are deterministic and identical to what is done to the real map. The dashed line closes the loop; only the spectra leave it, and their statistics are compared with the formulas of the previous sections.

is therefore a correct draw of a whole sky. We draw them with our own generator rather than `healpy.synalm`, so that every random number goes through the reproducible stream `rng_for("ch08", ...)` (Chapter 6):

Listing 8.1: Drawing one Gaussian sky (`code/ch08/lib_cmbsim.py`)

```
159 def synalm(cl, lmax: int, rng: np.random.Generator) -> np.ndarray:
160     """Gaussian a_lm (healpy m >= 0 layout) with <|a_lm|^2> = C_l, from our own generator.
161
162     a_l0 ~ N(0, C_l) is real; for m > 0, Re and Im ~ N(0, C_l/2) independently.
163     """
164     ell, m = hp.Alm.getlm(lmax)
165     sig = np.sqrt(np.asarray(cl, dtype=float)[ell])
166     re = rng.standard_normal(ell.size)
167     im = rng.standard_normal(ell.size)
168     return np.where(m == 0, sig * re, sig * (re + 1j * im) / np.sqrt(2.0)).astype(complex)
```

Line 165 picks the standard deviation $\sqrt{C_\ell}$ for every stored coefficient; line 168 uses the real part alone for $m = 0$ and divides the complex draw by $\sqrt{2}$ for $m > 0$, so that $\langle |a_{\ell m}|^2 \rangle = C_\ell$ in both cases. With $\ell \le 767$ there are $768 \times 769/2 = 295\,296$ stored coefficients per sky.

Step 2: the instrument. The convolution theorem (Section 8.2.1) makes the beam a multiplication of each $a_{\ell m}$ by B_ℓ; the pixel window is applied the same way, as a factor p_ℓ. The function `observe_signal` is two lines: `almxfl` multiplies by $T_\ell = B_\ell p_\ell$, and `alm2map` synthesises the $N_{\mathrm{side}} = 256$ map. One simplification hides here. A real map averages the beamed sky over each pixel, and HEALPix pixels have slightly different shapes, so p_ℓ is only the sky-averaged effect [7]. Applying it as an exact factor assumes every pixel has the average shape. The error this makes is far below the precision of anything we measure, but a real pipeline that cared about it would simulate the pointing and the pixelisation instead [Hivon §3.2].

Step 3: the noise. Independent Gaussian pixel noise is drawn with the depth of the experiment, $\sigma = 14.6\,\mu\mathrm{K}$ per pixel. To test the cross-spectrum of Section 8.3.3 on the same skies, each simulation draws two half-mission noise maps $n^{(1)}, n^{(2)}$, each with variance $2\sigma^2$ because each half has half the observing time. The full-mission noise is their average, $(n^{(1)} + n^{(2)})/2$, of variance σ^2, which is exactly how co-adding two halves of a real mission works. A further noise map with the pole-heavy variance pattern of Section 8.2.2 tests inhomogeneous noise.

Step 4: the analysis. The map is transformed back with `healpy.map2alm` up to $\ell = 512 = 2N_{\rm side}$, the range in which the pixel quadrature reproduces the orthogonality of the $Y_{\ell m}$ (Chapter 7). The transform of a pixel map is a quadrature, not an exact integral, and healpy can refine it iteratively. Three iterations make the signal transform accurate to about 10^{-5}; for white noise, whose power fills every multipole up to the pixel scale, one iteration already reproduces its spectrum to the Monte Carlo precision, so the noise maps use one. Then `alm2cl` averages over m and `debias` applies (8.20).

One sky, seven observations. The loop of `simulate` does all of this, and it observes each simulated sky in seven ways at once:

Listing 8.2: The Monte Carlo loop (`code/ch08/lib_cmbsim.py`)

```
229     for i in range(nsim):
230         a = synalm(cl[: exp.lmax_sim + 1], exp.lmax_sim, rng)
231         s = observe_signal(a, exp)
232         n1 = noise_map(exp, rng, scale=np.sqrt(2.0))          # half-mission noise,
    variance 2 sigma^2
233         n2 = noise_map(exp, rng, scale=np.sqrt(2.0))
234         a_s = map2alm(w * s, L, iter_signal)
235         a_1 = map2alm(w * n1, L, iter_noise)
236         a_2 = map2alm(w * n2, L, iter_noise)
237         a_n = 0.5 * (a_1 + a_2)                               # map2alm is linear
238         out["sky"][i] = cross_cl(hp.resize_alm(a, exp.lmax_sim, exp.lmax_sim, L, L))
239         out["sig"][i] = cross_cl(a_s)
240         out["auto"][i] = cross_cl(a_s + a_n)
241         out["cross"][i] = cross_cl(a_s + a_1, a_s + a_2)
242         out["noise"][i] = cross_cl(a_n)
243         if varmap is not None:
244             a_i = map2alm(w * noise_map(exp, rng, varmap=varmap), L, iter_noise)
245             out["inh"][i] = cross_cl(a_s + a_i)
246             out["ninh"][i] = cross_cl(a_i)
```

Lines 234–236 make one signal transform and two half-noise transforms. Because a transform is linear, the full-mission noise needs no transform of its own (line 237), and every spectrum in lines 238–242 is formed from these three sets of coefficients: the sky itself (`sky`, cosmic variance only), the beamed sky without noise (`sig`), the full-mission map (`auto`), the cross-spectrum of the two halves (`cross`) and the noise alone (`noise`); lines 243–246 add the inhomogeneous noise with and without the sky. All seven see the *same* sky. When two estimators are compared on the same simulated skies, the sky's own fluctuation is common to both and cancels in their difference, so the difference is measured far more precisely than either one. This is the method of **common random numbers**, and it is why the bias of the cross-spectrum relative to the auto-spectrum can be measured to a fraction of a per cent with a few thousand skies (Figure 8.12).

The driver script. The run itself is a short script:

Listing 8.3: Running and caching the full-sky Monte Carlo (`code/ch08/05_mc_run.py`)

```
11 import sys, pathlib, time
12 sys.path.insert(0, str(pathlib.Path(__file__).resolve().parents[1]))
13 sys.path.insert(0, str(pathlib.Path(__file__).resolve().parent))
14 import numpy as np
15 from common import save_numbers, rng_for
16 from camb_fiducial import load_fiducial
17 import lib_cmbsim as cs
18
19 N_SIM = 2000
```

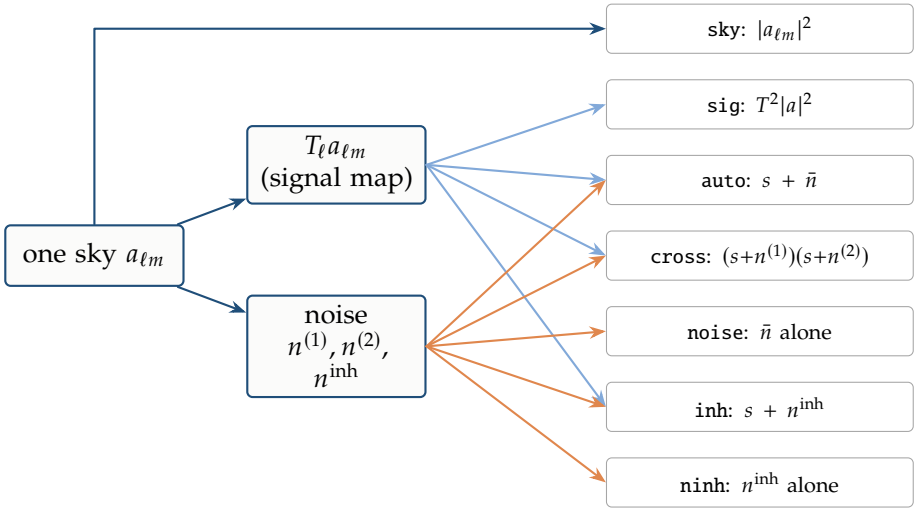

Figure 8.12: Each simulated sky is observed seven ways. Blue lines carry the beamed signal, orange lines the noise; a spectrum fed by both lines contains both. Because the seven spectra share one sky, comparisons between them are free of the sky's own fluctuation.

```
ell, cl = load_fiducial()
exp = cs.Experiment()
varmap = cs.variance_pattern(exp.nside, contrast=4.0)

def make():
    rng = rng_for("ch08", "05_mc_run")
    t0 = time.time()
    d = cs.simulate(exp, cl, N_SIM, rng, varmap=varmap, progress=200)
    d["seconds"] = np.array(time.time() - t0)
    return d

sims = cs.cached("mc_fullsky", make)
secs = float(sims["seconds"])
save_numbers("ch08", "05_mc_run", {
    "EightANsim": N_SIM,
    "EightAMinutes": f"{secs / 60:.0f}",
    "EightASecPerSky": f"{secs / N_SIM:.2f}",
})
print(f"{N_SIM} skies in {secs / 60:.1f} min")
```

The function `cs.cached` runs `make()` once and writes the seven arrays of spectra to the file `mc_fullsky.npz` in `data/ch08/`; every later call reads them back, so the analysis scripts `06`–`10` and `12` all work on the same skies without recomputing them. The run took 6 minutes, 0.19 s per sky, for $N_{\mathrm{sim}} = 2000$.

Example: what the run stores. Seven spectra of 513 multipoles in single precision, for 2000 skies, occupy $7 \times 513 \times 4 \times 2000 \approx 29$ MB. The maps themselves would be 786 432 pixels in double precision, 6.3 MB each, or 88 GB for seven maps of 2000 skies. Storing spectra and not maps is what makes the run fit on a laptop disk; any statistic of $\widehat{C}_\ell$ can still be computed later.

Example: how many skies to plan for. The number of simulations is chosen before the run, from what is to be measured. An error bar estimated from N simulations has a relative Monte Carlo error of $1/\sqrt{2(N-1)}$ (the sampling error of a standard deviation, Chapter 3), so 10%

needs $N = 1 + 1/(2 \times 0.1^2) = 51$ skies. A bias is harder. In a bin of 25 multipoles around $\ell = 400$, one simulated estimate scatters by 1.68%, and the mean of N of them by $1.68\%/\sqrt{N}$; to see a bias of 0.1% at one standard deviation needs $N = (1.68/0.1)^2 \approx 281$ skies. The 2000 skies of the run resolve a bias of about 0.04% per bin.

Example: why $N_{\rm side} = 256$. The resolution must be fine enough to show both regimes of the problem, the cosmic-variance-limited one and the noise-limited one. With a 30′ beam and 200 μK arcmin, the noise takes over at $\ell_{\rm eq} = 436$, inside the trusted range $\ell \le 512$ of $N_{\rm side} = 256$, so this resolution is enough. One pair of transforms there takes 0.04 s on this laptop. The cost grows as $N_{\rm pix}^{3/2} \propto N_{\rm side}^3$: 0.24 s at $N_{\rm side} = 512$, 1.2 s at 1024, and an extrapolated 10 s at 2048, the Planck resolution.

What the laptop version gives up. Each choice above is a reduction of what a research analysis does, and each has a price.

- *Resolution.* Planck analyses its temperature maps at $N_{\rm side} = 2048$ up to $\ell \approx 2500$ [70]; we use $N_{\rm side} = 256$ and $\ell \le 512$. At the same 2000 skies that would take about 19 s per sky, roughly ten hours of the laptop's full processor instead of six minutes, and 0.40 GB per map. The cut keeps 4.2% of the harmonic modes, so a cosmic-variance-limited amplitude would be measured 4.9 times less precisely; the beam was widened to match, so the two regimes of the problem, and every statement about them, are unchanged.
- *Number of simulations.* The Planck 2018 likelihood analysis validates its spectra with, and builds its low-ℓ polarisation likelihood from, 300 end-to-end simulations of the full mission (FFP10) [70]; we use 2000 Gaussian skies. An error bar from 300 simulations carries a Monte Carlo error of 4.1%, ours 1.6%. We can afford more because each of ours is cheap, and we pay for it in realism.
- *Realism of a simulated sky.* An end-to-end simulation generates the timestream of every detector along the real scan, with correlated $1/f$ noise, and runs the real map-maker on it [Hivon §3.2–3.3]; we draw the noise directly in pixels, white and uncorrelated. Our simulations can therefore test only what this model contains: the stripes, the filtering and the noise correlations of a real map are absent.
- *Beam.* Real effective beams are measured on planets, are not circular, and carry their own uncertainty; ours is an exact circular Gaussian. Suppose the beam used in the analysis is wrong by a small fraction $\epsilon = \delta B_\ell / B_\ell$. The estimator $\widehat{C}_\ell = (\widehat{C}_\ell^{\rm obs} - N_\ell)/T_\ell^2$ then divides by $B_\ell^2(1+\epsilon)^2$ instead of B_ℓ^2, which multiplies the estimate by $(1+\epsilon)^{-2} \approx 1 - 2\epsilon$: a relative bias of $-2\,\delta B_\ell / B_\ell$, an effect this pipeline cannot show.

Section 8.8 sets these choices beside the full analysis step by step.

8.6 What the simulations show

The run of Section 8.5 produced 2000 simulated skies of the toy experiment: a 30′ Gaussian beam, $N_{\rm side} = 256$ pixels, 200 μK arcmin of white noise, the Planck 2018 fiducial spectrum. Each sky was observed seven ways and its spectra were stored up to $\ell = 512$. Every formula of the previous sections makes a definite prediction for these numbers. We now take the predictions one at a time, in the order of the sub-questions of Section 8.1: the mean, the width, the shape, and the number of simulations it took to know.

8.6.1 The mean: is the bias gone?

The left panel of Figure 8.13 plots the average over the simulations of the raw observed spectrum $\widehat{C}_\ell^{\,\mathrm{obs}}$, the average of $|d_{\ell m}|^2$ over m on the noisy map. It lies on the prediction $T_\ell^2 C_\ell + N_\ell$ of (8.19) at every multipole: on the beamed sky $T_\ell^2 C_\ell$ at low ℓ, on the flat noise N_ℓ at high ℓ. The noise-only maps give the noise power directly, and their average over all multipoles and all simulations is 1.0001 ± 0.0001 times $\sigma^2 \Omega_{\mathrm{pix}}$, confirming (8.16).

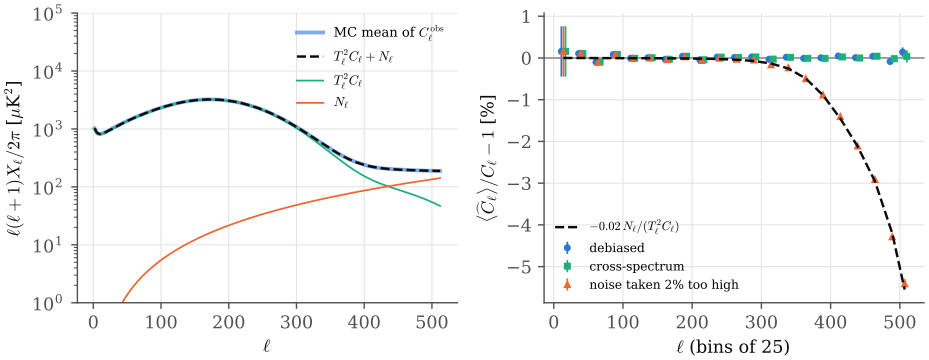

Figure 8.13: The mean of the estimators over 2000 simulated skies. Left: the raw observed spectrum (blue) follows $T_\ell^2 C_\ell + N_\ell$ (dashed), the sum of the beamed sky (green) and the noise (orange). Right: the fractional bias in bins of 25 multipoles. The debiased estimator (blue) and the cross-spectrum of the two half maps (green) scatter around zero within their Monte Carlo error bars. Subtracting a noise level that is 2% too high (orange) produces the negative bias predicted by (8.24) (dashed).

The real test is the debiased estimator (8.20), plotted as a fractional bias in 21 bins of 25 multipoles in the right panel. Its points scatter around zero, the largest by 0.16%, with typical Monte Carlo error bars of 0.04%. Is that zero? Say what was observed: 21 small deviations from zero, each measured with a known Monte Carlo error. What could have produced them? Either the estimator is unbiased and the deviations are the fluctuation of a finite set of simulations, or there is a real bias. Only the first hypothesis predicts how large the deviations should be, so it is the null hypothesis of Chapter 4: if it is true, each deviation divided by its error is a standard Gaussian, and the sum of their squares is a χ^2 variable with 21 degrees of freedom. The observed sum is 20.5. The question is then whether a value this large, or larger, would be unremarkable if there were no bias, and the answer is yes: the probability is $p = 0.49$. The simulations see no bias at the level of 0.04% per bin. The cross-spectrum, with no noise subtracted at all, passes the same test with $\chi^2 = 15.5$ ($p = 0.79$), as (8.26) predicted.

Example: three ways to get it wrong. The same simulations show what the corrections are worth, because the wrong estimators can be computed from the same stored spectra.

- *No noise subtraction.* The bias is +0.16% in the first bin, where the noise is negligible, and +278% in the last, close to the $N_\ell/(T_\ell^2 C_\ell) \approx 3.0$ of Section 8.3.

- *Pixel window forgotten.* Dividing by B_ℓ^2 instead of $B_\ell^2 p_\ell^2$ leaves the factor p_ℓ^2 in the estimate. In the last bin that is a bias of −31%, the 32% power suppression computed in Section 8.2.1.

- *Noise level 2% too high.* The last bin is biased by −5.4%; the prediction $-0.02\, N_\ell/(T_\ell^2 C_\ell)$ of (8.24), averaged over the bin, is −5.5%.

8.6.2 The width: does the variance follow the formula?

For each multipole, divide the sample variance of the 2000 simulated $\widehat{C}_\ell$ by the prediction (8.29). If the formula is right, the ratio is one up to Monte Carlo error. How large is that error? For Gaussian draws the sample variance of n of them is a scaled χ^2_{n-1}, and the variance $2(n-1)$ of that χ^2 gives it a relative error $\sqrt{2/(n-1)}$ (7.97). A heavier tail than the Gaussian makes occasional draws large, and their squares then move the sample variance further; the fourth moment enters, and the relative error becomes $\sqrt{2/(n-1) + \kappa/n}$, with κ the excess kurtosis of one draw (7.99). Our draws are values of $\widehat{C}_\ell$, a scaled and shifted χ^2_ν, so $\kappa = 12/\nu$ by (8.33). With $\nu = 2\ell + 1$ this is negligible except at the lowest multipoles; at $\ell = 100$ the expected spread of the ratio is 3.2%.

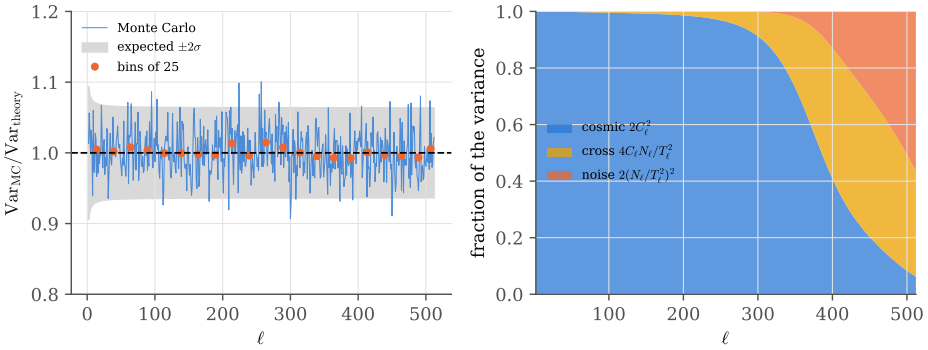

Figure 8.14: The scatter of the debiased estimator. Left: Monte Carlo variance divided by the prediction $2(C_\ell + N_\ell/T_\ell^2)^2/(2\ell+1)$ at every multipole (blue), with the band in which 95% of the points should fall (grey) and bin averages (orange). Right: the share of the three terms of (8.30) in the variance. The cosmic variance (blue) gives way to the sky–noise cross term (yellow) and then to the pure noise term (orange).

The left panel of Figure 8.14 shows the result. Averaged over $\ell = 2$–512, the ratio is 1.001 ± 0.001. The sum of the squared standardised deviations is 498 for 511 multipoles ($p = 0.65$), and 5.1% of the multipoles fall outside the two-standard-deviation band, against the 4.6% expected. The sky-only spectra, observed with no instrument, give a variance ratio of 1.001 against the cosmic variance of Chapter 7. The right panel splits the prediction into the three terms of (8.30). At $\ell = 512$ the pure noise term carries 56% of the variance and the cross term 37%; the noise terms pass half of the total at $\ell = 386$, the multipole where $r_\ell = \sqrt{2} - 1$.

Example: the price of the cross-spectrum. Section 8.3.3 predicted that the cross-spectrum of two half maps, which needs no noise model, scatters more than the auto-spectrum, by the factor $\sqrt{[(S+2N)^2 + S^2]/[2(S+N)^2]}$ with $S = T_\ell^2 C_\ell$ and $N = N_\ell$. Because both estimators are computed on the same simulated skies, the ratio of their scatters is measured with the sky's fluctuation cancelled. Figure 8.15 shows it following the prediction from 1 at low ℓ towards $\sqrt{2}$; at the top of the band the predicted factor is 1.25 and the simulations give 1.24.

Example: the amplitude of the whole spectrum. The cumulative signal-to-noise of Section 8.4.3 predicts that the inverse-variance weighted amplitude $\hat{A}$ of (8.36), built from all multipoles up to 512, has an error $1/\mathrm{SNR}(\le 512) = 0.00358$. On the simulated skies its scatter is 0.00364, with a Monte Carlo error of 1.6%, and its mean is 1.00004 ± 0.00008. The points in the right panel of Figure 8.10 repeat the comparison for other ℓ_{max}.

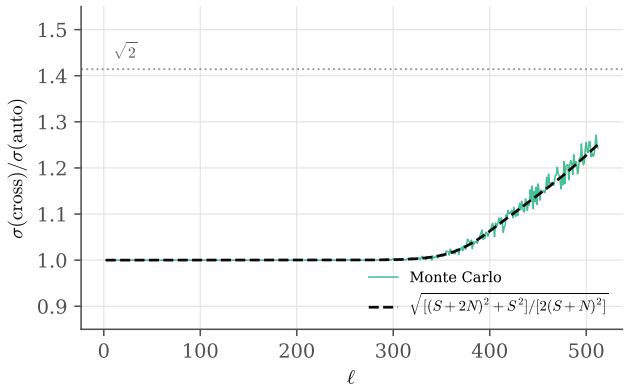

Figure 8.15: Scatter of the cross-spectrum of two half maps divided by that of the auto-spectrum of the full map, on the same simulated skies (green), and the prediction (dashed). The ratio is one where the sky dominates and climbs towards $\sqrt{2}$ (dotted) where the noise does.

8.6.3 The shape: shifted χ^2 or Gaussian?

Figure 8.16 compares the histograms of $\widehat{C}_\ell/C_\ell$ at four multipoles with the shifted, scaled χ^2 of (8.32) and with a Gaussian of the same mean and width. The Kolmogorov–Smirnov test of Chapter 4 measures the largest distance between the cumulative distribution of the simulations and that of a model; its p-values for the shifted χ^2 are 0.09, 0.19, 0.64 and 0.10 at $\ell = 3$, 30, 436 and 512, none of them small. At $\ell = 3$ the measured skewness is 1.07, the χ^2_7 value is 1.07, and the Gaussian, which has no skewness, is rejected with $p = 1 \times 10^{-5}$. By $\ell = 30$ the two models are hard to tell apart by eye, and by ℓ_{eq} they coincide.

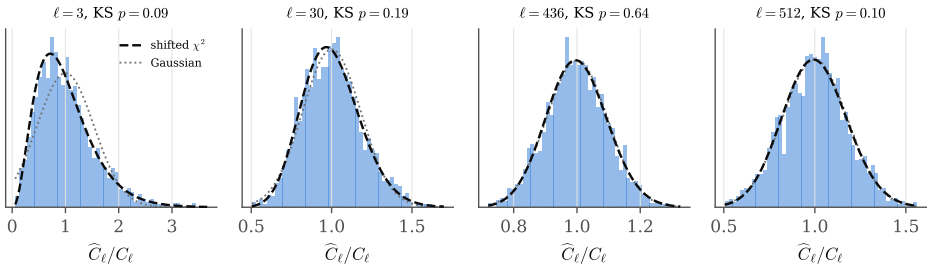

Figure 8.16: Histograms of $\widehat{C}_\ell/C_\ell$ over the simulated skies at four multipoles, with the shifted χ^2 (dashed) and the Gaussian of the same mean and width (dotted). At $\ell = 3$ the distribution is strongly skewed and only the χ^2 follows it; at higher ℓ the two models merge.

8.6.4 When the noise is not uniform

Real scans revisit some parts of the sky more often than others. The simulations include a noise map whose pixel variance follows the pattern $\sigma_p^2 \propto 1/(1 + 4\cos^2\theta)$, the inverse of a hit count that is five times larger at the poles than at the equator, normalised so that its sky average equals the uniform σ^2. The relative variance then runs from 0.36 at the poles to 1.81 at the equator (Figure 8.17, left).

Two predictions were made in Section 8.2.2. The *bias* is Ω_{pix} times the mean pixel variance (8.17), whatever the pattern: the simulations give 0.9999 ± 0.0001 times the uniform value. The *scatter* depends on the full pattern. For the noise alone, write its harmonic covariance $N_{mm'} \equiv \langle n_{\ell m} n^*_{\ell m'} \rangle$ at fixed ℓ, from (8.14). A pattern that depends only on θ does not couple

different m, because the ϕ integral of $e^{i(m'-m)\phi}$ vanishes, so $N_{mm'} = \delta_{mm'} N_{mm}$. The modes are still independent Gaussians, but with different variances N_{mm}, and

$$\operatorname{Var}\Big(\frac{1}{2\ell+1}\sum_m |n_{\ell m}|^2\Big) \overset{(1)}{=} \frac{2}{(2\ell+1)^2}\sum_m N_{mm}^2 \overset{(2)}{\geq} \frac{2}{(2\ell+1)^3}\Big(\sum_m N_{mm}\Big)^2 \overset{(3)}{=} \frac{2\,\bar{N}_\ell^2}{2\ell+1}. \tag{8.37}$$

(1) Each of the $2\ell+1$ real degrees of freedom of mode m is Gaussian with variance set by N_{mm}, so, as in (8.29), each contributes $2N_{mm}^2$; the reality condition $n_{\ell,-m} = (-1)^m n_{\ell m}^*$ pairs m with $-m$ and is already counted in the sum over all m.

(2) Cauchy–Schwarz, $\big(\sum_m 1 \cdot N_{mm}\big)^2 \leq (2\ell+1)\sum_m N_{mm}^2$.

(3) $\bar{N}_\ell = \sum_m N_{mm}/(2\ell+1)$ is the average noise power of (8.17).

The right-hand side is the white-noise variance with the same mean power. Non-uniform noise therefore never decreases the scatter at fixed bias, and increases it by the factor $(2\ell+1)\sum_m N_{mm}^2/(\sum_m N_{mm})^2$, a measure of how unequal the mode variances are. Script `09_inhomogeneous.py` computes N_{mm} exactly for our pattern from (8.14), ring by ring, and predicts a factor 1.053 above $\ell = 100$; the simulations give 1.055. With the sky added, each mode has variance $T_\ell^2 C_\ell + N_{mm}$, the prediction becomes $\sum_m (T_\ell^2 C_\ell + N_{mm})^2$ over its uniform value, 1.030 at $\ell = 512$, and the simulations give 1.024; below $\ell = 100$, where the sky dominates, the ratio is 1.000.

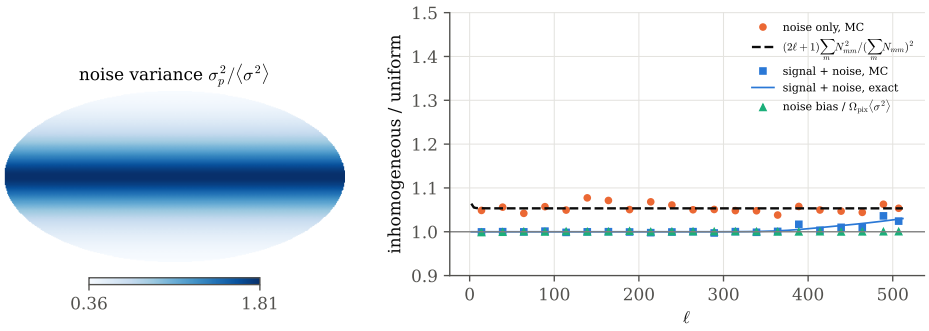

Figure 8.17: Inhomogeneous noise. Left: the relative pixel noise variance of the simulated scan, low at the well-observed poles. Right: inhomogeneous over uniform noise, for the noise bias (green, equal to one), the scatter of the noise spectrum (orange points against the exact prediction, dashed) and the scatter of the full spectrum (blue). The scatter rises by a few per cent only, because each harmonic mode averages the noise over a large part of the sky.

Example: why the increase is only five per cent. A naive guess would be that the variance of the noise spectrum grows like the sky average of σ_p^4 over $\langle\sigma^2\rangle^2$, which for this pattern is 1.230. The exact factor $(2\ell+1)\sum_m N_{mm}^2/(\sum_m N_{mm})^2$ is much closer to one, because N_{mm} is not a pixel variance. By (8.14) it is $N_{mm} = \Omega_{\rm pix}^2 \sum_p \sigma_p^2 |Y_{\ell m}(\hat{\boldsymbol{n}}_p)|^2$: the pixel variance weighted by the mode's own $|Y_{\ell m}|^2$, which integrates to one over the sky, so each N_{mm} is $\Omega_{\rm pix}$ times an average of σ^2 over the sky. Measure σ^2 in units of its sky mean, $\sigma^2(\theta) = c/(1+4\cos^2\theta)$ with $c = 1.81$, and let $x = \cos\theta$.

- The $m = 0$ mode spreads along whole meridians: averaged over its oscillations, $|Y_{\ell 0}|^2$ weights x by $1/(\pi\sqrt{1-x^2})$, which reaches the poles. Writing $x = \sin\phi$ turns the average into $\frac{1}{\pi}\int_0^\pi c\,\mathrm{d}\phi/(1+4\sin^2\phi) = c/\sqrt{5}$, so $N_{00} \approx 0.81$ in these units, although the pole pixels themselves have 0.36.

- The $|m| = \ell$ modes are confined to a narrow band around the equator, so they see only the equatorial value, $N_{\ell\ell} \approx c = 1.81$.
- In between, a mode with $\mu = |m|/\ell$ reaches up to $|x| = \sqrt{1-\mu^2}$, and the same average gives $N_{mm} \approx c/\sqrt{5-4\mu^2}$.

So the mode variances run only from 0.81 to 1.81, while the pixel variances run from 0.36 to 1.81. For large ℓ the m are spread evenly in μ, the sums over m become integrals over μ, and

$$\frac{(2\ell+1)\sum_m N_{mm}^2}{\left(\sum_m N_{mm}\right)^2} \approx \frac{\int_0^1 c^2\,\mathrm{d}\mu/(5-4\mu^2)}{\left[\int_0^1 c\,\mathrm{d}\mu/\sqrt{5-4\mu^2}\right]^2} = \frac{3.262\times 0.323}{1^2} = 1.053,$$

the denominator being one because the average of N_{mm} over m is the sky mean (8.17). This is the exact prediction 1.053 quoted above. The naive $\langle\sigma^4\rangle/\langle\sigma^2\rangle^2$ is larger because it treats every pixel as a separate mode with its own variance; a harmonic mode instead averages many pixels, quiet and noisy together, and only the leftover difference between polar-reaching and equatorial modes counts.

8.6.5 How many simulations did it take?

The last sub-question of Section 8.1 is about the method itself. Figure 8.18 follows the estimates in one bin, $\ell = 400$–424, as the number of simulated skies N grows. The running estimate of the bias wanders inside the envelope $\pm\sigma/\sqrt{N}$, with $\sigma = 1.68\%$ the scatter of one binned estimate. The relative error of the estimated error bar, measured as the spread over 200 random reorderings of the skies, falls as $1/\sqrt{2(N-1)}$: at $N = 107$ it is 6.9%, against the predicted 6.9%. An error bar good to 10% needs about 51 skies, a bias measured to 0.1% about 281.

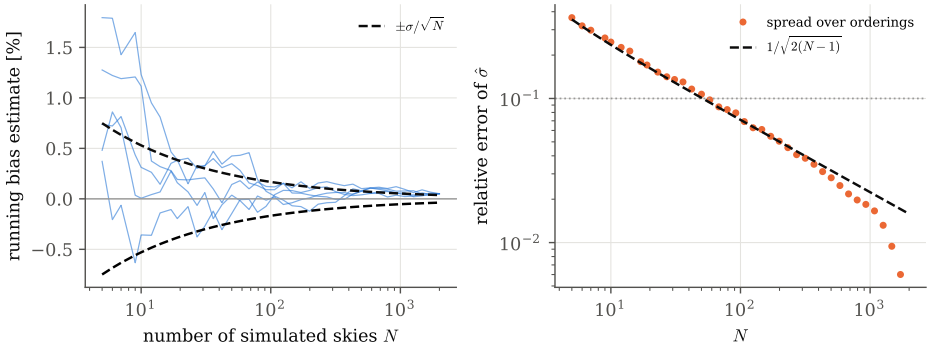

Figure 8.18: Convergence with the number of simulations, in the bin $\ell = 400$–424. Left: five running estimates of the fractional bias, each from a different ordering of the skies, inside the $\pm\sigma/\sqrt{N}$ envelope (dashed). Right: the relative error of the estimated error bar, from the spread over 200 orderings (points), and $1/\sqrt{2(N-1)}$ (dashed); the dotted line marks 10%. Near the 2000 skies available the points drop below the line, because every ordering then draws nearly the same skies.

Key idea: The full-sky verdict

On the full sky with a beam, a pixel window and white or inhomogeneous noise, the simulations reproduce the bias (8.19), the variance (8.29), the distribution (8.32) and the inhomogeneous-noise scatter (8.37), each to its Monte Carlo precision. The machine is therefore trusted where no formula exists.

8.7 Reproducing the literature

Two papers set up the full-sky problem. Knox [138] wrote down the error bar of a spectrum measured from a full-sky map with a Gaussian beam and white noise, and used it to forecast what a satellite could learn about inflation. Hivon et al. [140] built the MASTER method, the pseudo-C_ℓ estimator calibrated by Monte Carlo, and tested it on simulated observations of the Boomerang balloon. Both papers quote numbers that our code can recompute. Agreement is the check that the machine of Section 8.5 measures what the field measures; a disagreement has to be explained, not ignored.

8.7.1 Knox (1995): the error bar of a beamed, noisy map

His question. In 1995 COBE had measured the large-angle anisotropy, and satellites that would map the whole sky at much finer resolution were being proposed. Their promise was to measure C_ℓ out to $\ell \sim 1000$, and through it the shape of the primordial spectrum that inflation predicts. Knox asked how well such a map could actually pin down C_ℓ, given that any real instrument blurs the sky with a beam of finite width and adds detector noise. He wanted one formula that gives the error bar at every ℓ from a few numbers describing the instrument, so that designs could be compared before any of them was built.

His setup. Four ingredients enter, and each has a plain meaning.

- *The sky.* A Gaussian random field with a spectrum C_ℓ from a cosmological model. Knox used the standard cold-dark-matter model of the time, normalised to the quadrupole COBE measured; we use the Planck 2018 best fit (Table 8.1).
- *The beam.* The telescope sees each direction blurred by a Gaussian beam, given by its full width at half maximum (FWHM).
- *The pixel noise.* The map is stored in pixels of solid angle $\Omega_{\rm pix}$, and each pixel carries detector noise of standard deviation $\sigma_{\rm pix}$, independent from pixel to pixel. For a year of observation he took $\sigma_{\rm pix} = 22\,\mu$K in $20' \times 20'$ pixels [Knox1995 p. 7].
- *The sky fraction.* A satellite sees the whole sky, $f_{\rm sky} = 1$.

What he forecasts is the standard deviation ΔC_ℓ of the estimated spectrum at each ℓ, and from it the errors on the inflationary parameters. The noise of a pixel and its size combine into one number, $w^{-1} = \sigma_{\rm pix}^2 \Omega_{\rm pix}$: a pixel twice as large has half the noise variance per unit area, so only this product matters. For his satellite $w^{-1} = 22^2 \times (1/3)^2\,\mu\text{K}^2\,\text{deg}^2$, so $w^{-1/2} = 7.33\,\mu\text{K deg}$; he quotes 7.5, the same number to the precision of his $\sigma_{\rm pix}$.

The sky rms, and the signal-to-noise per pixel. How large is the signal in one pixel, compared with the noise? Knox gives the rms of the sky seen through his $20'$ beam as $92.5\,\mu$K. It follows in three moves. The temperature in direction $\hat{\boldsymbol{n}}$ is the beamed sum of the harmonics, $T(\hat{\boldsymbol{n}}) = \sum_{\ell m} B_\ell a_{\ell m} Y_{\ell m}(\hat{\boldsymbol{n}})$ by the convolution theorem (8.6). The map is real, so $T^2 = TT^*$, and

$$\langle T^2 \rangle \overset{(1)}{=} \sum_{\ell m} \sum_{\ell' m'} B_\ell B_{\ell'} \langle a_{\ell m} a^*_{\ell' m'} \rangle\, Y_{\ell m}(\hat{\boldsymbol{n}}) Y^*_{\ell' m'}(\hat{\boldsymbol{n}}) \overset{(2)}{=} \sum_\ell B_\ell^2 C_\ell \sum_m |Y_{\ell m}(\hat{\boldsymbol{n}})|^2 \overset{(3)}{=} \sum_\ell \frac{(2\ell+1)\, C_\ell\, W_\ell}{4\pi},$$

(1) Multiply the sum by its complex conjugate and average over skies; only the $a_{\ell m}$ are random.
(2) Different (ℓ, m) are uncorrelated and $\langle |a_{\ell m}|^2 \rangle = C_\ell$, so only $\ell' = \ell$, $m' = m$ survives.

	Knox (1995)	ours
cosmology	standard CDM: $h = 0.5$, $\Omega_b h^2 = 0.0125$, no Λ, $n_S = 0.94$, tensors $r = 0.28$, COBE-normalised [Knox1995 p. 4–5]	Planck 2018 best fit
sky fraction	1	1
pixel noise	22 μK in $20' \times 20'$ pixels	the same
noise weight $w^{-1/2}$	7.5 μK deg	7.33 μK deg
beam FWHM	$20'$	$20'$
Fig. 2 experiments	$20'$ and $40'$, $w^{-1/2} = 15$ and 30 μK deg	the same; maps for $w^{-1/2} = 15$

Table 8.1: Knox's experiment and ours. Only the cosmology differs.

(3) The addition theorem $\sum_m |Y_{\ell m}|^2 = (2\ell + 1)/4\pi$, used in (8.17); Knox writes the beam window B_ℓ^2 as W_ℓ.

The direction has dropped out: every pixel has the same signal variance. Our fiducial spectrum gives $\langle T^2 \rangle^{1/2} = 95\,\mu$K (script `11_knox_reproduction.py`). Divided by the noise per pixel, his rms gives $92.5/22 = 4.2$, the "signal-to-noise of about 4 per pixel" he quotes; ours gives 4.3. The number says that the map is signal-dominated pixel by pixel, but not by a wide margin: the noise is a quarter of the signal. Most of the pixel rms comes from the large scales, so at the small scales the beam has already turned down, the noise takes over, and that is why the beam and the noise set the error bars at high ℓ. That two such different cosmologies give rms values within a few per cent is a consequence of both being normalised to the measured large-scale amplitude.

His notation, and ours. Knox's map has $N_{\rm pix}$ pixels of solid angle $\Omega_{\rm pix} = 4\pi/N_{\rm pix}$, each carrying the beamed sky plus a noise of variance $\sigma^2_{\rm pix}$, independent from pixel to pixel. His map coefficients $a_{\ell m}^{\rm MAP}$ are our observed $d_{\ell m}$ of Section 8.3; his $C_\ell^{\rm MAP} = \sum_m |a_{\ell m}^{\rm MAP}|^2/(2\ell+1)$ is our $\widehat{C}_\ell^{\rm obs}$ of (8.18); his $C_\ell^{\rm est}$ is our debiased, deconvolved $\widehat{C}_\ell$ of (8.20); and his ΔC_ℓ is its standard deviation [Knox1995 (4), (25)–(30)]. Three instrument quantities appear in his formulas.

- The noise variance of each harmonic coefficient. By (8.15) it is $\sigma^2_{\rm pix}\Omega_{\rm pix}$, which Knox writes $4\pi\sigma^2_{\rm pix}/N_{\rm pix}$ (his eq. 27), the same number. He calls its inverse the weight per solid angle, $w \equiv (\sigma^2_{\rm pix}\Omega_{\rm pix})^{-1}$, so his w^{-1} is our noise power N_ℓ of (8.16).

- The beam window. His map is smoothed by a Gaussian beam of width $\sigma_b = {\rm FWHM}/\sqrt{8\ln 2}$ (8.7), so the sky power is multiplied by $B_\ell^2 = e^{-\ell(\ell+1)\sigma_b^2}$ (8.10), which he writes as $e^{-\ell^2\sigma_b^2}$.

- No pixel window: his footnote states that the formula ignores pixelisation, so $p_\ell = 1$ and our transfer function (8.12) is $T_\ell = B_\ell$.

His equation (5), derived. Knox's eq. (5) is our variance (8.29) rewritten in these quantities. That variance came from counting: at each ℓ the map supplies $\nu = 2\ell + 1$ independent Gaussian numbers u_k (8.21) of variance $T_\ell^2 C_\ell + N_\ell$, and the scaled sum of their squares is a χ^2_ν variable

with variance 2ν. Then

$$(\Delta C_\ell)^2 \equiv \mathrm{Var}(\widehat{C}_\ell) \overset{(1)}{=} \frac{2}{2\ell+1}\left(C_\ell + \frac{N_\ell}{T_\ell^2}\right)^2 \overset{(2)}{=} \frac{2}{2\ell+1}\left(C_\ell + \frac{w^{-1}}{B_\ell^2}\right)^2$$
$$\overset{(3)}{=} \frac{2}{2\ell+1}\left(C_\ell + w^{-1}e^{\ell^2\sigma_b^2}\right)^2, \tag{8.38}$$

$$\frac{\Delta C_\ell}{C_\ell} \overset{(4)}{=} \sqrt{\frac{2}{2\ell+1}}\left(1 + \frac{w^{-1}e^{\ell^2\sigma_b^2}}{C_\ell}\right) \overset{(5)}{=} \sqrt{\frac{2}{2\ell+1}}\left(1 + \frac{\ell^2\, w^{-1}e^{\ell^2\sigma_b^2}}{\ell^2 C_\ell}\right). \tag{8.39}$$

(1) The full-sky variance (8.29).

(2) $N_\ell = \sigma_{\mathrm{pix}}^2\Omega_{\mathrm{pix}} = w^{-1}$ by (8.16), and $T_\ell = B_\ell$ because the pixel window is ignored.

(3) $1/B_\ell^2 = e^{\ell(\ell+1)\sigma_b^2}$, with $\ell(\ell+1)$ replaced by ℓ^2. The two differ by a factor $e^{\ell\sigma_b^2}$, which for a 20′ beam ($\sigma_b = 8.5' = 2.47\times10^{-3}$ rad) is 1.006 at $\ell = 1000$, and 1.025 for a 40′ beam. This line is Knox's eq. (4).

(4) Take the square root (both factors are positive) and divide by C_ℓ.

(5) Multiply the numerator and the denominator of the noise term by ℓ^2. Knox chose this form because $\ell^2 C_\ell$ changes by less than a factor of ten between $\ell = 2$ and $\ell \approx 1000$, so the ℓ-dependence of the noise term is carried visibly by $\ell^2 e^{\ell^2\sigma_b^2}$ [Knox1995 p. 8].

Equation (8.39) is his eq. (5). The first factor is the cosmic variance of Chapter 7; the bracket says by how much the detector inflates it, and the inflation grows like $e^{\ell^2\sigma_b^2}$ because the beam turns down the sky and leaves the noise alone (Section 8.2.2). On part of the sky the mode count of Section 8.4.2 replaces $\nu = 2\ell+1$ in step 1 by $(2\ell+1)f_{\mathrm{sky}}$, which multiplies (8.39) by $1/\sqrt{f_{\mathrm{sky}}}$:

$$\frac{\Delta C_\ell}{C_\ell} \approx \sqrt{\frac{2}{(2\ell+1)\,f_{\mathrm{sky}}}}\left(1 + \frac{w^{-1}e^{\ell^2\sigma_b^2}}{C_\ell}\right), \tag{8.40}$$

the single-multipole case $\Delta\ell = 1$ of (8.34). Knox's satellite sees the whole sky, $f_{\mathrm{sky}} = 1$, and his figure uses (8.39) as it stands.

His Fig. 2. Knox plotted (8.39) for four experiments: beams of 20′ and 40′, each with $w^{-1/2} = 15$ and 30 μK deg (the noise degraded by a factor of two to four by foreground removal) [Knox1995 p. 9–10]. The arXiv version of the paper carries the captions but not the plotted curves, so the comparison is made with his formula itself, evaluated for our fiducial spectrum. The left panel of Figure 8.19 redraws his figure: for each pair (FWHM, $w^{-1/2}$) it plots the right-hand side of (8.39) with C_ℓ the Planck 2018 fiducial spectrum, σ_b from the FWHM, and $w^{-1} = (w^{-1/2}\times\pi/180)^2\,\mu\mathrm{K}^2\,\mathrm{sr}$, for $2 \le \ell \le 1000$. His conclusion, that at fixed w the smaller beam is more precise at every ℓ, holds at every multipole up to 1000 for both noise levels. It is visible in (8.39) directly: at fixed w, a smaller σ_b lowers $e^{\ell^2\sigma_b^2}$ at every ℓ and changes nothing else.

His formula, tested with maps. Knox never made a map. He drew each C_ℓ^{est} directly from its $\chi^2_{2\ell+1}$ distribution [Knox1995 p. 8]. A map contains things a formula can leave out, so we simulated the two $w^{-1/2} = 15\,\mu$K deg experiments as full maps. Script `11_knox_reproduction.py` does five things for each experiment:

1. draws a sky from the fiducial C_ℓ and smooths it with the 20′ or 40′ beam;
2. stores it in pixels at $N_{\mathrm{side}} = 512$, which applies the pixel window p_ℓ;

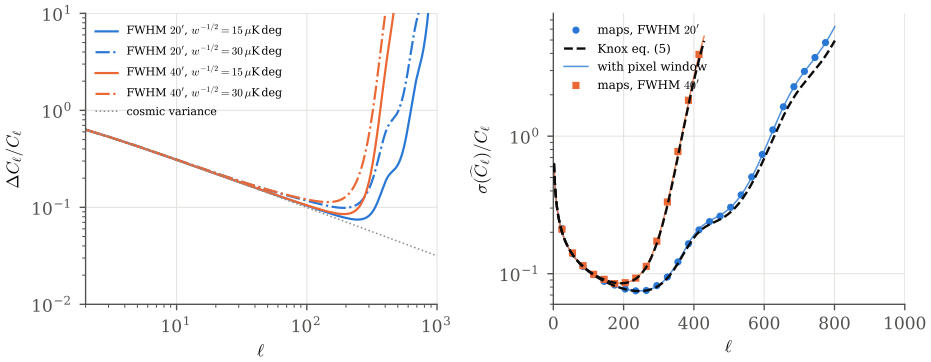

Figure 8.19: Knox's Fig. 2, redone. Left: $\Delta C_\ell / C_\ell$ of (8.39) (his eq. 5) for his four experiments, with our fiducial spectrum: the 20′ beam (blue) beats the 40′ beam (orange) at every ℓ for both noise levels (solid and dash-dotted). Right: the two $w^{-1/2} = 15\,\mu$K deg experiments simulated with maps at $N_{\rm side} = 512$. The simulated scatter (points) follows Knox's formula (dashed) until the pixel window, which his formula leaves out, becomes visible; the formula with the pixel window divided out (thin solid) follows the points everywhere.

3. adds white noise of depth $w^{-1/2} = 15\,\mu$K deg $= 900\,\mu$K arcmin;

4. computes $\widehat{C}_\ell$ with (8.20) up to $\ell = 1000$, dividing by the full $T_\ell^2 = B_\ell^2 p_\ell^2$;

5. repeats this for 300 skies (in 5.0 minutes), takes the standard deviation of $\widehat{C}_\ell$ over the skies at each ℓ, and divides it by two predictions: (8.29) with the pixel window included, and Knox's (8.38) as printed.

The right panel of Figure 8.19 shows the result, and Table 8.3 lists the numbers. Against (8.29), the simulated scatter averaged over ℓ is 1.000 times the prediction for the 20′ beam and 0.999 for the 40′ beam, where the Monte Carlo error is 4.1% per multipole. Against Knox's formula as printed, the median ratio is 1.053 for the 20′ beam and 1.013 for the 40′ beam, and for the 20′ beam it climbs to 1.25 near $\ell = 801$.

Why his formula and the maps differ. The cause is the pixel window. Knox's footnote says that his formula ignores pixelisation, which is harmless when the pixels are several times smaller than the beam. Our 6.9′ pixels are three times smaller than the 20′ beam, yet by $\ell \approx 800$ the pixel window has turned the signal down by a further $p_\ell^2 \approx 0.8$. Dividing it out turns the noise on the sky, N_ℓ / T_ℓ^2, up by $1/p_\ell^2 \approx 1.25$. Near $\ell = 801$ the noise term dominates the bracket of (8.29), so the error bar rises by about the same factor, which is the 1.25 the maps show. The 40′ experiment loses its signal to the beam well before the pixel window matters, so its ratio stays close to one. A formula can be correct for the assumptions it states and still not describe a pixelised map.

His shortcut, and what it teaches about cost. Drawing 300 sets of spectra directly from the shifted χ^2 of (8.32) takes 23 ms, against minutes for the maps, and gives the same scatter to a ratio of 0.999. On the full sky with white noise the map step adds nothing, because the distribution of $\widehat{C}_\ell$ is known exactly. Maps become necessary as soon as something breaks that distribution: a mask, inhomogeneous or correlated noise, an asymmetric beam. The cheapest simulation that still contains the effect under study is the right one, and that choice is what keeps a research pipeline on a laptop.

8.7.2 Hivon et al. (2002): MASTER in the full-sky limit

Their question. By 2002 balloon experiments such as Boomerang had maps with hundreds of thousands of pixels, far beyond the reach of the likelihood of Section 8.1.1. The cheap alternative is the **pseudo-spectrum** $\tilde{C}_\ell$: compute the spectrum of the observed map as if it were a complete sky. But the map covers only a patch, has been filtered to remove slow detector drifts, is blurred by the beam and contains noise, so on average $\tilde{C}_\ell$ is not C_ℓ: it is biased, and power from neighbouring multipoles is mixed into it. Hivon et al. asked how to correct this cheap estimator using nothing but simulations of the experiment, and how many simulations that takes.

Their setup. Each thing the observation does to the sky gets one symbol, and it helps to meet them one at a time.

- *The mask.* Only a patch of sky is kept. Cutting the sky mixes multipoles, and the mixing is described by a **mode-coupling matrix** $M_{\ell\ell'}$: how much of the true power at ℓ' ends up in the pseudo-spectrum at ℓ.
- *The filter.* The time-ordered data are high-pass filtered before the map is made, which removes large-scale power by a factor F_ℓ at each ℓ, measured from noise-free simulations.
- *The beam and the pixel.* Their window B_ℓ is the beam times the pixel window, our T_ℓ of (8.12).
- *The noise.* Its average power in the pseudo-spectrum, $\langle\tilde{N}_\ell\rangle$, is measured from noise-only simulations.

Their test simulated the Boomerang long-duration flight (Table 8.2) [Hivon §4.1].

	Hivon et al. (2002)	ours
beam FWHM	10′	30′
map resolution	$N_{\rm side} = 512$	$N_{\rm side} = 256$
noise	measured spectrum of one detector, with its $1/f$ rise and scan lines	white, uniform
filter	sharp high-pass	none
sky region	ellipse, $f_{\rm sky} = 1.82\%$	full sky
simulations	450 noise-only, 250 noise-free, 1350 signal plus noise	2000 signal plus noise

Table 8.2: The MASTER test and ours.

Their notation, and ours. Their pseudo-spectrum $\tilde{C}_\ell$ of the observed map is our $\widehat{C}_\ell^{\rm obs}$ of (8.18) when the sky is complete; their B_ℓ is our $T_\ell = B_\ell p_\ell$; their $\langle\tilde{N}_\ell\rangle$ is our average noise power $\bar{N}_\ell$ of (8.17); their C_b and N_b are our spectrum and noise power averaged over a bin b of $\Delta\ell$ multipoles; their F_ℓ and $M_{\ell\ell'}$ have no counterpart on our full, unfiltered sky.

Their master equation. Why does the average pseudo-spectrum take the form of a matrix acting on C_ℓ? Three moves give it.

1. The observed sky is the true sky times the mask, $s(\hat{\boldsymbol{n}})M(\hat{\boldsymbol{n}})$, with $M = 1$ on the patch and 0 elsewhere.

2. In harmonic space a product becomes a sum: each coefficient of the masked sky is a sum of the true coefficients $a_{\ell'm'}$ over all ℓ', weighted by the harmonics of the mask itself (Section 8.4.2). So one ℓ of the pseudo-spectrum receives power from several ℓ'.

3. Square the coefficients and average over skies. Different true coefficients are uncorrelated, so only the diagonal terms $\langle |a_{\ell'm'}|^2 \rangle = C_{\ell'}$ survive. What remains is a fixed matrix, set by the mask alone, acting on the vector of $C_{\ell'}$: $M_{\ell\ell'}$.

The filter and the beam act on the sky before the mask, so they multiply each $C_{\ell'}$ by $F_{\ell'}B_{\ell'}^2$, and the noise adds its own average power. This is Hivon's eq. (15), and the form of $M_{\ell\ell'}$ is derived for the masked sky in Section 8.10.1. With no mask ($M = 1$ everywhere) and no filter,

$$\langle \tilde{C}_\ell \rangle \overset{(1)}{=} \sum_{\ell'} M_{\ell\ell'} F_{\ell'} B_{\ell'}^2 \langle C_{\ell'} \rangle + \langle \tilde{N}_\ell \rangle \overset{(2)}{=} T_\ell^2 \, C_\ell + \bar{N}_\ell ,$$

(1) Hivon's eq. (15).
(2) With $M = 1$ the masked sky is the sky, no multipoles are mixed and $M_{\ell\ell'} = \delta_{\ell\ell'}$; no filter means $F_\ell = 1$; $B_\ell = T_\ell$ and $\langle \tilde{N}_\ell \rangle = \bar{N}_\ell$ of (8.17).

which is our (8.19): what remains is the beam, the pixel window and the noise. Every statement of the paper about those three can therefore be tested on our full-sky simulations; the statements about the mask are taken up with the masked sky.

Noise-bias removal. Hivon et al. found the recovered spectrum unbiased both where the signal dominates and where the signal-to-noise is very low [Hivon §4.2, Fig. 5]. Our debiased estimator passes the corresponding test with $\chi^2 = 20.5$ for 21 bins (Section 8.6.1).

The analytic error bar. Their rule of thumb [Hivon (16)–(17)] gives the error of a bin of $\Delta\ell$ multipoles as $(C_b + N_b/T_b^2)\sqrt{2/\nu_b}$ with $\nu_b = (2\ell_b+1)\Delta\ell\, f_{\rm sky} w_2^2/w_4$, and they found their simulated errors "almost identical" to it. The rule follows from (8.29) in two steps. The binned estimate is the plain average $\widehat{C}_b = \Delta\ell^{-1} \sum_{\ell\in b} \widehat{C}_\ell$ over the $\Delta\ell$ multipoles of bin b, centred on ℓ_b. On the full sky,

$$\begin{aligned} \mathrm{Var}\big(\widehat{C}_b\big) &\overset{(1)}{=} \frac{1}{\Delta\ell^2} \sum_{\ell\in b} \mathrm{Var}\big(\widehat{C}_\ell\big) \overset{(2)}{=} \frac{1}{\Delta\ell^2} \sum_{\ell\in b} \frac{2}{2\ell+1} \Big(C_\ell + \frac{N_\ell}{T_\ell^2} \Big)^2 \\ &\overset{(3)}{\approx} \frac{2}{(2\ell_b+1)\,\Delta\ell} \Big(C_b + \frac{N_b}{T_b^2} \Big)^2 . \end{aligned} \tag{8.41}$$

(1) Different multipoles of a full sky are independent, so the variances of the $\Delta\ell$ terms add, and the factor $1/\Delta\ell$ comes out squared.
(2) The single-multipole variance (8.29).
(3) If C_ℓ, N_ℓ/T_ℓ^2 and $2\ell+1$ change little across the bin, the $\Delta\ell$ terms are all close to the one at ℓ_b, and their sum is $\Delta\ell$ times it.

The square root of (8.41) is $(C_b + N_b/T_b^2)\sqrt{2/\nu_b}$ with $\nu_b = (2\ell_b+1)\Delta\ell$, the number of modes in the bin. On part of the sky the mode count of Section 8.4.2 multiplies ν_b by $f_{\rm sky}$, and by w_2^2/w_4 for a weighted mask, which gives their eqs. (16)–(17). The quantity compared is therefore our simulated standard deviation of $\widehat{C}_b$ divided by the square root of (8.41) with $f_{\rm sky} = 1$, and, separately, divided by the square root of line 2, which makes no assumption about the bin. On the full sky, in bins of $\Delta\ell = 50$, our simulated error divided by the rule lies between 0.989 and 1.098 in the bins above $\ell = 63$, with a Monte Carlo error of 1.6%. The first bin, $\ell = 13$–62, is the

exception, with a ratio of 1.85. The rule evaluates the spectrum at the bin average, but C_ℓ falls by a factor of about twenty across that bin, and the variance of a bin average, $\sum_\ell \mathrm{Var}(\widehat{C}_\ell)/\Delta\ell^2$, is dominated by the largest C_ℓ in it. The exact expression, line 2 of (8.41), gives ratios between 0.987 and 1.040 in every bin. The rule fails exactly at its step 3: it needs a spectrum that is nearly constant across the bin.

How fast the calibrations converge. MASTER estimates three things by simulation: the transfer function, the noise power, and the error bars. Each estimate comes from a finite number N of simulations, so each carries a Monte Carlo error of its own. The question is: *how large is that error, and how does it shrink with N?* Hivon et al. give the answers as their eqs. (38)–(42) [Hivon (38)–(42)]. We derive them from the mode count of (8.41).

The transfer function and the noise power. Each is an average over the N simulations of one binned spectrum, call it X_b: the noise-free spectrum divided by the input spectrum for the transfer function, the noise-only spectrum for the noise power. In one simulation, X_b is built from $\nu_b = (2\ell_b + 1)\Delta\ell$ independent modes, so by (8.41) it scatters by $\sigma(X_b) = \sqrt{2/\nu_b}\,\langle X_b\rangle$. Averaging N independent simulations reduces that scatter by $\sqrt{N}$.

The error bar. It is the standard deviation s of $\widehat{C}_b$ over the N simulations. With many modes in a bin, $\widehat{C}_b$ is close to Gaussian, and then $(N-1)s^2/\sigma^2$ is a χ^2_{N-1} variable (Chapter 3), whose variance we know.

Then

$$\frac{\delta\bar{X}_b}{\langle X_b\rangle} \overset{(1)}{=} \frac{\sigma(X_b)/\sqrt{N}}{\langle X_b\rangle} \overset{(2)}{=} \sqrt{\frac{2}{(2\ell_b+1)\,\Delta\ell\,N}}, \tag{8.42}$$

$$\frac{\delta s}{s} \overset{(3)}{=} \frac{1}{2}\,\frac{\delta(s^2)}{\sigma^2} \overset{(4)}{=} \frac{1}{2}\sqrt{\frac{2}{N-1}} = \frac{1}{\sqrt{2(N-1)}}. \tag{8.43}$$

(1) The average of N independent copies has $1/N$ times the variance of one.

(2) $\sigma(X_b) = \sqrt{2/\nu_b}\,\langle X_b\rangle$ with $\nu_b = (2\ell_b+1)\Delta\ell$; on part of the sky ν_b carries the factor f_{sky}, which gives [Hivon (19), (38)–(39)].

(3) Error propagation for $s = \sqrt{s^2}$: $\delta s = \delta(s^2)/(2s)$, and $s \approx \sigma$.

(4) $s^2 = \sigma^2\chi^2_{N-1}/(N-1)$ and $\mathrm{Var}(\chi^2_{N-1}) = 2(N-1)$, so $\delta(s^2) = \sigma^2\sqrt{2/(N-1)}$.

Third, the error that an N-simulation noise estimate puts on $\widehat{C}_\ell$, relative to its statistical error, is $N_\ell/(T_\ell^2 C_\ell + N_\ell)\cdot N^{-1/2}$, derived in (8.25). What is compared is the scatter of each Monte Carlo estimate between disjoint groups of N of our skies, divided by (8.42), (8.43) or (8.25). Script `12_hivon_convergence.py` measures all four by splitting our 2000 skies into disjoint groups of $N = 25$ to 400 (Figure 8.20). At $N = 100$ the measured scatter divided by our formula is 1.00 for the transfer function, 0.99 for the noise power, 1.01 for the error bar and 0.98 for the noise-induced error, each ±0.01.

The published coefficients are larger, and most of the difference can be traced. Take the transfer function and the noise power at $\ell \approx 400$, $\Delta\ell = 50$ and $N = 100$. Our full-sky formula (8.42) gives 0.072%; Hivon's numbers are 0.6–0.9%. Two causes act through the mode count ν_b, and the error goes as $1/\sqrt{\nu_b}$.

- *The sky fraction.* Their region is 1.82% of the sky, so ν_b carries the factor $f_{\mathrm{sky}} = 0.0182$ and the error rises by $1/\sqrt{0.0182} = 7.4$: from 0.072% to 0.53%. After this step their numbers are still $0.6/0.53 = 1.13$ to $0.9/0.53 = 1.70$ times ours.

- *The weighting.* They weighted their region with a cosine-apodised window, for which

$w_2^2/w_4 = 0.5$. In (8.34) this factor multiplies $f_{\rm sky}$, so it halves ν_b and raises the error by $\sqrt{2} = 1.41$: from 0.53% to 0.75%.

Their range now sits on either side of ours: $0.6/0.75 = 0.8$ and $0.9/0.75 = 1.2$. What is left, a factor between 0.8 and 1.2, depends on details of their region that our full-sky model does not contain, such as the uneven number of observations across the patch and the correlated noise of their detector. We do not reproduce it, and with a full sky we cannot. For the error bar, their "$0.1\sqrt{100/N}$" is a rounded upper value of $1/\sqrt{2(N-1)} = 7.1\%$ at $N = 100$, which our groups reproduce. For the noise-induced error, their $0.1\sqrt{100/N}$ is exactly $1/\sqrt{N}$, our (8.25) in the deeply noise-dominated limit; in our last bin the noise is 0.68 of the power, so the formula gives 6.8% and the groups give 6.6%.

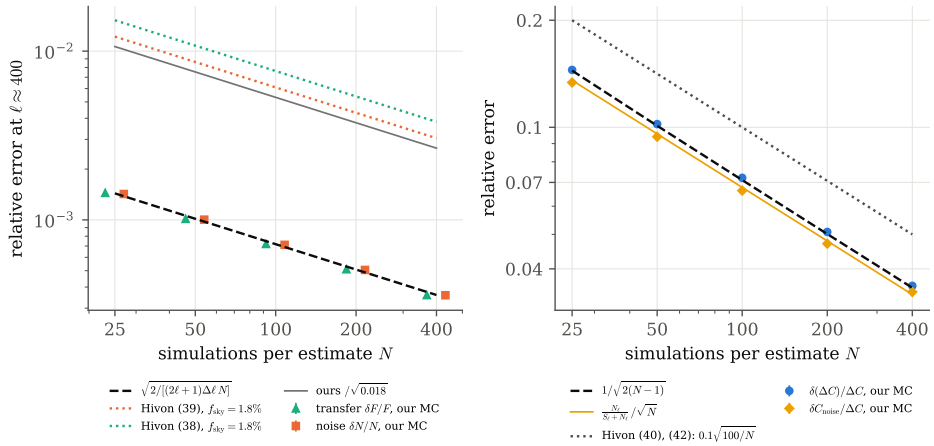

Figure 8.20: Hivon et al.'s convergence laws against our simulations. Left: the relative Monte Carlo error of the transfer function (green) and of the noise power (orange) at $\ell \approx 400$ in bins of 50, from disjoint groups of N skies, on the full-sky law (dashed). Hivon's published laws for 1.8% of the sky (dotted) lie above it by about $1/\sqrt{f_{\rm sky}}$ (grey). Right: the relative error of an estimated error bar (blue) and the error a noise estimate adds to $\widehat{C}_\ell$ (yellow), against $1/\sqrt{2(N-1)}$ (dashed), its noise-weighted version (yellow line) and Hivon's $0.1\sqrt{100/N}$ (dotted).

The shape of the distribution. Hivon et al. showed that at small numbers of modes a χ^2_ν with no free parameter describes the simulated estimates far better than a Gaussian of the same mean and width [Hivon §4.2, Fig. 6]. On the full sky the number of modes is small only at the lowest multipoles. At $\ell = 3$, $\nu = 7$, the shifted χ^2 passes the Kolmogorov–Smirnov test with $p = 0.09$ and the Gaussian fails with $p = 1 \times 10^{-5}$ (Section 8.6.3). Their small $f_{\rm sky}$ brought the same effect up to $\ell \sim 100$; that version needs the mask.

What reproducing it taught us. On the full sky every claim MASTER makes about the beam, the pixel window and the noise is checked by our machine, and the one failure we found, in the first bin, shows that the binned rule of thumb needs a spectrum that is flat across the bin. The claims that depend on the mask are not reproduced here.

8.7.3 Planck's pivot: why A_s and n_s are quoted at $k_* = 0.05\,\mathrm{Mpc}^{-1}$

Planck reports two numbers for the primordial fluctuations: their amplitude, $\ln(10^{10}A_s) = 3.044 \pm 0.014$, and their tilt, $n_s = 0.9649 \pm 0.0042$ (Chapter T1). The amplitude is the one "which we define at the pivot scale $k_0 = 0.05\,\mathrm{Mpc}^{-1}$" [25]. WMAP quoted its amplitude at a different

scale, $k = 0.002\,\mathrm{Mpc}^{-1}$, and Planck still quotes the tensor-to-scalar ratio there, $r_{0.002} < 0.10$ [25]. Why does an amplitude need a scale attached to it at all, and why this one?

The spectrum is a straight line. The primordial spectrum is a power law,

$$\mathcal{P}(k) = A_s \left(\frac{k}{k_0}\right)^{n_s - 1}, \tag{8.44}$$

so $\ln \mathcal{P} = \ln A_s + (n_s - 1)\ln(k/k_0)$. Plotted as $\ln \mathcal{P}$ against $\ln k$ it is a straight line. Its slope is $n_s - 1$. Its height at the point $k = k_0$ is $\ln A_s$. That point, the **pivot**, is our choice: we may describe the same line by its height at any k we like. The slope stays the same whichever point we choose. The height changes, and so does something less obvious: how strongly the measured height and the measured slope are correlated.

Think of fitting a straight line through points. If we report the height of the line far to the left of the data, any error in the slope swings that height up or down, so height and slope come out strongly correlated. If we report the height in the middle of the data, a small change of slope just pivots the line about that point, and the height hardly moves: the two errors are independent. The pivot scale is the same idea. The question, in words: *at which k do the measured amplitude and the measured tilt become uncorrelated, and where does that k sit?*

Step 1: what moving the pivot does. Call $A(k_0)$ the amplitude quoted at k_0, and write n for n_s. The same spectrum, evaluated at another point k_1, has height $A(k_1) = A(k_0)\,(k_1/k_0)^{n-1}$; this is just (8.44) at $k = k_1$. Write $L = \ln(k_1/k_0)$ for the distance between the two points in $\ln k$. It is a fixed number, not a measured one. Then

$$\begin{aligned} \ln A(k_1) &\overset{(1)}{=} \ln A(k_0) + (n-1)\,L, \\ \operatorname{Cov}\big(\ln A(k_1), n\big) &\overset{(2)}{=} \operatorname{Cov}\big(\ln A(k_0), n\big) + L\,\operatorname{Var}(n), \\ \operatorname{Var}\big(\ln A(k_1)\big) &\overset{(3)}{=} \operatorname{Var}\big(\ln A(k_0)\big) + 2L\,\operatorname{Cov}\big(\ln A(k_0), n\big) + L^2\,\operatorname{Var}(n). \end{aligned} \tag{8.45}$$

(1) Take the logarithm of $A(k_1) = A(k_0)(k_1/k_0)^{n-1}$.
(2) Take the covariance of both sides of line 1 with n. A covariance splits over a sum. The constant $-L$ hidden in $(n-1)L$ does not fluctuate, so it drops out, and the covariance of n with itself is its variance.
(3) The variance of a sum $X + LY$ is $\operatorname{Var} X + 2L\operatorname{Cov}(X,Y) + L^2 \operatorname{Var} Y$; here $X = \ln A(k_0)$ and $Y = n$.

Line 2 says that moving the pivot by L shifts the covariance by $L\ \operatorname{Var}(n)$. So there is exactly one pivot at which the covariance is zero. Setting line 2 to zero and solving for L gives the **decorrelation pivot**:

$$L_{\mathrm{dec}} = -\frac{\operatorname{Cov}\big(\ln A(k_0), n\big)}{\operatorname{Var}(n)}, \qquad k_{\mathrm{dec}} = k_0 \exp\!\left[-\frac{\operatorname{Cov}\big(\ln A(k_0), n\big)}{\operatorname{Var}(n)}\right]. \tag{8.46}$$

Line 3 gives a bonus. Its derivative with respect to L is $2\operatorname{Cov} + 2L\operatorname{Var}(n)$, which vanishes at the same L_{dec}. So the pivot that makes the two numbers independent is also the pivot at which the amplitude has its smallest error. All (8.46) needs is the covariance of the two numbers at one pivot, however it was obtained: from a Fisher matrix, a Markov chain or a fit.

Step 2: from wavenumber to multipole. The data are multipoles, the pivot is a wavenumber, so first we need to know which multipoles see which wavenumbers. The CMB is a picture of the last-scattering sphere, at comoving distance D_* from us. A wave of wavenumber k on that sphere has wavelength $2\pi/k$. Seen from a distance D_*, that length spans an angle of $2\pi/(kD_*)$ radians. A spherical harmonic of degree ℓ has an angular wavelength of $2\pi/\ell$. Matching the two, $\ell \approx kD_*$. CAMB gives $D_* = 13.87\,\mathrm{Gpc}$ for the fiducial model (see the cosmology notes). So the Planck pivot $0.05\,\mathrm{Mpc}^{-1}$ sits at $\ell \approx 694$, and the WMAP pivot $0.002\,\mathrm{Mpc}^{-1}$ at $\ell \approx 28$. The match is approximate: a wave whose crests are not perpendicular to our line of sight looks longer on the sky, so one k also feeds every ℓ below kD_*. Turned around: multipole ℓ receives power from a range of wavenumbers, through a kernel $G_\ell(k)$ that peaks near $k_\ell \equiv \ell/D_*$ and has a tail towards larger k. The temperature spectrum is linear in the primordial one,

$$C_\ell = \int G_\ell(k)\,\mathcal{P}(k)\,\mathrm{d}\ln k, \tag{8.47}$$

with $G_\ell \geq 0$ fixed by the physics between the early universe and last scattering, which CAMB computes.

Step 3: how much each multipole knows. To use (8.46) we need that covariance for a temperature measurement, and the Fisher matrix of Chapter 10 gives it. We already have the Fisher information of one C_ℓ, (8.31). We need it for the parameters θ_i that the spectrum depends on. Two facts make this a short step. On the full sky different multipoles are independent, so

their informations add. And the parameters reach the data only through C_ℓ, so the chain rule converts information on C_ℓ into information on θ_i:

$$F_{ij} \equiv \left\langle \frac{\partial^2(-\ln \mathcal{L})}{\partial\theta_i \partial\theta_j} \right\rangle \overset{(1)}{=} \sum_\ell \left\langle \frac{\partial^2(-\ln \mathcal{L}_\ell)}{\partial C_\ell^2} \right\rangle \frac{\partial C_\ell}{\partial\theta_i}\frac{\partial C_\ell}{\partial\theta_j} \overset{(2)}{=} \sum_\ell \frac{(2\ell+1) f_{\rm sky}}{2\,(C_\ell + N_\ell/T_\ell^2)^2} \frac{\partial C_\ell}{\partial\theta_i}\frac{\partial C_\ell}{\partial\theta_j}. \tag{8.48}$$

(1) Write $\ln \mathcal{L} = \sum_\ell \ln \mathcal{L}_\ell$ and differentiate twice with the chain rule. One term contains $\partial^2 C_\ell/\partial\theta_i\partial\theta_j$, but it is multiplied by the average slope of $-\ln \mathcal{L}_\ell$, which is zero at the true parameters (Chapter 3).
(2) The information on one C_ℓ is (8.31). On part of the sky there are only $(2\ell+1)f_{\rm sky}$ modes instead of $2\ell+1$ (Section 8.4.2).

Now the two parameters. How does C_ℓ change when each of them is nudged? Differentiate (8.47) under the integral; the kernel does not depend on A or n. The amplitude multiplies $\mathcal{P}(k)$ at every k, so $\partial\mathcal{P}/\partial\ln A = \mathcal{P}$. The tilt enters through $\ln\mathcal{P} = \ln A + (n-1)\ln(k/k_0)$, so $\partial\mathcal{P}/\partial n = \mathcal{P}\ln(k/k_0)$: raising n raises the spectrum more at large k and lowers it at $k < k_0$. Then

$$\frac{\partial C_\ell}{\partial \ln A} \overset{(1)}{=} \int G_\ell\, \mathcal{P}\, \mathrm{d}\ln k = C_\ell,$$
$$\frac{\partial C_\ell}{\partial n} \overset{(2)}{=} \int G_\ell\, \mathcal{P}\, \ln\frac{k}{k_0}\, \mathrm{d}\ln k \overset{(3)}{=} C_\ell \left\langle \ln\frac{k}{k_0} \right\rangle_\ell \overset{(4)}{\approx} C_\ell\, g_\ell, \qquad g_\ell \equiv \ln\frac{k_\ell}{k_0}.$$

(1) $\partial\mathcal{P}/\partial\ln A = \mathcal{P}$, and the integral is (8.47).
(2) $\partial\mathcal{P}/\partial n = \mathcal{P}\ln(k/k_0)$.
(3) Divide and multiply by C_ℓ: $\langle\cdot\rangle_\ell$ is the average over $\ln k$ with weight $G_\ell\mathcal{P}/C_\ell$, which integrates to one.
(4) Replace the kernel by a spike at its peak $k_\ell = \ell/D_*$ (Step 2). The tail of the kernel towards larger k makes this a shortcut, not an exact step; the script below keeps the full kernel.

So g_ℓ is the distance of multipole ℓ from the pivot in $\ln k$. Put the two derivatives into (8.48). Every term carries the same factor, which we name the **information weight** of multipole ℓ,

$$\mathcal{I}_\ell \equiv \frac{(2\ell+1)f_{\rm sky}}{2}\left[\frac{C_\ell}{C_\ell + N_\ell/T_\ell^2}\right]^2,$$

the information that multipole ℓ carries about $\ln A$: its number of modes, cut down where the noise on the sky N_ℓ/T_ℓ^2 exceeds the signal. Since $\frac{(2\ell+1)f_{\rm sky}}{2(C_\ell+N_\ell/T_\ell^2)^2} = \mathcal{I}_\ell/C_\ell^2$, the three entries are

$$F_{AA} = \sum_\ell \frac{\mathcal{I}_\ell}{C_\ell^2} C_\ell^2 = \sum_\ell \mathcal{I}_\ell, \qquad F_{An} = \sum_\ell \frac{\mathcal{I}_\ell}{C_\ell^2} C_\ell \cdot C_\ell g_\ell = \sum_\ell \mathcal{I}_\ell\, g_\ell, \qquad F_{nn} = \sum_\ell \mathcal{I}_\ell\, g_\ell^2,$$

so that

$$F = \begin{pmatrix} \sum_\ell \mathcal{I}_\ell & \sum_\ell \mathcal{I}_\ell g_\ell \\ \sum_\ell \mathcal{I}_\ell g_\ell & \sum_\ell \mathcal{I}_\ell g_\ell^2 \end{pmatrix}.$$

Its inverse is the covariance. For a 2×2 matrix $\left(\begin{smallmatrix} a & b \\ b & c \end{smallmatrix}\right)$ the inverse is $\left(\begin{smallmatrix} c & -b \\ -b & a \end{smallmatrix}\right)/\det F$, so the covariance of the two numbers is $-b/\det F$ and the variance of n is $a/\det F$. Put them into (8.46):

$$\ln\frac{k_{\rm dec}}{k_0} = -\frac{\mathrm{Cov}(\ln A, n)}{\mathrm{Var}(n)} \overset{(1)}{=} \frac{\sum_\ell \mathcal{I}_\ell g_\ell}{\sum_\ell \mathcal{I}_\ell} \overset{(2)}{=} \frac{\sum_\ell \mathcal{I}_\ell\, \ln(k_\ell/k_0)}{\sum_\ell \mathcal{I}_\ell},$$

(1) $-(-b/\det F)/(a/\det F) = b/a$; the determinant cancels.
(2) Write out g_ℓ.

Adding $\ln k_0$ to both sides, $\ln k_{\mathrm{dec}} = \sum_\ell \mathcal{I}_\ell \ln k_\ell / \sum_\ell \mathcal{I}_\ell$. In words: *the decorrelation pivot is the average of* $\ln k$ *over the scales the data measure, each scale counted with the weight of what it knows.* That is the straight-line picture made exact: the height and the slope are independent when the height is quoted in the middle of the data, and "middle" means the weighted middle. The sky fraction multiplies every $\mathcal{I}_\ell$, so it cancels: observing less sky widens the errors but does not move k_{dec}.

Step 4: the numbers. Script `14_pivot.py` does the calculation without the spike shortcut, for the Planck-like experiment of Table 8.4. It computes the temperature spectrum with CAMB; finds the derivatives of C_ℓ with respect to $\ln A$ and n by nudging each up and down, at both pivots; builds the Fisher matrix (8.48); inverts it to get the covariance; and puts that covariance into (8.46) to get k_{dec}.

beam FWHM	$7'$
white-noise depth	$33\,\mu$K arcmin
sky fraction	$f_{\mathrm{sky}} = 0.6$
multipoles	$2 \le \ell \le 2500$, temperature only
free parameters	$\ln A$ and n; then all six ΛCDM parameters, with a Gaussian prior of width 0.0073 on τ standing in for the large-angle polarisation that fixes it

Table 8.4: The idealised Planck-like experiment of the pivot calculation.

quantity	at $0.05\,\mathrm{Mpc}^{-1}$	at $0.002\,\mathrm{Mpc}^{-1}$	reason
correlation of $\ln A$ and n	-0.74	-0.99	0.002 lies far from the weighted middle of the data
moved from 0.05 by (8.45)	—	-0.99	the shift is exact
k_{dec} [Mpc^{-1}]	0.083	0.083	a property of the data, not of the pivot
$\sigma(\ln A)$	0.0017	0.0094	the $L^2\,\mathrm{Var}(n)$ term of line 3
correlation, six parameters free	-0.21	-0.81	a common amplitude error from τ

Table 8.5: The pivot calculation at the two pivots.

Table 8.5 collects the results, and Figure 8.21 shows the correlation for every pivot together with the weights $\mathcal{I}_\ell$. Each difference has a cause that the steps above can size.

The correlation. With only $\ln A$ and n free, $k_{\mathrm{dec}} = 0.083\,\mathrm{Mpc}^{-1}$, that is $\ell_{\mathrm{dec}} \approx 1155$. The Planck pivot is at $\ell \approx 694$, not far below it, and the correlation there is moderate. The WMAP pivot is at $\ell \approx 28$, far to the left of almost all the information, and there the two numbers are almost perfectly anti-correlated: the straight-line picture of the height read off far from the data.

The check of Step 1. Computing the Fisher matrix directly at $0.002\,\mathrm{Mpc}^{-1}$ and moving the covariance there from $0.05\,\mathrm{Mpc}^{-1}$ with (8.45) give the same correlation, and both pivots give the same k_{dec}: the decorrelation scale belongs to the data. The spike shortcut of Step 3, the $\mathcal{I}_\ell$-weighted average of $\ln \ell$, gives $\ell \approx 972$. It falls short of the exact 1155 because the kernel's tail towards larger k makes each multipole see slightly larger k than ℓ/D_*.

The amplitude error. Moving from 0.05 to $0.002\,\mathrm{Mpc}^{-1}$ is a step $L = \ln(0.002/0.05) = -3.22$. Line 3 of (8.45) then gives $\mathrm{Var}(\ln A)$ at 0.002 as $0.0017^2 + 2L\,\mathrm{Cov} + L^2\,\mathrm{Var}(n)$. With $\sigma(n) = 0.0025$

and the correlation −0.74, the three terms are 0.29, 2.0 and 6.5 in units of 10^{-5}; the square root of their sum is 0.0094, the 0.0094 of the table. The $L^2\,\mathrm{Var}(n)$ term carries three quarters of it: quoted far from the data, the height inherits the uncertainty of the slope, magnified by the distance.

Marginalising. With all six ΛCDM parameters free, the covariance of $\ln A$ and n is read from the inverse of the full six-by-six Fisher matrix, so each error now includes what the other parameters can absorb. On all but the largest scales the temperature spectrum fixes only the combination $A\,e^{-2\tau}$, so the prior of width 0.0073 on τ leaves $\ln A$ an error of about $2 \times 0.0073 = 0.015$ at every pivot. That common error is much larger than the slope term $L\,\sigma(n)$ for any pivot near the data, so the correlation, which is the slope term over the total, shrinks: −0.21 at $0.05\,\mathrm{Mpc}^{-1}$. At $0.002\,\mathrm{Mpc}^{-1}$, L is large enough that the slope term still wins, and the correlation stays at −0.81. The tilt, for its part, trades with the matter densities that shape the acoustic peaks, and those trades do not weigh all multipoles equally; the weighted middle in (8.46) moves to $k_{\mathrm{dec}} = 0.091\,\mathrm{Mpc}^{-1}$. The size of that shift comes from the full matrix, not from a formula we can write by hand.

What this says about the choices. For this idealised experiment the exact decorrelation scale is near $\ell \approx 1155$, where the weight $\mathcal{I}_\ell$ peaks before the beam and the noise cut it off. The Planck pivot, $0.05\,\mathrm{Mpc}^{-1}$ at $\ell \approx 694$, is not exactly there. It is a round number inside the band of scales where the temperature information is concentrated, and there the correlation is modest. The Planck paper fixes the pivot by definition and calls the tilt measured "around the pivot scale of $k \simeq 0.05\,\mathrm{Mpc}^{-1}$" robust [25]; it does not quote a decorrelation scale of its own, which for the real likelihood also depends on the polarisation spectra and on the foreground model.

WMAP's choice answered a different need. Its temperature spectrum was limited by cosmic variance only over the first few hundred multipoles. For a noiseless spectrum that stops at $\ell = 500$, (8.46) gives $k_{\mathrm{dec}} = 0.030\,\mathrm{Mpc}^{-1}$ ($\ell \approx 416$). WMAP's pivot, $0.002\,\mathrm{Mpc}^{-1}$ at $\ell \approx 28$, is far to the left of that. It sits at the large-scale end, where tensor modes contribute (they fade above $\ell \sim 100$) and where COBE had fixed the normalisation. There the amplitude and the tilt are almost perfectly anti-correlated, −0.98 for the same noiseless spectrum. Neither pivot is wrong. A pivot is a choice of where to read off the height of a line, and (8.45) converts one choice into another. A pivot near k_{dec} simply gives two numbers that can be read separately.

8.8 How it is done in research

The toy pipeline of a beamed, noisy full sky has every structural element of a real temperature analysis and almost none of its detail. It is worth seeing the real thing once, in the order in which it runs, because every later chapter that uses $\widehat{C}_\ell$ inherits its choices. The description follows the Planck 2018 temperature analysis [70] and the MASTER method [Hivon §3.6], with modern implementations such as NaMaster [142].

The data products. An analysis starts from the time-ordered data of every detector, with its pointing, and from three calibrations made on the same data: the beam of each detector, measured by scanning planets; the noise spectrum of each detector, measured from the timestream itself; and the gain. Map-making turns the timestream into maps at $N_{\mathrm{side}} = 2048$ for each high-frequency channel and for each *split* of the data (the two half-missions, two sets of detectors), together with hit counts and pixel noise variances. Masks remove the Galaxy and bright point sources and are apodised. The *effective* beam window function of each map, which combines the beams of the detectors that went into it with the way the scan crossed each pixel, is computed from the beam measurements and the scan. Finally a large set of simulations is

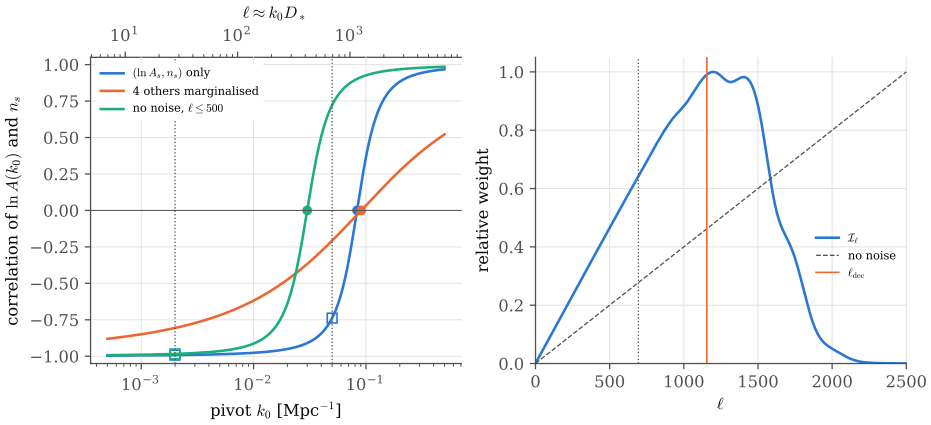

Figure 8.21: The pivot scale. Left: the correlation of $\ln A(k_0)$ and n_s as a function of the pivot k_0, for the Planck-like experiment with $(\ln A_s, n_s)$ alone (blue) and with the other four parameters marginalised (orange), and for a noiseless spectrum cut at $\ell = 500$ (green). The curves follow from one Fisher matrix at $0.05\,\mathrm{Mpc}^{-1}$ moved along by (8.45); the open squares are Fisher matrices computed directly at each pivot, and the dots mark $k_{\rm dec}$, where each curve crosses zero. The top axis converts k_0 to $\ell \approx k_0 D_*$. Right: the weight $\mathcal{I}_\ell$, the information on $\ln A_s$ per multipole, rises like $2\ell + 1$ until the beam and the noise cut it off; its weighted centre in $\ln \ell$ is $\ell_{\rm dec}$ (orange). The dotted lines mark 0.002 and $0.05\,\mathrm{Mpc}^{-1}$ (left) and $0.05\,\mathrm{Mpc}^{-1}$ (right).

produced end to end: CMB skies, foregrounds and noise timestreams, run through the same map-maker. In Planck 2018 these are the 300 FFP10 realisations [70].

The steps.

1. *Maps.* Generalised least squares, or a destriper that removes the $1/f$ drifts, solves $\boldsymbol{d} = \mathsf{A}\boldsymbol{s} + \boldsymbol{n}$ for the map [HobsonBMC (10.10)–(10.13)].

2. *Pseudo-spectra.* Each masked, apodised map is transformed; spectra are formed between *different* splits, so that the noise bias never enters (Section 8.3.3).

3. *Deconvolution.* The mode coupling of the mask is computed exactly from the mask's own spectrum and inverted in bins of ℓ; the effective beam and pixel window are divided out [Hivon (14)–(26)]. A transfer function measured on noise-free simulations corrects for any filtering [Hivon (18)].

4. *Covariance.* The covariance of the binned spectra, which a mask makes non-diagonal, is computed with analytic approximations for masked, noisy pseudo-spectra and checked on simulations, or estimated directly from simulations with the correction for a finite number of them [6].

5. *Likelihood.* Above $\ell = 30$ the binned cross-spectra of the frequency maps enter a Gaussian likelihood together with foreground and instrument nuisance parameters, for $30 \leq \ell \leq 2508$ [70]. Below $\ell = 30$, where the distribution is visibly a skewed χ^2 (Section 8.4.1), the likelihood is computed from the low-resolution map itself, with Gibbs sampling of the sky and the spectrum together [70].

The checks. None of this is trusted until it has passed tests designed to fail if something is wrong. *Null tests* difference two splits of the same sky: the signal cancels, and the spectrum of the difference must be consistent with the noise model alone. *Consistency tests* compare spectra from different frequencies, detector sets and masks, which must agree after foregrounds are

accounted for. *End-to-end tests* run the entire pipeline on the simulations as if they were data and check that the input spectrum and parameters come back without bias and with error bars that cover the truth as often as they claim [70]. The full-sky checks of Section 8.6 are the smallest version of the last kind.

Taxonomy: Research pipeline and its laptop version

step	research version	here	cost of the reduction
sky model	Gaussian CMB + foregrounds, $N_{\rm side} = 2048$	Gaussian CMB, $N_{\rm side} = 256$	$\ell \le 512$: 4.2% of the modes
beam	measured, asymmetric, per detector, with errors	circular Gaussian, 30′	no beam-error term
noise	correlated $1/f$ timestream through map-maker	white pixel noise (and one pattern)	no stripes or noise correlations
spectra	half-mission cross-spectra, masked	full sky, auto and cross	mask in the masked-sky analysis
simulations	300 end-to-end FFP10	2000 Gaussian skies, 6 min	MC error 1.6% vs 4.1%, but less realism
full-scale run	computing cluster	extrapolated: 5 h for 1000 Gaussian skies at 2048	breaks the 10-minute budget
storage	maps on disk	spectra only, 29 MB	1000 maps at 2048: 403 GB

The reductions in the table are deliberate. Each removes something expensive whose effect on the statistics of $\widehat{C}_\ell$ is either known exactly on the full sky or is not the subject here. What cannot be removed is the structure: random sky, deterministic instrument, random noise, the same analysis on data and simulations, and statistics read off the simulations. That structure is the same at $N_{\rm side} = 256$ and at 2048.

How this is used in real research: Verification and research with the same machine

On the full sky the simulations *verify*: every number they produced had an analytic prediction, and agreement tested the code. In research the same loop is the *instrument*, used where no prediction exists: the transfer function of a filtered scan [Hivon (18)], the noise power of coloured, inhomogeneous, filtered noise [Hivon §3.3], and the covariance and distribution of the binned spectrum of a masked sky, which the likelihood of Chapter 9 and the Fisher forecast of Chapter 10 need.

The beam and the noise also change the map in ways the spectrum does not show. The beam removes the smallest hot and cold spots, and the noise adds a grain of tiny new ones. Counts of spots, their connectivity and the other shape statistics of Chapter 12 respond to both, and the same simulations, which already produce beamed, noisy maps, will provide their sampling distributions.

Recap

- An instrument multiplies each $a_{\ell m}$ by $T_\ell = B_\ell p_\ell$ (beam times pixel window, $B_\ell = e^{-\ell(\ell+1)\sigma_b^2/2}$ for a Gaussian beam) and adds noise after the smoothing; uniform white noise has $N_\ell = \sigma^2 \Omega_{\rm pix}$ at every ℓ, and any noise pattern has mean power $\Omega_{\rm pix}\langle\sigma^2\rangle$.
- The observed spectrum averages to $T_\ell^2 C_\ell + N_\ell$. Subtracting N_ℓ and dividing by

T_ℓ^2 gives an unbiased estimator, which on the full sky is the maximum-likelihood estimator and reaches the Cramér–Rao bound. Cross-spectra of independent halves need no noise subtraction and cost at most $\sqrt{2}$ in error.

- Its variance is $2(C_\ell + N_\ell/T_\ell^2)^2/(2\ell+1)$ (Knox), its distribution a shifted, scaled $\chi^2_{2\ell+1}$, skewed at low ℓ and straddling zero where the noise dominates. The noise supplies half the variance once $N_\ell/(T_\ell^2 C_\ell) > \sqrt{2}-1$.
- The f_{sky} version of the formula counts modes; it holds for wide bins with many modes and fails at low ℓ and small patches.
- The cumulative signal-to-noise $[\sum_\ell \mathrm{SNR}_\ell^2]^{1/2}$ is one over the error of an overall amplitude; it saturates a little beyond the multipole where noise and signal are equal.
- 2000 simulated skies at $N_{\mathrm{side}} = 256$, six minutes on a laptop, reproduce all of these to their Monte Carlo precision, and reproduce the full-sky content of Knox (1995) and Hivon et al. (2002) (Table 8.3).
- An error bar needs about 50 simulations for 10% precision; a bias needs $(\sigma/\mathrm{target})^2$.

8.9 A sky with holes in it

The full-sky experiment of Section 8.2 could see every direction. No real temperature map can be used that way. The disc of the Milky Way shines in microwaves through synchrotron radiation, free–free emission and warm dust, and a band of the sky around the Galactic plane is brighter in foregrounds than in CMB; a few thousand radio galaxies and dusty galaxies add bright points everywhere else (see the cosmology notes, and Chapter T1 for the map of these objects). A ground-based or balloon telescope sees only a patch to begin with. The analysis therefore multiplies the map by a **mask** that is zero where the sky cannot be trusted and one (or a smooth value between zero and one) where it can.

The beam and the pixel window of Section 8.2.1 were easy to undo because they act on each multipole separately: they multiply $a_{\ell m}$ by a number T_ℓ. A mask acts on each *direction* separately: it multiplies the map, point by point. A product in one space is a convolution in the other, so the mask mixes the multipoles. Every $a_{\ell m}$ of the masked sky is a weighted sum of many $a_{\ell' m'}$ of the true sky, and every measured power is a blend of the true powers at neighbouring ℓ. The full-sky facts of Chapter 7 and Section 8.4 (independent $a_{\ell m}$, a diagonal covariance, a $\chi^2_{2\ell+1}$ law) all fail at once, and with them every formula we have so far.

In words, the questions are these:

1. What does multiplying the map by a mask do to each $a_{\ell m}$, and to the measured spectrum on average?
2. Can the average be undone, so that an unbiased estimate of C_ℓ comes out, and what does undoing it cost?
3. What does the mask do to the scatter of the estimates, to the correlations between multipoles and to the shape of their distribution?
4. How many simulated skies does it take to measure all of that well enough to put into a likelihood?

The first two have closed-form answers. The last two have none in general, and that is where the Monte Carlo loop of Section 8.5 stops verifying and starts measuring.

8.9.1 A one-dimensional warm-up: where the power of a wave goes

The mechanism is easiest to see on a line. Take a periodic box of length L and a pure wave $f(x) = \cos(2\pi k_0 x/L)$ with $k_0 = 40$. Its Fourier spectrum has all of its power at $k = \pm k_0$ and none anywhere else. Now "observe" it only on 40% of the box: multiply it by a window $W(x)$ that is one on an interval of length $a = 0.4L$ and zero outside.

With Fourier coefficients $\tilde{g}_k = \frac{1}{L}\int_0^L g(x)e^{-2\pi ikx/L}\mathrm{d}x$ and the expansion $W(x) = \sum_q \tilde{W}_q e^{2\pi iqx/L}$, the coefficients of the product are

$$\widetilde{(Wf)}_k \overset{(1)}{=} \frac{1}{L}\int_0^L \sum_q \tilde{W}_q e^{2\pi iqx/L}\,\tfrac{1}{2}\big(e^{2\pi ik_0x/L} + e^{-2\pi ik_0x/L}\big)e^{-2\pi ikx/L}\mathrm{d}x$$
$$\overset{(2)}{=} \tfrac{1}{2}\big(\tilde{W}_{k-k_0} + \tilde{W}_{k+k_0}\big). \tag{8.49}$$

(1) Insert the Fourier series of W and write the cosine as two exponentials.

(2) $\frac{1}{L}\int_0^L e^{2\pi i(q\pm k_0-k)x/L}\mathrm{d}x$ is one when $q = k \mp k_0$ and zero otherwise, so each sum over q keeps a single term.

The single spike at k_0 has become a copy of the window's own spectrum, centred on k_0. Whatever power the window has at a distance q from zero, the masked wave has at a distance q from k_0. This is **leakage**, and the window's spectrum is its kernel.

Example: how much leaks far away. For the sharp-edged window centred at x_c,

$$\tilde{W}_q \overset{(1)}{=} \frac{1}{L}\int_{x_c-a/2}^{x_c+a/2} e^{-2\pi iqx/L}\mathrm{d}x \overset{(2)}{=} e^{-2\pi iqx_c/L}\,\frac{\sin(\pi qa/L)}{\pi q}, \qquad |\tilde{W}_q|^2 = \frac{\sin^2(\pi qa/L)}{\pi^2 q^2}. \tag{8.50}$$

(1) The window is one on the interval and zero elsewhere.

(2) Integrate the exponential and use $e^{i\alpha} - e^{-i\alpha} = 2i\sin\alpha$.

The tail falls only as $1/q^2$, because the window jumps. The fraction of the power that lands more than Q modes away from the spike is the tail of this sum divided by the total. The total is $\sum_q |\tilde{W}_q|^2 = \frac{1}{L}\int W^2\mathrm{d}x = a/L$ by Parseval. In the tail $\sin^2$ averages to $\frac{1}{2}$ and there are two sides, so the tail is about $2\times\frac{1}{2}\sum_{q>Q} 1/(\pi^2q^2) \approx 1/(\pi^2 Q)$. For $Q = 10$ and $a/L = 0.4$ the leaked fraction is $1/(\pi^2\times 10\times 0.4) = 0.025$. The script `20_leakage_1d.py` measures 0.026.

Example: the same window with soft edges. Replace each jump by a half-period of a cosine, rising from zero to one over a few per cent of the box, keeping the same total length. A function whose derivatives are all continuous has Fourier coefficients that fall faster than any power of q, so the far tail nearly disappears: the script measures 1.6×10^{-3}, sixteen times less (Figure 8.22). The price is visible in the left panel: part of the observed interval is now down-weighted, so less of the wave is used at full weight. Softening the edge of a window to suppress leakage is called **apodisation** (from the Greek "removing the feet" of the kernel).

Everything that follows on the sphere is this picture with spherical harmonics in place of plane waves. One difference matters: on the line the window was fixed and the wave was unique, whereas the sky has $2\ell+1$ modes at each ℓ and the window couples each of them to many others, so the bookkeeping needs the angular-momentum coupling rules of quantum mechanics. The physics is identical: a mask with sharp edges has a slowly falling spectrum and leaks power far away; a tapered mask leaks less and uses the sky less efficiently.

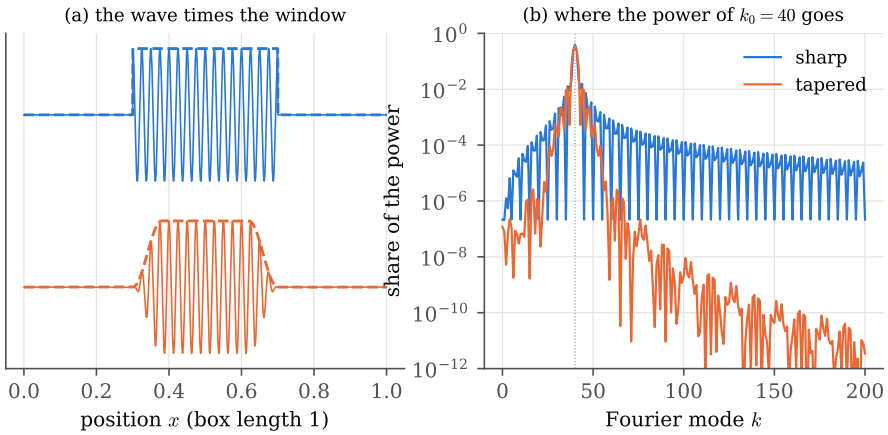

Figure 8.22: A single Fourier mode seen through 40% of the box. Left: the wave times a sharp window (blue) and times a cosine-tapered window (orange), offset for clarity. Right: the share of the power that lands at each Fourier mode. The sharp window spreads the spike at $k_0 = 40$ into a slowly falling comb of side lobes; the tapered one keeps it within a few modes and then falls by ten more decades.

8.9.2 The window and its moments

Working definition 8.5 (window, mask, sky fraction and moments)

A **window** $W(\hat{\boldsymbol{n}})$ assigns to each direction $\hat{\boldsymbol{n}}$ a weight between zero and one [one where the sky is used at full weight, zero where it is thrown away]. A binary window is a **mask** in the narrow sense. Its observed **sky fraction** $f_{\rm sky}$ is the fraction of the sphere where $W \neq 0$, and its **moments** w_i are defined by

$$f_{\rm sky} w_i = \frac{1}{4\pi} \int_{4\pi} \mathrm{d}\Omega \, W^i(\hat{\boldsymbol{n}}) \qquad \text{[Hivon (9)]},$$

so that w_i is the average of W^i over the observed region and $w_i = 1$ for every i when W is binary. The window's harmonic coefficients and power spectrum are

$$w_{\ell m} = \int \mathrm{d}\Omega \, W(\hat{\boldsymbol{n}}) Y^*_{\ell m}(\hat{\boldsymbol{n}}), \qquad \mathcal{W}_\ell = \frac{1}{2\ell+1} \sum_m |w_{\ell m}|^2 \qquad \text{[Hivon (10)]}.$$

Operationally: on HEALPix, $f_{\rm sky}$ is the fraction of pixels with $W > 0$, w_i is the mean of W^i over those pixels, and $\mathcal{W}_\ell$ is `anafast` applied to the mask itself.

The window's spectrum $\mathcal{W}_\ell$ will turn out to be the kernel of the mode coupling, the spherical version of $|\tilde{W}_q|^2$ in (8.50). Two of its values are fixed by the moments. The monopole is the square of the mean of the window,

$$\mathcal{W}_0 \overset{(1)}{=} |w_{00}|^2 \overset{(2)}{=} \left| \frac{1}{\sqrt{4\pi}} \int \mathrm{d}\Omega \, W \right|^2 \overset{(3)}{=} \left| \frac{4\pi f_{\rm sky} w_1}{\sqrt{4\pi}} \right|^2 = 4\pi f_{\rm sky}^2 w_1^2, \tag{8.51}$$

(1) At $\ell = 0$ there is one value of m, so the average over m is that single term.
(2) $Y_{00} = 1/\sqrt{4\pi}$, a constant.
(3) The definition of w_1 with $i = 1$.

and the weighted sum of all of them is the total of W^2 over the sky:

$$\sum_{\ell\geq 0}(2\ell+1)\mathcal{W}_\ell \overset{(1)}{=} \sum_{\ell m}|w_{\ell m}|^2 \overset{(2)}{=} \int \mathrm{d}\Omega\, W^2(\hat{\boldsymbol{n}}) \overset{(3)}{=} 4\pi f_{\mathrm{sky}} w_2. \tag{8.52}$$

(1) The definition of $\mathcal{W}_\ell$, multiplied by $2\ell+1$.
(2) Parseval's theorem on the sphere: expand $W = \sum w_{\ell m} Y_{\ell m}$ in $\int WW^*$ and use the orthonormality $\int Y_{\ell m} Y^*_{\ell' m'} = \delta_{\ell\ell'}\delta_{mm'}$ (Section 7.8.1). W is real, so $W^2 = |W|^2$.
(3) The definition of w_2 with $i = 2$.

These are the two identities quoted after [Hivon (10)]. The first says how much of the window is a constant offset; the second, how much power it has in total. The second is the one that will reappear as the white-noise level of a masked map.

Example: the controlled masks. To study the effect of sky coverage and of shape separately we use eight windows on $N_{\mathrm{side}} = 256$ maps (Figure 8.23, script `21_masks.py`): the full sky; polar caps keeping 10, 30 and 70% of the sky; the 10% cap with a 10° cosine taper; a Galactic-like band cut $|b| < 20°$ around the equator, binary and with a 5° taper; and 400 randomly placed holes of radius 1°, the shape of a point-source mask. A cap of half-opening θ_c has area $2\pi(1-\cos\theta_c)$, so a cap holding a fraction f_{sky} of the sphere has $\cos\theta_c = 1-2f_{\mathrm{sky}}$: $\theta_c = 36.87°, 66.42°$ and $113.58°$. The band keeps $f_{\mathrm{sky}} = 1-\sin 20° = 0.6580$, and the pixels give 0.6576. Each hole removes $2\pi(1-\cos 1°)$ steradians, and 400 of them would remove $400\times 2\pi(1-\cos 1°)/4\pi = 0.0305$ of the sky if they never touched; the pixels report 0.0301, because a few random holes overlap.

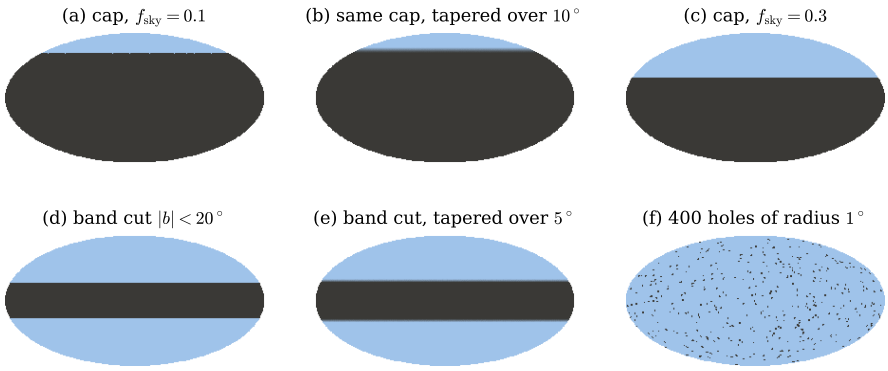

Figure 8.23: The controlled masks, in Mollweide projection with the north pole at the top. Blue is the observed sky, dark grey the removed sky. The tapers of (b) and (e) are visible as a paler rim inside the edge.

Example: the moments of a tapered cap. The taper of the 10% cap is $W = \sin^2(\pi d/2\Delta)$ for a distance $d < \Delta = 10°$ inside the edge, and $W = 1$ deeper in. How much statistical weight does such a taper cost? The moments need the averages of $W^2 = \sin^4(\pi d/2\Delta)$ and $W^4 = \sin^8(\pi d/2\Delta)$ over the cap, and the cap splits into two parts where these are easy: a core where $W = 1$, and a rim where W rises from zero.

How much of the cap is rim? The cap's edge is at $\theta_c = 36.87°$, where $\cos\theta_c = 0.8$, so the cap has area $2\pi(1-0.8) = 1.257$ sr. The rim runs from $\theta = 26.87°$ to $36.87°$ and has area $2\pi(\cos 26.87° - \cos 36.87°) = 2\pi(0.892 - 0.800) = 0.578$ sr. That is $0.578/1.257 = 0.46$ of the cap, and the core is the remaining $1 - 0.46 = 0.54$.

The average over the rim. Across the rim the variable $u = \pi d/2\Delta$ runs over a quarter period, $0 \le u \le \pi/2$. If the rim's area were spread evenly in d, the rim averages would be the

averages of $\sin^4 u$ and $\sin^8 u$ over that quarter period. For $\sin^4$ the double-angle identity $\sin^2 u = \frac{1}{2}(1 - \cos 2u)$ does it:

$$\langle \sin^4 u \rangle \overset{(1)}{=} \tfrac{1}{4}\big\langle 1 - 2\cos 2u + \cos^2 2u \big\rangle \overset{(2)}{=} \tfrac{1}{4}\big(1 - 0 + \tfrac{1}{2}\big) = \tfrac{3}{8}.$$

(1) Square $\frac{1}{2}(1 - \cos 2u)$.

(2) Over $0 \le u \le \pi/2$, $2u$ covers half a period of the cosine: $\int_0^{\pi/2} \cos 2u \, du = 0$, and $\cos^2 2u = \frac{1}{2}(1 + \cos 4u)$ averages to $\frac{1}{2}$.

For higher powers, integrating $\int_0^{\pi/2} \sin^k u \, du$ by parts once gives the step $I_k = \frac{k-1}{k} I_{k-2}$, so the average of $\sin^{2n} u$ is $\frac{(2n-1)(2n-3)\cdots 1}{(2n)(2n-2)\cdots 2}$: $\frac{3}{4} \cdot \frac{1}{2} = \frac{3}{8}$ for $n = 2$, as above, and $\frac{7}{8} \cdot \frac{5}{6} \cdot \frac{3}{4} \cdot \frac{1}{2} = \frac{35}{128}$ for $n = 4$. Then

$$w_2 \approx 0.54 \times 1 + 0.46 \times \tfrac{3}{8} = 0.71, \qquad w_4 \approx 0.54 \times 1 + 0.46 \times \tfrac{35}{128} = 0.67.$$

The approximation is the even spread of area in d. The area of a thin ring is proportional to $\sin\theta$, which grows from 0.45 at the inner edge of the rim to 0.60 at the outer edge, so the outer part of the rim, where W is small, has about a third more area per degree than the inner part. The pixel averages, $w_2 = 0.698$ and $w_4 = 0.653$, are a little lower than the estimate for exactly that reason. A taper this wide changes the effective sky fraction of [Hivon (17)], $f_{\rm sky} w_2^2 / w_4$, from 0.100 to 0.075: a quarter of the sky's statistical weight is given up to soften the edge.

Table 8.6 collects the moments of every mask. For a binary mask all the w_i are one and only $f_{\rm sky}$ matters; a taper lowers w_2 and w_4 and with them the effective sky fraction. Both identities, (8.51) and (8.52), hold for every mask: the first to within 10^{-15} (rounding), the second to within 5×10^{-4}, the power the mask has above the $\ell = 767$ at which the sum was stopped.

mask	$f_{\rm sky}$	w_2	w_4	w_2^2/w_4	$f_{\rm sky} w_2^2/w_4$
cap 0.1	0.100	1.000	1.000	1.000	0.100
cap 0.1, 10° taper	0.100	0.698	0.653	0.746	0.075
cap 0.3	0.300	1.000	1.000	1.000	0.300
cap 0.7	0.700	1.000	1.000	1.000	0.700
band $\lvert b\rvert < 20°$	0.658	1.000	1.000	1.000	0.658
band, 5° taper	0.658	0.924	0.911	0.936	0.616
400 holes of 1°	0.970	1.000	1.000	1.000	0.970

Table 8.6: Sky fraction and moments of the controlled masks at $N_{\rm side} = 256$. The last column is the effective sky fraction that enters the mode count of [Hivon (17)].

The spectrum of a mask. The kernel of the leakage is $\mathcal{W}_\ell$, and its tail decides how far power can travel. For a cap the tail can be worked out. A cap is symmetric about the pole, so only $m = 0$ survives, and with $x = \cos\theta$, $x_c = \cos\theta_c$,

$$w_{\ell 0} \overset{(1)}{=} 2\pi \sqrt{\frac{2\ell+1}{4\pi}} \int_{x_c}^{1} P_\ell(x)\, dx \overset{(2)}{=} 2\pi \sqrt{\frac{2\ell+1}{4\pi}} \, \frac{P_{\ell-1}(x_c) - P_{\ell+1}(x_c)}{2\ell+1}, \tag{8.53}$$

(1) $Y_{\ell 0} = \sqrt{(2\ell+1)/4\pi}\, P_\ell(\cos\theta)$, $W = 1$ for $\theta < \theta_c$, and the ϕ integral gives 2π.

(2) The Legendre identity $(2\ell+1)P_\ell = P'_{\ell+1} - P'_{\ell-1}$ integrates to $\int_{x_c}^1 P_\ell \, dx = [P_{\ell+1} - P_{\ell-1}]_{x_c}^1/(2\ell+1)$, and $P_\ell(1) = 1$ for every ℓ.

How fast does this fall at large ℓ? There the Legendre polynomial is a slowly decaying cosine, $P_\ell(\cos\theta_c) \approx \sqrt{2/(\pi\ell\sin\theta_c)}\cos[(\ell+\tfrac{1}{2})\theta_c - \pi/4]$. Three factors of (8.53) depend on ℓ, and they are best counted one at a time.

$$\begin{aligned}
\sqrt{\frac{2\ell+1}{4\pi}} &\overset{(1)}{\propto} \ell^{1/2},\\
P_{\ell-1}(x_c) - P_{\ell+1}(x_c) &\overset{(2)}{=} \sqrt{\frac{2}{\pi\ell\sin\theta_c}}\,\big[\cos(\varphi-\theta_c) - \cos(\varphi+\theta_c)\big]\\
&\overset{(3)}{=} \sqrt{\frac{2}{\pi\ell\sin\theta_c}}\,2\sin\theta_c\,\sin\varphi \;\propto\; \ell^{-1/2},\\
\frac{1}{2\ell+1} &\overset{(4)}{\propto} \ell^{-1}.
\end{aligned}$$

(1) The normalisation of $Y_{\ell 0}$ grows as the square root of ℓ.
(2) The asymptotic form for $\ell \mp 1$, with $\varphi \equiv (\ell+\tfrac{1}{2})\theta_c - \pi/4$; the amplitudes for $\ell-1$ and $\ell+1$ differ from the one at ℓ only by a relative $O(1/\ell)$.
(3) $\cos(\varphi-\theta_c) - \cos(\varphi+\theta_c) = 2\sin\varphi\sin\theta_c$. The phases of the two polynomials differ by $2\theta_c$, which is not small for a cap, so the difference is as large as each term: no cancellation.
(4) The factor from the integral.

The product is $\ell^{1/2}\times\ell^{-1/2}\times\ell^{-1}$, so $w_{\ell 0} \propto \ell^{-1}$, oscillating with $\sin\varphi$, and $\mathcal{W}_\ell = |w_{\ell 0}|^2/(2\ell+1) \propto \ell^{-2}/\ell = \ell^{-3}$. Weighted by the number of modes, $(2\ell+1)\mathcal{W}_\ell \propto \ell^{-2}$: the same $1/q^2$ tail as the sharp window on the line. Figure 8.24 shows it: the binary cap and band fall by about three decades per decade of ℓ, the tapered versions drop by ten decades by $\ell \approx 200$ and then sit on the floor of the numerical precision. The holes behave differently. Each hole is a small disc of radius 1°, nearly a point on large scales, and 400 randomly placed points have a nearly flat spectrum up to $\ell \sim 180°/1°$; their $\mathcal{W}_\ell$ is small but does not fall. That will make the holes a poor neighbour for the high-ℓ spectrum.

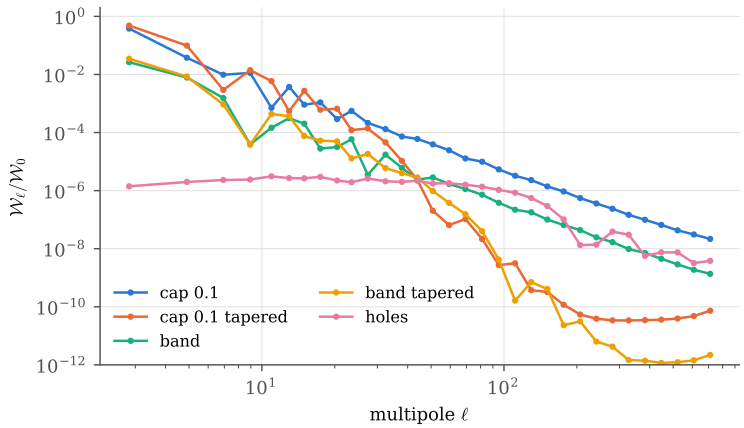

Figure 8.24: The power spectra of the masks, normalised to their monopole. The sharp cap and band fall slowly, about as ℓ^{-3}; their tapered versions collapse by ten decades and then stop at the numerical floor. The holes have a low, flat spectrum that stays up to the highest ℓ.

8.9.3 The pseudo-spectrum

The quantity we can compute from a masked map is the obvious one: transform the masked map and average the squared coefficients over m. With the masked coefficients

$$\tilde{a}_{\ell m} = \int \mathrm{d}\Omega\, \Delta T(\hat{\boldsymbol{n}}) W(\hat{\boldsymbol{n}}) Y^*_{\ell m}(\hat{\boldsymbol{n}}) \approx \Omega_{\mathrm{pix}} \sum_p W(p)\, \Delta T(p)\, Y^*_{\ell m}(p), \tag{8.54}$$

$$\widetilde{C}_\ell = \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} |\tilde{a}_{\ell m}|^2, \tag{8.55}$$

[Hivon (11)–(13)], where the sum runs over the pixels p of area Ω_{pix} and ΔT is the observed map of Section 8.2, sky plus noise. $\widetilde{C}_\ell$ is the **pseudo-spectrum** (or pseudo-C_ℓ), and an estimator built on it is a **pseudo-C_ℓ estimator**. The cosmology notes write the same construction as $\widetilde{\Theta} = \Theta W$ with the mask expanded in $w_{\ell m}$ (see the cosmology notes). On the full sky $W = 1$ and $\widetilde{C}_\ell$ is the observed spectrum of Section 8.3.

Computing (8.54) for every (ℓ, m) by brute force costs $N_{\mathrm{pix}} \ell^2_{\mathrm{max}}$ operations, but on a grid of iso-latitude rings, like HEALPix, the sum over ϕ along each ring is a fast Fourier transform and the cost drops to $N_{\mathrm{pix}}^{1/2} \ell^2_{\mathrm{max}}$ [Hivon §2.2]. That is the reason the pseudo-spectrum, and not a likelihood, is the workhorse at high ℓ: for a Planck map it is a few seconds, where the exact likelihood of Section 8.1.1 needs N^3_{pix} operations. Our transforms use `map2alm` with `iter=0`, which is exactly the pixel sum (8.54); iterating would try to correct the quadrature error, which is negligible below $\ell = 2N_{\mathrm{side}}$ (Section 7.11.3) and is part of what the coupling calculation of Section 8.10 has to reproduce anyway.

Key idea: A mask is a product in the sky, a convolution in ℓ

Multiplying the map by W multiplies nothing in harmonic space; it convolves. Each pseudo-coefficient $\tilde{a}_{\ell m}$ is a combination of true coefficients at many (ℓ', m'), with weights set by the window's own coefficients $w_{\ell m}$. A sharp edge gives the window a tail $\propto \ell^{-3}$ and moves power far; a smooth edge confines it to neighbouring multipoles.

The code. The masks are a few lines each. A cap is a test on the colatitude of each pixel; the taper is applied to the distance d from the edge, measured inwards:

Listing 8.4: Masks and their cosine taper (`code/ch08/lib_masks.py`)

```
def taper(d, width):
    """Cosine taper of the distance d (rad) from the mask edge: 0 outside, 1 deep inside.

    W = 0 for d <= 0;  W = (1 - cos(pi d / width)) / 2  for 0 < d < width;  W = 1 beyond.
    width = 0 gives the binary (top-hat) mask.
    """
    d = np.asarray(d, dtype=float)
    if width <= 0:
        return (d > 0).astype(float)
    x = np.clip(d / width, 0.0, 1.0)
    return 0.5 * (1.0 - np.cos(np.pi * x))

def _angles(nside):
    theta, phi = hp.pix2ang(nside, np.arange(hp.nside2npix(nside)))
    return theta, phi

```

```
def cap(nside, fsky, apo_deg=0.0):
    """Observed region = a cap around the north pole holding a fraction fsky of the sphere.

    A cap of half-opening theta_c has area 2 pi (1 - cos theta_c), so cos theta_c = 1 - 2
    fsky.
    The taper (if any) eats into the cap from its edge inwards.
    """
    theta, _ = _angles(nside)
    theta_c = np.arccos(1.0 - 2.0 * fsky)
    return taper(theta_c - theta, apo_deg * DEG)
```

`taper` returns 0 outside the mask, rises as $\sin^2(\pi d/2\Delta) = \frac{1}{2}[1-\cos(\pi d/\Delta)]$ across a rim of width Δ, and returns 1 deeper in; with $\Delta = 0$ it is the binary mask. `cap` converts the requested sky fraction into the half-opening angle with $\cos\theta_c = 1 - 2f_{\rm sky}$ and applies the taper to $\theta_c - \theta$. Because the taper eats into the cap from its edge, the area with $W > 0$, and hence $f_{\rm sky}$, is the same with and without it, and only the moments change (Table 8.6).

The simulation itself is the loop of Section 8.5 with one extra line. Each of the 2000 skies is drawn from the fiducial spectrum, smoothed by the 30′ beam and the pixel window, and given white noise of 200 μK arcmin (the experiment of Section 8.2); then the same map is multiplied by each of the eight masks and transformed:

Listing 8.5: The cut-sky Monte Carlo: one sky, eight masks (`code/ch08/23_mc_masked.py`)

```
def pcl(m):
    return hp.alm2cl(hp.map2alm(m, lmax=L, iter=0))

def run_chunk(c):
    path = DATA / f"mc_masked_{c}.npz"
    if path.exists():
        return
    rng = rng_for("ch08", "23_mc_masked", stream=c)
    out = {k: np.empty((PER_CHUNK, L + 1), np.float32) for k in
           ["sky"] + ["pcl_" + k for k in KEYS] + ["filt_s", "filt_sn", "filt_n"]}
    t0 = time.time()
    for i in range(PER_CHUNK):
        a = cs.synalm(cl[: exp.lmax_sim + 1], exp.lmax_sim, rng)    # the sky, l <= 767
        s = cs.observe_signal(a, exp)                                # beam and pixel window
        n = cs.noise_map(exp, rng)                                   # white pixel noise
        out["sky"][i] = hp.alm2cl(a)
        d = s + n
        for k in KEYS:
            out["pcl_" + k][i] = pcl(MASKS[k] * d)
```

`pcl` is (8.54)–(8.55). Observing the *same* sky through all eight masks (line 67) is the common-random-numbers trick of Section 8.5: differences between masks are then differences of geometry, not of luck. The sky's own full-sky spectrum (line 64) is stored as well, so that every estimate can also be compared with the spectrum of the very sky it came from. The run was split into eight chunks of 250 skies with their own random streams, so that an interruption costs at most one chunk; it took 22 CPU-minutes, 0.66 s per sky for one synthesis and nine transforms. The full research version of this loop simulates maps at $N_{\rm side} = 2048$ up to $\ell \approx 2500$, with the real scan and noise; ours stops at $N_{\rm side} = 256$ and $\ell = 767$, which keeps the acoustic peaks and the start of the damping tail and gives up the high-ℓ multipoles where the beam has removed the signal anyway.

Watch out: Which sky fraction?

Three different "sky fractions" appear in cut-sky formulas, and they are equal only for a binary mask. $f_{\rm sky}$ counts the pixels with $W \neq 0$; $f_{\rm sky} w_2$ is the factor by which a mask lowers the power of white noise (Section 8.10); $f_{\rm sky} w_2^2/w_4$ counts the effective number of modes (Section 8.12). Using $f_{\rm sky}$ for a tapered mask overestimates the number of modes, by a factor $0.100/0.075 = 1.33$ for our tapered cap.

8.10 The mode-coupling matrix

On the line, the masked wave's spectrum was the window's spectrum shifted to k_0 (Section 8.9.1). On the sphere the pseudo-spectrum $\widetilde{C}_\ell$ of (8.55), the m-average of the squared coefficients of the masked map, is again fixed on average by the window's spectrum $\mathcal{W}_\ell$ (Section 8.9.2) and the true spectrum C_ℓ. The question is: if the sky has spectrum C_ℓ and we observe it through a window W, what is $\langle \widetilde{C}_\ell \rangle$, the average of the pseudo-spectrum over skies? The answer is a matrix, the **mode-coupling matrix** $M_{\ell\ell'}$, and the whole of the MASTER method rests on it.

8.10.1 From the window to the coupling kernel

Masked coefficients are linear in the true ones. Expand the true sky as $\Delta T = \sum_{\ell' m'} a_{\ell' m'} Y_{\ell' m'}$ inside the integral (8.54):

$$\tilde{a}_{\ell m} = \sum_{\ell' m'} K_{\ell m, \ell' m'}\, a_{\ell' m'}, \qquad K_{\ell m, \ell' m'} \equiv \int \mathrm{d}\Omega\, Y^*_{\ell m}(\hat{\boldsymbol{n}})\, W(\hat{\boldsymbol{n}})\, Y_{\ell' m'}(\hat{\boldsymbol{n}}) \tag{8.56}$$

[Hivon (A16)–(A18)], [141, eqs 5a–6]. A physicist will recognise K: it is the matrix element $\langle \ell m | \hat{W} | \ell' m' \rangle$ of the operator "multiply by W" in the basis of angular-momentum eigenstates. A potential $V(\theta, \phi)$ in quantum mechanics couples the states $|\ell' m'\rangle$ in exactly this way, and the selection rules of atomic transitions are the selection rules of mode coupling. On the full sky $W = 1$, the operator is the identity, and $K_{\ell m, \ell' m'} = \delta_{\ell\ell'}\delta_{mm'}$. Because $\tilde{a}_{\ell m}$ is a linear combination of Gaussian variables it is Gaussian, but the $\tilde{a}_{\ell m}$ are no longer independent [Hivon §A.2]. Their covariance takes two moves:

$$\langle \tilde{a}_{\ell m} \tilde{a}^*_{\ell'' m''} \rangle \overset{(1)}{=} \sum_{\ell' m'} \sum_{\ell''' m'''} K_{\ell m, \ell' m'} K^*_{\ell'' m'', \ell''' m'''} \langle a_{\ell' m'} a^*_{\ell''' m'''} \rangle \overset{(2)}{=} \sum_{\ell' m'} C_{\ell'}\, K_{\ell m, \ell' m'} K^*_{\ell'' m'', \ell' m'}. \tag{8.57}$$

(1) Write both masked coefficients with (8.56), each with its own summation indices. The matrix K is fixed by the window, so the average over skies acts only on the true coefficients.

(2) Full-sky isotropy, $\langle a_{\ell' m'} a^*_{\ell''' m'''} \rangle = C_{\ell'} \delta_{\ell'\ell'''} \delta_{m' m'''}$ (Section 7.9): the Kronecker deltas collapse the second double sum onto the first.

Three spherical harmonics and the $3j$ symbols. To evaluate K we expand the window as well, $W = \sum_{LM} w_{LM} Y_{LM}$, which leaves an integral of three harmonics. It is the **Gaunt integral**:

$$\int \mathrm{d}\Omega\, Y_{\ell_1 m_1} Y_{\ell_2 m_2} Y_{\ell_3 m_3} = \sqrt{\frac{(2\ell_1+1)(2\ell_2+1)(2\ell_3+1)}{4\pi}} \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{pmatrix}, \tag{8.58}$$

with $Y^*_{\ell m} = (-1)^m Y_{\ell, -m}$ for the conjugate [Hivon (A20)]. The formula comes from the quantum theory of angular momentum, where the product of two harmonics is expanded in single harmonics with Clebsch–Gordan coefficients; we take it from there. Two of its consequences can be checked by hand, and they are the ones that matter physically. Each harmonic carries

a factor $e^{im_i\phi}$, so the ϕ integral of the product is $\int_0^{2\pi} e^{i(m_1+m_2+m_3)\phi}\mathrm{d}\phi$, which vanishes unless $m_1+m_2+m_3=0$: the projections are conserved. And $Y_{\ell_1 m_1}Y_{\ell_2 m_2}$ is a polynomial of degree $\ell_1+\ell_2$ in the components of $\hat{\boldsymbol{n}}$, so it contains no harmonic above $\ell_1+\ell_2$, and is orthogonal to $Y_{\ell_3 m_3}$ when $\ell_3 > \ell_1+\ell_2$; the same argument for each pair says that the three ℓ's must form a triangle. The arrays in brackets are **Wigner $3j$ symbols** [the amplitude for three angular momenta ℓ_1, ℓ_2, ℓ_3 with projections m_1, m_2, m_3 to add up to zero total angular momentum], the symmetric form of the Clebsch–Gordan coefficients of quantum mechanics, $\begin{pmatrix} j_1 & j_2 & j_3 \\ m_1 & m_2 & m_3 \end{pmatrix} = \frac{(-1)^{j_1-j_2-m_3}}{\sqrt{2j_3+1}}\langle j_1 m_1\, j_2 m_2 | j_3 -m_3\rangle$. Four of their properties do all the work [Hivon (A21)–(A24)]:

1. *Triangle rule:* the symbol vanishes unless $|\ell_1-\ell_2| \le \ell_3 \le \ell_1+\ell_2$, as for adding two angular momenta in quantum mechanics.
2. *Projections:* it vanishes unless $m_1+m_2+m_3=0$.
3. *Parity:* with all $m_i=0$ it vanishes when $\ell_1+\ell_2+\ell_3$ is odd (the product of three harmonics with $m=0$ is odd under $\hat{\boldsymbol{n}}\to-\hat{\boldsymbol{n}}$ and integrates to zero).
4. *Orthogonality:*

$$\sum_{\ell_3 m_3}(2\ell_3+1)\begin{pmatrix}\ell_1 & \ell_2 & \ell_3\\ m_1 & m_2 & m_3\end{pmatrix}\begin{pmatrix}\ell_1 & \ell_2 & \ell_3\\ m_1' & m_2' & m_3\end{pmatrix} = \delta_{m_1 m_1'}\delta_{m_2 m_2'},$$

$$\sum_{m_1 m_2}\begin{pmatrix}\ell_1 & \ell_2 & \ell_3\\ m_1 & m_2 & m_3\end{pmatrix}\begin{pmatrix}\ell_1 & \ell_2 & \ell_3'\\ m_1 & m_2 & m_3'\end{pmatrix} = \frac{\delta_{\ell_3\ell_3'}\delta_{m_3 m_3'}}{2\ell_3+1},$$

   the second for ℓ_3 inside the triangle.

Finally, an even permutation of the columns leaves a $3j$ symbol unchanged and an odd one multiplies it by $(-1)^{\ell_1+\ell_2+\ell_3}$, so its *square* is symmetric in its columns.

The one sum that does the work. Before the main calculation, one double sum that it will meet. Fix ℓ and ℓ', take any numbers c_{LM}, and ask for the total over all projections m, m' of $\left|\sum_{LM} c_{LM}\,(\ell\ L\ \ell';\ -m\ M\ m')\right|^2$, where $(\ell\ L\ \ell';\ -m\ M\ m')$ is the $3j$ symbol with that top and bottom row. Then

$$\sum_{mm'}\left|\sum_{LM} c_{LM}\begin{pmatrix}\ell & L & \ell'\\ -m & M & m'\end{pmatrix}\right|^2 \overset{(1)}{=} \sum_{LM}\sum_{L'M'} c_{LM}\,c^*_{L'M'}\sum_{mm'}\begin{pmatrix}\ell' & \ell & L\\ m' & -m & M\end{pmatrix}\begin{pmatrix}\ell' & \ell & L'\\ m' & -m & M'\end{pmatrix}$$
$$\overset{(2)}{=} \sum_{LM}\sum_{L'M'} c_{LM}\,c^*_{L'M'}\,\frac{\delta_{LL'}\delta_{MM'}}{2L+1} \overset{(3)}{=} \sum_{LM}\frac{|c_{LM}|^2}{2L+1}. \tag{8.59}$$

(1) Write $|z|^2 = zz^*$ as a double sum over (L,M) and (L',M'); the $3j$ symbols are real, and the order of the sums can be exchanged. Move the columns cyclically, $(\ell\ L\ \ell') \to (\ell'\ \ell\ L)$, an even permutation that leaves each symbol unchanged.
(2) The second orthogonality relation, with $\ell_1=\ell'$, $\ell_2=\ell$ and the summed projections $m_1=m'$, $m_2=-m$ (as m runs from $-\ell$ to ℓ, so does $-m$); L, M, L', M' are held fixed, in the roles of $\ell_3, m_3, \ell_3', m_3'$. Terms with L outside the triangle vanish on both sides.
(3) The Kronecker deltas leave only $L'=L$, $M'=M$.

All the cross terms between different (L,M) have dropped out: the squared modulus of a sum has become a sum of squared moduli.

The average pseudo-spectrum. Now everything is in place. Insert (8.56) into (8.55) and average:

$$\begin{aligned}
\langle \widetilde{C}_\ell \rangle &\overset{(1)}{=} \frac{1}{2\ell+1} \sum_m \sum_{\ell' m'} C_{\ell'} \, |K_{\ell m, \ell' m'}|^2 \\
&\overset{(2)}{=} \frac{1}{2\ell+1} \sum_{\ell'} C_{\ell'} \sum_{mm'} \Big| \sum_{LM} w_{LM} (-1)^m \sqrt{\tfrac{(2\ell+1)(2L+1)(2\ell'+1)}{4\pi}} \begin{pmatrix} \ell & L & \ell' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} \ell & L & \ell' \\ -m & M & m' \end{pmatrix} \Big|^2 \\
&\overset{(3)}{=} \sum_{\ell'} C_{\ell'} \frac{2\ell'+1}{4\pi} \sum_{LM} |w_{LM}|^2 (2L+1) \begin{pmatrix} \ell & L & \ell' \\ 0 & 0 & 0 \end{pmatrix}^2 \frac{1}{2L+1} \\
&\overset{(4)}{=} \sum_{\ell'} \underbrace{C_{\ell'} \frac{2\ell'+1}{4\pi} \sum_L (2L+1) \mathcal{W}_L \begin{pmatrix} \ell & \ell' & L \\ 0 & 0 & 0 \end{pmatrix}^2}_{M_{\ell\ell'}} .
\end{aligned} \tag{8.60}$$

(1) $\widetilde{C}_\ell$ is the m-average of $|\tilde{a}_{\ell m}|^2$; with (8.57) at $\ell'' = \ell$, $m'' = m$, the average of $|\tilde{a}_{\ell m}|^2$ is $\sum_{\ell' m'} C_{\ell'} |K_{\ell m, \ell' m'}|^2$.
(2) Expand W in K and use the Gaunt integral (8.58) with $Y^*_{\ell m} = (-1)^m Y_{\ell,-m}$.
(3) The sign $(-1)^m$ does not depend on (L, M) and has modulus one, so it drops out of the squared modulus. Take the factor $\sqrt{(2\ell+1)(2\ell'+1)/4\pi}$ out of the square too, and apply (8.59) with $c_{LM} = w_{LM}\sqrt{2L+1}\,(\ell\ L\ \ell';0\ 0\ 0)$. The $(2\ell+1)$ that comes out cancels the prefactor $1/(2\ell+1)$.
(4) $\sum_M |w_{LM}|^2 = (2L+1)\mathcal{W}_L$ by the definition of the window's spectrum, and the squared symbol is symmetric in its columns.

This is [Hivon (A27)–(A31)], $\langle \widetilde{C}_\ell \rangle = \sum_{\ell'} M_{\ell\ell'} C_{\ell'}$ [Hivon (14)], with

$$M_{\ell\ell'} = \frac{2\ell'+1}{4\pi} \sum_L (2L+1) \mathcal{W}_L \begin{pmatrix} \ell & \ell' & L \\ 0 & 0 & 0 \end{pmatrix}^2 . \tag{8.61}$$

The matrix depends only on the window, through its spectrum, and not on the sky. It is not symmetric because of the factor $2\ell'+1$; Efstathiou [141] writes it as $M_{\ell\ell'} = (2\ell'+1)\,\Xi(\ell, \ell', \mathcal{W})$ and uses the symmetric matrix $G_{\ell\ell'} = M_{\ell\ell'}/(2\ell'+1)$ [141, eqs 9–11]. NaMaster writes the same expression with $P_L^{vw} = (2L+1)\,\mathrm{PCL}_L(v, w)$, the window's spectrum times its mode count, in place of $(2L+1)\mathcal{W}_L$ [142, eq. 12]; for two different windows v and w on two maps it uses their cross-spectrum, which reduces to ours when $v = w = W$.

Beam, noise and filtering. The beam and the pixel window act on the sky *before* the mask is applied: the instrument records the smoothed sky, and the mask is applied to the recorded map. The true spectrum in (8.60) is therefore $T_{\ell'}^2 C_{\ell'}$, with $T_\ell = B_\ell p_\ell$ of Section 8.2.1. A filter on the timestream or the map, which suppresses some scales, is modelled by a **transfer function** F_ℓ in the same place. Noise is added before masking too, and its masked power $\langle \widetilde{N}_\ell \rangle$ simply adds:

Key idea: The master equation of the cut sky

$$\langle \widetilde{C}_\ell \rangle = \sum_{\ell'} M_{\ell\ell'} \, F_{\ell'} \, T_{\ell'}^2 \, \langle C_{\ell'} \rangle + \langle \widetilde{N}_\ell \rangle \qquad \text{[Hivon (15)]},$$

with $M_{\ell\ell'}$ from (8.61). The coupling depends on the window alone; the beam and filter sit inside the sum, at the true multipole ℓ'.

Example: the full sky. For $W = 1$, $w_{00} = \sqrt{4\pi}$ and every other w_{LM} vanishes, so $\mathcal{W}_0 = 4\pi$ and $\mathcal{W}_{L>0} = 0$. Then

$$M_{\ell\ell'} \overset{(1)}{=} \frac{2\ell'+1}{4\pi}\, 4\pi \begin{pmatrix} \ell & \ell' & 0 \\ 0 & 0 & 0 \end{pmatrix}^2 \overset{(2)}{=} (2\ell'+1)\frac{\delta_{\ell\ell'}}{2\ell+1} = \delta_{\ell\ell'}.$$

(1) Only $L = 0$ survives the sum in (8.61).

(2) With $\ell_3 = 0$ the triangle rule forces $\ell = \ell'$, and $\begin{pmatrix} \ell & \ell & 0 \\ 0 & 0 & 0 \end{pmatrix} = (-1)^\ell/\sqrt{2\ell+1}$.

No coupling, as it must be.

Example: white noise through a mask. Uniform white noise has the same power N at every multipole. Its masked power is

$$\begin{aligned} \langle \widetilde{N}_\ell \rangle &\overset{(1)}{=} N \sum_{\ell'} M_{\ell\ell'} \overset{(2)}{=} \frac{N}{4\pi} \sum_L (2L+1)\mathcal{W}_L \sum_{\ell'} (2\ell'+1) \begin{pmatrix} \ell & \ell' & L \\ 0 & 0 & 0 \end{pmatrix}^2 \\ &\overset{(3)}{=} \frac{N}{4\pi} \sum_L (2L+1)\mathcal{W}_L \overset{(4)}{=} N f_{\rm sky} w_2. \end{aligned} \tag{8.62}$$

(1) The master equation with $C_{\ell'} = N$ for every ℓ' and no beam (noise is not smoothed).

(2) Insert (8.61) and exchange the sums.

(3) The first orthogonality relation with all projections zero: only $m_3 = 0$ survives and $\sum_{\ell'}(2\ell'+1)(\ell\ \ell'\ L;0\ 0\ 0)^2 = 1$.

(4) Parseval for the window, (8.52).

This is [Hivon (A32)]. Masked white noise stays white, at a level lowered by the average of W^2 over the sky: each pixel's noise is multiplied by W, so its variance by W^2. The same steps with the roles of ℓ and ℓ' exchanged give the column rule $\sum_\ell (2\ell+1)M_{\ell\ell'} = (2\ell'+1) f_{\rm sky} w_2$: all the power of one true multipole is redistributed, and its total is lowered by the same factor. These two *sum rules* are the first test of any coupling code.

Example: the flat-sky limit. On a small patch the sphere looks flat and the harmonics become plane waves [Hivon (A1)–(A15)]. The coupling of two Fourier modes is then simply the window's Fourier coefficient at their difference, $K_{\boldsymbol{k}_1\boldsymbol{k}_2} = \tilde{w}(\boldsymbol{k}_2 - \boldsymbol{k}_1)$, the two-dimensional version of (8.49), and the average power becomes $\langle \widetilde{C}_{k_1} \rangle = \int k_2 \mathrm{d}k_2\, M_{k_1k_2} \langle C_{k_2} \rangle$ with $M_{k_1k_2} = 2\pi \int k_3 \mathrm{d}k_3\, \mathcal{W}(k_3) J(k_1,k_2,k_3)$ [Hivon (A14)]. Here $J(k_1,k_2,k_3) = \frac{2}{\pi}(2k_1^2k_2^2 + 2k_1^2k_3^2 + 2k_2^2k_3^2 - k_1^4 - k_2^4 - k_3^4)^{-1/2}$ [Hivon (A10)] is the density of ways in which three vectors of lengths k_1, k_2, k_3 can close into a triangle, $\boldsymbol{k}_1 = \boldsymbol{k}_2 + \boldsymbol{k}_3$, which is momentum conservation. For large multipoles the squared $3j$ symbol tends to exactly the same expression in (ℓ_1, ℓ_2, ℓ_3) [Hivon (A26)]: the triangle rule of angular momentum is the triangle of momentum conservation, and the curved-sky kernel reduces to the flat one.

8.10.2 Computing the $3j$ symbols and the matrix

Only symbols with all projections zero enter (8.61), and for those there is a closed form. For even $J = \ell_1 + \ell_2 + \ell_3$ and $g = J/2$,

$$\begin{pmatrix} \ell_1 & \ell_2 & \ell_3 \\ 0 & 0 & 0 \end{pmatrix}^2 = \frac{(J-2\ell_1)!\,(J-2\ell_2)!\,(J-2\ell_3)!}{(J+1)!} \left[\frac{g!}{(g-\ell_1)!\,(g-\ell_2)!\,(g-\ell_3)!} \right]^2 \tag{8.63}$$

[Hivon (A25)], and zero for odd J.

Example: one symbol by hand. For $(2,2,2)$: $J=6$, $g=3$. The first factor is $2!\,2!\,2!/7! = 8/5040$ and the bracket is $3!/(1!\,1!\,1!) = 6$, so the square is $8\times 36/5040 = 2/35 = 0.057143$. The code returns 0.057143.

The factorials overflow a double-precision number beyond 170!, long before $\ell = 767$. The standard cure is to work with logarithms: $\ln n!$ is the log-gamma function $\ln\Gamma(n+1)$, the logarithm of (8.63) is a sum of eight such terms, and one exponential at the end gives a number of ordinary size. No recursion is needed for this family of symbols, and the closed form is exact up to rounding. Checked against the exact rational values from `sympy.physics.wigner` for six triples up to $(400, 380, 30)$, the worst relative error is 1.026×10^{-12}, and the orthogonality sum $\sum_{\ell_3}(2\ell_3+1)(100\ 140\ \ell_3;0\ 0\ 0)^2$ comes out as 1.000000000000.

    return M
```

`_w3j000_sq` first applies the selection rules (odd J, triangle) and returns zero without computing anything; otherwise it evaluates the logarithm of (8.63) from a precomputed table `lf` of $\ln n!$. `_coupling` is (8.61) literally: for each pair (ℓ,ℓ') it sums over the multipoles L of the window allowed by the triangle rule, starting at $|\ell-\ell'|$ and stepping by two to skip the odd-parity terms that vanish. The loop over rows runs in parallel (`prange`, compiled by `numba`). For $\ell,\ell' \le 767$ a matrix takes a few seconds. It needs the window's spectrum up to $L = \ell+\ell'$, so the masks' spectra were computed to $L = 1535$ (script `22_coupling.py`).

The sum rules, numerically. The white-noise rule $\sum_{\ell'} M_{\ell\ell'} = f_{\rm sky} w_2$ holds for every row $\ell \le 400$ to within 8.0×10^{-4} for the sharp 10% cap, 2.4×10^{-5} for its tapered version and 7.0×10^{-4} for the holes; the residue is the part of each row that would lie beyond $\ell' = 767$ and is cut off. Sharp masks have the slowest tails and lose the most.

8.10.3 Checking the matrix against the sky

A formula with this many indices deserves two independent checks, one without random numbers and one with them.

A direct check, mode by mode. A sky whose power is all in one multipole ℓ' is a sum of its $2\ell'+1$ real modes: the real $Y_{\ell'0}$ with variance $C_{\ell'}$, and the real and imaginary parts of $a_{\ell'm'}$ for $m' > 0$, each with variance $C_{\ell'}/2$ (Section 7.10.1). Because the modes are independent, the average pseudo-spectrum of such a sky is the variance-weighted sum of the pseudo-spectra of each masked mode. Setting $C_{\ell'} = 1$ that sum is the column $M_{\ell\ell'}$ of the matrix, computed with $2\ell'+1$ map transforms and no $3j$ symbol and no random number. Script `24_coupling_check.py` does this for $\ell' = 20$ and 100 through the 10% cap and the band. The two computations agree to 8.5×10^{-13} wherever the column carries power (Figure 8.25). This is also the "Monte Carlo of the mask response" in its cheapest form: one transform per mode, nothing random.

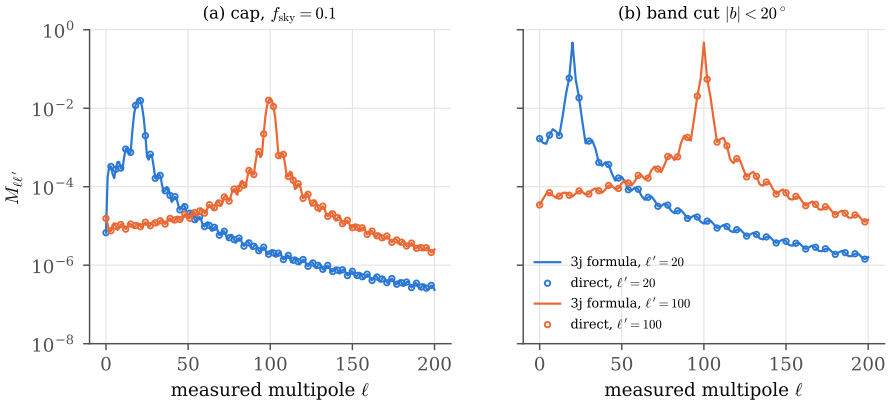

Figure 8.25: Two columns of the coupling matrix, $\ell' = 20$ (blue) and $\ell' = 100$ (orange), from the $3j$ formula (lines) and from transforming each masked real mode of that multipole (circles). (a) The 10% cap. (b) The band cut, shown at the multipoles of the same parity as ℓ' only: the band is symmetric about the equator and does not couple multipoles of opposite parity.

The band and parity. The right panel of Figure 8.25 shows a selection rule at work. The band is symmetric under $\theta \to \pi - \theta$, the reflection through the equator. Its coefficients w_{LM} are nonzero only for even L (and $M = 0$), because Y_{L0} is odd under the reflection for odd L. The parity rule of the $3j$ symbol then requires $\ell + \ell' + L$ even, so $\ell + \ell'$ is even: the band couples ℓ' only to multipoles of the same parity. The caps have no such symmetry and couple everything.

The Monte Carlo check. The second check uses the 2000 simulated skies of Section 8.9.3, with beam, pixel window and noise. For each mask we compare the mean of the simulated pseudo-spectra with the master equation, $\sum_{\ell'} M_{\ell\ell'} T_{\ell'}^2 C_{\ell'} + N f_{\rm sky} w_2$, and divide the difference by the Monte Carlo error of the mean, the simulated standard deviation over $\sqrt{2000}$. If the formula is right, these pulls are draws of a standard Gaussian, and their mean square over $2 \le \ell \le 600$ should be close to one. It is 1.05 on the full sky, 1.04 for the 30% cap, 1.06 for the band, 1.07

for the holes and 0.87 and 0.81 for the sharp and tapered 10% caps (Figure 8.26). The last two are a little below one, and that is expected: through a small cap neighbouring multipoles are strongly correlated (Section 8.12), so the 599 pulls contain only about 60 independent numbers, and their mean square scatters by about $\sqrt{2/60} \approx 0.2$ around one.

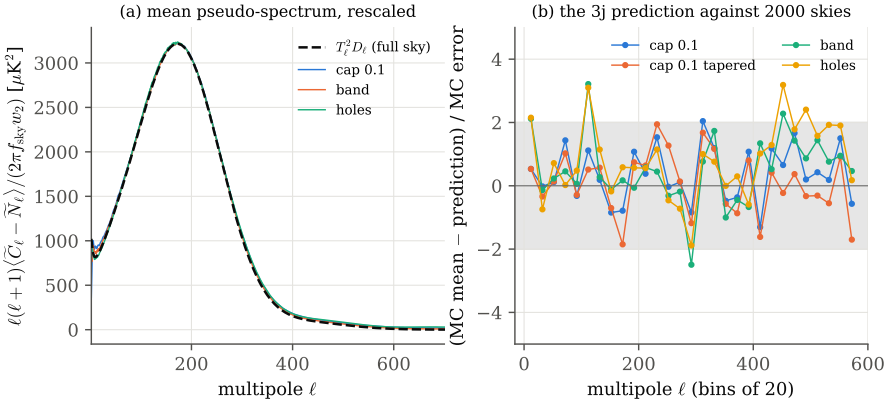

Figure 8.26: The master equation against 2000 simulated skies. (a) The mean pseudo-spectrum through four masks, noise subtracted and divided by $f_{\rm sky} w_2$, on the full-sky spectrum (dashed): at this scale the coupling is invisible except as a smoothing of the curve. (b) The mean minus the prediction of (8.61), in units of its Monte Carlo error, in bins of 20 multipoles: the residuals scatter within ±2 (grey) with no trend.

Watch out: The coupling needs the window to twice the band limit

$M_{\ell\ell'}$ involves $\mathcal{W}_L$ up to $L = \ell + \ell'$. Computing the mask's spectrum only to the analysis band limit $\ell_{\rm max}$ silently drops the coupling between the highest multipoles, worst for sharp masks whose spectra fall slowly. Compute $\mathcal{W}_L$ to $2\ell_{\rm max}$, and if the pixelisation cannot represent the mask that far ($L > 3N_{\rm side}$ on HEALPix), compute the mask at a higher resolution than the data.

8.10.4 Leakage and apodisation on the sphere

Figure 8.27 shows what happens to the power of a single true multipole, $\ell' = 100$, through each mask: the share $(2\ell + 1)M_{\ell,100}/\sum_\ell (2\ell + 1)M_{\ell,100}$ that lands at each measured ℓ. Every mask keeps most of the power near ℓ', in a central peak whose width is set by the size of the observed region, as for any diffraction pattern: a region of angular size Θ cannot resolve multipoles closer than about π/Θ. Outside the peak the masks differ by orders of magnitude, exactly as the one-dimensional windows did. The fraction landing more than 20 multipoles away is 2.9% for the sharp 10% cap and 0.33% for the tapered one; 1.3% for the sharp band and 0.44% for the tapered one; 1.5% and 0.63% for the 30% and 70% caps; and 2.3% for the holes, whose flat window spectrum carries power to every multipole.

Apodisation therefore buys a clean kernel and pays in two ways. The tapered region uses the sky at less than full weight, so the effective sky fraction $f_{\rm sky} w_2^2/w_4$ drops (Table 8.6); and the observed region is effectively smaller, so the central peak is wider and neighbouring multipoles become even more correlated. Whether the trade is worth it depends on the spectrum. A spectrum that falls steeply, like the CMB in its damping tail behind a 30′ beam, is ruined by a tail that carries power from the acoustic peaks into multipoles where there is almost none of their own; there apodisation is indispensable (Section 8.11.1). For a nearly flat spectrum leakage hardly matters, and the sharp mask, which keeps more modes, gives smaller error bars. Hivon et al. make the same point for their patch: a well-chosen apodisation can improve the

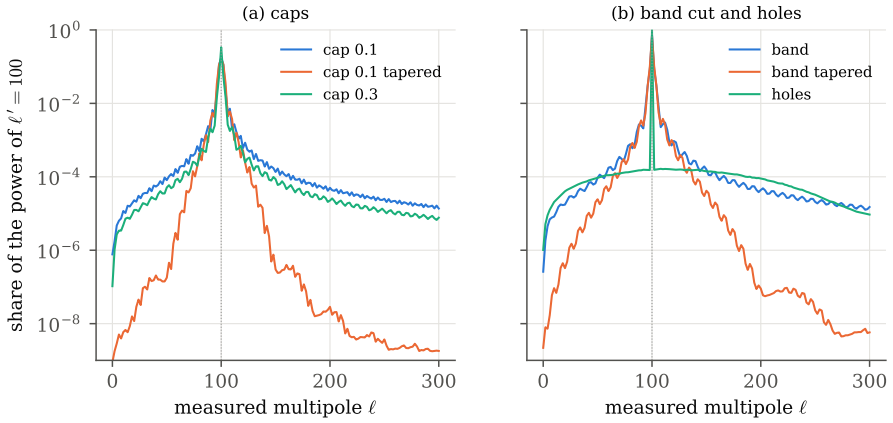

Figure 8.27: Where the power of the true multipole $\ell' = 100$ goes. (a) Caps: the sharp 10% cap (blue) and 30% cap (green) leak a slowly falling tail to all ℓ; the tapered 10% cap (orange) has a wider central peak but tails eight decades lower. (b) The band cut (blue), its tapered version (orange), and the holes (green), whose leakage is nearly flat in ℓ.

achievable spectral resolution of a non-convex survey [Hivon §3.1].

Example: the price of the taper in modes. At $\ell = 200$ in a bin of $\Delta\ell = 20$, the sharp 10% cap offers $(2\ell+1)\Delta\ell\, f_{\rm sky} = 802$ modes by the counting of [Hivon (17)]; the tapered cap offers $(2\ell+1)\Delta\ell\, f_{\rm sky} w_2^2/w_4 = 401 \times 20 \times 0.075 = 600$. If the bin were cosmic-variance limited its error would grow by $\sqrt{802/600} = 1.16$. That is the price of the taper; the next section shows what it buys.

8.11 Undoing the mask

The master equation of Section 8.10 says what the mask does on average: $\langle \widetilde{C}_\ell \rangle = \sum_{\ell'} M_{\ell\ell'} F_{\ell'} T_{\ell'}^2 C_{\ell'} + \langle \widetilde{N}_\ell \rangle$, with $M_{\ell\ell'}$ the coupling matrix of the window, T_ℓ the beam times the pixel window and F_ℓ the transfer function of any filter. We observe $\widetilde{C}_\ell$ and want C_ℓ. Three recipes suggest themselves, in increasing order of effort. Divide by a single number, the fraction of the sky that was used. Invert the matrix, multipole by multipole. Or average the multipoles into bins first and invert a small matrix between bins. We take them one at a time and ask of each the question that matters for an estimator: is it unbiased, and if not, why not?

8.11.1 The naive estimator: divide by the sky fraction

The quickest guess is that a mask removes a fraction of the power and nothing else:

$$\widehat{C}_\ell^{\,\rm naive} = \frac{\widetilde{C}_\ell - \langle \widetilde{N}_\ell \rangle}{f_{\rm sky} w_2\, T_\ell^2}. \tag{8.64}$$

It has a respectable origin. For a flat spectrum it is exact: the row rule $\sum_{\ell'} M_{\ell\ell'} = f_{\rm sky} w_2$ of (8.62) says that a constant spectrum comes out of the mask multiplied by $f_{\rm sky} w_2$ and nothing else. The question is how far a curved spectrum departs from that. Subtracting the exact average,

$$\langle \widehat{C}_\ell^{\,\rm naive} \rangle - C_\ell \overset{(1)}{=} \frac{\sum_{\ell'} M_{\ell\ell'} T_{\ell'}^2 C_{\ell'}}{f_{\rm sky} w_2 T_\ell^2} - C_\ell \overset{(2)}{=} \frac{\sum_{\ell'} M_{\ell\ell'} \big(S_{\ell'} - S_\ell\big)}{f_{\rm sky} w_2\, T_\ell^2}, \qquad S_\ell \equiv T_\ell^2 C_\ell, \tag{8.65}$$

(1) The master equation with $F = 1$; the noise term cancels against the subtraction.
(2) Write $C_\ell = S_\ell / T_\ell^2$ and use the row rule to put S_ℓ inside the sum as $\sum_{\ell'} M_{\ell\ell'} S_\ell / (f_{\text{sky}} w_2)$.

so the bias is the kernel-weighted difference between the smoothed spectrum S at the true multipoles ℓ' and at the measured one. Two mechanisms make it nonzero, one near ℓ and one far from it.

Near ℓ: curvature. Divide by $C_\ell = S_\ell / T_\ell^2$ and call $\kappa_{\ell'} \equiv M_{\ell\ell'} / (f_{\text{sky}} w_2)$ the kernel; by the row rule its weights add up to one. Where the spectrum is smooth over the kernel, expand $S_{\ell'}$ around ℓ:

$$\frac{\langle \widehat{C}_\ell^{\text{naive}} \rangle - C_\ell}{C_\ell} \overset{(1)}{=} \sum_{\ell'} \kappa_{\ell'} \frac{S_{\ell'} - S_\ell}{S_\ell} \overset{(2)}{=} \frac{S'_\ell}{S_\ell} \sum_{\ell'} \kappa_{\ell'} (\ell' - \ell) + \frac{S''_\ell}{2 S_\ell} \sum_{\ell'} \kappa_{\ell'} (\ell' - \ell)^2 \overset{(3)}{=} \frac{1}{2} \sigma_K^2 \frac{S''_\ell}{S_\ell}.$$

(1) (8.65) divided by $C_\ell = S_\ell / T_\ell^2$.
(2) Taylor's expansion $S_{\ell'} = S_\ell + (\ell' - \ell) S'_\ell + \frac{1}{2} (\ell' - \ell)^2 S''_\ell$, with the derivatives taken with respect to ℓ; the constant term cancels.
(3) For a kernel symmetric about ℓ the first moment $\sum \kappa_{\ell'} (\ell' - \ell)$ vanishes (the factor $2\ell' + 1$ in M makes it slightly asymmetric, by a relative σ_K / ℓ); the second moment is the kernel's variance, σ_K^2.

At a peak $S'' < 0$ and the estimate comes out low; in a trough $S'' > 0$ and it comes out high. The mask smooths the peaks and fills the troughs.

Far from ℓ: leakage. If a fraction ε of the kernel's weight sits far away, at multipoles where S is near its peak value S_{peak}, the second piece of the bias is about $\varepsilon \, S_{\text{peak}} / S_\ell$. A tiny ε is harmless where S_ℓ is near the peak, and dominant where S_ℓ is a small fraction of it.

Example: why the damping tail is hit hardest. Compare the first peak, $\ell = 220$, with the damping tail at $\ell = 580$, and put a number on S_{peak} / S_ℓ. Behind the 30′ beam ($\sigma_b = 12.7' = 3.7 \times 10^{-3}$ rad, $\sigma_b^2 = 1.37 \times 10^{-5}$) the beam window is $e^{-\ell(\ell+1)\sigma_b^2}$. At $\ell = 220$, $\ell(\ell+1)\sigma_b^2 = 48\,620 \times 1.37 \times 10^{-5} = 0.67$ and the window is $e^{-0.67} = 0.51$; at $\ell = 580$, $336\,980 \times 1.37 \times 10^{-5} = 4.6$ and the window is $e^{-4.6} = 0.010$. The spectrum itself is $C_\ell = 2\pi D_\ell / \ell(\ell+1)$ with $D_{220} \approx 5700$ and $D_{580} \approx 2000\,\mu\text{K}^2$, so

$$\frac{C_{220}}{C_{580}} = \frac{5700/48\,620}{2000/336\,980} = \frac{0.117}{0.0059} \approx 20, \qquad \frac{S_{220}}{S_{580}} = 20 \times \frac{0.51}{0.010} \approx 1000.$$

How much leakage does it take to double the power seen at $\ell = 580$? The leaked power must equal S_{580}, which is 10^{-3} of the peak. The peak is about a hundred multipoles wide, so each of its multipoles needs to send only $10^{-3}/100 = 10^{-5}$ of its power to $\ell = 580$. The sharp 10% cap sends 2.9% of the power of each multipole more than twenty multipoles away (Section 8.10.4). Spread over the several hundred multipoles of the range, that is a few parts in 10^5 per multipole: the same size as the threshold. So the far term should be of the order of the true power at $\ell = 580$. That is what the simulations show (Figure 8.28a): the naive estimate through the sharp cap is biased by +4% in the first bin, rises slowly and reaches 112% near $\ell = 580$; through the holes it reaches 122%, and through the sharp band 49%. Tapering cures most of it: 7% for the tapered cap and 3% for the tapered band at the worst multipole. Even then a few per cent remain, much more than the error of an average over thousands of skies, so the naive estimator cannot be used for a precision spectrum.

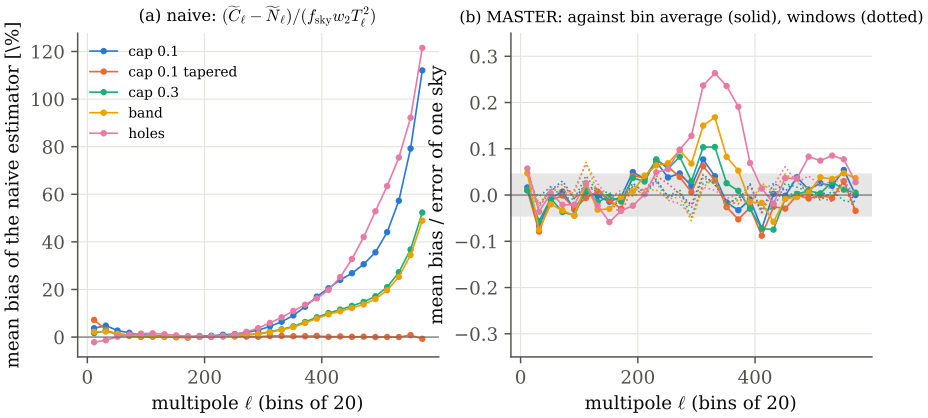

Figure 8.28: Bias of the two estimators over 2000 skies, in bins of 20 multipoles. (a) The naive estimator (8.64), in per cent: small at low ℓ, then rising steeply where the beam has removed most of the signal and leakage from the acoustic peaks takes over; the tapered cap (orange) stays within a few per cent. (b) MASTER, as a fraction of the error of a single sky, against the bin average of the input D_ℓ (solid) and against the bandpower-window prediction (dotted). The grey band is ±2 Monte Carlo errors of the mean.

8.11.2 Inverting the matrix, multipole by multipole

If M is invertible, $\widehat{C}_\ell = \sum_{\ell'} (M^{-1})_{\ell\ell'} (\widetilde{C}_{\ell'} - \langle \widetilde{N}_{\ell'} \rangle)/T_\ell^2$ is unbiased for every spectrum [141, eq. 12]. The condition number of M (the ratio of its largest to its smallest singular value, $2 \le \ell, \ell' \le 767$) tells us whether that is possible. It is 1.1 for the full sky, 1.8 for the 70% cap, 1.8 for the band and 1.1 for the holes, all harmless. For the 30% cap it is 1.3×10^{16} and for the 10% cap 1.3×10^{17}: those matrices are singular to machine precision. Figure 8.29 shows the eigenvalues. For the small caps a fixed fraction of them, 59% and 27%, falls off a cliff to the rounding floor, while for every other mask none does.

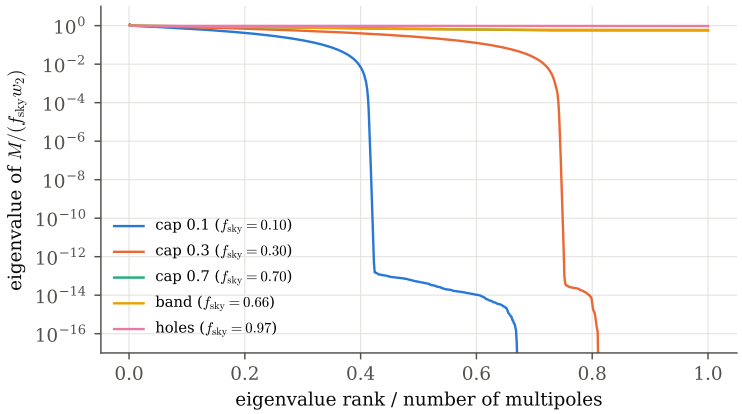

Figure 8.29: Eigenvalues of the coupling matrix (symmetrised and divided by $f_{\rm sky} w_2$), sorted and plotted against their rank as a fraction of the 766 multipoles. The 10% cap (blue) has a cliff at 0.41 and the 30% cap (orange) at 0.74: beyond it the eigenvalues are pure rounding. The 70% cap, the band and the holes have no cliff.

The event, and what could have produced it. The observed fact is sharp: a fixed fraction of the eigenvalues vanishes, 59% for one cap and 27% for the other, and none for the band, which removes far more sky than the 70% cap leaves out. So it is not the amount of sky that matters.

The candidates are the shape of the region, its size, and its smoothness, and the clean way to decide between them is to look at the coupling from the side of real space.

What the masked map measures in real space. Take the masked map $W\Delta T$ and average the product of its values over all pairs of directions $(\hat{\boldsymbol{n}}_1, \hat{\boldsymbol{n}}_2)$ an angle ϑ apart, anywhere on the sphere (where $W = 0$ the product is simply zero). Call the result the pseudo-correlation function $\widetilde{C}(\vartheta)$. Now average over skies. The window is fixed, so for each pair $\langle W_1\Delta T_1\, W_2\Delta T_2\rangle = W_1W_2\langle\Delta T_1\Delta T_2\rangle$, and for a statistically isotropic sky $\langle\Delta T_1\Delta T_2\rangle = C(\vartheta)$ depends only on the separation (Section 7.9.4). It is the same number for every pair in the average, so it comes out:

$$\langle\widetilde{C}(\vartheta)\rangle = C(\vartheta)\,\Xi_W(\vartheta), \qquad \Xi_W(\vartheta) \equiv \text{average of } W(\hat{\boldsymbol{n}}_1)W(\hat{\boldsymbol{n}}_2) \text{ over pairs a distance } \vartheta \text{ apart.}$$

The window's pair function Ξ_W is the fraction of pairs at separation ϑ that the window keeps, weighted by W; on the full sky $\Xi_W = 1$, and the masked map measures $C(\vartheta)$ itself.

The same statement in multipoles. A pair average of any fixed field f on the sphere has a Legendre series whose coefficients are the field's spectrum $f_\ell = \sum_m |f_{\ell m}|^2/(2\ell+1)$. With $x = \hat{\boldsymbol{n}}_1\cdot\hat{\boldsymbol{n}}_2$ and $x_0 = \cos\vartheta$,

$$\begin{aligned}
&\frac{\int \mathrm{d}\Omega_1 \int \mathrm{d}\Omega_2\, f(\hat{\boldsymbol{n}}_1) f(\hat{\boldsymbol{n}}_2)\,\delta(x - x_0)}{\int \mathrm{d}\Omega_1 \int \mathrm{d}\Omega_2\,\delta(x - x_0)} \\
&\overset{(1)}{=} \frac{1}{8\pi^2}\sum_\ell \frac{2\ell+1}{2} P_\ell(x_0) \int \mathrm{d}\Omega_1 \int \mathrm{d}\Omega_2\, f_1 f_2\, P_\ell(x) \\
&\overset{(2)}{=} \frac{1}{8\pi^2}\sum_\ell \frac{2\ell+1}{2} P_\ell(x_0)\,\frac{4\pi}{2\ell+1}\sum_m |f_{\ell m}|^2 \overset{(3)}{=} \sum_\ell \frac{2\ell+1}{4\pi} f_\ell\, P_\ell(\cos\vartheta).
\end{aligned}$$

(1) The denominator counts the pairs: 4π for $\hat{\boldsymbol{n}}_1$ times 2π for the uniform cos of the angle to $\hat{\boldsymbol{n}}_2$. In the numerator, write the delta function by the completeness of the Legendre polynomials, $\delta(x - x_0) = \sum_\ell \frac{2\ell+1}{2} P_\ell(x) P_\ell(x_0)$.

(2) The addition theorem, $P_\ell(\hat{\boldsymbol{n}}_1\cdot\hat{\boldsymbol{n}}_2) = \frac{4\pi}{2\ell+1}\sum_m Y_{\ell m}(\hat{\boldsymbol{n}}_1) Y^*_{\ell m}(\hat{\boldsymbol{n}}_2)$, splits the double integral into the product of $\int f Y_{\ell m}$ and $\int f Y^*_{\ell m}$, which are $f^*_{\ell m}$ and $f_{\ell m}$ for a real field.

(3) $\sum_m |f_{\ell m}|^2 = (2\ell+1) f_\ell$, and the constants combine as $\frac{1}{8\pi^2}\cdot\frac{2\ell+1}{2}\cdot\frac{4\pi}{2\ell+1}\cdot(2\ell+1) = \frac{2\ell+1}{4\pi}$.

With $f = W\Delta T$ and with $f = W$ this gives

$$\widetilde{C}(\vartheta) = \sum_\ell \frac{2\ell+1}{4\pi}\widetilde{C}_\ell P_\ell(\cos\vartheta), \qquad \Xi_W(\vartheta) = \sum_L \frac{2L+1}{4\pi}\mathcal{W}_L P_L(\cos\vartheta).$$

A product in ϑ is a convolution in ℓ, and the Legendre transform of $\langle\widetilde{C}(\vartheta)\rangle = C(\vartheta)\Xi_W(\vartheta)$ gives back the coupling matrix:

$$\begin{aligned}
\langle\widetilde{C}_\ell\rangle &\overset{(1)}{=} 2\pi\int_{-1}^{1} \mathrm{d}x\, P_\ell(x)\, C(x)\,\Xi_W(x) \overset{(2)}{=} 2\pi\sum_{\ell' L}\frac{2\ell'+1}{4\pi}C_{\ell'}\frac{2L+1}{4\pi}\mathcal{W}_L\int_{-1}^{1} P_\ell P_{\ell'} P_L\,\mathrm{d}x \\
&\overset{(3)}{=} \sum_{\ell'} C_{\ell'}\,\frac{2\ell'+1}{4\pi}\sum_L (2L+1)\mathcal{W}_L \begin{pmatrix}\ell & \ell' & L\\ 0 & 0 & 0\end{pmatrix}^2 = \sum_{\ell'} M_{\ell\ell'} C_{\ell'}.
\end{aligned} \tag{8.66}$$

(1) The inverse Legendre transform, $C_\ell = 2\pi\int P_\ell(x) C(x)\mathrm{d}x$ with $x = \cos\vartheta$ (Section 7.9.4), applied to $\widetilde{C}$, and the product rule.

(2) Expand both $C(x)$ and $\Xi_W(x)$ in Legendre series.

(3) $\int_{-1}^{1} P_\ell P_{\ell'} P_L\,\mathrm{d}x = 2\begin{pmatrix}\ell & \ell' & L\\ 0 & 0 & 0\end{pmatrix}^2$, the Gaunt integral (8.58) with all $m = 0$ and $Y_{\ell 0} = \sqrt{(2\ell+1)/4\pi}\,P_\ell$, integrated over ϕ.

The second derivation of (8.61) also explains the cliff. Now go through the candidates. *The cap:* no two points of a cap of half-opening θ_c are more than $2\theta_c$ apart, so $\Xi_W(\vartheta) = 0$ for $\vartheta > 2\theta_c$, and the data say nothing about $C(\vartheta)$ there. Any change of the C_ℓ that changes $C(\vartheta)$ only beyond $2\theta_c$ leaves every $\widetilde{C}_\ell$ untouched, and such changes form the null space of M. How large is it? Count numbers. A spectrum $C_2, \ldots, C_{\ell_{\max}}$ is about $\ell_{\max}$ numbers, and so is the function $C(\vartheta)$ it describes: a Legendre series stopped at $\ell_{\max}$ cannot change on scales finer than about $\pi/\ell_{\max}$ in angle, so it is fixed by about one value per cell of that width, $\ell_{\max}$ cells across $[0, \pi]$. The data fix $C(\vartheta)$ only in the cells with $\vartheta < 2\theta_c$, about $\ell_{\max} \cdot 2\theta_c/\pi$ numbers. The remaining $\ell_{\max}(1 - 2\theta_c/\pi)$ combinations of the C_ℓ change $C(\vartheta)$ only where the window has no pairs; they leave every $\widetilde{C}_\ell$ unchanged, so they are directions in which M gives zero. The predicted fraction of zero singular values is $1 - 2\theta_c/\pi$. For the 10% cap, $2\theta_c = 73.7°$ and the prediction is 59.0%; for the 30% cap, $2\theta_c = 132.8°$ and 26.2%. The simulations' cliffs are at 59% and 27%. *The* 70% *cap* has $2\theta_c = 227° > 180°$: every separation is observed and nothing is lost. *The band* removes a great deal of sky but keeps two caps, which contain pairs at every separation up to antipodal, so Ξ_W never vanishes. *The holes* remove small discs and leave pairs at every separation.

Key idea: When the coupling matrix can be inverted

$M_{\ell\ell'}$ is invertible exactly when the window contains pairs of directions at every separation $0 \le \vartheta \le \pi$, so that the true correlation function is seen, through Ξ_W, at all angles. A patch of angular diameter $\Theta < \pi$ loses a fraction $1 - \Theta/\pi$ of the multipole information to null modes. Large Galactic cuts are invertible; small patches never are.

This is the content of Efstathiou's rule of thumb, that M remains invertible for Galactic cuts up to about 30° above and below the plane, "if the two-point correlation function can be determined on all angular scales from the data within the uncut sky" [141, §2.1]. He also points out the difference between M and the coupling K of the coefficients themselves: K is singular for *any* cut, because combinations of $a_{\ell m}$ that live entirely inside the cut region leave no trace in the observed sky. The spectrum, a much smaller set of numbers, can be recovered when the coefficients cannot.

8.11.3 Binning first: the MASTER estimator

When M cannot be inverted, or when its inverse would amplify noise, the cure is to ask for less. The counting of Section 8.11.2 says how much less. A patch of diameter Θ ($2\theta_c$ for a cap) fixes $C(\vartheta)$ only for $\vartheta < \Theta$, about $\ell_{\max}\Theta/\pi$ numbers out of $\ell_{\max}$: one number for every π/Θ multipoles. What the data can determine is therefore not each C_ℓ but averages of the spectrum over blocks of about $\delta\ell \sim \pi/\Theta$ multipoles, and the null combinations are the ones that change sign within such a block, so that the block average does not see them. So we estimate averages over bins of multipoles, at least π/Θ wide, and assume that the spectrum is constant inside each.

Which spectrum is nearly constant across a bin? Not C_ℓ. On the large-scale plateau $\ell(\ell+1)C_\ell$ is about constant, so $C_\ell \propto 1/\ell(\ell+1)$: across a bin from $\ell = 22$ to 41, C_ℓ falls by a factor $(41 \cdot 42)/(22 \cdot 23) = 3.4$ while $\ell(\ell+1)C_\ell$ stays flat. The quantity to hold constant is therefore the "flattened" spectrum $D_\ell = \ell(\ell+1)C_\ell/2\pi$ [Hivon §3.4].

Working definition 8.6 (binning operators and the MASTER estimator)

For bins b with edges $\ell_{\rm low}^{(b)} \le \ell < \ell_{\rm low}^{(b+1)}$, the **binning operator** and its reciprocal are

$$P_{b\ell} = \frac{1}{2\pi}\frac{\ell(\ell+1)}{\ell_{\rm low}^{(b+1)} - \ell_{\rm low}^{(b)}}, \qquad Q_{\ell b} = \frac{2\pi}{\ell(\ell+1)} \qquad \text{for } \ell \text{ in bin } b\text{, zero otherwise}$$

[Hivon (20)–(21)]: P turns a spectrum C_ℓ into bin averages of D_ℓ, and Q turns a constant D_b back into a C_ℓ that is flat in D across the bin. The binned coupling and the **MASTER estimator** are

$$K_{bb'} = P_{b\ell} M_{\ell\ell'} F_{\ell'} T_{\ell'}^2 Q_{\ell' b'}, \qquad \widehat{D}_b = K^{-1}_{bb'} P_{b'\ell} \big(\widetilde{C}_\ell - \langle \widetilde{N}_\ell \rangle_{\rm MC}\big)$$

[Hivon (25)–(26)], with sums over repeated indices. $\langle \widetilde{N}_\ell \rangle_{\rm MC}$ is the noise pseudo-spectrum from noise-only simulations, and $\widehat{\mathcal{N}}_b = K^{-1}_{bb'} P_{b'\ell} \langle \widetilde{N}_\ell \rangle_{\rm MC}$ is the **noise on the sky** [Hivon (27)].

Why the recipe is unbiased, and for what, takes one chain. Start from the master equation and bin it:

$$P_{b\ell}\big(\langle \widetilde{C}_\ell \rangle - \langle \widetilde{N}_\ell \rangle\big) \overset{(1)}{=} P_{b\ell} M_{\ell\ell'} F_{\ell'} T_{\ell'}^2 C_{\ell'} \overset{(2)}{=} P_{b\ell} M_{\ell\ell'} F_{\ell'} T_{\ell'}^2 Q_{\ell' b'} D_{b'} \overset{(3)}{=} K_{bb'} D_{b'}, \tag{8.67}$$

(1) The master equation, multiplied by P (Hivon's (22)–(23)).
(2) *The assumption:* inside each bin D_ℓ is a constant $D_{b'}$, so $C_{\ell'} = Q_{\ell' b'} D_{b'}$.
(3) The definition of K.

A square system of $n_{\rm bins}$ equations, which a handful of bins makes small and well conditioned. Its solution is [Hivon (24)], and replacing the average by the measurement gives the estimator. The estimator is linear in the data, so its mean is $K^{-1}P(\langle \widetilde{C} \rangle - \langle \widetilde{N} \rangle)$ exactly; step (2) is the only approximation, and it is a statement about the *sky*, not about the estimator. For the real spectrum,

$$\langle \widehat{D}_b \rangle = \sum_\ell \mathcal{F}_{b\ell} C_\ell, \qquad \mathcal{F}_{b\ell} = \sum_{b'} K^{-1}_{bb'} \sum_{\ell'} P_{b'\ell'} M_{\ell'\ell} F_\ell T_\ell^2, \tag{8.68}$$

the **bandpower window functions** of NaMaster [142, eqs 18–19]. If D_ℓ really is flat in every bin, $\mathcal{F}_{b\ell} C_\ell$ is the plain bin average; otherwise the two differ by a known, deterministic amount, and the honest comparison of theory with data passes the theory through $\mathcal{F}$.

Example: the full sky. With $M = \mathbb{1}$ and $F = 1$, $K_{bb'}$ is diagonal and $K_{bb} = \langle T_\ell^2 \rangle_b$, the average of the squared beam over the bin (the factors $\ell(\ell+1)/2\pi$ of P and $2\pi/\ell(\ell+1)$ of Q cancel). Then $\widehat{D}_b = \langle T_\ell^2 \widetilde{D}_\ell \rangle_b / \langle T_\ell^2 \rangle_b$: a beam-weighted bin average, not the plain one. Where D_ℓ changes across a bin the two differ. Over 2000 skies the full-sky MASTER mean differs from the plain bin average by up to 10.8 Monte Carlo errors of the mean, but from the window prediction (8.68) by at most 2.7, which is what thirty Gaussian pulls give by chance. In units of the error bar of a *single* sky the bin-average offset is $0.24\,\sigma$ at most.

The cut-sky results. We ran MASTER with bins of 20 from $\ell = 2$ on every mask, with the noise on the sky subtracted (Figure 8.28b, script `25_master.py`). Against the bandpower windows the mean over 2000 skies agrees to within 2.0 Monte Carlo errors for the 10% cap, 2.2 for the 30% cap, 3.2 for the band and 3.0 for the holes, in the worst of the thirty bins below $\ell = 600$: MASTER is unbiased. Against the plain bin average the largest offset is $0.08\,\sigma$ (sharp 10% cap), $0.17\,\sigma$ (band) and $0.26\,\sigma$ (holes) of a single sky, a fraction of the error bar that a single measurement would not notice, but which a likelihood built on the plain bin average would

turn into a systematic shift. The same recipe works for the singular 10% cap. Its diameter is $2\theta_c = 73.7^\circ = 1.29\,\mathrm{rad}$, so the data fix one number per $\pi/1.29 \approx 2.4$ multipoles. A bin of 20 multipoles averages over about eight such blocks; every null combination changes sign within a block and averages to nearly zero across the bin, so it drops out of the binned equations, and $K_{bb'}$ is invertible: its condition number is 1.2×10^4, against 1.3×10^{17} for M, and close to the full sky's $7.3e+03$, which comes from the beam and the pixel window alone.

Watch out: Compare theory through the bandpower windows

A MASTER bandpower is an average of C_ℓ with weights $\mathcal{F}_{b\ell}$, not the plain bin average of D_ℓ. Comparing data with the binned theory $P_{b\ell}C_\ell$ introduces a bias that grows with the curvature of the spectrum across the bin and with the number of simulations used to test it. Binning should be chosen after the simulations are done [Hivon §3.4], and the theory compared through (8.68).

8.11.4 A filter on the map: the transfer function

Real data are filtered before the spectrum is taken. Timestreams are high-pass filtered to suppress the $1/f$ drift of the detectors, signals synchronous with the scan are removed, and the largest scales, poorly constrained by a small survey and liable to contaminate everything else, are cut away [Hivon §3.2]. A filter acts along the scan direction and therefore breaks isotropy: its effect on the spectrum is not a function of ℓ alone, and writing it as a transfer function F_ℓ in the master equation is an ansatz to be tested. Hivon et al. measure it by simulation. They run $N_{\mathrm{MC}}^{(\mathrm{s})}$ noise-free skies of a known spectrum C_ℓ^{th} through the full filtered observation, average their pseudo-spectra, and solve the master equation for F:

$$\langle \widetilde{C}_\ell \rangle_{\mathrm{MC}} = \sum_{\ell'} M_{\ell\ell'} F_{\ell'} T_{\ell'}^2 C_{\ell'}^{\mathrm{th}}.$$

A first guess. If $F_{\ell'}T_{\ell'}^2C_{\ell'}^{\mathrm{th}}$ hardly changes across the kernel, it can be taken out of the sum at $\ell' = \ell$, and the row rule $\sum_{\ell'} M_{\ell\ell'} = f_{\mathrm{sky}} w_2$ leaves $\langle \widetilde{C}_\ell \rangle_{\mathrm{MC}} \approx f_{\mathrm{sky}} w_2 F_\ell T_\ell^2 C_\ell^{\mathrm{th}}$, so $F_\ell^{(0)} = \langle \widetilde{C}_\ell \rangle_{\mathrm{MC}} / (f_{\mathrm{sky}} w_2 T_\ell^2 C_\ell^{\mathrm{th}})$. This is the naive estimator of Section 8.11.1 applied to the filter, and it inherits its bias wherever the spectrum is curved.

A correction. Write the true transfer function as the guess plus a correction, $F = F^{(0)} + \delta F$, and insert it into the master equation:

$$\langle \widetilde{C}_\ell \rangle_{\mathrm{MC}} \overset{(1)}{=} \sum_{\ell'} M_{\ell\ell'} F_{\ell'}^{(0)} T_{\ell'}^2 C_{\ell'}^{\mathrm{th}} + \sum_{\ell'} M_{\ell\ell'}\, \delta F_{\ell'} T_{\ell'}^2 C_{\ell'}^{\mathrm{th}} \overset{(2)}{\approx} \sum_{\ell'} M_{\ell\ell'} F_{\ell'}^{(0)} T_{\ell'}^2 C_{\ell'}^{\mathrm{th}} + f_{\mathrm{sky}} w_2\, \delta F_\ell T_\ell^2 C_\ell^{\mathrm{th}},$$

(1) The master equation is linear in F.
(2) The first-guess approximation, now applied only to the correction: if $\delta F_{\ell'} T_{\ell'}^2 C_{\ell'}^{\mathrm{th}}$ varies slowly across the kernel, the row rule turns its sum into $f_{\mathrm{sky}} w_2$ times its value at ℓ.

Solving for δF_ℓ, and replacing the simulated average by a running average S over about 50 multipoles to smooth its Monte Carlo noise,

$$F_\ell = F_\ell^{(0)} + \frac{S\big(\langle \widetilde{C}_\ell \rangle_{\mathrm{MC}}\big) - \sum_{\ell'} M_{\ell\ell'} F_{\ell'}^{(0)} T_{\ell'}^2 C_{\ell'}^{\mathrm{th}}}{T_\ell^2 C_\ell^{\mathrm{th}} f_{\mathrm{sky}} w_2} \tag{8.69}$$

[Hivon (18)]. The exact coupled term now carries the curvature of the spectrum, and only the correction is treated approximately; one such step was enough for their patch. The step relies

on δF being smooth. Where $F^{(0)}$ has inherited a large leakage bias with the shape of the acoustic peaks, δF has that shape too, and the step can overshoot (we meet this below).

How well F is known. F_ℓ is, up to fixed factors, the average of $N_{\rm MC}^{(\rm s)}$ independent simulated pseudo-spectra, smoothed over about $\Delta\ell$ multipoles. Each pseudo-spectrum, so smoothed, carries about $\nu = (2\ell+1)\Delta\ell\, f_{\rm sky}$ modes and has a relative variance $2/\nu$ (Section 8.4.2); an average of $N_{\rm MC}^{(\rm s)}$ of them divides that by $N_{\rm MC}^{(\rm s)}$. So $\delta F_\ell/F_\ell \approx \sqrt{2/[(2\ell+1)\Delta\ell\, f_{\rm sky}]}/\sqrt{N_{\rm MC}^{(\rm s)}}$ [Hivon (16), (19)]. They also showed that F barely depends on the assumed spectrum: for a flat and an open universe, whose first peaks are at $\ell \approx 220$ and 420, the two transfer functions differ by less than 1% for $50 < \ell < 1000$ [Hivon Fig. 2].

Example: a ring filter on the 10% cap. Our toy filter imitates destriping: on each ring of constant latitude inside the 10% cap, subtract the mean of the observed pixels (`ring_filter` in `23_mc_masked.py`). It removes, ring by ring, the pattern a scan along that ring cannot distinguish from a detector offset, and with it most of the largest-scale power. The first 500 signal-only skies calibrate F; the other 1500 skies, with noise, test it (Figure 8.30). Two observations stand out.

The ratio $F^{(0)}$ is a poor starting point: at $300 \le \ell \le 600$ its median is 1.26, larger than one, because it inherits the leakage bias of the naive estimator, and one step of (8.69) brings it only to 1.06 and oscillates wildly at low ℓ. For the sharp cap, the running average S and the coupled guess do not cancel: the iteration converges only if $F^{(0)}$ is already close. The robust alternative uses the binning of MASTER for F as well: take F constant in each bin, $F_\ell = R_{\ell b} F_b$ with $R_{\ell b} = 1$ in bin b, and solve the small linear system $P_{b\ell} M_{\ell\ell'} T^2_{\ell'} C^{\rm th}_{\ell'} R_{\ell' b'} F_{b'} = P_{b\ell} \langle \widetilde{C}_\ell \rangle_{\rm MC}$ directly. It gives $F_b = 0.88$ in the first bin ($2 \le \ell < 22$), 0.97 in the second, 0.991 in the fifth and 1.000 at high ℓ: the filter takes out large scales only, as it should.

With this F, MASTER on the independent test skies is unbiased again: in the first bin the error is -1.3%, against -13% if the filter is ignored (-3.6% in the second), and the largest offset from the bin average is 0.13 of a single sky's error bar. How well do 500 skies know F? Solve for F_b separately in 4 disjoint groups of 500 skies. Above $\ell = 100$ their scatter is 1.55 ± 0.13 times the prediction [Hivon (19)]: through a cap this small, deconvolution correlates the bins and the counting formula is optimistic, but even so 500 skies pin F down to well under a per cent above $\ell \approx 100$.

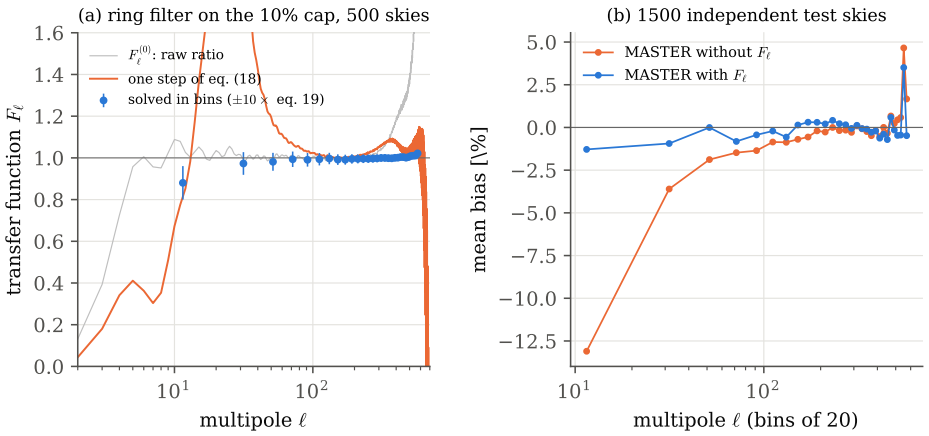

Figure 8.30: The transfer function of the ring filter on the 10% cap. (a) The raw ratio $F^{(0)}$ (grey), one step of (8.69) (orange) and the solution in bins (blue, error bars ten times the prediction of [Hivon (19)]). (b) MASTER on 1500 test skies, mean bias in per cent, without F (orange) and with it (blue): ignoring the filter loses 13% of the power in the first bin.

A full analysis measures F with end-to-end simulations: the sky is turned into timestreams with the real pointing, filtered exactly as the data, and made into maps by the same map-maker. That is what Hivon et al. did for Boomerang, and its cost, about half a CPU-day for 300 simulations on the computers of 2001 [Hivon (33)], is why our version filters the maps instead of timestreams. The reduction keeps the logic (simulate, average, solve for F, test on independent skies) and loses the realism of the scan: our F describes a toy filter, not an instrument.

8.12 The scatter of a cut-sky spectrum

MASTER (Section 8.11.3) gives an unbiased estimate. A likelihood needs much more than a mean: the width of the scatter of every estimate, the correlations between estimates at different multipoles, and the shape of the distribution. On the full sky all three had exact answers (Sections 7.12 and 8.4.1): $(2\ell+1)\widehat{C}_\ell/C_\ell$ is $\chi^2_{2\ell+1}$, the variance is $2C_\ell^2/(2\ell+1)$ plus noise, and different multipoles are independent. A mask breaks all three, and for a general mask none has a closed form. The 2000 simulated skies of Section 8.9.3 are now the instrument, and the formulas are what is being tested.

8.12.1 The shape of the distribution

What the simulations show. Figure 8.31 shows the distribution of the pseudo-spectrum, divided by its mean, at $\ell = 2$, 10 and 50, on the full sky and through the 30% and 10% caps. At $\ell = 50$ every panel is a narrow, nearly symmetric bump. At $\ell = 2$ the distributions are lopsided: a peak well below the mean and a long tail to large values. Through the 10% cap the quadrupole's most probable value is close to zero. The fraction of skies that fall below their own mean, $\frac{1}{2}$ for a symmetric law, is 0.58 on the full sky at $\ell = 2$, 0.60 through the 30% cap and 0.64 through the 10% cap: a typical sky shows less large-scale power than the theory predicts on average, and the smaller the patch, the more so.

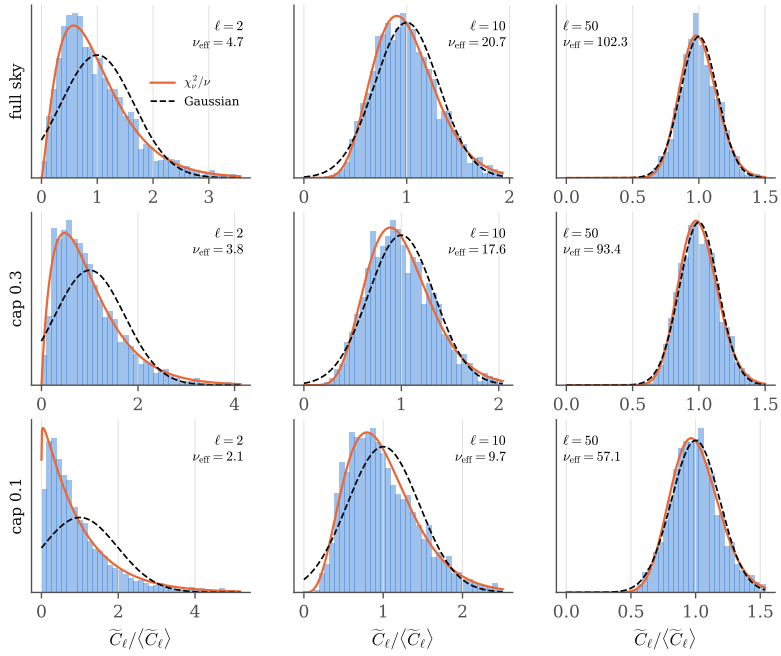

Figure 8.31: Histograms of $\widetilde{C}_\ell/\langle\widetilde{C}_\ell\rangle$ over 2000 skies, at $\ell = 2$, 10 and 50 (columns) for the full sky and the 30% and 10% caps (rows). Orange: a χ^2_ν/ν with $\nu = \nu_{\rm eff}$ fixed by the simulated mean and variance; dashed: the Gaussian of the same mean and variance. The white line marks the mean.

What could have produced that shape? Two candidates come to mind. The first is the central limit theorem: $\widetilde{C}_\ell$ is a sum of $2\ell+1$ squared coefficients, so perhaps it is Gaussian. The histograms rule this out at low ℓ, and the reason is that the sum has few terms. The second is the full-sky law with fewer degrees of freedom: a scaled χ^2_ν with ν the number of independent modes the patch supplies. That candidate has a precise justification. The masked coefficients are jointly Gaussian with the covariance (8.57), and $\widetilde{C}_\ell$ is a quadratic form in them.

The real numbers inside one pseudo-multipole. The masked map is real, so $\tilde{a}_{\ell,-m} = (-1)^m \tilde{a}^*_{\ell m}$: the coefficients with negative m repeat those with positive m, and $\tilde{a}_{\ell 0}$ is real. Collect the independent real numbers as in Section 7.10.1: $z_0 = \tilde{a}_{\ell 0}$, and for each $m = 1, \dots, \ell$ the two numbers $\sqrt{2}\,\mathrm{Re}\,\tilde{a}_{\ell m}$ and $\sqrt{2}\,\mathrm{Im}\,\tilde{a}_{\ell m}$. That is $1 + 2\ell$ real numbers, a vector $\boldsymbol{z}$. Then

$$(2\ell+1)\widetilde{C}_\ell = \sum_{m=-\ell}^{\ell} |\tilde{a}_{\ell m}|^2 = \tilde{a}_{\ell 0}^2 + 2\sum_{m=1}^{\ell} \left[(\mathrm{Re}\,\tilde{a}_{\ell m})^2 + (\mathrm{Im}\,\tilde{a}_{\ell m})^2\right] = \boldsymbol{z}^{\mathsf{T}}\boldsymbol{z},$$

because $|\tilde{a}_{\ell,-m}| = |\tilde{a}_{\ell m}|$ counts each positive m twice; the factors $\sqrt{2}$ give every component of $\boldsymbol{z}$ the same weight one. The covariance Σ of $\boldsymbol{z}$ follows from (8.57) and the reality condition, by taking real and imaginary parts. Then

$$(2\ell+1)\widetilde{C}_\ell \overset{(1)}{=} \boldsymbol{u}^{\mathsf{T}}\Sigma\,\boldsymbol{u} \overset{(2)}{=} \boldsymbol{u}^{\mathsf{T}} O \Lambda O^{\mathsf{T}} \boldsymbol{u} \overset{(3)}{=} \sum_k \lambda_k\, v_k^2, \qquad v_k \overset{\text{iid}}{\sim} \mathcal{N}(0,1), \tag{8.70}$$

(1) Write $\boldsymbol{z} = \Sigma^{1/2}\boldsymbol{u}$ with $\boldsymbol{u}$ a vector of independent standard Gaussians; then $\boldsymbol{z}^{\mathsf{T}}\boldsymbol{z} = \boldsymbol{u}^{\mathsf{T}}\Sigma\boldsymbol{u}$.
(2) Diagonalise the symmetric matrix $\Sigma = O\Lambda O^{\mathsf{T}}$ with O orthogonal and $\Lambda = \mathrm{diag}(\lambda_k)$.
(3) $\boldsymbol{v} = O^{\mathsf{T}}\boldsymbol{u}$ is again a vector of independent standard Gaussians, because an orthogonal rotation preserves the identity covariance.

A cut-sky pseudo-multipole is a weighted sum of independent χ^2_1 variables, with weights equal to the eigenvalues of the covariance of its own coefficients. On the full sky all the weights are equal to C_ℓ and the sum is $C_\ell \chi^2_{2\ell+1}$. Through a mask the weights spread out.

Which χ^2 looks most like it? Try the model $Y = c\,\chi^2_\nu/\nu$, a scaled χ^2 with two free numbers, c and ν, and choose them so that Y has the same mean and variance as $X \equiv (2\ell+1)\widetilde{C}_\ell = \sum_k \lambda_k v_k^2$:

$$\langle Y\rangle \overset{(1)}{=} c = \sum_k \lambda_k = \langle X\rangle, \qquad \mathrm{Var}\,Y \overset{(2)}{=} \frac{c^2}{\nu^2}\,2\nu = \frac{2c^2}{\nu} = 2\sum_k \lambda_k^2 = \mathrm{Var}\,X,$$

$$\Longrightarrow \quad \nu_{\text{eff}} \overset{(3)}{=} \frac{2\langle X\rangle^2}{\mathrm{Var}\,X} = \frac{2\langle \widetilde{C}_\ell\rangle^2}{\mathrm{Var}\,\widetilde{C}_\ell} = \frac{\left(\sum_k \lambda_k\right)^2}{\sum_k \lambda_k^2} \overset{(4)}{\le} 2\ell+1. \tag{8.71}$$

(1) A χ^2_ν has mean ν; each v_k^2 is a χ^2_1 with mean one.
(2) A χ^2_ν has variance 2ν, and a constant factor comes out squared; the v_k^2 are independent, so their variances $2\lambda_k^2$ add.
(3) Solve the second equation for ν and insert $c = \langle X\rangle$. The factor $2\ell+1$ cancels in the ratio.
(4) The Cauchy–Schwarz inequality for the vectors $(1,\dots,1)$ and $(\lambda_1,\dots,\lambda_{2\ell+1})$: $\left(\sum_k 1\cdot\lambda_k\right)^2 \le \left(\sum_k 1^2\right)\left(\sum_k \lambda_k^2\right) = (2\ell+1)\sum_k \lambda_k^2$, with equality only when the two vectors are parallel, that is, when all the weights are equal.

A few large weights and many small ones make ν_{eff} small. This moment-matched χ^2 is the Welch–Satterthwaite approximation; it is exact in its first two moments and approximate beyond.

The third moment as a test. Cumulants of independent terms add, and a constant factor λ multiplies the third cumulant by λ^3. A χ^2_1 has variance 2 and third cumulant 8 (Section 8.4.1), so

$\lambda_k v_k^2$ contributes $2\lambda_k^2$ and $8\lambda_k^3$. The skewness, third cumulant over variance to the power 3/2, is

$$\frac{8\sum_k \lambda_k^3}{\left(2\sum_k \lambda_k^2\right)^{3/2}} = \frac{\sqrt{8}\sum_k \lambda_k^3}{\left(\sum_k \lambda_k^2\right)^{3/2}} \qquad \text{against} \qquad \sqrt{\frac{8}{\nu_{\text{eff}}}} \quad \text{for the model.}$$

With n equal weights the left side is $\sqrt{8}\,n\lambda^3/(n\lambda^2)^{3/2} = \sqrt{8/n}$ and the two agree exactly; they stay close as long as the weights are not too unequal.

The mode count for a smooth spectrum. Hivon et al.'s count can be recovered from (8.71) with one picture of the modes. At high ℓ a mode of multipole ℓ is a short wave, and the window acts on it locally: a mode concentrated near direction $\hat{\boldsymbol{n}}$ is multiplied by $W(\hat{\boldsymbol{n}})$, and its variance by $W(\hat{\boldsymbol{n}})^2$. If the spectrum is smooth, so that it does not matter which neighbouring multipole the mode came from, the $2\ell+1$ eigenvalues are $\lambda_k \approx C_\ell W(\hat{\boldsymbol{n}}_k)^2$, with the $2\ell+1$ directions $\hat{\boldsymbol{n}}_k$ spread evenly over the sphere. Sums over k then become sky averages, which are the moments of the workdef in Section 8.9.2:

$$\sum_k \lambda_k \overset{(1)}{=} (2\ell+1)\,C_\ell \frac{1}{4\pi}\int \mathrm{d}\Omega\, W^2 = (2\ell+1) C_\ell f_{\text{sky}} w_2, \qquad \sum_k \lambda_k^2 \overset{(2)}{=} (2\ell+1)\,C_\ell^2 f_{\text{sky}} w_4,$$
$$\nu_{\text{eff}} \overset{(3)}{=} \frac{(2\ell+1)^2 C_\ell^2 f_{\text{sky}}^2 w_2^2}{(2\ell+1) C_\ell^2 f_{\text{sky}} w_4} = (2\ell+1)\, f_{\text{sky}} \frac{w_2^2}{w_4}. \tag{8.72}$$

(1) An average over evenly spread directions is the sky average; $\frac{1}{4\pi}\int W^2 = f_{\text{sky}} w_2$ by the definition of the moments.
(2) The same with $\lambda_k^2 \propto W^4$.
(3) (8.71).

For a bin of $\Delta\ell$ multipoles, treated as independent, the count is multiplied by $\Delta\ell$. A binary mask gives $(2\ell+1)f_{\text{sky}}$: the fraction of the modes that land on the patch. A taper gives the modes near the edge less weight than the others, which makes the λ_k unequal and lowers the count by $w_2^2/w_4 \le 1$. The picture assumes that each mode belongs to one multipole and sees the window at one place; that is the assumption tested below.

Working definition 8.7 (effective number of modes)

The **effective number of modes** of an estimate X that is a positive quadratic form in Gaussian variables is $\nu_{\text{eff}} = 2\langle X\rangle^2/\mathrm{Var}\,X$. *Operationally:* from N simulations, divide twice the squared mean by the variance; then model X as $\langle X\rangle \chi^2_{\nu_{\text{eff}}}/\nu_{\text{eff}}$. On the full sky $\nu_{\text{eff}} = 2\ell+1$ for $\widehat{C}_\ell$; for a bin of $\Delta\ell$ multipoles on a patch [Hivon (17)] predicts $\nu_\ell = (2\ell+1)\Delta\ell\, f_{\text{sky}} w_2^2/w_4$, which is (8.72) times $\Delta\ell$.

The numbers. On the full sky the simulations give $\nu_{\text{eff}} = 4.7$ at $\ell = 2$ against the exact 5 (the difference is the Monte Carlo error of a variance, ±3.2%, together with the noise and the beam, which are not quite negligible), 20.7 at $\ell = 10$ and 102.3 at $\ell = 50$. Through the 30% cap, 3.8, 17.6 and 93.4; through the 10% cap, 2.1, 9.7 and 57.1. The scaled χ^2 fits where the Gaussian does not. To test the two models fairly, the mean and ν_{eff} are fitted on half of the skies and the test is run on the other half, so that no model is tuned to the very skies it is judged on. The fitted mean and ν_{eff} carry noise of their own, which makes the distance a little larger than the textbook rule expects, so its 5% critical value is found the same way the test is run: draw as many values as there are skies from the model itself, fit on one half, measure the distance on the other, and repeat 300 times. That gives 0.060. The Kolmogorov–Smirnov distance between the test skies and the model is 0.034 for the χ^2 and 0.115 for the Gaussian on the full sky at

$\ell = 2$; 0.022 against 0.117 through the 30% cap; and 0.066 against 0.167 through the 10% cap. At $\ell = 2$ the Gaussian is far beyond the critical value every time, and the χ^2 is much closer. Through the 10% cap even the χ^2 distance grows, to around the critical value or past it: with $\nu_{\rm eff} \approx 2$ the weights are very unequal, and matching two moments is no longer quite enough. By $\ell = 50$ both models pass: their distances are similar and below the critical value (0.050 and 0.044 through the 30% cap, 0.033 and 0.020 through the 10% cap). With this many modes the distribution is close to Gaussian, and both models describe it. The ratio of the simulated skewness to the χ^2 value $\sqrt{8/\nu_{\rm eff}}$ is one to within the Monte Carlo noise at every ℓ and for every mask (Figure 8.32b).

The hidden assumption in the mode count. The plain claim is [Hivon (17)]: a patch supplies $(2\ell + 1) f_{\rm sky} w_2^2 / w_4$ modes per multipole. The everyday question behind it is: how many independent numbers does one pseudo-multipole of the patch contain? The claim answers it as if each pseudo-multipole held only modes of its own ℓ, fewer of them, and nothing from its neighbours. Figure 8.32a puts that to the test, plotting the simulated $\nu_{\rm eff}$ divided by the count. On the full sky the ratio is one (1.00 at high ℓ), and for the holes, which barely couple anything, 1.02. For the caps it is *larger* than one and grows as the patch shrinks: 1.40 for 70%, 2.90 for 30%, 5.21 for 10% and 6.42 for the tapered 10% cap. The band, which couples each multipole to its same-parity neighbours, has 1.36. A single pseudo-multipole of a small cap contains *more* effective modes than the count. Two steps explain the size of the excess and where it goes.

Step one: whose modes are inside $\widetilde{C}_\ell$? The count (8.72) gives each pseudo-multipole the modes of its own ℓ only. But the coupling kernel feeds $\widetilde{C}_\ell$ the power of every true multipole within its width, and each of those brings its own $\approx (2\ell + 1) f_{\rm sky}$ independent modes. For a patch of diameter Θ the kernel has a half-width of about π/Θ (Section 8.10.4). For the 10% cap, $\Theta = 2\theta_c = 1.29$ rad and $\pi/\Theta \approx 2.4$, so the kernel spans about $2 \times 2.4 + 1 \approx 6$ multipoles, and $\widetilde{C}_\ell$ holds roughly five to six times the counted modes, which is the measured 5.21. For the 30% cap, $\Theta = 2.32$ rad gives $2 \times 1.35 + 1 \approx 3.7$, against the measured 2.90: the estimate is rough, since the kernel's edges carry little weight, but it follows the trend.

Step two: the same modes are counted again next door. $\widetilde{C}_{\ell+1}$ draws on a window of about six multipoles shifted by one, so the two windows share about five of their six multipoles, and the two pseudo-multipoles share that fraction of their modes. Two sums that share a fraction r of their independent terms are correlated at about r: here $5/6 \approx 0.8$, close to the measured 0.88 of Section 8.12.2.

So a single pseudo-multipole of a small patch has about five times the counted modes, but they are not its own. Taken at face value, its $\nu_{\rm eff}$ would make an average over neighbouring multipoles look five times less noisy than it is, because the same modes would be counted once in each neighbour. For a bin wide compared with the kernel the sharing averages out and the count is right again. One-line lesson: counting modes is a statement about bins wider than the kernel, never about single multipoles.

What this means for the likelihood is the subject of Chapter 9, but the lesson can be said now, starting from the observation. *The event:* one sky, and one number from it, the quadrupole $\widetilde{C}_2 = x$ through the 10% cap. *What could have produced it?* Any true spectrum: every candidate C_2 would have produced skies with a spread of values, and the observed x is one draw. *How probable is x under each candidate?* The distribution of the estimate, computed for each C_2 and then read at the fixed observed x as a function of C_2, answers that; it is the likelihood (Sections 3.8 and 8.4.1). It measures how readily each candidate spectrum, plus the fluctuation of one sky, turns into the number we actually saw.

Use the scaled χ^2 just found, with mean C_2 and $\nu_{\rm eff} \approx 2$ (we measured 2.1). A χ^2_2 has density

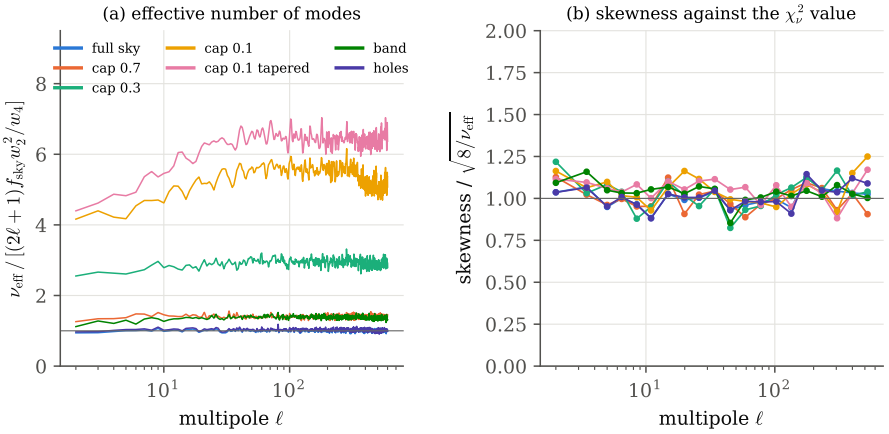

Figure 8.32: (a) The effective number of modes of a single pseudo-multipole from 2000 skies, divided by the count $(2\ell+1) f_{\rm sky} w_2^2/w_4$ of [Hivon (17)]. The smaller the cap, the more each multipole borrows from its neighbours, and the larger the ratio. (b) The simulated skewness divided by the $\chi^2_{\nu_{\rm eff}}$ value $\sqrt{8/\nu_{\rm eff}}$: one for every mask, so the moment-matched χ^2 gets the third moment right too.

$\frac{1}{2} e^{-y/2}$, so $x = C_2\, y/2$ has density, and likelihood,

$$\mathcal{L}(C_2) = \frac{1}{C_2}\, e^{-x/C_2},$$

against the Gaussian of the same mean and variance,

$$\mathcal{L}_{\rm G}(C_2) = \frac{1}{\sqrt{2\pi}\, C_2}\, e^{-(x-C_2)^2/2C_2^2}$$

(a scaled χ^2_ν has variance $2C_2^2/\nu = C_2^2$). Compare a candidate twice the observed value with one equal to it. The exact likelihood gives $\mathcal{L}(2x)/\mathcal{L}(x) = \frac{1}{2} e^{-1/2}/e^{-1} = 0.82$: a spectrum twice as large as what we saw is almost as plausible, because a χ^2_2 often falls well below its mean. The Gaussian gives $\mathcal{L}_{\rm G}(2x)/\mathcal{L}_{\rm G}(x) = \frac{1}{2} e^{-1/8} = 0.44$, half as much. Where does each peak? The exact likelihood at $C_2 = x$. The Gaussian at $C_2 = 0.62\, x$ (setting the derivative of $-\ln C_2 - (x - C_2)^2/2C_2^2$ to zero gives $u^2 - u - 1 = 0$ for $u = x/C_2$, so $u = 1.62$). A Gaussian likelihood of the same width therefore favours spectra that are too low, because it does not know that most skies fall below their mean. Hivon et al. made the same observation for their Boomerang bins and concluded that at small sky coverage the likelihood must be modelled as a χ^2 at low ℓ [Hivon §4.2]; we repeat their test in Section 8.14.1.

8.12.2 Correlations between multipoles

The exact covariance. For a Gaussian sky the covariance of the pseudo-spectrum follows from the covariance (8.57) of the masked coefficients by Wick's theorem. For jointly Gaussian complex variables with zero mean, $\langle x x^* y y^* \rangle = \langle x x^* \rangle \langle y y^* \rangle + \langle x y \rangle \langle x^* y^* \rangle + \langle x y^* \rangle \langle x^* y \rangle$ (the sum over the ways of pairing the four factors, Section 3.5.4). Then

$$\begin{aligned}
\mathrm{Cov}\big(\widetilde{C}_\ell, \widetilde{C}_{\ell'}\big) &\overset{(1)}{=} \frac{1}{(2\ell+1)(2\ell'+1)} \sum_{mm'} \Big(\langle |\tilde{a}_{\ell m}|^2 |\tilde{a}_{\ell' m'}|^2 \rangle - \langle |\tilde{a}_{\ell m}|^2 \rangle \langle |\tilde{a}_{\ell' m'}|^2 \rangle \Big) \\
&\overset{(2)}{=} \frac{1}{(2\ell+1)(2\ell'+1)} \sum_{mm'} \Big(|\langle \tilde{a}_{\ell m} \tilde{a}^*_{\ell' m'} \rangle|^2 + |\langle \tilde{a}_{\ell m} \tilde{a}_{\ell' m'} \rangle|^2 \Big) \\
&\overset{(3)}{=} \frac{2}{(2\ell+1)(2\ell'+1)} \sum_{mm'} |\langle \tilde{a}_{\ell m} \tilde{a}^*_{\ell' m'} \rangle|^2 .
\end{aligned} \tag{8.73}$$

(1) The definition (8.55) of $\widetilde{C}_\ell$ in both factors, and bilinearity of the covariance.
(2) Wick's theorem with $x = \tilde{a}_{\ell m}$, $y = \tilde{a}_{\ell' m'}$: the first pairing cancels the product of means, and $\langle xy^*\rangle\langle x^*y\rangle = |\langle xy^*\rangle|^2$, $\langle xy\rangle\langle x^*y^*\rangle = |\langle xy\rangle|^2$.
(3) The masked map is real, so $\tilde{a}_{\ell' m'} = (-1)^{m'}\tilde{a}^*_{\ell',-m'}$ and $|\langle \tilde{a}_{\ell m}\tilde{a}_{\ell' m'}\rangle| = |\langle \tilde{a}_{\ell m}\tilde{a}^*_{\ell',-m'}\rangle|$; summing over all m', the second sum is the first one relabelled.

This is [141, eqs 14 and 18]. On the full sky, $\langle a_{\ell m}a^*_{\ell' m'}\rangle = C_\ell\delta_{\ell\ell'}\delta_{mm'}$, the sum has $2\ell+1$ equal terms, and the covariance is $2C_\ell^2/(2\ell+1)$ on the diagonal and zero elsewhere, as it must be. Through a mask, the covariance (8.57) connects (ℓ, m) to every (ℓ', m') the window couples, and the spectrum inherits those correlations, squared.

An exact calculation for an azimuthal mask. For a mask that is the same along every ring of constant latitude, like the band, the exact covariance can be computed without any $3j$ symbol, because the window cannot change m. Write $Y_{\ell m} = \lambda_{\ell m}(\theta)e^{im\phi}$ with $\lambda_{\ell m}$ real, and do the integral (8.56) as the HEALPix pixel sum: rings r at colatitude θ_r, each with $n_{\phi,r}$ pixels at $\phi_j = \phi_{0,r} + 2\pi j/n_{\phi,r}$, all of area $\Omega_{\rm pix}$ and window value W_r. Then

$$K_{\ell m,\ell' m'} \overset{(1)}{=} \sum_r \Omega_{\rm pix} W_r\, \lambda_{\ell m}(\theta_r)\lambda_{\ell' m'}(\theta_r)\, e^{i(m'-m)\phi_{0,r}} \sum_{j=0}^{n_{\phi,r}-1} e^{2\pi i(m'-m)j/n_{\phi,r}}$$
$$\overset{(2)}{=} \delta_{mm'}\, K^{(m)}_{\ell\ell'}, \qquad K^{(m)}_{\ell\ell'} \equiv \sum_{\text{rings } r} n_{\phi,r}\, \Omega_{\rm pix}\, W_r\, \lambda_{\ell m}(\theta_r)\lambda_{\ell' m}(\theta_r). \tag{8.74}$$

(1) The pixel sum of $Y^*_{\ell m} W Y_{\ell' m'}$; W and θ are constant along a ring, so only the phase $e^{i(m'-m)\phi_j}$ changes from pixel to pixel.
(2) The sum over j is a geometric series in $q = e^{2\pi i(m'-m)/n_{\phi,r}}$, equal to $(1-q^{n_{\phi,r}})/(1-q) = 0$ when $q \neq 1$, because $q^{n_{\phi,r}} = e^{2\pi i(m'-m)} = 1$; and equal to $n_{\phi,r}$ when $q = 1$, that is $m' = m$ (this needs $|m'-m| < n_{\phi,r}$; it can fail only on the few short rings next to the poles, where $\lambda_{\ell m} \propto \sin^{|m|}\theta$ is negligible for the large $|m|$ concerned).

The window couples ℓ to ℓ' but never m to $m' \neq m$. Two covariances follow. The signal enters through (8.57), with the beam and pixel window on the true spectrum, and K real and diagonal in m: $\sum_L K^{(m)}_{\ell L} T_L^2 C_L K^{(m)}_{\ell' L}$. The noise, white with variance σ^2 per pixel and independent between pixels, is masked pixel by pixel, so the step of (8.14) picks up W_r^2 in each pixel and the same ring sum applies: $N\sum_r n_{\phi,r}\Omega_{\rm pix}W_r^2\lambda_{\ell m}\lambda_{\ell' m}$, with $N = \sigma^2\Omega_{\rm pix}$. Together, $\langle \tilde{a}_{\ell m}\tilde{a}^*_{\ell' m}\rangle = \sum_L K^{(m)}_{\ell L}T_L^2C_LK^{(m)}_{\ell' L} + N\sum_r n_{\phi,r}\Omega_{\rm pix}W_r^2\lambda_{\ell m}\lambda_{\ell' m}$. The functions $\lambda_{\ell m}$ are computed with the standard three-term recursion in ℓ at fixed m, which needs no factorials and is stable to ℓ of several thousand (`lambda_lm` in `lib_masks.py`). Inserting into (8.73) gives the exact covariance of the band's pseudo-spectrum at $\ell, \ell' \le 40$ in seconds. The ratio of the simulated variance to the exact one has mean 1.005 and scatter 0.035 over those multipoles, which is the ±3.2% expected of a variance from 2000 skies: the simulations and the exact formula agree.

What the correlation matrices look like. Figure 8.33 shows the correlation matrix $\mathrm{Corr}(\widetilde{C}_\ell, \widetilde{C}_{\ell'}) = \mathrm{Cov}/\sqrt{\mathrm{Var}\ \mathrm{Var}}$ for $2 \le \ell, \ell' \le 100$ from the simulations, and Figure 8.34 the correlation of each multipole with its first and second neighbours. Three dependences stand out. *On the sky fraction:* the correlation with the next multipole is 0.13 for the 70% cap, 0.65 for the 30% cap and 0.88 for the 10% cap; with the second neighbour, 0.03, 0.14 and 0.60. The width of the correlated band in ℓ grows as the patch shrinks, as π/Θ for a patch of size Θ. *On the geometry:* the band has no correlation with its immediate neighbour (−0.00) but 0.11 with the next-but-one, the parity selection of Section 8.10.3 seen in the covariance; the holes, which remove 3% of the sky

in small pieces, correlate nothing (−0.00). *On apodisation:* the tapered 10% cap is even more correlated than the sharp one, 0.92 and 0.72, because its effective region is smaller and its kernel wider. *On ℓ:* hardly at all; the curves of Figure 8.34 are flat from $\ell = 10$ to 600, because the kernel width is set by the patch, not by the multipole. A correlation estimated from 2000 skies has a noise of $1/\sqrt{2000} = 0.022$ (Section 3.5.2), so every value quoted here is far above noise except those of the holes and the band's first neighbour.

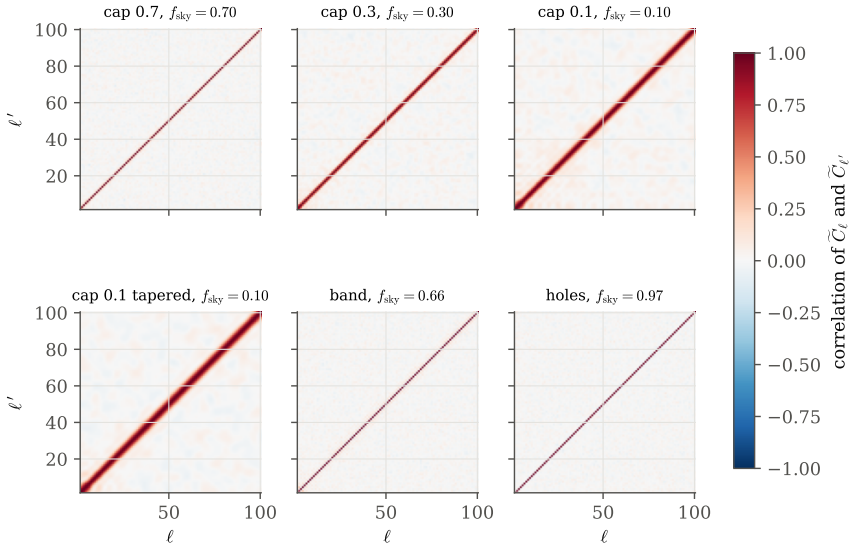

Figure 8.33: Correlation matrices of $\widetilde{C}_\ell$ for $2 \le \ell, \ell' \le 100$ from 2000 skies. The diagonal band widens as the cap shrinks from 70% to 10% and widens further when the 10% cap is tapered. The band cut and the holes leave the matrix nearly diagonal (the band's correlation with $\ell \pm 2$ is too faint to see at this scale).

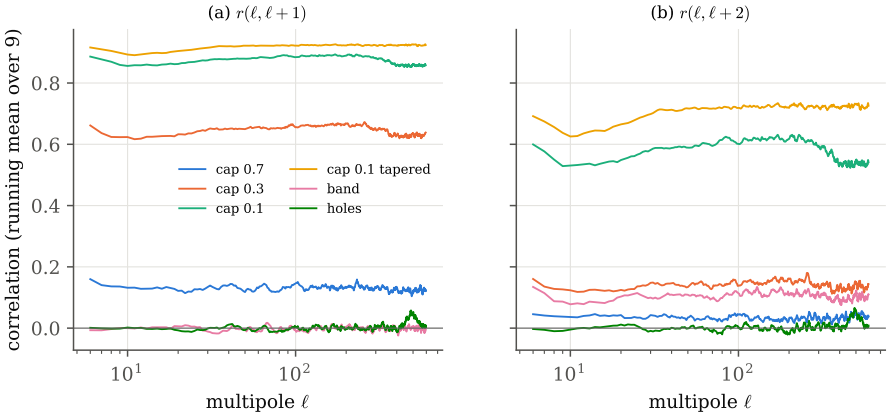

Figure 8.34: Correlation of $\widetilde{C}_\ell$ with $\widetilde{C}_{\ell+1}$ (a) and $\widetilde{C}_{\ell+2}$ (b), smoothed over nine multipoles. The level is set by the mask and is almost independent of ℓ. The band correlates only multipoles of the same parity: zero in (a), nonzero in (b).

8.12.3 Quick formulas against the simulations

Efstathiou's approximation. The exact covariance (8.73) needs every element of the $\tilde{a}$ covariance. There are about $\ell_{\max}^2$ pairs (ℓ, m), so about $\ell_{\max}^4$ elements, and each is a sum (8.57) over another $\ell_{\max}^2$ pairs (ℓ_1, m_1): a cost of order $\ell_{\max}^6$ for a general mask, 2×10^{17} operations at $\ell_{\max} = 767$. Efstathiou [141] found a shortcut for multipoles above the width of the kernel.

The approximation, and its error. In the sum (8.57) for $\langle \tilde{a}_{\ell m} \tilde{a}^*_{\ell' m'} \rangle$, the product $K_{\ell m, \ell_1 m_1} K^*_{\ell' m', \ell_1 m_1}$ is appreciable only for ℓ_1 within the kernel width of both ℓ and ℓ'. Write $C_{\ell_1} = \sqrt{C_\ell C_{\ell'}}\,(1 + \epsilon_{\ell_1})$ there. If the spectrum changes by less than a fraction ϵ across the kernel, every $|\epsilon_{\ell_1}| \lesssim \epsilon$, and dropping them changes the sum by a relative $O(\epsilon)$. For $\ell = \ell'$ the replacement is $C_{\ell_1} \to C_\ell$, exact for a spectrum that is constant across the kernel. Then

$$\langle \tilde{a}_{\ell m} \tilde{a}^*_{\ell' m'} \rangle \overset{(1)}{=} \sum_{\ell_1 m_1} C_{\ell_1} \langle \ell m | \hat{W} | \ell_1 m_1 \rangle \langle \ell_1 m_1 | \hat{W} | \ell' m' \rangle \overset{(2)}{\approx} \sqrt{C_\ell C_{\ell'}}\, \langle \ell m | \hat{W}^2 | \ell' m' \rangle,$$

$$\mathrm{Cov}\big(\widetilde{C}_\ell, \widetilde{C}_{\ell'}\big) \overset{(3)}{\approx} \frac{2 C_\ell C_{\ell'}}{(2\ell+1)(2\ell'+1)} \sum_{m m'} |\langle \ell m | \hat{W}^2 | \ell' m' \rangle|^2 \overset{(4)}{=} 2 C_\ell C_{\ell'}\, \Xi\big(\ell, \ell', \mathcal{W}^{(2)}\big), \tag{8.75}$$

(1) (8.57) with $K_{\ell m, \ell_1 m_1} = \langle \ell m | \hat{W} | \ell_1 m_1 \rangle$ and $K^*_{\ell' m', \ell_1 m_1} = \langle \ell_1 m_1 | \hat{W} | \ell' m' \rangle$ ($\hat{W}$ is real, hence Hermitian).

(2) The approximation, then completeness, $\sum_{\ell_1 m_1} |\ell_1 m_1\rangle\langle \ell_1 m_1| = \mathbb{1}$: two multiplications by W are one multiplication by W^2.

(3) Insert into the exact result (8.73).

(4) The sum over m, m', worked out below.

For step 4, notice that $\langle \ell m | \hat{W}^2 | \ell' m' \rangle$ is the coupling K of (8.56) for a different window, W^2 in place of W. Expand $W^2 = \sum_{LM} w^{(2)}_{LM} Y_{LM}$, with spectrum $\mathcal{W}^{(2)}_L$. Then

$$\sum_{m m'} |\langle \ell m | \hat{W}^2 | \ell' m' \rangle|^2 \overset{(1)}{=} \frac{(2\ell+1)(2\ell'+1)}{4\pi} \sum_{m m'} \Big| \sum_{LM} w^{(2)}_{LM} \sqrt{2L+1} \begin{pmatrix} \ell & L & \ell' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} \ell & L & \ell' \\ -m & M & m' \end{pmatrix} \Big|^2$$

$$\overset{(2)}{=} \frac{(2\ell+1)(2\ell'+1)}{4\pi} \sum_{LM} |w^{(2)}_{LM}|^2 \begin{pmatrix} \ell & \ell' & L \\ 0 & 0 & 0 \end{pmatrix}^2 \overset{(3)}{=} (2\ell+1)(2\ell'+1)\, \Xi\big(\ell, \ell', \mathcal{W}^{(2)}\big),$$

(1) The Gaunt integral (8.58), exactly as in line 2 of (8.60), with $w^{(2)}$ for w; the sign $(-1)^m$ has modulus one and has been dropped.

(2) The collapse (8.59) with $c_{LM} = w^{(2)}_{LM} \sqrt{2L+1}\,(\ell\ L\ \ell'; 0\ 0\ 0)$, and the squared symbol is symmetric in its columns.

(3) $\sum_M |w^{(2)}_{LM}|^2 = (2L+1)\mathcal{W}^{(2)}_L$, and the definition $\Xi(\ell, \ell', \mathcal{W}) \equiv \sum_L \frac{2L+1}{4\pi} \mathcal{W}_L (\ell\ \ell'\ L; 0\ 0\ 0)^2$.

Each element of the approximate covariance is now one sum over L, about $\ell_{\max}$ terms, for each of the $\ell^2_{\max}$ pairs (ℓ, ℓ'): a cost of order $\ell^3_{\max}$, 4.5×10^8 operations at $\ell_{\max} = 767$, against 2×10^{17}. This is [141, eqs 15a–15b]. For a binary mask $W^2 = W$, and the covariance is $2 C_\ell C_{\ell'} G_{\ell\ell'}$ with the symmetric coupling matrix $G = M/(2\ell'+1)$ [141, eq. 16]; for the deconvolved estimate it is $M^{-1} V (M^{-1})^{\mathsf{T}}$ [141, eq. 17], and for MASTER bandpowers the same with $K^{-1}P$. With beam and noise, C_ℓ is the spectrum of the field that was masked, $T^2_\ell C_\ell + N$. A common refinement replaces it by the coupled spectrum $\sum_{\ell'} M_{\ell\ell'} (T^2_{\ell'} C_{\ell'} + N)/f_{\mathrm{sky}} w_2$, which already contains the power that leaked in from elsewhere.

Key idea: Covariance of the cut-sky spectrum

For a Gaussian sky, $\mathrm{Cov}(\widetilde{C}_\ell, \widetilde{C}_{\ell'}) = \frac{2}{(2\ell+1)(2\ell'+1)} \sum_{m m'} |\langle \tilde{a}_{\ell m} \tilde{a}^*_{\ell' m'} \rangle|^2$ exactly. Above the width of the coupling kernel it is approximately $2 C_\ell C_{\ell'}\, \Xi(\ell, \ell', \mathcal{W}^{(2)})$: the full-sky cosmic variance spread over neighbouring multipoles by the spectrum of the *squared* window. Below it, only the exact form or simulations will do.

How good is it? Figure 8.35a divides the approximation's variance of $\widetilde{C}_\ell$ by the simulated one. At high ℓ (100–600) the plain approximation gives 0.976 (70% cap), 0.930 (30%), 0.825 (10%),

0.929 (band) and 0.843 (holes); with the coupled spectrum the same ratios become 1.004, 0.995, 0.970, 0.992 and 0.996. The refinement matters exactly where leakage matters: sharp, small or holey masks at high ℓ, where the power that leaked in from the acoustic peaks carries its own variance. At low ℓ the approximation fails, as it was designed to. At $\ell = 2$ it is off by factors of 3.34 and 6.33 for the 30% and 10% caps, at $\ell = 10$ by 0.82 and 0.62. Against the exact band covariance (Figure 8.35b) the approximation is 1.43 times the truth at $\ell = 2$, 0.83 at $\ell = 4$, 0.90 at $\ell = 20$ and 0.95 at $\ell = 40$. Efstathiou found the same pattern for a $\pm 10^\circ$ cut, accurate at $\ell \gtrsim 20$ and wrong by up to 25% at $\ell = 2$ [141, §2.2]; our $\pm 20^\circ$ cut removes twice as much and the low-ℓ error is correspondingly larger.

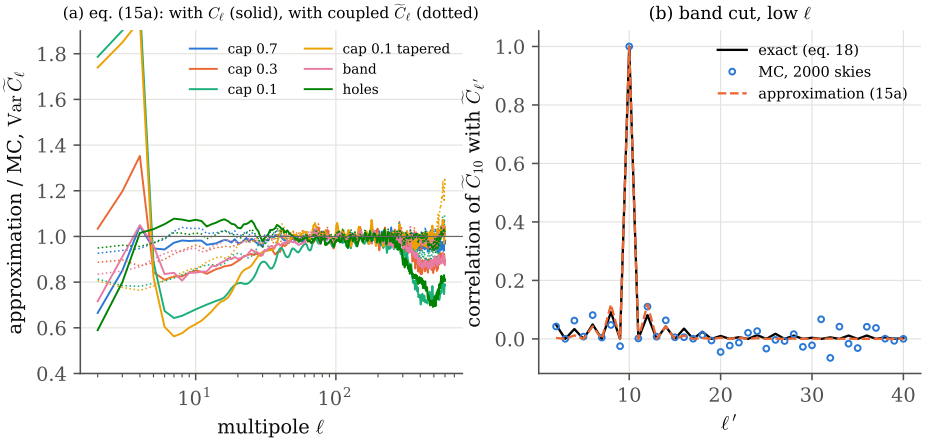

Figure 8.35: (a) Efstathiou's approximation (8.75) for the variance of $\widetilde{C}_\ell$, divided by the simulated variance, for six masks: with the masked spectrum (solid) and with the coupled spectrum (dotted). Above $\ell \approx 30$ it is good to a few per cent with the refinement; at low ℓ it fails by large factors. (b) The band cut: correlation of $\widetilde{C}_{10}$ with $\widetilde{C}_{\ell'}$, exact from (8.74) (black), from 2000 skies (blue circles) and from the approximation (orange dashed). Only multipoles of the same parity as $\ell = 10$ are correlated, and the three agree on the pattern.

Knox's formula, for the MASTER bins. The simplest error bar of all is the mode-counting rule of Section 8.4.2, $\operatorname{Var}\widehat{D}_b = 2(D_b + N_b)^2/[(2\ell_b + 1)\Delta\ell\, f_{\rm sky}]$, with N_b the binned noise on the sky. Figure 8.36 divides the simulated variance of the MASTER bandpowers (bins of 20) by it. On the full sky the ratio is 1.00 at high ℓ and 1.05 in the first bin, the full-sky verification of Section 8.6.2 in another guise. Through the masks it is larger than one almost everywhere and grows as the patch shrinks: at high ℓ, 1.08 for the 70% cap, 1.18 for 30%, 1.40 for 10% and 1.18 for the band. The holes are fine at low ℓ (1.00) and worst at the highest multipoles (1.33), where the leaked power of the peaks adds variance that mode counting knows nothing about. For the tapered cap the version with Hivon's w_2^2/w_4 gives 1.15, while $f_{\rm sky}$ alone gives 1.54, the pitfall of Section 8.9.3 in numbers. The Monte Carlo error of each ratio is 3.2%.

Why is the excess there at all, in a bin of 20 multipoles, many times wider than the kernel? The counting formula is the variance of an *optimal* estimate from the modes the patch contains. MASTER is not optimal: it weights every pixel of the window equally whatever the signal-to-noise, and the deconvolution K^{-1} undoes the smoothing of the coupling. Undoing a smoothing amplifies the scatter, and a two-bin toy shows by how much. The MASTER bandpowers are $\widehat{\boldsymbol{D}} = K^{-1}\boldsymbol{y}$ with $\boldsymbol{y} = P(\widetilde{\boldsymbol{C}} - \langle\widetilde{\boldsymbol{N}}\rangle)$, so their covariance is $K^{-1}\operatorname{Cov}(\boldsymbol{y})(K^{-1})^{\mathsf{T}}$. Take two bins with unit diagonal and coupling c between them, and give the two binned pseudo-spectra equal variance σ^2 and no correlation:

$$K = \begin{pmatrix} 1 & c \\ c & 1 \end{pmatrix}, \quad K^{-1} \overset{(1)}{=} \frac{1}{1-c^2}\begin{pmatrix} 1 & -c \\ -c & 1 \end{pmatrix}, \quad \operatorname{Var}\widehat{D}_1 \overset{(2)}{=} \sigma^2\,\frac{1+c^2}{(1-c^2)^2}.$$

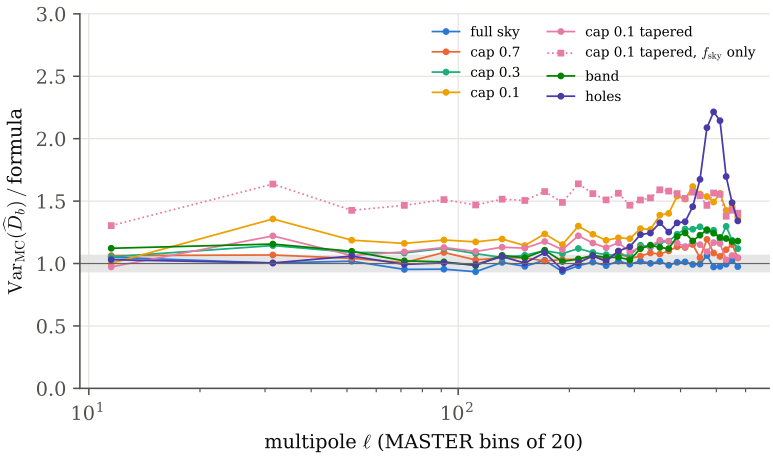

Figure 8.36: Simulated variance of the MASTER bandpowers divided by the mode-counting formula, bins of 20 multipoles. The full sky sits on one; the smaller the patch, the larger the excess. For the tapered cap the formula with $f_{\mathrm{sky}} w_2^2/w_4$ (solid pink) does much better than with f_{sky} alone (dotted pink). The holes rise at the highest multipoles, where leakage dominates.

(1) The inverse of a 2×2 matrix: swap the diagonal, negate the off-diagonal, divide by the determinant $1 - c^2$.
(2) $\widehat{D}_1 = (y_1 - c y_2)/(1 - c^2)$, and the variances of independent terms add: $\sigma^2(1 + c^2)/(1 - c^2)^2$.

The factor exceeds one for every $c \neq 0$ and grows with c: 1.13 for $c = 0.2$, 1.32 for $c = 0.3$. The inverse has a negative off-diagonal entry, the "wing" that subtracts the neighbour's leaked power, and that subtraction brings in the neighbour's scatter too (the long negative wings of K^{-1} in Figure 8.40 are the same thing for a real patch). A wider kernel means larger couplings between bins, so the amplification grows as the patch shrinks. A 40% excess in the variance is an excess of $\sqrt{1.40} = 1.18$, or 18%, in the error bar, the price of an estimator that is fast and unbiased. Efstathiou showed that at high ℓ the pseudo-C_ℓ estimator with suitable weights is nonetheless nearly as good as the optimal quadratic one [141, §§3–5], and that at low ℓ the optimal one should be used instead, the hybrid strategy of real analyses (Section 8.15).

Watch out: Quick covariances at low ℓ

Both the mode-counting formula and Efstathiou's approximation assume that the spectrum is constant across the coupling kernel. At low ℓ, and for any patch smaller than a hemisphere, they are wrong by tens of per cent to factors of several, and the distribution is not Gaussian anyway. Use the exact expression (8.73) (cheap at low resolution), or simulations, for the multipoles below a few times π/Θ.

The laptop version of these tests uses 2000 Gaussian skies at $N_{\mathrm{side}} = 256$, which measure each variance to 3.2% and each correlation to ± 0.022; a research covariance is built from a few hundred end-to-end simulations at full resolution together with an analytic model of the Efstathiou type that includes the noise and the beam for every pair of maps, and the simulations serve to validate and correct the model rather than to replace it [70]. What the reduction costs is resolution ($\ell \leq 767$ instead of 2500) and realism (no foreground residuals, no correlated noise), not the logic of the test.

8.13 How many simulations?

Everything in Section 8.12 came from 2000 simulated skies, and the next step of a real analysis puts the simulated covariance into a likelihood: the probability of the bandpowers $\widehat{\boldsymbol{D}}$ we actually observed, read as a function of the parameters $\boldsymbol{\theta}$. For each $\boldsymbol{\theta}$ the model predicts $\boldsymbol{D}(\boldsymbol{\theta})$, and the question is how probable the fluctuation $\widehat{\boldsymbol{D}} - \boldsymbol{D}(\boldsymbol{\theta})$ is that would turn that prediction into our data (Section 3.8). For Gaussian bandpowers that probability is proportional to $\exp[-\frac{1}{2}(\widehat{\boldsymbol{D}} - \boldsymbol{D})^{\mathsf{T}}\mathbf{C}^{-1}(\widehat{\boldsymbol{D}} - \boldsymbol{D})]$, so $-2\ln\mathcal{L} = (\widehat{\boldsymbol{D}} - \boldsymbol{D})^{\mathsf{T}}\mathbf{C}^{-1}(\widehat{\boldsymbol{D}} - \boldsymbol{D})$ plus a constant, and it needs the inverse of the covariance, the **precision matrix**. Take the MASTER bandpowers of the 30% cap of Section 8.11.3: $p = 29$ bins of 20 multipoles below $\ell = 600$, with neighbouring bins correlated through the mask. With 2000 simulations the covariance is good to a few per cent. A full-resolution end-to-end simulation of a real experiment costs hours, not a second, and a few hundred of them is a typical budget. The question is how few we can afford, and what goes wrong when there are too few. Two different things go wrong, and they need to be kept apart: the elements of the estimated covariance are noisy, and the inverse of a noisy matrix is biased.

8.13.1 Noise in the elements

The sample covariance from N independent Gaussian draws has, element by element, the variance $(\Sigma_{aa}\Sigma_{bb} + \Sigma_{ab}^2)/(N-1)$ of (3.42). On the diagonal that is a relative error $\sqrt{2/(N-1)}$, and for a correlation coefficient near zero an absolute error of about $1/\sqrt{N}$. To see this on the CMB, script `28_nsims.py` draws subsets of N skies from the 2000 and compares each subset's covariance with the one from all of them. Because the reference is itself built from a finite set, the subset fluctuates around it with a variance smaller by the finite-population factor $1 - N/N_{\mathrm{all}}$: a subset that is the whole set does not fluctuate at all. At $N = 100$ the measured rms error is 0.139 on the diagonal, and $\sqrt{2/99} \times \sqrt{1 - 100/2000} = 0.139$; for the correlations it is 0.098, and $\sqrt{1/100} \times \sqrt{0.95} = 0.098$ (Figure 8.37).

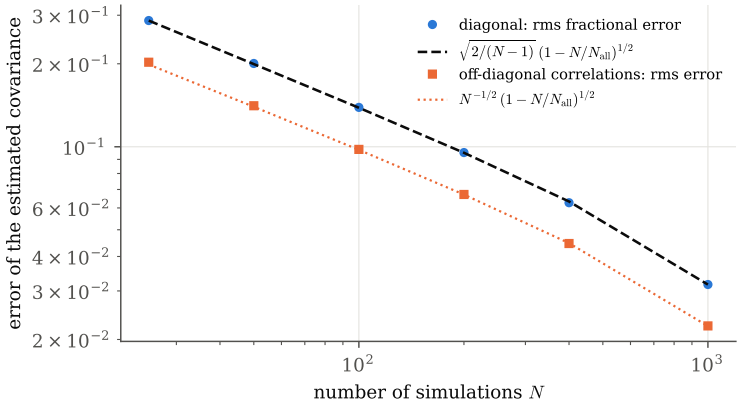

Figure 8.37: Noise in a covariance estimated from N of the 2000 simulated skies, for the 29 MASTER bins of the 30% cap. Blue: rms relative error of the diagonal elements; orange: rms error of the off-diagonal correlation coefficients. The lines are $\sqrt{2/(N-1)}$ and $1/\sqrt{N}$, each with the finite-population factor $(1 - N/N_{\mathrm{all}})^{1/2}$.

Example: can we see the correlations at all? The 70% cap correlates neighbouring multipoles at $r = 0.13$ (Section 8.12.2). To detect that at three standard deviations from a covariance estimated from N skies we need $3/\sqrt{N} < 0.13$, so $N > (3/0.13)^2 \approx 530$. With 100 skies such a correlation is indistinguishable from the spurious ones that every pair of bins shows at the level

of ±0.1. The correlations that matter for a likelihood are often exactly this small, and many of them add up.

8.13.2 Why the inverse is biased

Inverting a matrix is a nonlinear operation, and the average of a nonlinear function of a noisy quantity is not the function of its average. Inversion is not just nonlinear but convex: a fluctuation of the variance towards zero raises its inverse by more than a fluctuation of the same size away from zero lowers it. Jensen's inequality, $\mathbb{E}[1/X] \geq 1/\mathbb{E}[X]$ for a positive random X, makes the inverse of an unbiased covariance biased high. How much is a calculation that starts with one bin.

One bin. With $p = 1$ and $N = n$ draws, the sample variance (mean subtracted) is $s^2 = \sigma^2 \chi^2_k / k$ with $k = n - 1$ degrees of freedom (Chapter 3). Then

$$\mathbb{E}\Big[\frac{1}{s^2}\Big] \overset{(1)}{=} \frac{k}{\sigma^2}\,\mathbb{E}\Big[\frac{1}{\chi^2_k}\Big] \overset{(2)}{=} \frac{k}{\sigma^2}\int_0^\infty \frac{1}{x}\,\frac{x^{k/2-1}e^{-x/2}}{2^{k/2}\Gamma(k/2)}\,\mathrm{d}x \overset{(3)}{=} \frac{k}{\sigma^2}\,\frac{2^{k/2-1}\Gamma(k/2-1)}{2^{k/2}\Gamma(k/2)} \overset{(4)}{=} \frac{k}{k-2}\,\frac{1}{\sigma^2}. \tag{8.76}$$

(1) $1/s^2 = (k/\sigma^2)/\chi^2_k$, and constants come out of the expectation.
(2) The χ^2_k density.
(3) The integrand is $x^{(k/2-1)-1}e^{-x/2}$, a gamma integral equal to $\Gamma(k/2-1)\,2^{k/2-1}$; it converges for $k > 2$.
(4) $\Gamma(k/2) = (k/2-1)\Gamma(k/2-1)$, so the ratio is $\frac{1}{2}/(k/2-1) = 1/(k-2)$.

With $k = n-1$ the bias factor is $(n-1)/(n-3)$: 11% for 20 simulations, harmless for a thousand.

Many bins. For p bins the same mechanism acts in each direction, and the number of directions makes it worse. Collect the $k = n - 1$ mean-subtracted draws (after the rotation of Section 3.5.4, k independent vectors $\boldsymbol{z}_j \sim \mathcal{N}(\mathbf{0}, \Sigma)$) into $A = \sum_{j=1}^{k} \boldsymbol{z}_j \boldsymbol{z}_j^\mathsf{T} = k\widehat{\mathbf{C}}$, a Wishart matrix. Look at one diagonal element of its inverse, say the first. Block inversion of a symmetric matrix gives

$$\frac{1}{(A^{-1})_{11}} \overset{(1)}{=} A_{11} - A_{1r}A_{rr}^{-1}A_{r1} \overset{(2)}{=} \min_{\boldsymbol{\beta}} \sum_{j=1}^{k} \big(z_{1j} - \boldsymbol{\beta}^\mathsf{T}\boldsymbol{z}_{r,j}\big)^2 \;\sim\; \sigma^2_{1\,|\,r}\,\chi^2_{k-(p-1)}, \tag{8.77}$$

(1) The Schur complement: for a matrix split into the first index and the rest (r), the inverse's $(1,1)$ element is one over $A_{11} - A_{1r}A_{rr}^{-1}A_{r1}$.
(2) That expression is the residual sum of squares of the least-squares fit of the first component on the other $p-1$ components across the k draws ($\hat{\boldsymbol{\beta}} = A_{rr}^{-1}A_{r1}$). For Gaussian draws the residual of z_1 given the others is Gaussian with the conditional variance $\sigma^2_{1\,|\,r}$, and a fit with $p-1$ coefficients leaves a χ^2 with $k-(p-1)$ degrees of freedom (Chapter 3); this holds for any values of the regressors, hence also on average over them.

The conditional variance is again a Schur complement, of the true covariance: $\sigma^2_{1\,|\,r} = \Sigma_{11} - \Sigma_{1r}\Sigma_{rr}^{-1}\Sigma_{r1} = 1/(\Sigma^{-1})_{11}$. So $(A^{-1})_{11}$ is $(\Sigma^{-1})_{11}$ divided by a χ^2_{n-p} variable, and (8.76) with $k \to n-p$ gives its mean:

$$\mathbb{E}\big[(\widehat{\mathbf{C}}^{-1})_{11}\big] \overset{(1)}{=} k\;\mathbb{E}\big[(A^{-1})_{11}\big] \overset{(2)}{=} \frac{n-1}{n-p-2}\,(\Sigma^{-1})_{11}. \tag{8.78}$$

(1) $\widehat{\mathbf{C}} = A/k$, so $\widehat{\mathbf{C}}^{-1} = kA^{-1}$, with $k = n-1$.

(2) $\mathbb{E}[1/\chi^2_{n-p}] = 1/(n-p-2)$ from (8.76).

Nothing was special about the first index: in a rotated basis any unit vector $\boldsymbol{u}$ can be the first axis, so $\boldsymbol{u}^\mathsf{T}\,\mathbb{E}[\widehat{\mathbf{C}}^{-1}]\boldsymbol{u} = \frac{n-1}{n-p-2}\boldsymbol{u}^\mathsf{T}\Sigma^{-1}\boldsymbol{u}$ for every $\boldsymbol{u}$, and two symmetric matrices with equal quadratic forms are equal. The whole precision matrix is biased by the same factor [6, eq. 16].

Key idea: The Hartlap factor, and why it is there

For a covariance estimated from n Gaussian simulations of p bins ($p < n-2$),

$$\mathbb{E}\big[\widehat{\mathbf{C}}^{-1}\big] = \frac{n-1}{n-p-2}\,\mathbf{C}^{-1}, \qquad \widehat{\mathbf{C}^{-1}} = \frac{n-p-2}{n-1}\,\widehat{\mathbf{C}}^{-1} \text{ is unbiased}$$

[6, eq. 17]. Each direction of the inverse is one over a residual variance, and fitting the other $p-1$ directions costs $p-1$ degrees of freedom: the noisy matrix "explains away" part of every fluctuation, its small eigenvalues come out too small, and the inverse too large.

This is the factor quoted in (3.43); there it was stated, here it has been derived. Two more facts complete the picture [6, §§2.2, 4]. For $p > n-1$ the sample covariance is singular, because $n-1$ mean-subtracted vectors span at most $n-1$ dimensions, and no factor can rescue it. And the sample mean and the sample covariance of Gaussian draws are independent, so a χ^2 built from both is unbiased once the Hartlap factor is applied; a marginalised likelihood and a Fisher matrix are still biased by smaller, model-dependent amounts (about 8% in the likelihood, and up to 30% in $\sqrt{\det \mathbf{F}^{-1}}$ as $p/n \to 1$, in their examples).

Example: what forty bins and sixty simulations do. For $n = 60$ and $p = 40$ the factor is $(60-40-2)/(60-1) = 0.305$: without the correction every χ^2 is three times too large, and every error bar $\sqrt{3.3} = 1.8$ times too small.

8.13.3 Testing the Hartlap factor

Hartlap et al.'s experiment, repeated. Their test [6, §3.2, Fig. 1] draws $n = 60$ Gaussian vectors of $p_1 = 240$ bins, from three population covariances (constant diagonal, linearly falling diagonal, and a non-diagonal $\sigma^2/(1+\epsilon|i-j|)$ with $\epsilon = 0.05$, their eqs 18–20), rebins them to $p = 240/j$ bins by joining j neighbours, and compares the trace of the true precision matrix with the trace of the estimated one. We repeat it with 2000 repetitions instead of their 10^4 (Figure 8.38a). At $p = 40$ the raw ratio is 0.307 against the predicted $(n-p-2)/(n-1) = 0.305$, and after the correction every model and every p lies within 0.005 of one.

The same on the CMB. The sky is not a Gaussian vector of bandpowers: the bandpowers are quadratic in a Gaussian field and, at low ℓ, skewed. To see whether the factor still holds we take subsets of n skies from the 2000, invert the covariance of their $p = 29$ MASTER bins and compare with the precision matrix from all of them (Figure 8.38b). At $n = 60$ the trace ratio is 0.49, and the Hartlap factor is 0.49. The reference itself carries the factor $(2000-29-2)/(2000-1) = 0.985$, a 1.5% correction even with two thousand simulations.

8.13.4 From an unbiased precision matrix to a trustworthy error bar

An unbiased precision matrix is still a noisy one, and its noise reaches the parameters. Taylor, Joachimi, and Kitching [137] worked out how. Their result for the fractional scatter of a parameter's variance, estimated with a Hartlap-corrected precision matrix from N_S simulations

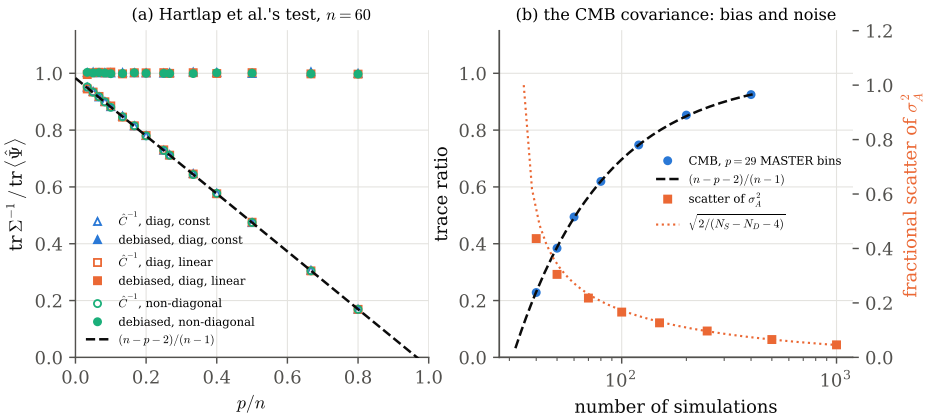

Figure 8.38: (a) Hartlap et al.'s test: the trace of the true precision matrix divided by that of the estimated one, for $n = 60$ and p up to 60, three covariance models (shapes), raw (open) and corrected (filled). The raw points follow $(n - p - 2)/(n - 1)$ (dashed) down to zero; the corrected ones sit at one. (b) The CMB: the same ratio for the MASTER bins of the 30% cap from subsets of n skies (blue, left axis), on the Hartlap curve; and the scatter of the fitted amplitude's variance (orange, right axis) against Taylor et al.'s $\sqrt{2/(N_S - N_D - 4)}$ (dotted).

of N_D data points, is $\varepsilon = \sqrt{2/(N_S - N_D - 4)}$ [137, eq. 55], and it leads to a planning rule:

$$N_S > \frac{2}{\varepsilon^2} + N_D + 4 \qquad \text{[137, eq. 58].} \tag{8.79}$$

The first term is the familiar $1/\sqrt{N}$ of any average; the second says that each data point costs one more simulation, the same degrees of freedom that appeared in the Hartlap factor. For a parameter error good to 5% the variance must be good to 10%, $\varepsilon = 0.1$, and (8.79) asks for $200 + N_D + 4$ simulations: 233 for our 29 bins.

The simplest case, exactly. For one parameter the calculation of (8.77) gives the whole distribution. Fit an amplitude A of the fiducial spectrum, $\boldsymbol{D} = A\boldsymbol{t}$ with $\boldsymbol{t}$ the fiducial bandpowers.

Its error bar. With a precision matrix Ψ the likelihood is quadratic in A: $-2\ln\mathcal{L}(A) = A^2\,\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t} - 2A\,\boldsymbol{t}^{\mathsf{T}}\Psi\widehat{\boldsymbol{D}} + \text{const}$. A Gaussian in A of width σ_A has $-2\ln\mathcal{L} = (A - \hat{A})^2/\sigma_A^2 + \text{const}$, and matching the coefficients of A^2 gives $\sigma_A^2 = 1/(\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t})$, one over the Fisher information (Chapter 10; the full chain is in Section 8.15.2). With the true covariance, $\sigma_A^2 = 1/(\boldsymbol{t}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{t})$.

Its distribution. Whiten the data: $\mathbf{C}^{-1/2}$ turns the simulated vectors into draws with identity covariance, and their sample covariance into $\widehat{S} = \mathbf{C}^{-1/2}\widehat{\mathbf{C}}\,\mathbf{C}^{-1/2}$. With $\boldsymbol{s} = \mathbf{C}^{-1/2}\boldsymbol{t}$ and the unit vector $\boldsymbol{u} = \boldsymbol{s}/|\boldsymbol{s}|$,

$$\boldsymbol{t}^{\mathsf{T}}\widehat{\mathbf{C}}^{-1}\boldsymbol{t} \overset{(1)}{=} \boldsymbol{s}^{\mathsf{T}}\widehat{S}^{-1}\boldsymbol{s} \overset{(2)}{=} |\boldsymbol{s}|^2\,\big(\widehat{S}'^{-1}\big)_{11} \overset{(3)}{=} \frac{1}{\sigma_A^2}\,\frac{n-1}{\chi^2_{n-p}}.$$

(1) $\widehat{\mathbf{C}}^{-1} = \mathbf{C}^{-1/2}\widehat{S}^{-1}\mathbf{C}^{-1/2}$.

(2) Rotate the basis so that $\boldsymbol{u}$ is the first axis; whitened Gaussian draws stay independent standard Gaussians under a rotation, and $\widehat{S}'$ is their sample covariance in the new basis.

(3) $|\boldsymbol{s}|^2 = \boldsymbol{t}^{\mathsf{T}}\mathbf{C}^{-1}\boldsymbol{t} = 1/\sigma_A^2$. For $\widehat{S}' = A/(n-1)$, (8.77) with $\Sigma = \mathbb{1}$ (so $\sigma^2_{1\,|\,r} = 1$) says $1/(A^{-1})_{11} \sim \chi^2_{n-p}$, hence $(\widehat{S}'^{-1})_{11} = (n-1)/\chi^2_{n-p}$.

Multiplying the inverse by the Hartlap factor, $\Psi = \frac{n-p-2}{n-1}\widehat{\mathbf{C}}^{-1}$, gives

$$\widehat{\sigma_A^2} = \frac{n-1}{n-p-2}\,\frac{1}{\boldsymbol{t}^{\mathsf{T}}\widehat{\mathbf{C}}^{-1}\boldsymbol{t}} = \sigma_A^2\,\frac{\chi^2_{n-p}}{n-p-2}, \qquad \frac{\mathbb{E}\,\widehat{\sigma_A^2}}{\sigma_A^2} = \frac{n-p}{n-p-2}, \qquad \frac{\sigma\big(\widehat{\sigma_A^2}\big)}{\mathbb{E}\,\widehat{\sigma_A^2}} = \sqrt{\frac{2}{n-p}}. \tag{8.80}$$

Even with the unbiased precision matrix, the parameter's variance is biased *high*, for the same convexity reason as before: σ_A^2 is one over a linear function of Ψ. The test of `28_nsims.py` draws n Gaussian bandpower vectors from the CMB covariance ($\sigma_A = 0.0069$ with the true precision matrix), 2000 times for each n. At $n = 40$ the mean of $\widehat{\sigma_A^2}$ is high by 22%, and (8.80) gives $(40-29)/(40-31) = 1.22$; its fractional scatter is 0.44, against $\sqrt{2/11} = 0.43$ from (8.80) and 0.53 from Taylor et al.'s general formula. At $n = 100$ the scatter is 0.166, against $\sqrt{2/71} = 0.168$ and 0.173. For a single parameter (8.80) is exact.

What the "−4" covers. The same calculation shows where Taylor et al.'s formula sits. Their expression is the relative scatter of the *information* $\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t} = 1/\widehat{\sigma_A^2}$, which is proportional to $1/\chi^2_k$ with $k = n-p$. From the gamma integral of (8.76), $\mathbb{E}[1/\chi^2_k] = 1/(k-2)$ and $\mathbb{E}[1/(\chi^2_k)^2] = 1/[(k-2)(k-4)]$, so

$$\mathrm{Var}\,\frac{1}{\chi^2_k} = \frac{1}{(k-2)(k-4)} - \frac{1}{(k-2)^2} = \frac{2}{(k-2)^2(k-4)}, \qquad \frac{\sigma(1/\chi^2_k)}{\mathbb{E}(1/\chi^2_k)} = \sqrt{\frac{2}{k-4}} = \sqrt{\frac{2}{N_S - N_D - 4}}.$$

The variance itself is proportional to χ^2_k, whose relative scatter is $\sqrt{2/k}$. The two agree when k is large, because a small relative error of a quantity is also the relative error of its inverse; at $k = 11$ the inverse χ^2, with its longer tail, scatters more. The "−4" is that tail, and a planning rule built on it errs on the safe side.

Watch out: Too few simulations cannot be repaired

When $p \geq n-1$ the sample covariance is singular. A pseudo-inverse obtained by discarding small singular values produces a finite matrix, but its bias depends on the covariance model and is not removed by any factor [6, §3.2]. Plan the simulations so that $n-p$ is comfortably larger than $2/\varepsilon^2$, compress the data into fewer bins, or model the covariance analytically and use simulations only to test the model.

What our numbers are worth. Our covariance uses 2000 skies for 29 bins. The Hartlap factor is 0.985, and by (8.80) the variance of a single parameter is uncertain by $\sqrt{2/1971} = 3.2\%$, its error bar by 1.6%. A research analysis has larger data vectors and dearer simulations. Planck's 300 end-to-end simulations [70] would give, for a vector of a few hundred bandpowers, an $n-p$ of order one hundred and a 14% uncertainty on each parameter variance. That is why the high-ℓ likelihoods of Planck and of the ground-based experiments use analytic covariances of the Efstathiou type, with the simulations used to test and correct them: the cost of a reduction in simulations is paid in the precision of the error bars, and the cure is to need fewer simulations, not to pretend that a small number is enough.

8.14 Reproducing the cut-sky literature

The full-sky content of Knox (1995) and Hivon et al. (2002) was reproduced in Section 8.7. The papers behind this part of the chapter make claims about masked skies, and each of them can be put to the same test: rebuild the experiment with our own code, at laptop scale, and set our numbers beside theirs. Hivon et al. tested MASTER on a simulated balloon survey of a

small patch. Efstathiou derived and tested an approximation for the covariance. Hartlap et al. derived and tested the bias of an inverted covariance, and Taylor et al. its consequences for error bars. The last three were reproduced along the way in Sections 8.12.3, 8.13.3 and 8.13.4; the first needs its own experiment.

8.14.1 Hivon et al. (2002): the Boomerang test

Their question. A balloon such as Boomerang maps a few per cent of the sky in one flight. Its detectors drift slowly, with a noise that rises as $1/f$ at low frequencies, so the timestreams are high-pass filtered before the map is made, and the filter removes large-scale power in a way that depends on how the sky was scanned. Neither the filter's effect on the spectrum nor the detector noise, once projected onto a map, has a formula. Hivon et al. asked whether the pseudo-spectrum recipe of Section 8.11, with every unknown measured on simulations, still delivers what a likelihood needs: an unbiased spectrum, an error bar that can be trusted, and the right shape of distribution. A small patch with a filter is the hard case on every count. The coupling kernel is widest for a small patch (Section 8.10.4), the filter acts on the large scales that a small patch barely resolves, and few modes per multipole make the distribution far from Gaussian (Section 8.12.1).

Their setup, one item at a time.

- *The patch and its weighting.* They analysed an ellipse inside the scanned region, under three weightings: a top-hat, a cosine taper and a Gaussian. A softer weighting lowers the leakage through the edge and pays for it in statistical weight, the trade of Section 8.10.4 and of the factor w_2^2/w_4 of Section 8.9.2. We keep the ellipse and the three weightings.

- *The filter.* Detector drifts are slow in time. Along a scan, slow in time means large on the sky, so the high-pass filter removes large-scale structure along the scan direction. We keep a sharp filter but idealise the scans.

- *The noise.* One detector's noise has a white level, a $1/f$ rise below a knee frequency, and lines at the harmonics of the scan. In the map the white part becomes pixel noise, set by how long each pixel was observed. We keep only the white part, at the same average depth.

- *The beam and the pixels.* Both kept.

- *The simulations.* Three sets with three jobs: noise-only skies measure the noise pseudo-spectrum $\langle \widetilde{N}_\ell \rangle$, and from it the noise on the sky; noise-free skies measure the transfer function F; signal-plus-noise skies test the whole recipe. We keep their sizes.

The values are in Table 8.7. The full version simulates timestreams with the real pointing and coloured noise and makes maps from them, which cost them half a CPU-day per 300 simulations [Hivon (33)]. What our reduction costs is the realism of the filter and of the noise: our transfer function is that of an ideal scan, and our noise has no stripes.

Two conversions behind our setup. *From scan frequency to azimuthal wavenumber.* Why does a filter in time remove a set of m? Put the patch on the equator of our coordinates and let the telescope sweep along a ring of constant colatitude θ at a speed v on the sky (radians of arc per second). The ring has radius $\sin\theta$, so the azimuth advances as $\phi = vt/\sin\theta$. A

	Hivon et al. (2002)	ours
data	one detector, about 5×10^7 samples, 4.4% of the sky scanned	maps simulated directly
analysis region	ellipse of semi-axes $20^\circ \times 12^\circ$, $f_{\rm sky} = 1.82\%$	the same, $f_{\rm sky} = 1.82\%$
weightings	top-hat, cosine, Gaussian	the same
beam, pixels	10′; $N_{\rm side} = 512$ (7′)	10′; $N_{\rm side} = 512$
filter	sharp high-pass at 100 mHz on the timestream, scans at $1^\circ/$s in azimuth	modes with $\lvert m\rvert < 50$ removed (ideal constant-latitude scans)
noise	$130\,\mu$K s$^{1/2}$ white, $1/f$ below a knee near 100 mHz, scan lines; about 500 s deg^{-2}	white, uniform, $350\,\mu$K arcmin
simulations	450 noise-only, 250 noise-free, 1350 signal plus noise	450, 252, 1350
cost	half a CPU-day per 300 simulations	31 minutes for all

Table 8.7: The Boomerang test [Hivon §4.1, Table 1] and our laptop version (`29_boomerang_mc.py`).

harmonic carries the factor $e^{im\phi}$, which along the scan becomes $e^{imvt/\sin\theta}$, an oscillation in time of frequency

$$\nu = \frac{m\,v}{2\pi \sin\theta}.$$

A high-pass filter at ν_c therefore removes every harmonic with $|m| < 2\pi\nu_c \sin\theta/v$, whatever its ℓ; near the equator $\sin\theta \approx 1$. Boomerang swung in azimuth at a rate $v_{\rm az}$ at an elevation $\theta_{\rm el}$. The azimuth circle at that elevation has radius $\cos\theta_{\rm el}$, so the speed on the sky is $v = v_{\rm az}\cos\theta_{\rm el}$, and the cut is $\ell_c = 2\pi\nu_c/(v_{\rm az}\cos\theta_{\rm el})$ [Hivon App. B]. With $\nu_c = 0.1$ Hz and $v_{\rm az} = 1^\circ/\text{s} = 0.0175$ rad/s, $2\pi\nu_c/v_{\rm az} = 0.628/0.0175 = 36$, and an elevation near 45° ($\cos\theta_{\rm el} \approx 0.7$) raises it to about 50. We take $\ell_c = 50$.

From detector noise to map depth. A white level of $130\,\mu$K s$^{1/2}$ means that averaging the timestream for t seconds leaves an error of $130/\sqrt{t}\,\mu$K. A pixel of area A (in deg^2) is observed for $t = 500\,\text{s deg}^{-2} \times A$ on average, so its noise is $\sigma_{\rm pix} = 130/\sqrt{500A}\,\mu$K. The product $\sigma_{\rm pix}\sqrt{A}$ no longer depends on the pixel size: $130/\sqrt{500} = 5.8\,\mu$K deg, or, with 60 arcmin to the degree, $350\,\mu$K arcmin, our depth of $350\,\mu$K arcmin.

Their key equations, and our symbols. Their estimator is MASTER, derived in Section 8.11.3 from the master equation of Section 8.10; their eqs. (15) and (24)–(26) are our master equation and the workdef of Section 8.11.3. Their flat-band power C_b is our D_b, their beam window B_ℓ our T_ℓ (beam times pixel window), and their $M_{\ell\ell'}$, F_ℓ, $P_{b\ell}$, $Q_{\ell b}$, $K_{bb'}$, $\langle\widetilde{N}_\ell\rangle_{\rm MC}$ and noise on the sky $\widehat{\mathcal{N}}_b$ are ours. Two more equations are compared below: their error bar (35)–(36), derived next, and the transfer function of a parallel scan (B7) and (B15), derived with the transfer test.

Their error bar, derived. The question in words: how many independent modes does one bin of a filtered, weighted patch hold? Start from the full sky and remove what the observation

removes, one factor at a time:

$$\operatorname{Var}\widehat{D}_b \overset{(1)}{=} \frac{2(D_b+N_b)^2}{(2\ell_b+1)\Delta\ell} \overset{(2)}{=} \frac{2(D_b+N_b)^2}{(2\ell_b+1)\Delta\ell\, f_{\rm sky}\, w_2^2/w_4} \overset{(3)}{=} \frac{2(D_b+N_b)^2}{\nu_b^f}, \qquad \nu_b^f = (2\ell_b+1)\,\Delta\ell\, f_{\rm sky}\,\frac{w_2^2}{w_4}\,F_b. \tag{8.81}$$

(1) The full-sky variance of a bin of $\Delta\ell$ multipoles centred on ℓ_b, (8.41): $2/(2\ell+1)$ per multipole, $\Delta\ell$ independent multipoles. It is written for D instead of C, since the factor $\ell(\ell+1)/2\pi$ is nearly constant across a bin; N_b is the binned noise on the sky.

(2) A weighted patch keeps $(2\ell+1)f_{\rm sky}w_2^2/w_4$ effective modes per multipole, (8.72).

(3) A sharp filter removes the modes whose along-scan frequency is below the cut and leaves the others untouched, and F_b is the fraction of modes it keeps ((8.82) below makes this explicit). Deconvolving by F_b restores the amplitude of the spectrum, but it is now estimated from fewer modes.

The square root is their analytic error bar, $\Delta\widehat{C}_b = (C_b + \widehat{\mathcal{N}}_b)\sqrt{2/\nu_b^f}$ [Hivon (36)], with ν_b^f their eq. (35). By the moment matching of (8.71), the same ν_b^f is the number of degrees of freedom of the χ^2 they compare with the histograms. In our language ν_b^f is the $\nu_{\rm eff}$ of a bin, as predicted by counting modes; $f_{\rm sky}$, w_i, F_b and $\Delta\ell$ are the same symbols. Step 2 carries the assumption tested in Section 8.12.1, that the bin is much wider than the coupling kernel. Here it is: the ellipse is at least $24^\circ = 0.42$ rad across, so the kernel is about $\pi/0.42 \approx 7.5$ multipoles wide, against bins of 50.

What we compute. `29_boomerang_mc.py` makes the three sets of skies: Gaussian skies of the fiducial spectrum, smoothed by the beam and the pixel window, filtered by removing the harmonics with $|m| < \ell_c$, plus white noise of the depth above, generated in harmonic space and filtered like the sky; it stores their pseudo-spectra through the three weightings. `30_boomerang.py` is MASTER exactly as in Section 8.11.3: bins of 50 centred on $50, 100, \ldots, 1250$; F_b solved in bins from the noise-free skies, with the binned system of Section 8.11.4; $\langle\widetilde{N}_\ell\rangle$ from the noise-only skies; then $K_{bb'}$, its inverse, and $\widehat{D}_b$ for every signal-plus-noise sky. The mean, scatter, correlations and histograms of those estimates are the comparisons below, and the numbers side by side are collected in Table 8.8.

The window factors (their Table 1). These depend only on the geometry. Ours, $w_2^2/w_4 = 1.000$, 0.514 and 0.223 for the top-hat, cosine and Gaussian weightings, agree with their 1, 0.514 and 0.223, and our sky fraction is 1.82% like theirs.

The transfer function (their Fig. 2 and App. B). What fraction of the power at multipole ℓ survives a sharp high-pass along parallel scans? *One plane wave first.* On a patch this small the sky is nearly flat, and a mode of multipole ℓ is a plane wave $e^{i\boldsymbol{k}\cdot\boldsymbol{x}}$ with $|\boldsymbol{k}| = \ell$. Let the scans run along x, and let the wave vector make an angle θ with them. Along a scan the wave is $e^{i\ell\cos\theta\, x}$: the scan sees only the along-scan wavenumber $\ell\cos\theta$, and since x grows in proportion to time, a time frequency proportional to $\ell\cos\theta$ (the flat-sky version of the m of the conversion above). The filter multiplies the wave's amplitude by its response $f(\ell\cos\theta)$, and its power by $f(\ell\cos\theta)^2$. *Then all directions.* An isotropic sky has waves of every direction with equal power, so the fraction of the power kept at ℓ is the average over θ, $F_\ell^{(0)} = \frac{1}{2\pi}\int_0^{2\pi} \mathrm{d}\theta\, f(\ell\cos\theta)^2$ [Hivon (B7)]. For a sharp cut, $f = 0$ below ℓ_c and 1 above,

$$F_\ell^{(0)} \overset{(1)}{=} 1 - \frac{1}{2\pi}\left|\{\theta : |\cos\theta| < \ell_c/\ell\}\right| \overset{(2)}{=} 1 - \frac{4\arcsin(\ell_c/\ell)}{2\pi} = 1 - \frac{2}{\pi}\arcsin\frac{\ell_c}{\ell} \qquad (\ell \geq \ell_c), \tag{8.82}$$

(1) The filter keeps a wave unless its along-scan frequency is below the cut; F is the fraction of directions kept.
(2) $|\cos\theta| < x$ holds within $\arcsin x$ of $\theta = \pi/2$ and of $3\pi/2$, on both sides: four arcs of length $\arcsin x$.

and $F^{(0)} = 0$ below ℓ_c [Hivon (B14)–(B15)]. The paper does not tabulate F, but it follows from their published degrees of freedom by solving (8.81) for F_b with the top-hat values. Our simulated F_b follows (8.82) closely; theirs agrees with both at $\ell = 50$ and lies about 10% lower above it (Table 8.8, Figure 8.39b). *Why they differ.* Their own Fig. 2 shows the same gap between the measured curves and the dotted toy model: real scans are not parallel lines, they cross the patch at varying angles and speeds, and the filter removes more. Our simulation implements the toy filter exactly, so it reproduces the toy curve and not their measurement.

How well F is known. Their eq. (38), $\delta F/F \approx a\,10^{-2}\sqrt{100/N}\sqrt{400/\ell}$, is the counting rule of Section 8.11.4 in their units. With $2\ell + 1 \approx 2\ell$,

$$\frac{\delta F}{F} = \sqrt{\frac{2}{2\ell\,\Delta\ell\,f_{\rm sky}N}} = \sqrt{\frac{400}{\ell}}\sqrt{\frac{100}{N}}\,\frac{1}{\sqrt{400\times100\times\Delta\ell\,f_{\rm sky}}},$$

and with $\Delta\ell = 50$ and $f_{\rm sky} = 0.0182$ the last factor is $1/\sqrt{36\,400} = 0.52\times10^{-2}$: counting predicts $a = 0.52$. Our 252 noise-free skies, split into their six chunks, give $a = 0.63 \pm 0.04$: a little above the counting value, and at the low end of their 0.6–0.9. Counting assumes each bin is measured on its own; the correction for the mask couples neighbouring bins, and that adds scatter, as the ring-filter test of Section 8.11.4 also found.

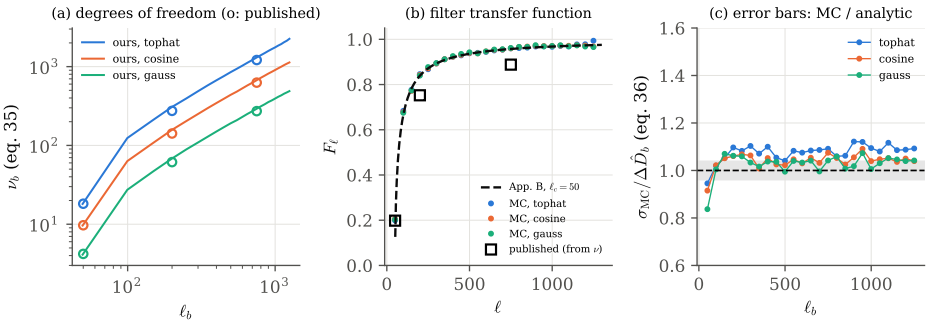

Figure 8.39: Our Boomerang test against the published numbers. (a) Degrees of freedom ν_b of [Hivon (35)] for the three weightings (lines) and the nine published values of their Fig. 6 (circles). (b) The transfer function: our simulated F_b (dots), the parallel-scan formula (8.82) (dashed), and the values implied by the published ν (squares). (c) The simulated error bars divided by the analytic ones of [Hivon (36)]; the grey band is the Monte Carlo error.

The degrees of freedom (their Fig. 6). Inserting our F into (8.81) gives our ν for the three weightings at $\ell = 50$, 200 and 750 (Figure 8.39a, Table 8.8). Above $\ell = 50$ ours are larger, and the difference is the ratio of the two transfer functions and nothing else: $307.2/274.6 = 1.12 = 0.846/0.75$. A sharper check of their table is internal. In (8.81) only w_2^2/w_4 changes between weightings, so multiplying their top-hat ν by our ratios of w_2^2/w_4 should give their cosine and Gaussian values. It does, to within 1%.

The binned kernel (their Fig. 3). Figure 8.40 shows the diagonal and two rows of $K_{bb'}$ and of its inverse for the top-hat window, in the format of their figure. The diagonal is 0.012 at $\ell_b = 200$ and falls to 1.0×10^{-3} at 1200, the beam, pixel window and $f_{\rm sky}w_2$ in one number; the

rows fall by four to six decades within a few hundred multipoles, and the inverse has the long negative wings of a deconvolution, as in their figure.

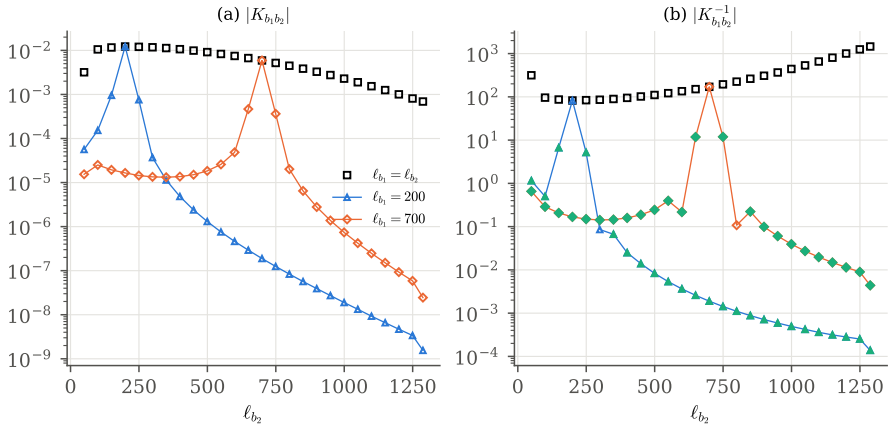

Figure 8.40: The binned coupling kernel of the top-hat ellipse ($f_{\rm sky} = 1.8\%$, $\Delta\ell = 50$), in the format of Hivon et al.'s Fig. 3. (a) $|K_{b_1 b_2}|$: the diagonal (squares) and the rows $\ell_{b_1} = 200$ and 700. (b) $|K^{-1}_{b_1 b_2}|$; green marks negative elements.

The recovered spectrum and its error bars (their Fig. 5): what they claimed. They found the mean of 1352 MASTER estimates "in perfect agreement (to an error on the mean)" with the bin-averaged input, and the simulated error bars "almost identical" to the analytic error bar (8.81) [Hivon §4.2]; off-diagonal correlations were "at most 10%".

How we test it. For the error bar we divide the simulated scatter of $\widehat{D}_b$ by the square root of (8.81). For the mean we use *pulls*, as in Section 8.10.3: the mean of our estimates in a bin, minus its prediction, divided by the Monte Carlo error of that mean (the scatter of single estimates over $\sqrt{1350}$). If the prediction is right, the pulls are draws of a standard Gaussian, and the largest of 25 should be about two, rarely above three. Two predictions are possible: the plain bin average of the input, as in the paper, or the bandpower-window prediction (8.68). The numbers for the three weightings are in Table 8.8 and Figure 8.39c, Figure 8.41. In short: the analytic error bar is a few per cent optimistic in most bins and pessimistic in the first; the mean agrees with the window prediction, with pulls larger than chance until the errors shared by all skies are counted; against the plain bin average it is off by up to a third of a single sky's error bar; and the top-hat's largest correlation exceeds 10%.

Why they differ. *The error bar is a few per cent too small.* Equation (8.81) counts modes, which gives the variance of an optimal estimate. MASTER is not optimal, and its deconvolution amplifies the scatter (Section 8.12.3); a 5% excess, against a Monte Carlo error of 2%, is invisible at the precision of "almost identical".

In the first bin it is too large. The bin $\ell = 25$–74 contains a steep rise of both D_ℓ and F_ℓ, and the rule evaluates them at the bin's centre. That is step 3 of (8.41), which failed in the full sky's first bin for the same reason (Section 8.7.2).

The pulls against the windows are larger than chance. All 1350 estimates share two things measured from smaller sets. They are deconvolved with the same F, measured from only 252 skies. Since $\widehat{D}_b \propto 1/F_b$, a relative error δ of F_b shifts every estimate by the same $-\delta D_b$. And the same noise power, measured from only 450 noise-only skies, is subtracted from every one of them, so its error shifts them all alike too. Averaging over 1350 skies shrinks their independent

scatter by $\sqrt{1350}$ but leaves the common shifts untouched, so in units of the Monte Carlo error of the mean they are magnified. For the top-hat, the scatter of F between the six chunks of the noise-free set gives common shifts of up to 3.1 such errors, and the noise power up to 1.7, largest in the noise-dominated bins at high ℓ. Adding both to the error of the mean, the largest pulls become 1.6, 1.5 and 2.0 for the three weightings: about what chance gives, since the largest of 25 standard normal numbers is typically about 2.

The plain bin average is the wrong prediction. The offsets from it sit in the first bin, where D_ℓ and F_ℓ rise steeply and the bandpower window differs from a flat average by 7%, and at the peaks and troughs; the bandpower windows account for them (the pitfall of Section 8.11.3). At the resolution of their Fig. 5 such offsets are invisible; with 1350 simulations they are measurable.

The top-hat correlates more. Beyond the first three bins the correlation matrix (Figure 8.41b) is diagonal-dominated, but the top-hat's largest off-diagonal correlation slightly exceeds their 10%. It has the sharpest edge, and so the longest leakage tail.

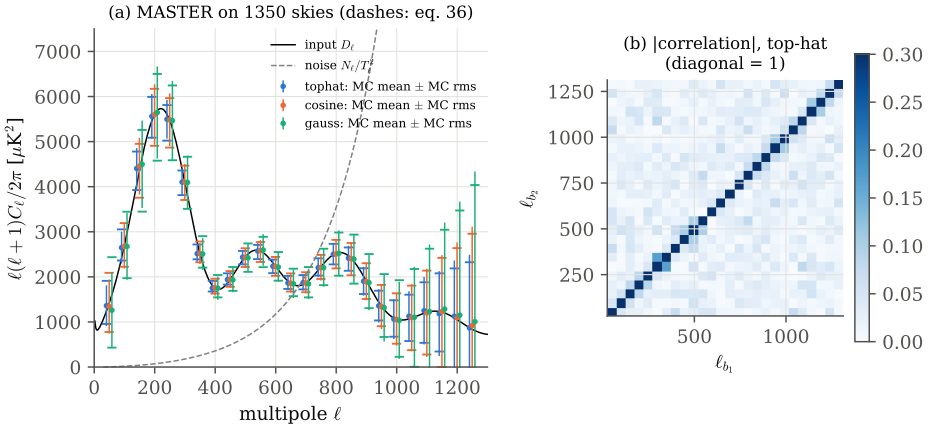

Figure 8.41: MASTER on 1350 simulated Boomerang-like skies, in the format of Hivon et al.'s Fig. 5. (a) Mean and scatter of the estimates for the three weightings (slightly offset in ℓ), the input spectrum (black), the analytic error bars of [Hivon (36)] (dashes) and the noise on the sky (grey dashed). (b) Absolute correlation matrix of the top-hat bandpowers.

The shape of the distribution (their Fig. 6). Their last test compared the histogram of the estimates in the bins at $\ell = 50$, 200 and 750 with a χ^2_ν with the ν of (8.81), with no free parameter, and with a Gaussian of the same mean and variance. Figure 8.42 is the same figure from our simulations. At $\ell = 50$, where ν is 18, 10 and 4, the histograms are skewed and the χ^2_ν follows them where the Gaussian does not, most clearly for the Gaussian weighting with $\nu \approx 4$; at $\ell = 200$ and 750 the two models coincide. Their conclusion carries over unchanged: for small sky coverage the likelihood of a low-ℓ bandpower must be modelled as a χ^2, not as a Gaussian [Hivon (37)].

Lesson. At the resolution of the paper's figures MASTER passes every test; with the same number of simulations, read as numbers, each few-per-cent residual becomes measurable and has a cause we can name: a non-optimal estimator, a transfer function measured once and shared by every estimate, and a theory that must be passed through the bandpower windows.

8.14.2 Efstathiou (2004), Hartlap et al. (2007), Taylor et al. (2013), NaMaster

Efstathiou. *His question:* through a Galactic cut, can a cheap pseudo-C_ℓ estimator be nearly as good as exact maximum likelihood, and can its covariance be computed without simulations?

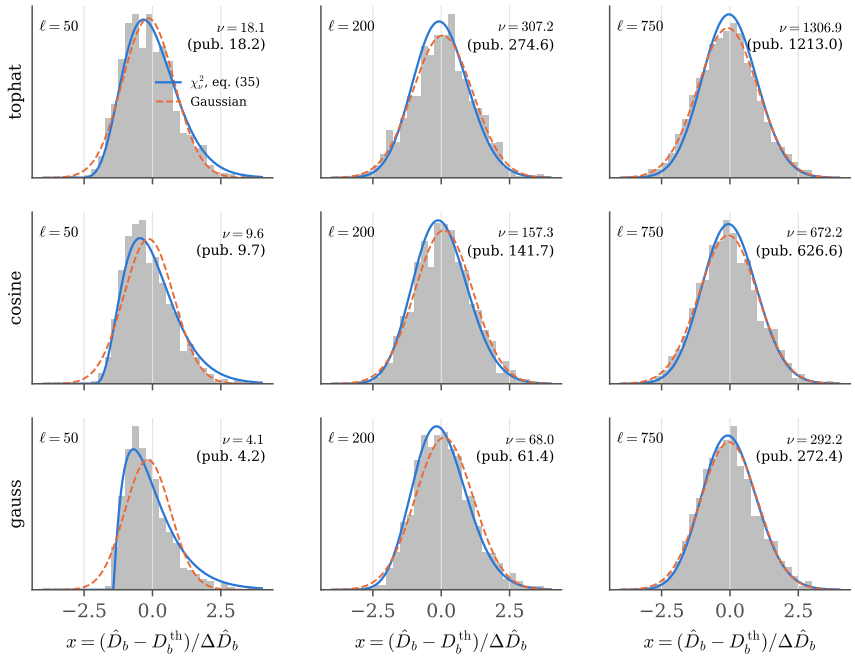

Figure 8.42: Distributions of the MASTER estimates, centred on the input and divided by the analytic error, at $\ell = 50$, 200 and 750 (columns) for the three weightings (rows), as in Hivon et al.'s Fig. 6. Blue: the χ^2_ν of eq. (35) with our ν (their published ν in brackets); orange dashed: a Gaussian of the same mean and variance.

His equations, here: the coupling matrix (his eqs. 9–11) is (8.61), with his symmetric $G_{\ell\ell'} = M_{\ell\ell'}/(2\ell'+1)$ and his $\Xi(\ell, \ell', \mathcal{W})$ ours; the exact covariance (his 14, 18) is (8.73); the approximation (15a) is (8.75), with his $W^{(2)}$ the spectrum $\mathcal{W}^{(2)}$ of the squared window. *What we ran:* the 2000 skies through a ±20° band, the exact band covariance from the ring sum (8.74), and the approximation against both. His Fig. 1 (the mean pseudo-spectrum is the input convolved with M, and the deconvolved estimate is unbiased) is our mean-square pull of 1.06 (Section 8.10.3) and the unbiased MASTER of Section 8.11.3; his Fig. 4 (exact covariance against simulations) is our ratio 1.005 ± 0.035, the Monte Carlo precision. *The difference:* his approximation is accurate at $\ell \gtrsim 20$ and wrong by up to 25% at $\ell = 2$; ours is wrong by 43% at $\ell = 2$ and 10% at $\ell = 20$. His cut of ±10° removes $\sin 10° = 17\%$ of the sky, ours $\sin 20° = 34\%$, twice as much; the wider cut widens the coupling kernel, and the approximation, which assumes the spectrum constant across the kernel, fails further up in ℓ. *Lesson:* the approximation is a high-ℓ tool, and the multipole where it becomes good moves up with the cut.

Hartlap et al. *Their question:* when a covariance is estimated from n simulations and inverted, is the inverse unbiased, and if not, by how much? *Their equation, here:* the factor $(n-p-2)/(n-1)$ of their eq. 17 is derived in (8.78); their n and p (simulations and data points) are ours, and their debiased inverse is our Ψ. *What we ran:* their Fig. 1 test, $n = 60$, $p_1 = 240$, three covariance models, with 2000 repetitions instead of 10^4 (Figure 8.38a). *Side by side:* the raw trace ratio follows $(n - p - 2)/(n - 1)$ and the corrected one is one to within 0.005. There is no difference to explain beyond the Monte Carlo noise. *Lesson:* the factor is exact for Gaussian vectors, and it holds for skewed CMB bandpowers too (Section 8.13.3).

Taylor et al. *Their question:* once the precision matrix is unbiased, how noisy is the error bar it gives, and how many simulations does a target precision need? *Their equations:* $\varepsilon = \sqrt{2/(N_S - N_D - 4)}$ (their eq. 55) and the planning rule (8.79) (their eq. 58), with their N_S, N_D

our n, p. *What we ran:* the one-parameter amplitude fit of Section 8.13.4, 2000 times for each n. *Side by side:* at $N_S = 40$ the scatter of $\widehat{\sigma_A^2}$ is 0.44, against 0.53 from their eq. (55) and 0.43 from the exact (8.80). *The difference:* their formula is the relative scatter of the Fisher information, an inverse χ^2_{n-p}, and the "−4" is that distribution's long tail; the variance itself is a χ^2_{n-p} and scatters as $\sqrt{2/(n-p)}$, smaller at small $n-p$ (Section 8.13.4). *Lesson:* their rule errs on the safe side; it asks for 233 simulations for 5% error bars on our 29 bins.

NaMaster, in words. NaMaster is the standard pseudo-C_ℓ code of current surveys [142], and the question for us is whether it computes what we derived. Its conventions map onto ours one to one. Its mode-coupling matrix for two spin-0 fields with masks v and w is $M^{00}_{\ell\ell'} = \frac{2\ell'+1}{4\pi}\sum_{\ell''} P^{vw}_{\ell''}(\ell\ \ell'\ \ell'';0\ 0\ 0)^2$ with $P^{vw}_{\ell''} = (2\ell''+1)\,\mathrm{PCL}_{\ell''}(v,w)$ [142, eq. 12], which for $v = w = W$ is our (8.61). Its bandpowers are weighted sums of the coupled pseudo-C_ℓ over the multipoles of each band, with weights normalised to one; the binned coupling matrix is inverted, and theory is compared with data only through the bandpower windows $\mathcal{F}_{q\ell}$ [142, eqs 15–19], our (8.68). The default weights are flat in C_ℓ; Hivon's flat-in-D_ℓ binning corresponds to weights proportional to $\ell(\ell+1)$. Beyond what we use, it handles spin-2 fields (polarisation, shear) with E/B purification, and deprojects foreground templates with the corresponding bias correction. NaMaster is not installed in our environment, so the comparison is with its published equations, not with its output.

8.15 How it is done in research

A real temperature analysis has one sky and a stack of simulations. Everything it publishes about the spectrum, from the error bar of a single bandpower to the claim that no systematic effect is left, is a statement about how the estimator behaves on simulated skies that went through the same mask and the same code as the data. The order in which a full-sky analysis runs (maps, spectra, deconvolution, covariance, likelihood, checks) was laid out in Section 8.8. The mask changes what each of those steps has to do, and a real analysis makes a definite choice at each one. Seeing those choices once, and then running a small analysis that makes the same ones on a laptop, ties together the pieces of this chapter.

8.15.1 The cut-sky choices of a real analysis

The reference here is the Planck 2018 high-ℓ temperature likelihood [70], which is a pseudo-C_ℓ analysis of exactly the kind built in Sections 8.9 to 8.11.

The mask. A Galactic mask is made by thresholding a map of foreground emission, so that it follows the dust and not a straight line of latitude, and it is multiplied by masks of point sources, of carbon monoxide line emission and of extended objects, each specific to the frequency of the map. Planck keeps 66%, 57% and 47% of the sky at 100, 143 and 217 GHz (the masks T66, T57 and T47), because dust is brighter at the higher frequency. The Galactic part is apodised with a Gaussian of 4.71° full width at half maximum and the point-source holes with one of 30′ [70, §3.2]. The reason given is the one of Section 8.10.4: a soft edge confines the coupling to neighbouring multipoles and makes the bandpowers less correlated. The price is the one we computed there in modes: the apodisation removes about 10% of the effective sky fraction [70, §3.2].

Table 8.8: Published cut-sky results and the same quantities from our code. Where three values are given for the Boomerang test they are for the top-hat, cosine and Gaussian weightings.

The coupling and the bandpowers. The coupling matrix of each mask is computed exactly from the mask's own spectrum, as in (8.61), and inverted in bins. The bins are $\Delta\ell = 5$ for $30 \le \ell \le 99$, 9 up to $\ell = 1503$, 17 up to 2013 and 33 up to 2508 [70, §3.2.5]. They are narrow because a 60% mask couples multipoles over only a few ℓ (Figure 8.27); they widen at high ℓ because there the noise, not the coupling, sets the useful resolution. The spectra are cross-spectra between the two half-missions and between detector sets, so that no noise bias enters (Section 8.3.3).

The covariance. Planck does not estimate its covariance from simulations. With hundreds of bandpowers for each of several cross-spectra, (8.79) would demand thousands of end-to-end simulations, and only 300 exist. The covariance is computed analytically for a fiducial model, with the large Galactic mask treated by the MASTER-type expressions of Section 8.12.3 (the approximation that Efstathiou derived), the point-source masks by a correction measured on Monte Carlo simulations, and the anisotropy of the noise by a heuristic correction [70, §3.1]. The 300 FFP10 end-to-end simulations are used to test the result [70].

The likelihood and the checks. Above $\ell = 30$ the bandpowers enter a Gaussian likelihood, $-2\ln\mathcal{L} = (\hat{C} - C(\theta))^{\mathsf{T}}\Sigma^{-1}(\hat{C} - C(\theta))$, with the covariance Σ fixed at the fiducial model. The Gaussian shape is a choice justified by the central limit theorem, and its symmetry causes a small bias for $30 \le \ell < 100$ [70, §3.1], which is the skewness of Section 8.12.1 seen from the likelihood side. Its size follows from the mode count (8.72). A bin of five multipoles at $\ell = 50$ on about 60% of the sky holds $\nu \approx (2\times 50+1)\times 5\times 0.6 \approx 300$ modes, so the scaled χ^2 has skewness $\sqrt{8/\nu} \approx 0.16$; at $\ell = 30$, $\nu \approx 180$ and the skewness is 0.21. Small, but not zero, and it is the multipole range where a symmetric likelihood errs most; above $\ell = 100$ the bins are wider and the skewness falls below 0.1.

Null tests difference half-missions, detector sets, and odd and even rings of the scan, so that the sky cancels and only noise and systematics remain. The logic is that of Section 4.1.1: we assume the difference is noise alone, because for that case the simulations give us its distribution; and we ask whether a result like the observed one, or one further in the same direction, would be unremarkable if that were true. The probability of such a result is the probability to exceed (PTE) under the simulations [70]; the null-test example of Section 8.15.2 works one through. Ground-based experiments such as ACT and SPT map patches of a few to a few tens of percent of the sky, filter their timestreams, and so add the transfer function of Section 8.11.4, measured on noise-free simulations; in every other respect their spectra are built the same way.

8.15.2 Our pipeline, end to end

The setting. The script `31_pipeline.py` runs the whole chain of Figure 8.43 once, on a sky whose random seed is kept apart from those of the simulations, so that it plays the part of the data. The instrument is the toy experiment of Section 8.2: $N_{\rm side} = 256$, a 30′ Gaussian beam and white noise of 200 μK arcmin. The data are two half-mission maps of the same sky, each with noise $\sqrt{2}$ larger, so that their average has the noise of the full experiment. The window is the product of a Galactic band, $|b| < 20°$ with a 5° cosine taper, and 400 randomly placed point-source holes of radius 1°, now themselves given a 1° taper (the band and the holes of Section 8.9.2, multiplied together). It keeps $f_{\rm sky} = 0.638$ of the sky with $w_2 = 0.878$. The questions are the ones a real analysis answers: what is the spectrum, how uncertain is it, is anything in the data that is not sky, and what amplitude of the fiducial spectrum does the data prefer?

Listing 8.7: One observation and its bandpowers (`code/ch08/31_pipeline.py`)

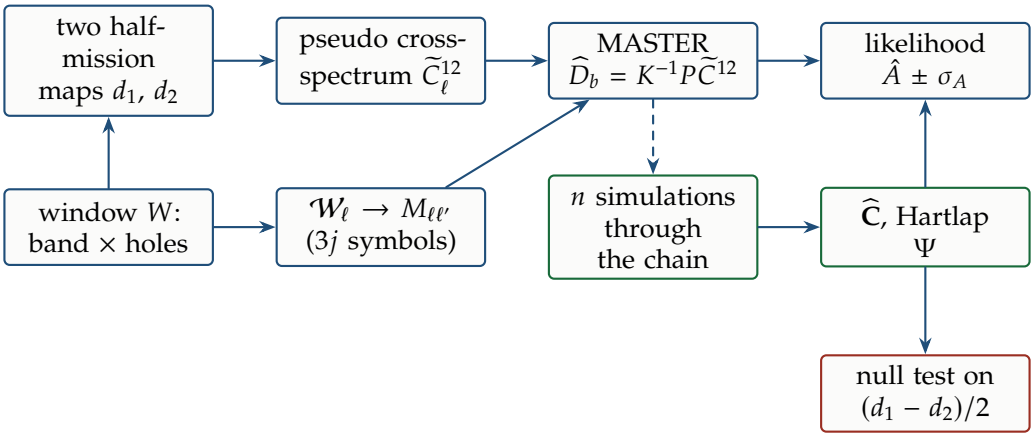

Figure 8.43: The cut-sky analysis as it runs. The window enters twice: it multiplies the maps and, through its spectrum alone, fixes the coupling matrix. The simulations (green) pass through the same chain as the data (the dashed arrow) and supply what no formula gives here: the covariance, its inverse and the distribution of the null test (red).

```python
def observe(rng, systematic=False):
    """Two half-mission maps of one sky: same signal, independent noise of variance 2 sigma^2."""
    a = cs.synalm(cl, L, rng)
    s = hp.alm2map(hp.almxfl(a, exp.transfer(L)), NSIDE, lmax=L)
    d1 = s + cs.noise_map(exp, rng, scale=np.sqrt(2.0))
    d2 = s + cs.noise_map(exp, rng, scale=np.sqrt(2.0))
    if systematic:
        d2 = d2 + STRIPE
    return d1, d2

def bandpowers(d1, d2):
    """MASTER cross-spectrum of the halves, and the MASTER spectrum of the half-difference."""
    a1 = hp.map2alm(W * d1, lmax=L, iter=0)
    a2 = hp.map2alm(W * d2, lmax=L, iter=0)
    cross = hp.alm2cl(a1, a2)
    null = hp.alm2cl(0.5 * (a1 - a2))
    return Kinv @ (P @ cross), Kinv @ (P @ null)
```

The code. `observe` draws one Gaussian sky from the fiducial spectrum, smooths it with the beam and pixel window, and adds two independent noise maps; the optional stripes are the systematic used below. `bandpowers` multiplies both maps by the window, transforms them, and forms two spectra: the cross spectrum of the halves and the spectrum of their half-difference, in which the sky cancels. Both are binned with P (bins of 20) and deconvolved with K^{-1}, the binned coupling of (8.68)'s definition with $F_\ell = 1$ (no filter) and T_ℓ^2 the beam and pixel window. The coupling matrix is computed once from the window's spectrum, and the same two functions run on the data and on each of the 400 simulations. The bandpowers used are the $p = 29$ bins with $22 \le \ell \le 601$.

The covariance and its inverse. The covariance of the $p = 29$ bandpowers is the sample covariance of the $n = 400$ simulations, and its inverse is corrected by the Hartlap factor of

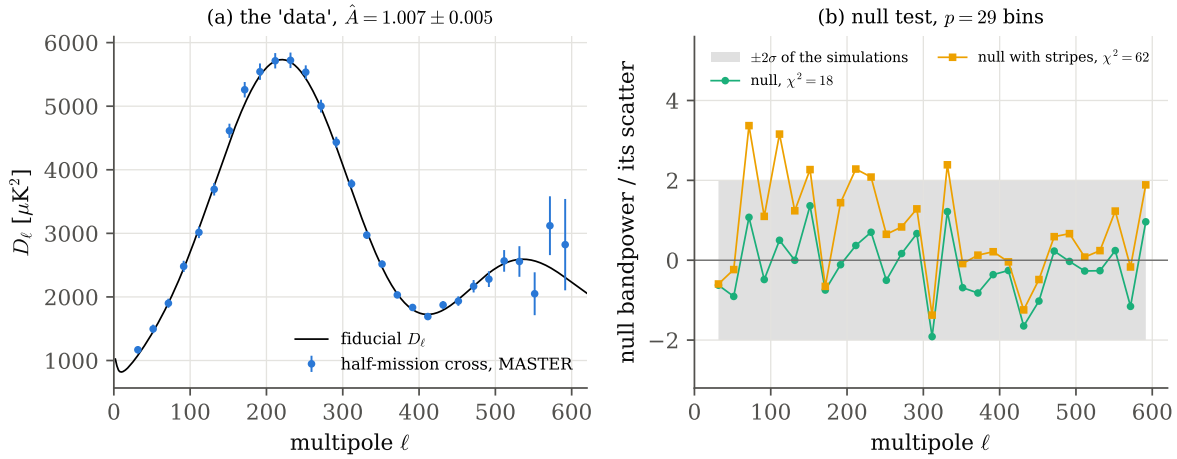

Figure 8.44: (a) The "data": MASTER bandpowers of the half-mission cross spectrum through the band-and-holes window, with error bars from the simulations, on the fiducial spectrum. (b) The null spectrum of the half-difference map, minus its simulated mean and divided by its simulated scatter, without (green) and with (orange) a 3 μK ring-striping systematic in the second half. The stripes add power, so almost every orange point sits above its green partner, most of all below $\ell \approx 350$; which orange points leave the grey band, and by how much, changes from one draw to the next.

Section 8.13.2:

$$\Psi = \frac{n-p-2}{n-1}\,\widehat{\mathbf{C}}^{-1} \overset{(1)}{=} \frac{400-29-2}{400-1}\,\widehat{\mathbf{C}}^{-1} \overset{(2)}{=} 0.925\,\widehat{\mathbf{C}}^{-1}.$$

(1) $n = 400$ simulations and $p = 29$ bins.
(2) $369/399 = 0.9248$, the script's 0.925.

Without the factor every χ^2 would be 8% too large and every error bar 4% too small. With it, the variance of a single parameter is still uncertain by $\sqrt{2/(n-p)} = \sqrt{2/371} = 7.3\%$ by (8.80), its error bar by 3.7%, and biased high by $(n-p)/(n-p-2) - 1 = 0.5\%$. Those are the cost of 400 simulations.

Example: the amplitude and its error bar. The simplest physics question is how much CMB power there is relative to the fiducial model. Write the model for the bandpowers as $\boldsymbol{D} = A\boldsymbol{t}$, with $\boldsymbol{t}$ the fiducial bandpowers $P_{b\ell}C_\ell^{\rm fid}$ and A a free amplitude, and the Gaussian likelihood with the precision matrix Ψ:

$$\begin{aligned} -2\ln\mathcal{L}(A) &\overset{(1)}{=} (\widehat{\boldsymbol{D}} - A\boldsymbol{t})^{\mathsf{T}}\Psi(\widehat{\boldsymbol{D}} - A\boldsymbol{t}) + \text{const} \\ &\overset{(2)}{=} A^2\,\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t} - 2A\,\boldsymbol{t}^{\mathsf{T}}\Psi\widehat{\boldsymbol{D}} + \widehat{\boldsymbol{D}}^{\mathsf{T}}\Psi\widehat{\boldsymbol{D}} + \text{const} \\ &\overset{(3)}{=} \frac{(A-\hat{A})^2}{\sigma_A^2} + \text{const}', \qquad \hat{A} = \frac{\boldsymbol{t}^{\mathsf{T}}\Psi\widehat{\boldsymbol{D}}}{\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t}}, \quad \sigma_A^2 = \frac{1}{\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t}}. \end{aligned}$$

(1) The Gaussian likelihood of the bandpowers, with the covariance fixed (it does not depend on A).
(2) Expand the quadratic form; Ψ is symmetric, so the two cross terms are equal.
(3) Complete the square in A; everything without A goes into the constant.

The likelihood in A is exactly Gaussian, with its peak at a weighted average of the bin-by-bin ratios $\widehat{D}_b/t_b$ and its width given by the Fisher information $\boldsymbol{t}^{\mathsf{T}}\Psi\boldsymbol{t}$ (Chapter 10). Because $\hat{A}$ is

linear in $\widehat{\boldsymbol{D}}$ and MASTER is unbiased, $\hat{A}$ is unbiased whatever Ψ is; the precision matrix only sets the weights, and a noisy one gives slightly suboptimal weights, not a bias. On the data $\hat{A} = 1.007 \pm 0.005$. Run on each simulation, the same estimator has mean 1.0006 and standard deviation 0.0046, which matches the Fisher width, and the interval $\hat{A} \pm \sigma_A$ covers the input $A = 1$ in 68% of the simulations, as a 68% interval should. The data sit within two standard deviations of the input, and the fit has $\chi^2 = 18.0$ for $p - 1 = 28$ degrees of freedom (PTE 0.93): one amplitude describes all 29 bins.

Example: a null test, and what could have produced its value. *The event.* The half-difference map $(d_1 - d_2)/2$ contains the noise of the two halves and no sky. Its bandpowers, minus their mean over the simulations, give $\chi^2 = 17.8$ with the precision matrix Ψ_{null} of the simulated null spectra, for $p = 29$ bins. *What could have produced it?* Two things: noise behaving as the simulations say, or noise plus something the simulations do not contain (a drift, a stripe, a calibration change between halves). *How probable is the value under the first?* The simulations answer directly: the fraction of simulated null spectra with a larger χ^2 is the PTE, 0.92 in this run. That is not small enough to doubt the noise model, and the test passes. It is a test of the first hypothesis alone (Chapter 4): a small PTE would say that the noise model fails, not what replaced it.

To see the test fail, the script adds to the second half a pattern of the kind a scan can leave: a random offset of 3 μK rms on every ring of constant latitude. Such a pattern $f(\theta)$ depends only on the colatitude, so its coefficients are $a_{\ell m} = \int f(\theta) \lambda_{\ell m}(\theta) \sin\theta \, \mathrm{d}\theta \int_0^{2\pi} e^{-im\phi} \mathrm{d}\phi$, and the ϕ integral vanishes for every $m \neq 0$. On the full sky all its power sits in the $m = 0$ modes, a little at every ℓ; the mask spreads it to other m. The null χ^2 becomes 62, with PTE = 0.003. Figure 8.44b shows why a χ^2 is the right summary. In this run the largest single excess is 3.4 standard deviations, which a reader scanning 29 bins might put down to bad luck. The χ^2 does better: it adds up the excess of every bin, the small ones as well as the large. Under noise alone it is a χ^2_{29}, with mean 29, variance $2 \times 29 = 58$ and standard deviation 7.6; the observed value lies $(62 - 29)/7.6 = 4.3$ standard deviations above the mean. A second, cruder count looks only at signs: under noise alone each bin is as likely to sit above zero as below, so the number of high bins is binomial with mean 14.5 and standard deviation $\sqrt{29/4} = 2.7$. Here 20 of the 29 bins are high, and 20 or more would happen by chance with probability $p = 0.031$. The count throws away how far each bin is from zero, so it is weaker than the χ^2: stripes that push a few bins far up can leave it unremarkable. Is this one data set a lucky catch? The script repeats the test on 20 fresh data sets, each with its own sky, noise and stripes. The null χ^2 has median 63, so stripes of this size usually fail the test. But not always: the lowest of the 20, 41, lies only 1.5 standard deviations above the mean, a value noise alone reaches often enough that the test could pass. A null test that passes does not prove the data are clean; it says the contamination is not much larger than the noise.

Example: why the simulated χ^2 values come out low. There is a subtlety in using the same simulations for the covariance and for the null distribution. For the simulations themselves, with residuals $\boldsymbol{r}_i = \boldsymbol{v}_i - \bar{\boldsymbol{v}}$,

$$\begin{aligned}\frac{1}{n}\sum_{i=1}^{n} \boldsymbol{r}_i^{\mathsf{T}} \Psi \boldsymbol{r}_i &\overset{(1)}{=} \frac{n-p-2}{n(n-1)} \sum_i \operatorname{tr}\!\left(\widehat{\mathbf{C}}^{-1} \boldsymbol{r}_i \boldsymbol{r}_i^{\mathsf{T}}\right) \\ &\overset{(2)}{=} \frac{n-p-2}{n(n-1)} \operatorname{tr}\!\left(\widehat{\mathbf{C}}^{-1} (n-1)\widehat{\mathbf{C}}\right) \\ &\overset{(3)}{=} \frac{(n-p-2)\,p}{n} = \frac{369 \times 29}{400} = 26.75.\end{aligned}$$

(1) $\Psi = \frac{n-p-2}{n-1}\widehat{\mathbf{C}}^{-1}$, and a number equals its own trace, $\boldsymbol{r}^{\mathsf{T}}\mathsf{A}\boldsymbol{r} = \mathrm{tr}(\mathsf{A}\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}})$.
(2) The sum of the outer products of the residuals is $(n-1)\widehat{\mathbf{C}}$, by the definition of the sample covariance.
(3) $\mathrm{tr}\,\mathbb{1}_p = p$.

This is an identity, true for every set of simulations, and the script finds 26.8 (scatter 7.2). An independent data vector $\boldsymbol{d}$ behaves differently, and three facts give its value. *The residual's covariance.* $\boldsymbol{r} = \boldsymbol{d} - \bar{v}$, with $\boldsymbol{d}$ independent of the simulations; $\boldsymbol{d}$ has covariance $\mathbf{C}$ and the mean of n simulations has $\mathbf{C}/n$, so $\mathbb{E}[\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}}] = \mathbf{C}(1+1/n)$. *Independence.* Ψ is built from the simulations, so it is independent of $\boldsymbol{d}$; for Gaussian draws the sample covariance is also independent of the sample mean $\bar{v}$ (Section 8.13.2), so Ψ is independent of $\boldsymbol{r}$ and the average of the product factorises. *Unbiasedness.* $\mathbb{E}[\Psi] = \mathbf{C}^{-1}$, by (8.78) with the Hartlap factor. Then

$$\mathbb{E}[\boldsymbol{r}^{\mathsf{T}}\Psi\boldsymbol{r}] = \mathbb{E}\,\mathrm{tr}(\Psi\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}}) = \mathrm{tr}\big(\mathbb{E}[\Psi]\;\mathbb{E}[\boldsymbol{r}\boldsymbol{r}^{\mathsf{T}}]\big) = \mathrm{tr}\big(\mathbf{C}^{-1}\mathbf{C}(1+1/n)\big) = p\,(1+1/n) = 29.07.$$

The simulations, by contrast, were used to build Ψ: each $\boldsymbol{r}_i$ helped make the covariance it is measured against, and the identity above gives 26.75. They fit their own covariance a little too well, so the reference distribution sits about two units of χ^2 low and the PTE of real data comes out slightly too small. The test errs towards failing, which is the safe side; a cleaner test keeps a separate set of simulations for the null distribution.

What the laptop version leaves out. Each step of Figure 8.43 was reduced to fit on a laptop. Each reduction removes something whose effect is either known or not the subject here, and each has a price.

Taxonomy: The cut-sky pipeline: research version and laptop version

step	research version	here	cost of the reduction
maps	several frequencies, $N_{\mathrm{side}} = 2048$, $\ell \le 2508$, foregrounds	one channel, $N_{\mathrm{side}} = 256$, CMB only, $\ell \le 601$	no damping tail, no foreground model
mask	thresholded foreground maps, thousands of sources, T66–T47 per frequency	geometric band, 400 random holes	same mathematics, not tied to real foregrounds
coupling	exact, from $\mathcal{W}_\ell$ to $2\ell_{\mathrm{max}}$	the same	none
noise	anisotropic, correlated, from the scan	white, uniform, two halves	no anisotropic-noise correction
covariance	analytic for a fiducial model, Monte Carlo corrections, tested on 300 end-to-end simulations	400 Gaussian simulations, Hartlap factor	7% uncertainty on a parameter variance; no systematics in $\mathbf{C}$
null tests	half-missions, detector sets, odd/even rings, every frequency	one half-mission null, one injected systematic	tests only what we put in
likelihood	multi-frequency, foreground and instrument nuisance parameters	one amplitude	no degeneracies to marginalise

The reduction that matters most for the statistics is in the covariance. At $N_{\mathrm{side}} = 2048$ and $\ell_{\mathrm{max}} = 2500$ each simulation costs about $(2048/256)^3 \approx 500$ times more than ours (the transform cost grows as $N_{\mathrm{pix}}^{1/2}\ell_{\mathrm{max}}^2 \propto N_{\mathrm{side}}^3$, [Hivon (30)]), and the data vector has hundreds of bins per spectrum. That is why a research analysis models its covariance and uses the simulations

to test the model, while ours can afford to use the simulations directly. The structure is the same in both: the same code on data and on simulations, and every statement about the data read off the simulations.

How this is used in real research: The simulations as the instrument

In Chapter 7 the simulations reproduced the $\chi^2_{2\ell+1}$ law and the cosmic variance, which were known in advance: they *verified* a formula, and agreement tested the code. In a cut-sky analysis the same loop is the measuring *instrument*. The transfer function of a filtered scan, the covariance that enters the likelihood, the distribution of a null-test χ^2 and the coverage of the final error bars exist only as properties of the simulations. Planck, ACT and SPT all compute their spectra with pseudo-C_ℓ estimators of this kind, and all of them obtain those four things, or test the analytic models of them, by running simulated skies through the pipeline.

8.15.3 A mask also changes the shapes in a map

The spectrum is not the only statistic a mask disturbs. Take an **excursion set** of a map [the region where the temperature is above a chosen threshold]. Its shape can be summarised by counting: the number of separate hot regions, and the number of holes inside them (cold islands surrounded by hot sky). The difference of the two counts is the Euler characteristic, a number that does not change under any continuous deformation of the regions (see the topology notes), and for a Gaussian field its average at each threshold is known exactly (Chapter 12).

A mask changes both counts, and not by blurring. A Galactic band that crosses a hot region cuts it in two, and the count of regions goes up by one. A point-source hole that falls inside a hot region punches a hole in it, and the count of holes goes up by one. Regions that touch the edge of the mask are cut open, and it is not clear whether they should be counted at all. Figure 8.45 shows the three cases. Schmalzing and Górski found that the shape statistics of a map stay unbiased if the field is smoothed first and cut afterwards, but that smoothing a map which has already been cut biases them by up to one standard deviation, and that the remedy is to use only pixels far from the cut [105]. The cure is the one of this chapter. The same mask is applied to every simulated sky, the shape statistics are computed on data and simulations alike, and their sampling distribution, their covariance and their inverse are read off the simulations. Chapter 12 builds those statistics, and the simulations of this chapter will provide their sampling distributions.

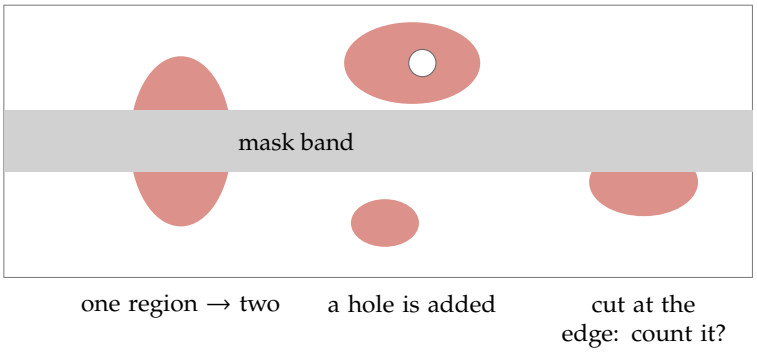

Figure 8.45: An excursion set (red) seen through a mask. Left: a hot region that crosses the band is counted as two. Centre: a point-source hole (white disc) inside a hot region adds a hole, while the small region below it is untouched. Right: a region cut open by the edge of the band; whether it counts, and as what, is a choice the analysis must make and the simulations must share.

Recap

- A window W multiplies the map; in harmonic space it convolves. The pseudo-coefficients $\tilde{a}_{\ell m}$ mix true coefficients at many (ℓ', m') through the window's own $w_{\ell m}$, and a sharp edge gives a mask spectrum $\mathcal{W}_\ell \propto \ell^{-3}$ that moves power far in ℓ. The moments $f_{\rm sky} w_i = \frac{1}{4\pi}\int W^i$ set the simple scalings.
- On average $\langle \widetilde{C}_\ell \rangle = \sum_{\ell'} M_{\ell\ell'} F_{\ell'} T^2_{\ell'} C_{\ell'} + \langle \widetilde{N}_\ell \rangle$, with $M_{\ell\ell'} = \frac{2\ell'+1}{4\pi}\sum_L (2L+1)\mathcal{W}_L (\ell\,\ell'\,L;0\,0\,0)^2$ computed from the mask alone; the matrix passes a direct mode-by-mode check and the mean of the simulated skies.
- Dividing by $f_{\rm sky} w_2$ is exact only for a flat spectrum and biases a curved one. M itself is invertible only if the window contains pairs of directions at every separation; small patches have null modes. MASTER inverts the coupling in bins, $\widehat{D}_b = K^{-1}_{bb'} P_{b'\ell}(\widetilde{C}_\ell - \langle \widetilde{N}_\ell \rangle)$, is unbiased for the binned spectrum, and is compared with theory through the bandpower windows $\mathcal{F}_{b\ell}$. A filter adds a transfer function, measured on noise-free simulations.
- Apodisation trades sky (modes) for locality of the coupling and less leakage.
- The cut-sky estimate is a weighted sum of χ^2_1 variables: approximately $\chi^2_{\nu_{\rm eff}}$ with $\nu_{\rm eff} = 2\langle X\rangle^2/{\rm Var}\, X < 2\ell + 1$, skewed at low ℓ and Gaussian at high ℓ. Hivon's $\nu = (2\ell+1)\Delta\ell f_{\rm sky} w_2^2/w_4$ counts modes and fails where the mask's correlations matter.
- Neighbouring multipoles are correlated. The exact covariance is a sum over $|\langle \tilde{a}\tilde{a}^* \rangle|^2$; above the width of the kernel it is close to $2C_\ell C_{\ell'} \Xi(\ell, \ell', \mathcal{W}^{(2)})$ (Efstathiou), and Knox's $2C_\ell^2/[(2\ell+1)f_{\rm sky}]$ is a mode count that underestimates the scatter of a sharp mask.
- A covariance from n simulations of p bins is noisy element by element, and its inverse is biased by $(n-1)/(n-p-2)$; the Hartlap factor removes the bias, not the noise. A parameter variance is then uncertain by $\sqrt{2/(n-p)}$, and $n > 2/\varepsilon^2 + p + 4$ simulations give fractional precision ε.
- Our code reproduces the cut-sky results of Hivon et al., Efstathiou, Hartlap et al. and Taylor et al. (Table 8.8), and a half-mission analysis through a band-and-holes mask returns an unbiased amplitude with correct coverage, passes its null test and fails it when a 3 μK striping is added.
- A mask also cuts and pierces the regions of an excursion set: shape statistics must be computed through the same mask on data and simulations.

Reading the literature

- **The pseudo-C_ℓ method.** Hivon et al., the MASTER paper: the window and its moments, the coupling kernel through $3j$ symbols, the transfer function, binning, the Monte Carlo covariance and the Boomerang test [140]. Alonso, Sanchez and Slosar on NaMaster, the same framework written for spin-0 and spin-2 fields with bandpower windows and contaminant deprojection [142]. Hobson et al. (eds.), *Bayesian Methods in Cosmology*, Chapter 10, for the CMB data model with beam, noise and window and for where pseudo-C_ℓ estimators sit next to likelihood methods [HobsonBMC pp. 231–239].
- **Errors on a power spectrum.** Knox on noise, beam, sky fraction and cosmic variance [138]; Efstathiou on pseudo-C_ℓ against maximum likelihood, on the invertibility of the coupling and on the analytic covariance of a cut-sky spectrum [141]; Hamimeche and Lewis on the exact full-sky likelihood and its approximations [16].

- **Covariances from simulations.** Hartlap, Simon and Schneider on the bias of an inverted sample covariance [6]; Taylor, Joachimi and Kitching on how its noise propagates into parameter errors and how many simulations that requires [137].
- **A real analysis.** Planck 2018 results V, on power spectra and likelihoods: masks, apodisation, cross-spectra, binning, analytic covariances, end-to-end simulations and null tests [70]. Górski et al. on HEALPix [7].
- **Shapes through a mask.** Schmalzing and Górski on Minkowski functionals of CMB maps on an incomplete sky [105].

Chapter summary

An instrument never delivers the sky. It smooths it with a beam, adds noise, and sees only part of it. The beam and the noise act on each multipole separately and can be undone exactly, which is why the full-sky analysis was a verification: every property of the estimator had a formula, and the simulations confirmed it. A mask acts on each direction separately, which mixes the multipoles. The average can still be undone, with a coupling matrix computed from the mask alone, but the scatter, the correlations and the shape of the distribution of the estimates have no general formula. They are measured on simulated skies sent through the same mask and the same code as the data, and the number of simulations then sets the precision of everything that follows. In the pipeline

$$\text{physical model} \to \text{field} \to \text{summary } S \to \boxed{P(S \mid \theta)} \to \text{infer physics},$$

this chapter supplies the sampling distribution of the observed power spectrum: its mean (through $M_{\ell\ell'}$, T_ℓ and F_ℓ), its covariance (from simulations or a tested approximation), its shape (a χ^2 with an effective number of modes), and the correction for having measured its inverse from a finite set of skies. Chapters 9 and 10 turn that distribution into parameter constraints, Chapter 12 applies the same machinery to the shapes of the map, and Chapter 13 runs it on Planck data.

The instrument on the full sky

concept	operational meaning	used later in
observation model	sky $\to$ beam and pixel window $T_\ell = B_\ell p_\ell \to$ noise; each $a_{\ell m}$ multiplied by T_ℓ, noise added after	Chapters 9 and 13
noise power	uniform white noise: $N_\ell = \sigma^2_{\rm pix}\Omega_{\rm pix}$ at every ℓ; any pattern: $\Omega_{\rm pix}\langle\sigma^2\rangle$ on average	Chapters 10 and 13
debiased estimator	$(\widehat{C}_\ell^{\rm obs} - N_\ell)/T_\ell^2$: unbiased, the full-sky maximum-likelihood estimator	Chapters 9 and 10
cross-spectrum	spectrum between maps with independent noise: no noise bias, at most $\sqrt{2}$ larger error	Chapter 13
Knox formula	$\mathrm{Var}\,\widehat{C}_\ell = 2(C_\ell + N_\ell/T_\ell^2)^2/[(2\ell+1)f_{\rm sky}]$: cosmic variance plus noise, a mode count	Chapter 10
shape of $\widehat{C}_\ell$	shifted, scaled $\chi^2_{2\ell+1}$; skewed at low ℓ, can be negative where noise dominates	Chapter 9
cumulative S/N	$[\sum_\ell \mathrm{SNR}_\ell^2]^{1/2}$ is one over the error of an overall amplitude; saturates where noise equals signal	Chapter 10
Monte Carlo of an estimator	same code on many simulated skies; bias needs $(\sigma/\text{target})^2$ skies, a 10% error bar about 50	Chapters 9 and 12
verification vs research	full sky: simulations confirm formulas; cut sky: simulations are the measurement	Chapters 12 and 13

The cut sky

concept	operational meaning	used later in
window, moments	$W \in [0,1]$ per pixel; $f_{\rm sky}$ = fraction with $W > 0$, w_i = mean of W^i there; $\mathcal{W}_\ell$ = `anafast` of the mask	Chapters 12 and 13
pseudo-C_ℓ	spectrum of the masked map; mixes multipoles; mean $\sum M_{\ell\ell'} F T^2 C + \langle \widetilde{N} \rangle$	Chapter 13
coupling matrix $M_{\ell\ell'}$	from $\mathcal{W}_L$ and $3j$ symbols; depends on the mask only; rows sum to $f_{\rm sky} w_2$	Chapter 13
naive $f_{\rm sky}$ rescaling	divide by $f_{\rm sky} w_2$: exact for flat spectra, biased at peaks and in the damping tail	Chapter 13
null modes	M singular when the patch lacks pairs at some separations; small patches lose information	Chapter 13
MASTER	bin, then invert $K = PMFT^2Q$; unbiased bandpowers; compare theory through bandpower windows $\mathcal{F}_{b\ell}$	Chapters 9 and 13
transfer function F_ℓ	effect of a filter, measured on noise-free simulations; solve in bins	Chapter 13
apodisation	smooth mask edge: less leakage and correlation, fewer modes	Chapters 12 and 13
effective modes $\nu_{\rm eff}$	$2\langle X \rangle^2 / \mathrm{Var}\, X$; model X as $\langle X \rangle \chi^2_{\nu_{\rm eff}} / \nu_{\rm eff}$; non-Gaussian at low ℓ	Chapter 9
ℓ–ℓ' covariance	exact from $\lvert\langle \tilde{a} \tilde{a}^* \rangle\rvert^2$; Efstathiou's $2CC'\Xi(\mathcal{W}^{(2)})$ above the kernel width; Knox underestimates for sharp masks	Chapters 9 and 10
covariance from simulations	sample covariance of n skies; diagonal noisy by $\sqrt{2/(n-1)}$, correlations by $\pm 1/\sqrt{n}$; singular for $p \geq n$	Chapters 9 and 12
Hartlap factor	$(n-p-2)/(n-1)$ times the inverse sample covariance is unbiased	Chapters 9, 10 and 12
simulation budget	parameter variance uncertain by $\sqrt{2/(n-p)}$; $n > 2/\varepsilon^2 + p + 4$ (Taylor et al.)	Chapters 12 and 13
null test	spectrum of a difference of splits; χ^2 against simulations; PTE; catches coherent excesses	Chapter 13
masks and shapes	cuts and holes change counts of hot regions and holes; compute through the same mask on simulations	Chapter 12

Chapter 9

Markov Chains and MCMC: The Biased Random Walker

Where this chapter is going

By the end of Chapter 5 every inference problem had the same shape. The data $\boldsymbol{d}$ have been observed, the parameters $\boldsymbol{\theta}$ are the possible explanations, and Bayes' theorem gives the posterior $p(\boldsymbol{\theta} \mid \boldsymbol{d}) \propto \mathcal{L}(\boldsymbol{\theta})\, p(\boldsymbol{\theta})$, the likelihood times the prior. We can evaluate the right-hand side at any $\boldsymbol{\theta}$ we like. What we cannot do, once $\boldsymbol{\theta}$ has more than two or three components, is integrate it: the evidence $Z = p(\boldsymbol{d})$, every posterior mean, every marginal and every credible interval is an integral over the whole parameter space. A grid of 100 points per axis already needs 10^{12} evaluations for six cosmological parameters.

There is a way round the integrals, and the book has used it since Chapter 1: a large sample from a distribution *is* the distribution, for every practical purpose. Histogram the sample and you have the density; average a function over the sample and you have its expectation; ignore a column and you have marginalised over that parameter [Kruschke §7.1]. So the question becomes: how do we draw a large sample from a distribution that we can only evaluate, up to a constant, one point at a time?

Sometimes nature answers it for us. An oscillator of fixed energy, looked at at random instants, hands us a sample of its phase-space orbit with no effort at all, because its motion carries it over the orbit at exactly the right rate. That trick fails as soon as the system has more than a few degrees of freedom, and it does not exist for a posterior, which has no motion. So we build the motion ourselves: a random walker that hops from point to point, remembering only where it is now, with hopping rules chosen so that the fraction of time it spends anywhere equals the probability we want. Such a walker is a Markov chain. Three facts make it work: the target distribution is *stationary* (a walker distributed according to it stays so), the walker *forgets where it started* (every starting distribution converges to the same stationary one, at a rate we can compute), and *time averages equal ensemble averages* (the ergodic theorem), so one long walk is as good as many independent draws, only noisier. Metropolis–Hastings then gives a recipe for the hopping rule for *any* target, which is the biased random walker; diagnostics tell us when a finite walk can be trusted, and the same machine produces the posterior of cosmological parameters from a CMB power spectrum (Figure 9.1).

In the pipeline of the book (physical model → field → what matters → summary → sampling distribution → inference) this chapter is the last arrow. Chapters 7 and 8 produced the sampling distribution of a summary, $p(\widehat{C}_\ell \mid \boldsymbol{\theta})$; here that likelihood becomes a cloud of posterior samples from which every constraint is read off.

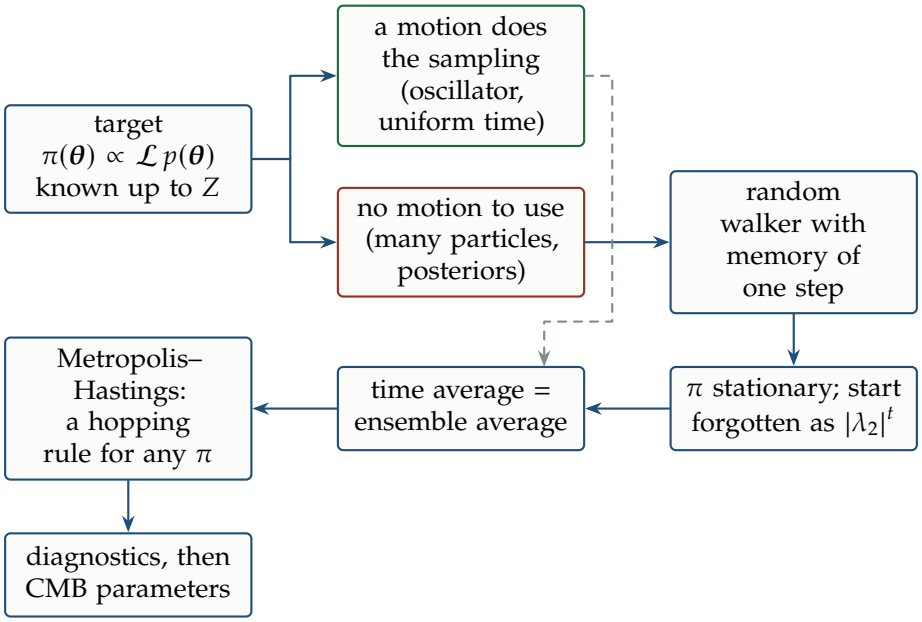

Figure 9.1: The route of the chapter. A distribution we can evaluate but not integrate is sampled directly when some motion already walks over it at the right rate (green), which is the oscillator. When there is no such motion (red) we construct a random walk whose long-run time fractions are the target; the dashed line marks that the oscillator and the Markov chain rest on the same property, equality of time and ensemble averages.

9.1 When the motion samples for us: the oscillator

The easiest sampling problem in physics has already been solved in Chapter 1, and it is worth seeing again why it was so easy, because the reason is exactly what a Markov chain will have to reproduce by force.

The question. A mass on a spring with fixed energy moves as $x(t) = A\cos\omega t$, $p(t) = -m\omega A\sin\omega t$. We look at it at a randomly chosen instant. Where do we find it? At this energy the possible states are the points (x, p) of the energy ellipse in phase space, so the ellipse is the sample space. The motion passes each of its points once per period, so a random instant picks a random point of it. To find the distribution of position, then, we histogram x for a large set of random instants. Before doing so, recall the chain of Section 1.11.3 that predicts what the histogram must look like.

Uniform time. "A randomly chosen instant" is a sampling prescription: every instant of one period $T = 2\pi/\omega$ is equally likely, $P(t)\,\mathrm{d}t = \mathrm{d}t/T$, which is (1.34).

From time to position. The position $x = A\cos\omega t$ changes at the speed $|\mathrm{d}x/\mathrm{d}t| = |v| = \omega\sqrt{A^2 - x^2}$, so the mass spends a time $\mathrm{d}t = \mathrm{d}x/|v|$ in the interval $[x, x + \mathrm{d}x]$, and it passes through that interval twice per period (once going out, once coming back). Adding the two visits,

$$P(x)\,\mathrm{d}x = 2 \times \frac{1}{T}\,\frac{\mathrm{d}x}{|v|} = \frac{2}{T}\,\frac{\mathrm{d}x}{\omega\sqrt{A^2 - x^2}}, \qquad \text{so} \qquad P(x) = \frac{1}{\pi\sqrt{A^2 - x^2}}, \qquad |x| < A, \tag{9.1}$$

the arcsine law, using $T\omega = 2\pi$ in the last step. It is large near the turning points because the mass is slow there.

The same law with no clock. Suppose we did not know that the instant is uniform, and asked instead which states of the energy shell $E < H < E + \Delta E$ are equally likely (the

microcanonical ensemble). The vertical strip of phase space over $[x, x + \mathrm{d}x]$ cuts the shell in two thin patches, at p_+ and p_-. Each patch has width $\mathrm{d}x$ and height Δp, and the height follows from $H = p^2/2m + \frac{1}{2}m\omega^2x^2$: at fixed x, $\mathrm{d}H = (p/m)\,\mathrm{d}p$, so $\Delta p = \Delta E/|v|$. The shell area inside the strip is therefore $2\,\mathrm{d}x\,\Delta E/|v|$, again proportional to $\mathrm{d}x/|v|$, and normalising gives (9.1) a second time.

Why the two agree. The first route averages over the instants of one trajectory; the second averages over all the states of the shell. They give the same answer because the time the motion spends in a patch of the shell, $\mathrm{d}x/|v|$, is proportional to the patch's area. Time average equals ensemble average, and that equality is what *ergodic* will mean below.

The sampler is one line. In units $m = \omega = 1$ the script draws a uniform phase $\theta = \omega t$ and lets the motion do the rest.

Listing 9.1: The oscillator: uniform phases, then the deterministic map to the orbit (`code/ch09/01_oscillator_phase_space.py`)

```
30 # --- the whole sampler: a random instant, then the deterministic motion -------------------
31 theta = rng.uniform(0.0, 2.0 * np.pi, size=N)   # random phase = omega * (random instant)
32 x = A * np.cos(theta)                            # where the motion has carried the
       oscillator
33 p = -A * np.sin(theta)                           # its momentum at that instant
34
35 # --- compare with the exact law, bin by bin (bin probabilities from CDF differences)
       -------
36 edges = np.linspace(-A, A, NBINS + 1)
37 counts, _ = np.histogram(x, bins=edges)
38 expected = N * np.diff(arcsine_cdf(edges, A))
39 chi2 = float(((counts - expected) ** 2 / expected).sum())
```

Line 31 is the only random line, and it chooses *when* we look. Lines 32–33 are the equation of motion: they carry the chosen instant to its point (x, p) of the orbit, the sampled element of the sample space. Lines 36–39 compare the histogram with (9.1) bin by bin, using the exact bin probabilities $F(x_{k+1}) - F(x_k)$ with $F(x) = \frac{1}{2} + \frac{1}{\pi}\arcsin(x/A)$ (Method 1 of Section 1.11.3). With $N = 50\,000$ phases the mismatch is $\chi^2 = 75.9$ over 80 bins, as it should be for a correct law (a χ^2 variable with ν degrees of freedom has mean ν and standard deviation $\sqrt{2\nu} \approx 13$ here), and the average of x^2 over the sampled instants is $0.501\,A^2$ against the exact $A^2/2$ (Figure 9.2).

Why it was so easy. Two things happened together. The equation of motion visits every state of the sample space, and it spends in each part of it a time proportional to that part's probability. So drawing from the distribution reduces to drawing a uniform time, which any random-number generator does. In the language of statistical mechanics the agreement of the two derivations of (9.1), uniform time and microcanonical shell area, says that the average of any quantity over one long trajectory equals its average over the ensemble of all states of the energy shell. That property has a name.

Key idea: Ergodicity: time average = ensemble average

A dynamics is **ergodic** on a set of states if, for every function g of the state, the average of g along one long trajectory equals the average of g over the set with the ensemble's probabilities. Then one trajectory, looked at at random times, is a sample of the ensemble. A Markov chain is useful for exactly this reason.

The hidden assumption, and a counterexample. For one oscillator the property is automatic: the energy shell is a single closed curve and the orbit is all of it. Nothing guarantees it in general,

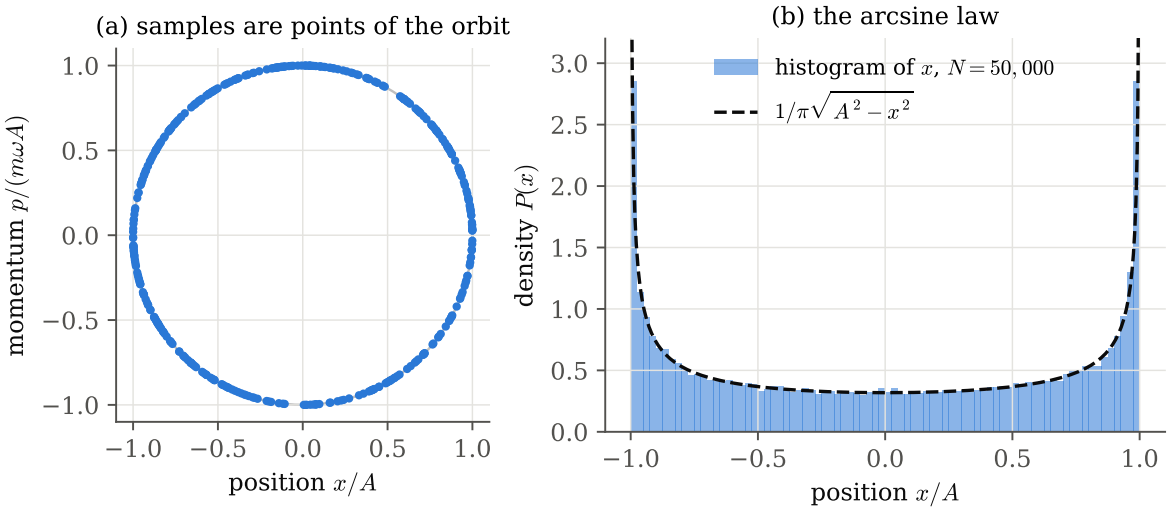

Figure 9.2: (a) Four hundred random instants, drawn as the phase-space points the oscillator occupies at those instants: every sample lies on the energy circle (scaled units), which is the whole sample space. (b) The positions of 5×10^4 such instants follow the arcsine law, piling up at the turning points where the mass moves slowly.

and a slightly bigger system already breaks it. Take two identical oscillators ($m = \omega = 1$) joined by a weak spring of stiffness $\kappa = 0.05$,

$$H = \tfrac{1}{2}(p_1^2 + p_2^2 + x_1^2 + x_2^2) + \tfrac{1}{2}\kappa(x_1 - x_2)^2, \tag{9.2}$$

start them with all the energy E in oscillator 1 ($x_1 = A$, everything else zero), and ask what fraction $u = E_1/E$ of the energy oscillator 1 holds, where $E_1 = \frac{1}{2}(p_1^2 + x_1^2)$. The energy shell $H = E$ is now a three-dimensional surface in a four-dimensional phase space. The microcanonical ensemble spreads probability evenly over all of it; the trajectory, started in one particular state, goes where its equations send it. Do the two agree?

The ensemble. Neglect the small spring term for the moment, so that $2H = z_1^2 + z_2^2 + z_3^2 + z_4^2$ with $z = (x_1, p_1, x_2, p_2)$, and the shell is a sphere of radius $\sqrt{2E}$. Uniform points on a sphere in four dimensions are Gaussian vectors rescaled to the right length (a standard Gaussian vector has a density that depends only on $|z|$, so its direction is uniform). Then

$$\begin{aligned} u = \frac{z_1^2 + z_2^2}{z_1^2 + z_2^2 + z_3^2 + z_4^2} &\overset{(1)}{=} \frac{X}{X+Y}, \qquad X, Y \overset{\text{iid}}{\sim} \operatorname{Exp}(\tfrac{1}{2}), \\ \mathrm{P}(u \le c) &\overset{(2)}{=} \int_0^\infty \tfrac{1}{2} e^{-y/2}\, \mathrm{P}\Big(X \le \tfrac{c}{1-c}\, y\Big)\, \mathrm{d}y \\ &\overset{(3)}{=} \int_0^\infty \tfrac{1}{2} e^{-y/2}\big(1 - e^{-cy/2(1-c)}\big)\, \mathrm{d}y \overset{(4)}{=} 1 - (1-c) = c. \end{aligned} \tag{9.3}$$

(1) The length rescaling cancels in the ratio, so we may use the Gaussian vector itself. $z_1^2 + z_2^2$ is a χ^2 variable with 2 degrees of freedom, which is the exponential distribution with rate $\frac{1}{2}$ (Chapter 2), and the two halves are independent.

(2) $X/(X+Y) \le c$ is the same as $X \le cY/(1-c)$; condition on $Y = y$ and average over its density $\frac{1}{2}e^{-y/2}$.

(3) The exponential CDF $\mathrm{P}(X \le a) = 1 - e^{-a/2}$.

(4) $\int_0^\infty \frac{1}{2} e^{-y/2} e^{-cy/2(1-c)} \mathrm{d}y = \frac{1}{2} \big/ \big(\frac{1}{2} + \frac{c}{2(1-c)}\big) = 1 - c$.

So over the energy shell the share of oscillator 1 is *uniform* on $[0,1]$: every split of the energy is equally likely.

The trajectory: two independent oscillators in disguise. The spring couples x_1 and x_2, but it only feels their difference. So use the sum and the difference as coordinates, the **normal modes** $q_\pm = (x_1 \pm x_2)/\sqrt{2}$, with momenta $P_\pm = (p_1 \pm p_2)/\sqrt{2}$. Inverting, $x_1 = (q_+ + q_-)/\sqrt{2}$ and $x_2 = (q_+ - q_-)/\sqrt{2}$, and the same for the momenta. Substituting into (9.2),

$$H \overset{(1)}{=} \tfrac{1}{2}\big(P_+^2 + P_-^2 + q_+^2 + q_-^2\big) + \tfrac{1}{2}\kappa(x_1 - x_2)^2 \overset{(2)}{=} \tfrac{1}{2}\big(P_+^2 + P_-^2 + q_+^2 + q_-^2\big) + \kappa q_-^2$$
$$\overset{(3)}{=} \tfrac{1}{2}\big(P_+^2 + \omega_+^2 q_+^2\big) + \tfrac{1}{2}\big(P_-^2 + \omega_-^2 q_-^2\big), \qquad \omega_+ = 1, \quad \omega_- = \sqrt{1+2\kappa}. \tag{9.4}$$

(1) $x_1^2 + x_2^2 = \tfrac{1}{2}\big[(q_+ + q_-)^2 + (q_+ - q_-)^2\big] = q_+^2 + q_-^2$, the cross terms cancelling; the same for $p_1^2 + p_2^2$.
(2) $x_1 - x_2 = \sqrt{2}\,q_-$, so $\tfrac{1}{2}\kappa(x_1 - x_2)^2 = \kappa q_-^2$.
(3) Collect the q_-^2 terms, $\tfrac{1}{2}q_-^2 + \kappa q_-^2 = \tfrac{1}{2}(1+2\kappa)q_-^2$.

The Hamiltonian is a sum of two uncoupled oscillators, of frequencies ω_+ and ω_-, and each keeps its own energy forever.

Solve each mode. The start $x_1 = A$, $x_2 = 0$, all momenta zero, gives $q_+(0) = q_-(0) = A/\sqrt{2}$ and zero initial momenta, so $q_\pm(t) = (A/\sqrt{2})\cos\omega_\pm t$. Back in the original coordinate,

$$x_1(t) \overset{(1)}{=} \tfrac{A}{2}\big(\cos\omega_+ t + \cos\omega_- t\big) \overset{(2)}{=} A\cos\bar\omega t\,\cos\tfrac{1}{2}\Delta\omega\, t, \qquad \bar\omega = \tfrac{1}{2}(\omega_+ + \omega_-), \quad \Delta\omega = \omega_- - \omega_+. \tag{9.5}$$

(1) $x_1 = (q_+ + q_-)/\sqrt{2}$.
(2) The sum-to-product identity $\cos a + \cos b = 2\cos\frac{a+b}{2}\cos\frac{a-b}{2}$, with $a = \omega_- t$, $b = \omega_+ t$.

Name the two factors. $\cos\bar\omega t$ is the fast *carrier*, the ordinary oscillation at nearly the natural frequency. $\cos\frac{1}{2}\Delta\omega\, t$ is the slow *beat*: for a weak spring $\Delta\omega \approx \kappa$ is small, so it changes little during one carrier cycle and acts as a slowly varying amplitude $a(t) = A\cos\frac{1}{2}\Delta\omega\, t$.

The energy share. Over one carrier cycle oscillator 1 is a plain oscillator of amplitude $a(t)$ and frequency $\bar\omega \approx 1$: $x_1 \simeq a\cos\bar\omega t$ and $p_1 \simeq -a\sin\bar\omega t$, the derivative of the slow factor being smaller by $\Delta\omega$. Then $E_1 = \frac{1}{2}(p_1^2 + x_1^2) \simeq \frac{1}{2}a^2(\sin^2\bar\omega t + \cos^2\bar\omega t) = \frac{1}{2}a^2$, the carrier dropping out entirely. With $E \simeq \frac{1}{2}A^2$ (the spring's share is of order κ),

$$u(t) = \frac{E_1}{E} \simeq \cos^2\phi, \qquad \phi = \tfrac{1}{2}\Delta\omega\, t. \tag{9.6}$$

During each beat the energy sloshes completely from one oscillator to the other and back (Figure 9.3a). At a random instant the beat phase ϕ is uniform, and the density of $u = \cos^2\phi$ follows from the change-of-variables rule of Section 1.11:

$$P(u) \overset{(1)}{=} 4 \times \frac{1}{2\pi}\left|\frac{\mathrm{d}\phi}{\mathrm{d}u}\right| \overset{(2)}{=} \frac{4}{2\pi}\,\frac{1}{2\big|\cos\phi\sin\phi\big|} \overset{(3)}{=} \frac{1}{\pi\sqrt{u(1-u)}}, \qquad 0 < u < 1. \tag{9.7}$$

(1) ϕ is uniform on $[0, 2\pi)$ and $\cos^2\phi$ takes each value in $(0,1)$ at four phases per period, which contribute equally.
(2) $\mathrm{d}u/\mathrm{d}\phi = -2\cos\phi\sin\phi$.
(3) $\big|\cos\phi\sin\phi\big| = \sqrt{\cos^2\phi\,(1-\cos^2\phi)} = \sqrt{u(1-u)}$.

It is the arcsine law again, now for the energy share: the trajectory lingers where the energy is almost all in one oscillator, because that is where the beat turns round.

The verdict. The script `02_two_oscillators.py` keeps the spring term, draws 2×10^5 exactly uniform points of the true shell (in scaled normal-mode coordinates H is again a sum of four squares) and 2×10^5 random instants of the trajectory. Both give the same mean share, 0.489 and 0.489 (slightly below $\frac{1}{2}$ because the spring holds a little energy). But the trajectory spends a fraction 0.205 of its time with $u<0.1$, while the shell has only 0.102 of its states there, close to the values $\frac{2}{\pi}\arcsin\sqrt{0.1}=0.205$ and 0.1 of (9.7) and (9.3); the second moments $\langle u^2\rangle$ are 0.357 and 0.318 (Figure 9.3b). Time average and ensemble average disagree.

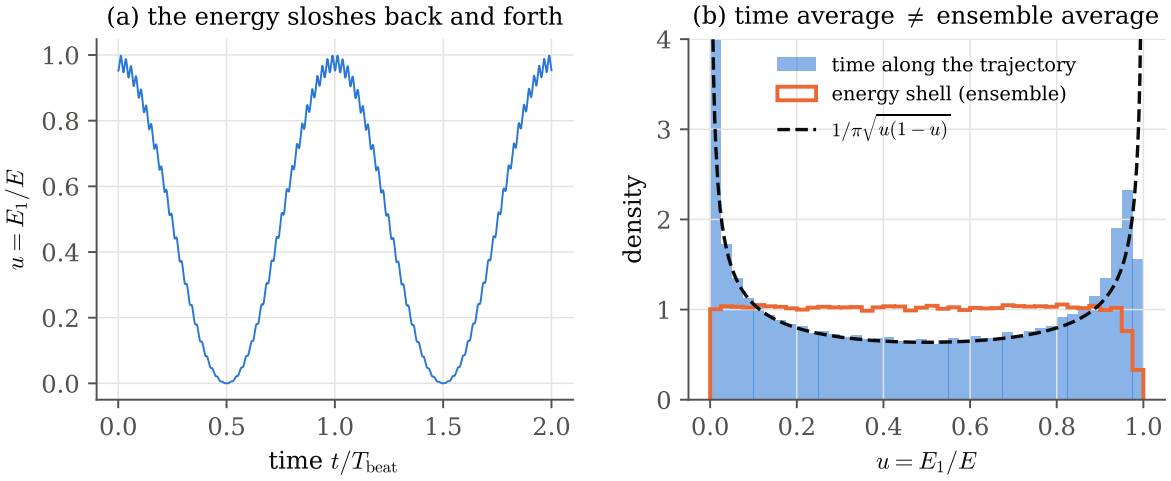

Figure 9.3: Two weakly coupled oscillators, started with all the energy in the first. (a) The first oscillator's share of the energy beats between 1 and 0 over two beat periods. (b) The time the trajectory spends at each share (blue) follows the arcsine curve and crowds at the ends; the energy shell itself (orange outline) gives every share the same weight. One trajectory is not a fair sample of the shell.

What went wrong is that the motion has more conserved quantities than the energy. Each normal-mode energy is constant, so the trajectory is trapped on a two-dimensional torus inside the three-dimensional shell and can never reach the states that the ensemble counts. Every linear system has this disease, one conserved energy per normal mode, which is why harmonic crystals do not thermalise on their own and why it took nonlinear couplings, collisions, or contact with a heat bath to justify statistical mechanics. The lesson is a sharp version of Chapter 1's: a motion samples a distribution only if it is ergodic for that distribution, and that has to be shown, not assumed.

Why this cannot be the general method. Even an ergodic motion is rarely usable as a sampler.

1. *Many degrees of freedom.* For N particles the energy shell is a surface of dimension $6N-1$. We cannot parametrise it to draw uniform points, and integrating the equations of motion for long enough to cover it, if the dynamics covers it at all, is as expensive as the problem we started with.
2. *The canonical ensemble.* A system in contact with a heat bath at temperature T is described by $\rho(x,p)\propto e^{-H(x,p)/kT}$. For one oscillator this is a product of Gaussians and trivial to sample. For N interacting particles the normalisation $\int e^{-H/kT}\,\mathrm{d}^{3N}x\,\mathrm{d}^{3N}p$ has no closed form, there is no orbit to follow (the bath changes the energy), and there is no direct sampler. Metropolis, the Rosenbluths and the Tellers met exactly this problem for a fluid of hard discs, and solved it with a random walk through configurations [36].
3. *Posteriors have no dynamics.* $p(\boldsymbol{\theta}\mid\boldsymbol{d})\propto\mathcal{L}(\boldsymbol{\theta})p(\boldsymbol{\theta})$ is a function on parameter space, known up to Z. Nothing moves.

Direct, independent sampling is hard for a second reason too: the generic methods, rejection sampling and the inverse CDF, need either an envelope that wastes exponentially many draws as the dimension grows or a CDF we cannot write down [Lambert §12.7].

So we keep the idea and change the motion. Instead of a deterministic orbit we use a *random* walker, and we choose its hopping rule so that the fraction of time it spends anywhere equals the target probability there. The walker will need four properties. Its next step should depend only on where it is now, so that a step is cheap to compute. The target should be an equilibrium of its motion. It should forget where it started. And one long walk should be a fair sample, time averages equal to ensemble averages. The first property defines a Markov chain; the other three are theorems about Markov chains.

What kind of random walker? The simplest one, which steps left or right with equal chance wherever it stands, is an *unbiased* walker; it has no preference for any place, so in the long run it spreads evenly and visits every region equally often (Section 9.7). That samples only a flat distribution. What we want instead is a *biased* walker, whose hopping rule depends on the target so that it stays longer where the target is larger and hurries through where it is small, in exactly the proportion that makes its fractions of time equal to the target probabilities.

9.2 A walker with a memory of one step

An elected politician lives on a chain of seven islands, numbered $\theta = 1, \ldots, 7$ from west to east [Kruschke §7.2.1]. He wants to visit each island in proportion to its population, but he does not know the total population, nor even how many islands there are. All his advisers can do is ask the mayor of the island he is on, and the mayor of a neighbouring island, how many people live there.

Kruschke's question. The story is Kruschke's way of asking the question every posterior sampler faces. Can a walker who never sees a distribution as a whole, only the ratio of its values at two neighbouring points, still end up visiting every point in proportion to the distribution? For a posterior the values are $\mathcal{L}(\boldsymbol{\theta})p(\boldsymbol{\theta})$, which we can compute at any point, and the total is the evidence Z, which we cannot (Chapter 9). If the politician can do without his total, a sampler can do without Z.

His setup. Every evening the politician flips a fair coin to propose the island to the east or to the west. If the proposed island has more people than the current one, he goes. If it has fewer, he goes only with probability $P_{\text{proposed}}/P_{\text{current}}$, decided by a spinner marked from 0 to 1; otherwise he stays another day. Beyond the ends lie two imaginary islands, 0 and 8, where nobody lives, so a proposal to go there is always refused [Kruschke §7.2.2]. In one table:

ingredient	Kruschke	meaning
islands	$\theta = 1, \ldots, 7$	the states the walker can be in
populations	$P(\theta) = \theta$	the target, known only up to its total 28
proposal	fair coin: east or west	where to try next, chosen blindly
acceptance	spinner: $\min\left(1, P_{\text{proposed}}/P_{\text{current}}\right)$	the only place the target enters
edges	islands 0 and 8 have $P = 0$	proposals off the ends are refused

The questions. Suppose he starts on island 4.

1. On day t, what is the probability that he is on island θ?

2. Over a long term of office, what fraction of his days does he spend on each island?

Kruschke's claim is that the second fraction is $\theta/28$, the island's share of the total population of $1+2+\cdots+7=28$, so that the politician reaches his goal without ever learning the total. His rule is the simplest case of the Metropolis algorithm. To check the claim we first need to know what kind of object the politician's itinerary is, and how its distribution moves from day to day; the reason the claim holds is his Eq. (7.2), which needs only that description and is derived after the transition matrix.

9.2.1 Stochastic processes and the Markov property

The itinerary $X_1, X_2, X_3, \ldots$ is a sequence of random variables, one per day, and the days are not independent: where he sleeps tomorrow depends on where he slept tonight. A collection of random variables $\{X_t : t \in \mathcal{T}\}$ indexed by time is a **stochastic process**. The values X_t lie in a set $\mathcal{X}$, the **state space**, and $\mathcal{T}$ is the **index set** [Wasserman p. 381]. Both may be discrete or continuous.

- An iid sequence $X_1, X_2, \ldots$ is a stochastic process, the simplest one, with no dependence at all.
- The daily weather, $\mathcal{X} = \{\text{sunny}, \text{cloudy}\}$, $\mathcal{T} = \{1, 2, \ldots\}$: discrete states, discrete time.
- A stock price or a detector's baseline voltage recorded continuously: a continuous state (for all practical purposes) and continuous time.
- The empirical CDF $\widehat{F}_n(x) = \frac{1}{n}\sum_i I(X_i \le x)$ of Chapter 3, viewed as a function of $x \in [0,1]$: for each x it is a random variable, so the whole curve is a process with continuous state and continuous "time" x.

Any joint distribution can be built up one variable at a time by the product rule of Chapter 1,

$$f(x_1,\ldots,x_n) = f(x_1)\,f(x_2\mid x_1)\,f(x_3\mid x_1,x_2)\cdots f(x_n\mid x_1,\ldots,x_{n-1}) = \prod_{i=1}^{n} f(x_i\mid \text{past}_i), \tag{9.8}$$

where $\text{past}_i = (x_1,\ldots,x_{i-1})$. In general the ith factor needs the whole past. The politician's rule needs much less: his decision tonight uses the population of the island he is on and of the island he proposes, and nothing about how he got there. The past influences the future only through the present.

Working definition 9.1 (Markov chain)

A discrete-time process $X_0, X_1, X_2, \ldots$ with values in a countable state space $\mathcal{X}$ is a **Markov chain** if, for every t and every state x,

$$\mathrm{P}(X_{t+1} = x \mid X_0, X_1, \ldots, X_t) = \mathrm{P}(X_{t+1} = x \mid X_t). \tag{9.9}$$

In words: given the present state [the value of X_t, one number], the next state is independent of the earlier history [the values $X_0,\ldots,X_{t-1}$]. The chain has a **memory of one step**. *Operational test:* if you can write a simulation whose step $t \to t+1$ reads only the current state (plus fresh random numbers), the process is a Markov chain.

For a Markov chain every conditional in (9.8) keeps only its last argument, and the joint law collapses to a product of one-step factors,

$$f(x_0,x_1,\ldots,x_n) = f(x_0)\,f(x_1\mid x_0)\,f(x_2\mid x_1)\cdots f(x_n\mid x_{n-1}). \tag{9.10}$$

As a graph, each variable has a single parent, the one before it (Figure 9.4a) [Wasserman p. 383]. Two remarks place the definition. First, independence is the special case in which the factor $f(x_{t+1} \mid x_t)$ does not depend on x_t at all, so the Markov property is the mildest generalisation of independence: dependence, but only on the immediate past [CasellaBerger §5.8.5]. Second, the name records the *amnesia* of the stepping rule. A chain whose step depends on the last m states is called a Markov chain of order m [Lambert §12.9]; it becomes an ordinary (first-order) chain if we take as the state the block of the last m values, so nothing new is needed for it.

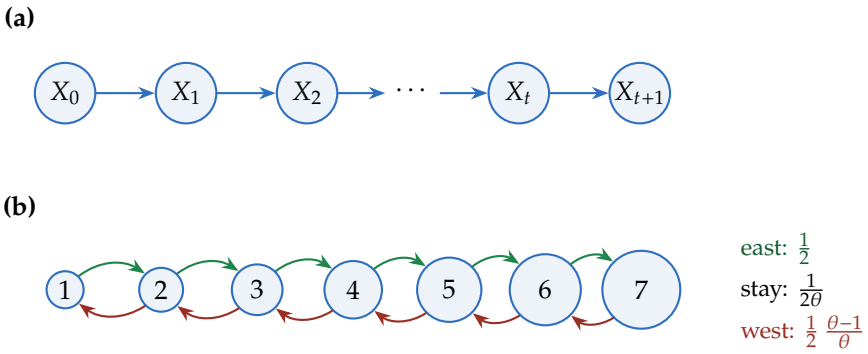

Figure 9.4: (a) A Markov chain as a graph: each variable depends directly only on the one before it. (b) The politician's chain. Circles are islands, drawn larger for more populous ones; upper (green) arrows are moves east, always accepted when proposed, and lower (red) arrows are moves west, accepted with the population ratio. Island 7's eastward proposal and island 1's westward one are always refused, which adds to the probability of staying.

9.2.2 The transition matrix

A Markov chain is **homogeneous** if the one-step probabilities $\mathrm{P}(X_{t+1} = j \mid X_t = i)$ do not change with t. All the chains of this chapter are homogeneous: the politician uses the same rule every night. A homogeneous chain on a finite state space is then described completely by one square table of numbers.

Working definition 9.2 (transition matrix)

For a homogeneous chain on states $1, \ldots, K$ the **transition probabilities** are $p_{ij} = \mathrm{P}(X_{t+1} = j \mid X_t = i)$, and the $K \times K$ **transition matrix** P has p_{ij} in row i [the state we are in] and column j [the state we may move to]. Every entry is non-negative and every row sums to one, $\sum_j p_{ij} = 1$, because from state i the chain must go somewhere. Each row is a probability mass function: the forecast for tomorrow given today. A matrix with these two properties is called a **stochastic matrix**.

Example: Wasserman's weather. Suppose sunny and cloudy days follow each other as a Markov chain, the weather tomorrow depending only on today's [Wasserman p. 385]. A typical transition matrix is

$$P = \begin{pmatrix} 0.4 & 0.6 \\ 0.8 & 0.2 \end{pmatrix} \qquad \text{(rows and columns: sunny, cloudy)}, \tag{9.11}$$

so after a sunny day there is a 60% chance of cloud, and after a cloudy day an 80% chance of sun. Each row sums to one; the columns need not.

Example: a random walk with absorbing barriers. On the states $1, \ldots, N$, flip a coin with $\mathrm{P}(\text{heads}) = p$, $q = 1 - p$, and step right on heads and left on tails, except that a walker who

reaches 1 or N stays there forever [Wasserman p. 384]. The transition matrix has $p_{i,i+1} = p$ and $p_{i,i-1} = q$ in the interior rows and $p_{11} = p_{NN} = 1$:

$$P = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 & 0 \\ q & 0 & p & \cdots & 0 & 0 \\ 0 & q & 0 & \ddots & 0 & 0 \\ \vdots & & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & q & 0 & p \\ 0 & 0 & \cdots & 0 & 0 & 1 \end{pmatrix}.$$

It is the gambler's ruin: a gambler with $i-1$ units of capital betting one unit at a time until he is broke or has reached a capital of $N-1$ units.

Example: the politician's matrix. From island θ the politician moves east only if the coin proposes east (probability $\frac{1}{2}$) and the move is accepted; since $P(\theta+1) > P(\theta)$ it always is. He moves west only if the coin proposes west and the spinner accepts, which happens with probability $P(\theta-1)/P(\theta) = (\theta-1)/\theta$. So for an interior island

$$\begin{aligned} p_{\theta,\theta+1} &\overset{(1)}{=} \tfrac{1}{2}\min\!\left(1, \tfrac{\theta+1}{\theta}\right) = \tfrac{1}{2}, \\ p_{\theta,\theta-1} &\overset{(2)}{=} \tfrac{1}{2}\min\!\left(1, \tfrac{\theta-1}{\theta}\right) = \frac{\theta-1}{2\theta}, \\ p_{\theta\theta} &\overset{(3)}{=} 1 - \tfrac{1}{2} - \frac{\theta-1}{2\theta} = \frac{1}{2\theta}. \end{aligned} \tag{9.12}$$

(1) The probability of a move is (probability of proposing it) × (probability of accepting it); here the proposed island is larger, so acceptance is certain.
(2) The proposed island is smaller, so the spinner accepts with the population ratio.
(3) The rejected proposals keep him where he is, and the row must sum to one.

At the ends the formulas change only through the empty islands: island 7 never moves east, so $p_{77} = 1 - \frac{6}{14} = \frac{4}{7}$, and island 1 never moves west, so $p_{11} = 1 - \frac{1}{2} = \frac{1}{2}$. Written out,

$$P = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} & 0 & 0 & 0 & 0 & 0 \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{2} & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{3} & \frac{1}{6} & \frac{1}{2} & 0 & 0 & 0 \\ 0 & 0 & \frac{3}{8} & \frac{1}{8} & \frac{1}{2} & 0 & 0 \\ 0 & 0 & 0 & \frac{2}{5} & \frac{1}{10} & \frac{1}{2} & 0 \\ 0 & 0 & 0 & 0 & \frac{5}{12} & \frac{1}{12} & \frac{1}{2} \\ 0 & 0 & 0 & 0 & 0 & \frac{3}{7} & \frac{4}{7} \end{pmatrix}. \tag{9.13}$$

This is the matrix Kruschke builds symbolically in his Eq. (7.3) [Kruschke §7.2.5]. The script builds it in four lines, which are the rule itself:

Listing 9.2: The politician's transition matrix, built from the proposal and the acceptance rule (`code/ch09/03_island_hopping.py`)

```
# --- transition matrix: propose a neighbour (prob 1/2 each), accept with min(1, ratio) ------
P = np.zeros((K, K))
for i in range(K):
    for j in (i - 1, i + 1):
        if 0 <= j < K:                          # islands outside 1..7 have population 0: never accepted
            P[i, j] = 0.5 * min(1.0, pop[j] / pop[i])
    P[i, i] = 1.0 - P[i].sum()                  # rejected proposals: stay put
```

Line 27 is "propose with probability $\frac{1}{2}$, accept with $\min(1, \text{ratio})$"; line 26 skips the empty islands, whose proposals are never accepted; line 28 puts every refused proposal on the diagonal.

His key equation, in our symbols. Kruschke's notation and ours name the same things differently. His island θ is our state i; his relative population $P(\theta)$ is our target π_i, up to the factor 28; his "probability of moving from θ to $\theta+1$" is our matrix entry $p_{\theta,\theta+1}$. His Eq. (7.2) compares the two directions across one bridge between neighbouring islands. Dividing the first line of (9.12) by the second line written for island $\theta+1$,

$$\frac{p_{\theta,\theta+1}}{p_{\theta+1,\theta}} = \frac{\frac{1}{2}}{\frac{1}{2}\,\theta/(\theta+1)} = \frac{P(\theta+1)}{P(\theta)} :$$

the ratio of the two hopping probabilities equals the ratio of the two populations, and the total 28 never appears. Why this ratio forces the long-run fractions to be $\theta/28$ is the subject of detailed balance (Section 9.4.2), where the same equation is rearranged into a statement about traffic across each bridge.

9.2.3 How a distribution moves: $p_{t+1} = p_t P$

We now answer the first question. Write the probabilities of being in each state on day t as a *row* vector $p_t = (p_t(1), \ldots, p_t(K))$, with $p_t(j) = \mathrm{P}(X_t = j)$. Today's distribution and the transition matrix fix tomorrow's: to be in j tomorrow the walker must be somewhere today and then jump to j, and the possible "somewheres" are disjoint, so

$$\begin{aligned} p_{t+1}(j) &\overset{(1)}{=} \sum_i \mathrm{P}(X_t = i,\ X_{t+1} = j) \overset{(2)}{=} \sum_i \mathrm{P}(X_t = i)\ \mathrm{P}(X_{t+1} = j \mid X_t = i) \\ &\overset{(3)}{=} \sum_i p_t(i)\, p_{ij}, \qquad \text{i.e.} \qquad p_{t+1} = p_t\, P. \end{aligned} \tag{9.14}$$

(1) Law of total probability over today's state i (Chapter 1).
(2) Product rule.
(3) Definitions of p_t and of p_{ij}; homogeneity lets us drop the t from p_{ij}. The sum over i of a row vector times the ith row of P is the vector–matrix product.

One step of the chain is one multiplication by P from the right. A stochastic matrix maps probability vectors to probability vectors: the entries of $p_t P$ are sums of non-negative terms, and they add up to $\sum_j \sum_i p_t(i) p_{ij} = \sum_i p_t(i) \sum_j p_{ij} = 1$.

Watch out: Rows or columns?

Probabilists write distributions as row vectors and multiply by P on the right, so the *rows* of P sum to one. Much of the physics literature (master equations, quantum channels) writes column vectors and uses the transpose. Before using a formula from elsewhere, check which index is "from" and which is "to". The stationary distribution is a *left* eigenvector of P in our convention.

Example: the politician's first two nights. On day 1 he is on island 4 for sure, $p_1 = (0,0,0,1,0,0,0)$. Multiplying a vector with a single 1 in position 4 by P picks out row 4 of (9.13):

$$p_2 = p_1 P = \left(0,\ 0,\ \tfrac{3}{8},\ \tfrac{1}{8},\ \tfrac{1}{2},\ 0,\ 0\right) = (0, 0, 0.375, 0.125, 0.5, 0, 0),$$

the three bars of Kruschke's panel $t = 2$ [Kruschke §7.2.3]. On day 3,

$$p_3(2) \overset{(1)}{=} \tfrac{3}{8}\cdot\tfrac{1}{3} = \tfrac{1}{8}, \qquad p_3(3) \overset{(2)}{=} \tfrac{3}{8}\cdot\tfrac{1}{6} + \tfrac{1}{8}\cdot\tfrac{3}{8} = \tfrac{7}{64}, \qquad p_3(4) \overset{(3)}{=} \tfrac{3}{8}\cdot\tfrac{1}{2} + \tfrac{1}{8}\cdot\tfrac{1}{8} + \tfrac{1}{2}\cdot\tfrac{2}{5} = \tfrac{129}{320},$$
$$p_3(5) \overset{(4)}{=} \tfrac{1}{8}\cdot\tfrac{1}{2} + \tfrac{1}{2}\cdot\tfrac{1}{10} = \tfrac{9}{80}, \qquad p_3(6) \overset{(5)}{=} \tfrac{1}{2}\cdot\tfrac{1}{2} = \tfrac{1}{4}, \qquad p_3(1) = p_3(7) = 0.$$

(1) Island 2 can be reached on day 3 only from island 3 (moving west, probability $p_{32} = \frac{1}{3}$).
(2) From island 3 by staying ($p_{33} = \frac{1}{6}$) or from island 4 by moving west ($p_{43} = \frac{3}{8}$).
(3) From 3 eastwards, from 4 by staying, from 5 westwards ($p_{54} = \frac{2}{5}$).
(4) From 4 eastwards and from 5 by staying ($p_{55} = \frac{1}{10}$).
(5) From 5 eastwards.

These are 0.125, 0.1094, 0.4031, 0.1125, 0.25, and they add up to one. After two nights he can be at most two islands from where he started, so islands 1 and 7 still have probability zero.

What p_t means, and how to simulate a chain. p_t is not what one politician does; one politician is on exactly one island each day. It is the histogram of where a large number of independent politicians would be on day t, all following the same rule from the same starting distribution [Wasserman p. 386]. Simulating one of them needs only the initial distribution p_0 and P: draw X_0 from p_0; if it came out i, draw X_1 from row i of P; if that came out j, draw X_2 from row j; and so on. In code, each draw from a row is one uniform number compared with the row's cumulative sums (the inverse-CDF method of Chapter 6); that is all `walk` and `step_many` in `lib_markov.py` do.

What we compute. Two things, for the same days Kruschke drew. The exact crowd histogram comes from repeated multiplication, $p_t = p_1 P^{t-1}$, with P the matrix (9.13) and p_1 the spike on island 4. The simulated one comes from running 20 000 independent politicians from island 4 and counting where they sleep on day t. The two are drawn together in Figure 9.5 for days 2, 3, 5, 13 and 99. The early distributions are lopsided, with a bulge over the starting island; by day 13 the shape is already close to a straight incline.

Side by side with Kruschke. Kruschke's Fig. 7.3 shows the same sequence of histograms as bars, read off his matrix [Kruschke §7.2.3]. At $t = 2$ there is something exact to compare; at later days the natural comparison is with the incline $\theta/28$ itself, measured by the total-variation distance $\frac{1}{2}\sum_\theta |p_t(\theta) - \theta/28|$ (the largest difference in probability that any set of islands can show, defined in Section 9.5).

quantity	Kruschke, Fig. 7.3	ours
$p_2(3)$, $p_2(4)$, $p_2(5)$	0.375, 0.125, 0.5	0.375, 0.125, 0.5
day 13, distance from $\theta/28$	close to the incline (by eye)	0.048
day 99, distance from $\theta/28$	indistinguishable (by eye)	1.5×10^{-6}

The day-2 values agree exactly, as they must: both are row 4 of the same matrix. What the calculation adds is the size of the remaining difference on later days, a number instead of a picture; how fast it shrinks is the subject of Section 9.5.

Many steps at once: the Chapman–Kolmogorov equations. Let $p_{ij}(n) = \mathrm{P}(X_{m+n} = j \mid X_m = i)$ be the probability of going from i to j in exactly n steps, and P_n the matrix of these **n-step**

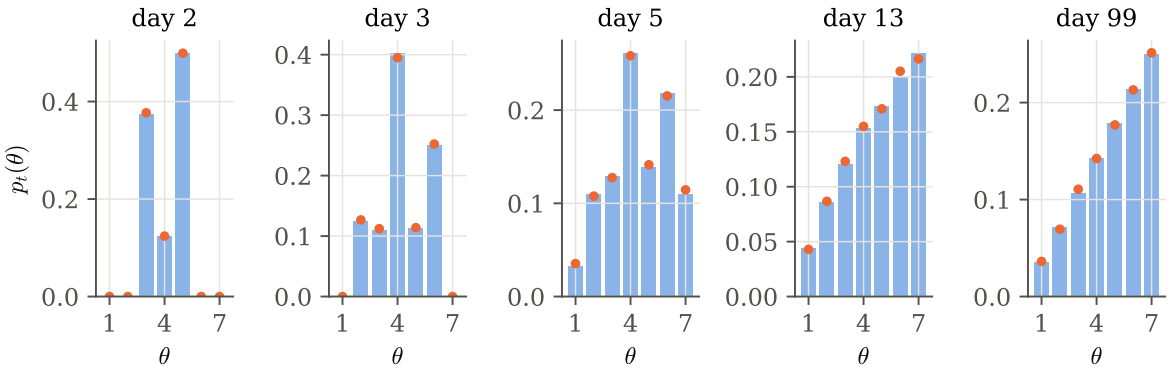

Figure 9.5: Where the politician is likely to be, starting from island 4. Bars are the exact $p_t = p_1 P^{t-1}$; dots are the fractions of 2×10^4 simulated politicians. The distribution spreads from its starting spike, overshoots, and settles into the incline $p(\theta) = \theta/28$, the same for every later day.

transition probabilities [Wasserman p. 385]. To go from i to j in $m + n$ steps the chain must be somewhere, say k, after the first m of them:

$$\begin{aligned} p_{ij}(m+n) = \mathrm{P}(X_{m+n} = j \mid X_0 = i) &\overset{(1)}{=} \sum_k \mathrm{P}(X_{m+n} = j,\ X_m = k \mid X_0 = i) \\ &\overset{(2)}{=} \sum_k \mathrm{P}(X_{m+n} = j \mid X_m = k,\ X_0 = i)\ \mathrm{P}(X_m = k \mid X_0 = i) \\ &\overset{(3)}{=} \sum_k \mathrm{P}(X_{m+n} = j \mid X_m = k)\ \mathrm{P}(X_m = k \mid X_0 = i) \overset{(4)}{=} \sum_k p_{ik}(m)\, p_{kj}(n). \end{aligned} \tag{9.15}$$

(1) Law of total probability over the intermediate state, inside the conditional probability given $X_0 = i$.
(2) Product rule in its conditional form, $\mathrm{P}(A, B \mid C) = \mathrm{P}(B \mid C)\,\mathrm{P}(A \mid B, C)$.
(3) The Markov property: once $X_m = k$ is known, X_0 is irrelevant for the future. (For $n > 1$ this uses (9.9) repeatedly, one step at a time.)
(4) Homogeneity: the probabilities depend only on the number of steps.

The last line is matrix multiplication, so $P_{m+n} = P_m P_n$. Since $P_1 = P$, we get $P_2 = P^2$, $P_3 = P^3$ and in general

$$P_n = P^n, \qquad p_n = p_0 P^n. \tag{9.16}$$

The second statement follows from the first by one more use of total probability, $p_n(j) = \sum_i \mathrm{P}(X_n = j \mid X_0 = i)\,\mathrm{P}(X_0 = i) = \sum_i p_0(i)\, p_{ij}(n)$, or simply by applying (9.14) n times. Every question about a homogeneous finite chain is therefore a question about the powers of one matrix, and the long-run behaviour is the behaviour of P^n as $n \to \infty$, which is a question about eigenvalues.

Example: the weather a week ahead. For Wasserman's weather (9.11), starting on a sunny day, $p_0 = (1, 0)$: $p_1 = (0.4, 0.6)$, $p_2 = (0.4 \cdot 0.4 + 0.6 \cdot 0.8,\ \ldots) = (0.64, 0.36)$, $p_3 = (0.544,\ \ldots)$, and $p_6(\text{sunny}) = 0.5732$. The forecast swings above and below a value near 0.571 with a shrinking amplitude. Section 9.5 shows that the value is $4/7$ and that the swing shrinks by the factor -0.4 each day.

9.2.4 The long run, seen in one trajectory

The second question is about a single politician over a long time, not about a crowd on one day. Figure 9.6a shows the first 500 days of one simulated trip on a logarithmic time axis, like Kruschke's Fig. 7.2: the politician wanders down to island 1 early on, then drifts east and spends most of his time among the larger islands. Counting his days over a trip of 100 000 days (Figure 9.6b), the fraction spent on each island differs from $\theta/28$ by at most 0.0025. The time he spends on an island tracks its population.

Two different facts. Figures 9.5 and 9.6 look alike but answer different questions. The first is a histogram over many politicians on one day t: it approaches $\theta/28$ as t grows, which is convergence of p_t (Section 9.5). The second is a histogram over the days of one politician: it approaches $\theta/28$ as the trip grows, which is the ergodic theorem (Section 9.6). Neither implies the other on sight: a crowd can settle while each member keeps a lopsided personal history, and one long history can be fair even when the crowd never settles (Section 9.4.1). Kruschke stops at showing that $\theta/28$ is *stable*, leaving the rest as "far beyond" his book [Kruschke §7.2.5]; both facts are proved in Sections 9.5 and 9.6.

The lesson. Reproducing the island figures turns a picture that "looks settled" into two separate limits, one over walkers and one over time, and only the second is what a single MCMC run relies on.

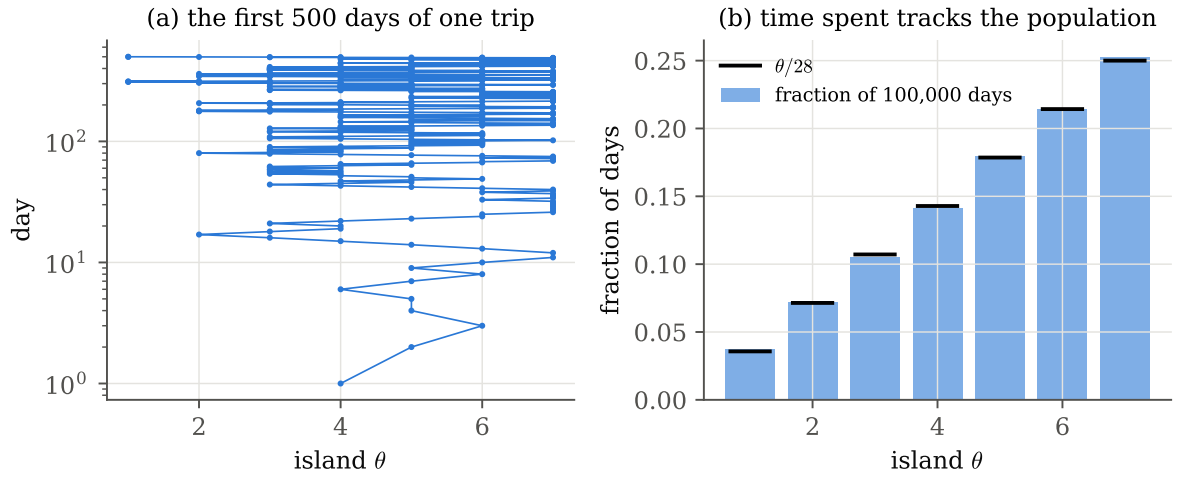

Figure 9.6: (a) One politician's first 500 days, with the day on a logarithmic axis so that the early wandering is visible. (b) The fraction of 10^5 days he spends on each island (bars) against the population shares $\theta/28$ (black ticks).

9.2.5 Reading the transition matrix off a history

So far P was given and we predicted the walk. The inverse question also arises: we observe one history $x_0, x_1, \ldots, x_n$ of a chain (a weather record, a sequence of detector states) and want to infer P. By (9.10) the probability of the observed history is a product of one-step factors, one per observed transition. Collecting equal factors, with n_{ij} the number of observed transitions from i to j,

$$\mathcal{L}(p_0, P) = p_0(x_0) \prod_{r=1}^{n} p_{x_{r-1}x_r} = p_0(x_0) \prod_{i,j} p_{ij}^{n_{ij}} \tag{9.17}$$

[Wasserman p. 394]. There is only one observation of the starting state, so p_0 cannot be learned; we maximise over P. Take the logarithm of (9.17),

$$\ln \mathcal{L} = \ln p_0(x_0) + \sum_i \Big(\sum_j n_{ij} \ln p_{ij} \Big).$$

The first term does not contain P at all, so it plays no part in the maximisation. The rest is a sum of one bracket per row i, and each bracket contains only the entries of its own row. The constraints are also one per row, $\sum_j p_{ij} = 1$. So changing row i changes only its own bracket, and each row can be maximised on its own, with its own Lagrange multiplier μ_i (the method of Chapter 3 for maximising under a constraint):

$$0 \overset{(1)}{=} \frac{\partial}{\partial p_{ij}} \Big[\sum_k n_{ik} \ln p_{ik} - \mu_i \Big(\sum_k p_{ik} - 1 \Big) \Big] = \frac{n_{ij}}{p_{ij}} - \mu_i \quad \Longrightarrow \quad p_{ij} = \frac{n_{ij}}{\mu_i},$$

$$1 \overset{(2)}{=} \sum_j p_{ij} = \frac{n_i}{\mu_i} \quad \Longrightarrow \quad \hat{p}_{ij} = \frac{n_{ij}}{n_i}, \qquad n_i = \sum_j n_{ij}. \tag{9.18}$$

(1) The part of $\ln \mathcal{L}$ that involves row i, plus the constraint for that row; set the derivative to zero. Only the $k = j$ terms depend on p_{ij}, and $\partial(n_{ij} \ln p_{ij})/\partial p_{ij} = n_{ij}/p_{ij}$, so the condition is $n_{ij}/p_{ij} = \mu_i$, that is $p_{ij} = n_{ij}/\mu_i$. It is a maximum: the second derivative of each term, $-n_{ij}/p_{ij}^2$, is negative, so the bracket is concave in the row and its only stationary point on the constraint is the top.

(2) Impose the constraint to find μ_i: it equals n_i, the number of departures from state i.

The estimate is the obvious one: of the n_i times we left state i, the fraction that went to j.

How uncertain is it? Fix a row i and look only at the n_i nights the chain spent in state i. By the Markov property each departure from i is a fresh draw from row i of P, whatever happened before, so the n_i destinations are independent draws from the same pmf $(p_{i1}, \ldots, p_{iK})$. Counting how many went to each j is then exactly the multinomial setting of Section 2.3, with n_i trials and cell probabilities p_{ij}:

$$\operatorname{Var}(n_{ij}) = n_i p_{ij}(1 - p_{ij}), \qquad \operatorname{Cov}(n_{ij}, n_{i\ell}) = -n_i p_{ij} p_{i\ell} \quad (j \neq \ell).$$

Dividing the counts by n_i gives the estimate $\hat{p}_{ij} = n_{ij}/n_i$, whose variance is $p_{ij}(1 - p_{ij})/n_i$, so its error bar is $\sqrt{\hat{p}_{ij}(1 - \hat{p}_{ij})/n_i}$. Different rows use different nights, so their errors are uncorrelated. For large n_i the multinomial counts are close to Normal (the central limit theorem applied to the sum of n_i indicator vectors), which gives $\sqrt{n_i}(\hat{p}_{ij} - p_{ij}) \rightsquigarrow \mathcal{N}$ with variance $p_{ij}(1 - p_{ij})$ [Wasserman p. 394, Thm 23.31].

One thing differs from ordinary multinomial counting: n_i is not fixed in advance but is itself random, since it depends on how often the chain happened to visit i. For an ergodic chain the fraction of time spent in i settles to π_i (Section 9.6), so n_i grows like $n\pi_i$ as the record lengthens, every row gets more and more departures, and the estimate is consistent with the error bar above shrinking as $1/\sqrt{n\pi_i}$.

Example: a thousand days of weather. The script `08_markov_mle.py` simulates 1000 days of the three-state weather chain used throughout Section 9.5 (sunny, cloudy, rainy; true rainy row $(0.6, 0, 0.4)$). The record visits sun, cloud and rain 518, 342 and 140 times, and gives for the rainy row $\hat{p}_{RS} = 0.664 \pm 0.04$ and $\hat{p}_{RR} = 0.336 \pm 0.04$, the error bars being $\sqrt{\hat{p}(1 - \hat{p})/n_R}$. Rain is the rarest state, so its row is the least well measured. Repeating the experiment on 2000 independent histories, the standardised error $(\hat{p}_{RS} - p_{RS})/\sqrt{p_{RS}(1 - p_{RS})/n_R}$ has mean 0.01 and standard deviation 1.013, and its histogram is a standard Normal (Figure 9.7): the multinomial error bar is right even though the visits to rain arrive in correlated clumps.

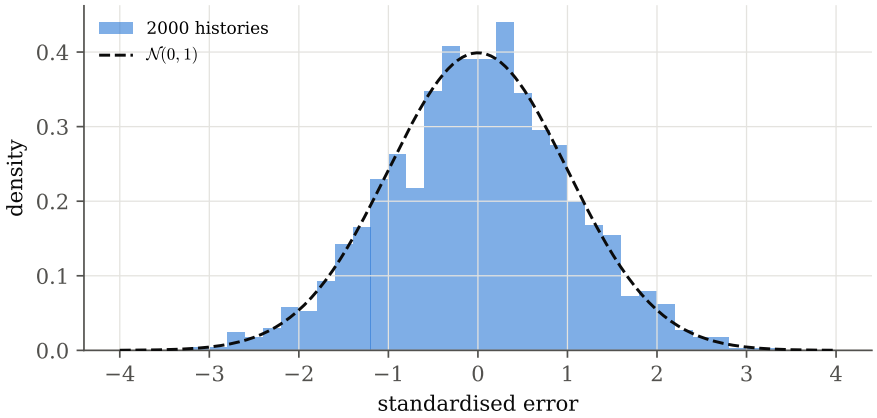

Figure 9.7: The error of the estimated rain-to-sun probability, in units of its multinomial standard error, over 2000 simulated thousand-day records. The histogram follows the standard Normal curve.

9.3 Who can reach whom: classifying the states

Not every Markov chain settles down. A fish that swims into a net never visits the rest of the ocean again; a rollercoaster car runs round its track forever and is at the top of the loop only at regular instants [Lambert §13.6.2]. Both are perfectly good Markov chains, but neither has a long-run histogram that is independent of where it started: the fish's histogram depends on when it was caught, and the car's distribution at time t keeps rotating instead of settling. Wasserman's Fig. 23.2 shows the same contrast for two simulated chains, one wandering off for good, one fluctuating about a fixed level [Wasserman p. 384]. Before proving that a chain converges we need words for the ways in which it can fail to: some states cannot be reached from others, some states are left and never revisited, and some are revisited only in a fixed rhythm.

The questions. For a given transition matrix P:

1. From state i, can the chain ever get to state j?
2. Having left i, is it certain to come back, and how long does that take on average?
3. Can it come back at any time, or only at multiples of some period?

9.3.1 Communication and irreducibility

State i **reaches** j (or j is **accessible** from i), written $i \to j$, if $p_{ij}(n) > 0$ for some $n \geq 0$; we count $n = 0$, so every state reaches itself. If $i \to j$ and $j \to i$ the two states **communicate**, $i \leftrightarrow j$ [Wasserman p. 387].

Communication is an equivalence relation: it is reflexive ($n = 0$), symmetric by definition, and transitive, because if $i \to j$ in m steps and $j \to k$ in n steps then

$$p_{ik}(m+n) \overset{(1)}{=} \sum_{\ell} p_{i\ell}(m)\, p_{\ell k}(n) \overset{(2)}{\geq} p_{ij}(m)\, p_{jk}(n) \overset{(3)}{>} 0.$$

(1) Chapman–Kolmogorov (9.15).
(2) All terms are non-negative; keep only the term $\ell = j$.

(3) Both factors are positive by assumption.

An equivalence relation cuts the state space into disjoint **communicating classes**, $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2 \cup \cdots$, with two states in the same class exactly when they communicate [Wasserman p. 387, Thm 23.12].

Working definition 9.3 (irreducible, closed, absorbing)

A chain is **irreducible** if all its states communicate [one single class, every state reachable from every other in some number of steps]. A set of states is **closed** if the chain can never leave it once inside [$p_{ij} = 0$ for every i in the set and j outside it]. A closed set consisting of one state is an **absorbing state** [$p_{ii} = 1$]. *Operational test:* draw the transition graph, an arrow $i \to j$ for every nonzero p_{ij}. The chain is irreducible if and only if from every node there is a path of arrows to every other node.

Example: four states, three classes. Wasserman's Ex. 23.13 has $\mathcal{X} = \{1, 2, 3, 4\}$ and

$$P = \begin{pmatrix} \frac{1}{3} & \frac{2}{3} & 0 & 0 \\ \frac{2}{3} & \frac{1}{3} & 0 & 0 \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Reading the graph (Figure 9.8a): 1 and 2 send arrows only to each other, so $\{1, 2\}$ is a class, and it is closed. State 3 sends arrows everywhere, but nothing comes back to 3 from any other state, so $\{3\}$ is a class on its own, and not closed. State 4 has $p_{44} = 1$: $\{4\}$ is a closed class and 4 is absorbing. A walker that starts in 3 stays there for a geometric number of steps (mean $1/(1 - \frac{1}{4}) = \frac{4}{3}$) and then falls for good into $\{1, 2\}$ or into 4. The odds of the two exits follow from row 3. Each night in state 3 the walker leaves with probability $1 - \frac{1}{4} = \frac{3}{4}$; it goes to 1 or 2 with probability $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$ and to 4 with probability $\frac{1}{4}$. Given that it leaves, the chances are therefore $(\frac{1}{2})/(\frac{3}{4}) = \frac{2}{3}$ for $\{1, 2\}$ and $(\frac{1}{4})/(\frac{3}{4}) = \frac{1}{3}$ for 4, the same on every night, so these are also the chances of the eventual exit. Where it ends up depends on luck, so this chain has no unique long-run histogram.

The politician's chain (9.13) is irreducible: every island sends an arrow to each neighbour, so any island reaches any other by a walk along the chain. The absorbing random walk of Section 9.2.2 is not: its classes are $\{1\}$, $\{N\}$ (both absorbing) and the interior $\{2, \ldots, N-1\}$, which is not closed.

9.3.2 Coming back: recurrence and transience

Start the chain in state i. Will it ever come back? State i is **recurrent** (or persistent) if

$$\mathrm{P}(X_n = i \text{ for some } n \geq 1 \mid X_0 = i) = 1,$$

and **transient** otherwise [Wasserman p. 388]. The test is the expected number of visits.

Key idea: Recurrence ⇔ infinitely many expected returns

State i is recurrent if and only if $\sum_n p_{ii}(n) = \infty$, and transient if and only if $\sum_n p_{ii}(n) < \infty$ [Wasserman p. 388, Thm 23.15].

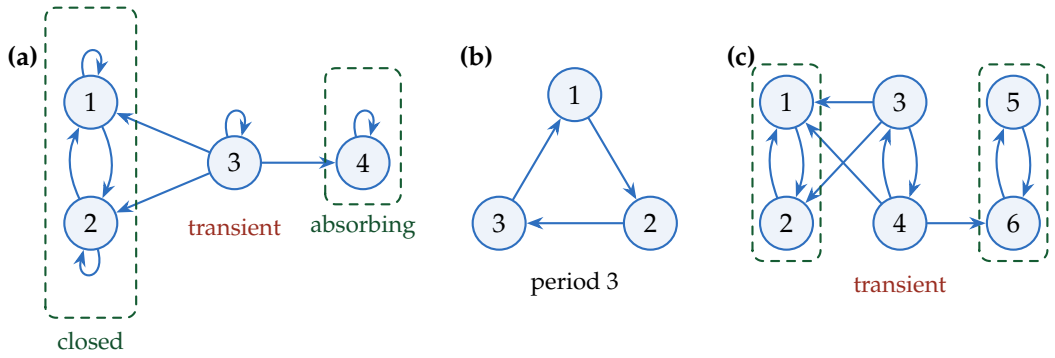

Figure 9.8: Transition graphs, an arrow for every nonzero transition probability. (a) Wasserman's Ex. 23.13: $\{1,2\}$ is a closed class, 4 is absorbing, and 3 leaks into both and is never re-entered. (b) A deterministic cycle: the chain returns to each state only every third step. (c) Ex. 23.28 (self-loops not drawn): two closed classes $\{1,2\}$ and $\{5,6\}$, and states 3 and 4 that eventually drain into one of them.

Why. Let $I_n = 1$ if $X_n = i$ and 0 otherwise, so that $Y = \sum_{n\geq 0} I_n$ counts the visits to i. Its mean, for a chain started at i, is

$$\mathbb{E}(Y \mid X_0 = i) \overset{(1)}{=} \sum_{n=0}^{\infty} \mathbb{E}(I_n \mid X_0 = i) \overset{(2)}{=} \sum_{n=0}^{\infty} \mathrm{P}(X_n = i \mid X_0 = i) \overset{(3)}{=} \sum_{n=0}^{\infty} p_{ii}(n). \tag{9.19}$$

(1) Linearity of expectation, which holds for infinite sums of non-negative terms.
(2) The mean of an indicator is the probability of its event.
(3) Definition of the n-step probability.

Now count the visits differently. Let a_i be the probability of ever returning. Each time the chain is at i, the Markov property makes the future a fresh copy of the chain started at i, so it returns again with probability a_i, independently of the past. If $a_i = 1$ it returns, returns again, and so on forever: $Y = \infty$ with probability one, and (9.19) diverges. If $a_i < 1$, each visit is the last with probability $1 - a_i$, so Y is geometric:

$$\mathrm{P}(Y = k \mid X_0 = i) = a_i^{k-1}(1 - a_i), \qquad \mathbb{E}(Y \mid X_0 = i) \overset{(1)}{=} \sum_{k\geq 1} k\, a_i^{k-1}(1 - a_i) \overset{(2)}{=} \frac{1 - a_i}{(1 - a_i)^2} = \frac{1}{1 - a_i} < \infty.$$

(1) Mean of the geometric distribution with "success" (no return) probability $1 - a_i$.
(2) $\sum_k k a^{k-1} = \frac{\mathrm{d}}{\mathrm{d}a} \sum_k a^k = 1/(1-a)^2$ for $|a| < 1$.

So a finite sum means transience and an infinite one means recurrence. For a finite chain there is a shortcut for the general facts [Wasserman p. 389, Thm 23.16]: recurrence and transience are properties of a whole class (if i is recurrent and $i \leftrightarrow j$, then j is recurrent, and likewise for transient); a finite chain has at least one recurrent state (it runs forever on finitely many states, so some state is visited infinitely often); and in a finite irreducible chain every state is recurrent. The state space always splits as $\mathcal{X} = \mathcal{X}_T \cup \mathcal{X}_1 \cup \mathcal{X}_2 \cup \cdots$, the transient states $\mathcal{X}_T$ plus closed irreducible classes of recurrent states (the **decomposition theorem**, [Wasserman p. 389, Thm 23.17]). In Figure 9.8a, $\mathcal{X}_T = \{3\}$ and the closed classes are $\{1,2\}$ and $\{4\}$.

Example: the random walk on the integers. A walker on $\{\ldots, -1, 0, 1, \ldots\}$ steps $+1$ with probability p and -1 with $q = 1 - p$ [Wasserman p. 389, Ex. 23.18]. All states communicate, so either all are recurrent or all are transient; test state 0. A return can happen only after an even number of steps, $2n$, with exactly n steps each way, in any order, so $p_{00}(2n) = \binom{2n}{n} p^n q^n$.

Stirling's formula $n! \simeq n^n e^{-n}\sqrt{2\pi n}$ gives the size of the binomial coefficient:

$$\binom{2n}{n} = \frac{(2n)!}{(n!)^2} \overset{(1)}{=} \frac{(2n)^{2n}e^{-2n}\sqrt{4\pi n}}{n^{2n}e^{-2n}\,2\pi n} \overset{(2)}{=} \frac{4^n}{\sqrt{\pi n}}, \qquad \text{so} \qquad p_{00}(2n) \simeq \frac{(4pq)^n}{\sqrt{\pi n}}. \tag{9.20}$$

(1) Stirling for $(2n)!$ in the numerator and for each $n!$ in the denominator.
(2) $(2n)^{2n}/n^{2n} = 4^n$ and $\sqrt{4\pi n}/(2\pi n) = 1/\sqrt{\pi n}$.

Since $pq \le \frac{1}{4}$ with equality only at $p = \frac{1}{2}$, two cases appear. For $p \neq \frac{1}{2}$, $4pq < 1$ and the terms decrease geometrically, the sum converges, and the walk is transient: it drifts away in the direction of the bias and returns only finitely often. For $p = \frac{1}{2}$, $p_{00}(2n) \simeq 1/\sqrt{\pi n}$, whose sum diverges like $\sqrt{n}$, and the walk is recurrent. Stirling is already good at $n = 10$, where exact over approximate is 0.9876 (Figure 9.9a).

The two cases can also be checked against the geometric law of the visits. The expected number of visits to 0, counting the start, is the full sum (9.19), and the binomial series $\sum_{n\ge0}\binom{2n}{n}x^n = (1-4x)^{-1/2}$ (valid for $|x| < \frac{1}{4}$) sums it in closed form with $x = pq$:

$$\sum_{n\ge0} p_{00}(2n) \overset{(1)}{=} (1-4pq)^{-1/2} \overset{(2)}{=} \big((p-q)^2\big)^{-1/2} \overset{(3)}{=} \frac{1}{|p-q|}.$$

(1) The binomial series with $x = pq$.
(2) $1 - 4pq = (p+q)^2 - 4pq = p^2 - 2pq + q^2 = (p-q)^2$, using $p + q = 1$.
(3) The positive square root of a square is the absolute value.

The same mean is $1/(1-a)$ by the geometric law of the visits found above, so $1/(1-a) = 1/|p-q|$, and the probability of ever returning is $a = 1 - |p-q|$. For $p = 0.6$: $x = 0.24$, $(1-0.96)^{-1/2} = 0.04^{-1/2} = 5$ visits on average including the start, so $\sum_{n\ge1} p_{00}(2n) = 4$ after removing the $n = 0$ term, and the probability of ever returning is $a = 1 - \frac{1}{5} = 0.8 = 1 - |0.6 - 0.4|$. Simulating 10 000 walkers for 10 000 steps (Figure 9.9b), the fraction that has come back at least once is 0.801 for $p = 0.6$, and 0.9916 for $p = \frac{1}{2}$, still creeping towards one.
